Patients with low-risk MDS should be considered for therapy only if they are receiving frequent transfusions or their disease is showing progression with increasing severity of cytopenias, appearance of new cytogenetic abnormalities, rise in blasts, or multiple incidents of bleeding and infection. At this point, it is appropriate to consider placing such a patient on an experimental protocol. The hallmark of MDS is proliferation in the presence of excessive intramedullary programmed cell death. The presence of an excess of proinflammatory cytokines, especially tumor necrosis factor α (TNF α), an increase in microvessel density (MVD) with clear evidence of neoangiogenesis, and a poorly defined immunologic component have all been demonstrated in a subset of MDS patients. These biologic insights suggested experimental therapeutic approaches, including antiangiogenic therapies, anticytokines (especially anti-TNF), cytoprotection, and immune modulation.

ANGIOGENESIS

There is considerable increase in MVD in the bone marrow of patients with MDS.³⁸ The most extensively studied cytokine thought to be responsible for the development of neovascularization is VEGF.³⁹ Others, such as TNF α and bFGF are also involved, but VEGF appears to be the major player. VEGF and its type III receptor are overexpressed by myeloblasts and monocytes derived from the malignant clone. The increase in MVD in the bone marrow is associated with a higher percentage of blasts, which in turn correlates with increased levels of VEGF, TNF α , and bFGF. This has been shown in MVD studies where ALIPs (abnormal localized immature precursors) within the bone marrows of MDS patients express higher levels of VEGF and VEGFR, specifically VEGFR-1. VEGF has multiple activities: stimulating release of proteases from endothelial cells resulting in degradation of the extracellular matrix; recruiting mediators of apoptosis, such as TNF α and soluble Fas (CD95) ligand; and activating cell adhesion molecules. VEGF also stimulates engraftment of myeloid leukemic and hematopoietic stem cells and regulates maturation of receptor-positive cells, thus stimulating endothelial cell maturation while inhibiting hematopoietic precursor, osteoblast, and dendritic cell maturation. VEGF deregulation can thus have severe repercussions on effective hematopoiesis.

ANTIANGIOGENESIS AGENTS

Many of the agents described in the above sections, such as the FTIs, TKIs, and ATO, exhibit multiple modes of action, including regulation of VEGF activity.

Thalidomide is an antiangiogenesis agent that inhibits cellular response to VEGF and proliferation of cells that express the VEGF receptor, and also has significant anti-TNF properties. Thalidomide and its analogs are described below. Other agents that have shown activity in a subset of low-risk patients include matrix metalloprotease inhibitors, which block the end results of VEGF's paracrine effects, i.e., extracellular matrix degradation, and the monoclonal antibody to VEGF, bevacizumab.

Thalidomide

Thalidomide was used in the sixties as a sedative and antiemetic agent. Severe teratogenic effects, however, led to its removal from the market. It has been reintroduced over the last decade for the treatment of ENL (erythema nodosum leprosum) and received FDA approval for this indication in 1998. It is currently used in combination with dexamethasone, in place of conventional chemotherapy, for the initial management of multiple myeloma. The drug has been found to have multiple mechanisms of action that would make it an ideal therapeutic agent in various cancers, especially melanoma, multiple myeloma, and MDS. These include accelerating degradation of TNF α RNA message; potent inhibition of angiogenesis via its action on VEGF and bFGF, and inhibition of the transcriptional regulator NF- κ B.^{40–42} In addition, thalidomide alters cellular adhesion and stimulates the Th1 immune response, possibly enhancing an antitumor response.⁴³ Thus, thalidomide shows anti-TNF α , antiangiogenic, and immune-modulatory properties.

A phase II trial was conducted at Rush University Medical Center in which 83 MDS patients of all subtypes were given thalidomide 100 mg once a day escalating to a target dose of 400 mg a day.⁴⁴ The overall response rate was 19%. Fifty-one patients were evaluable at 12 weeks, of whom 16 (almost 30%) had an erythroid response using the IWG criteria, 2/3 of which were major responses, most of those becoming transfusion independent or achieving a >50% reduction in transfusion requirements. Improvement in thrombocytopenia or neutropenia was less significant. The most common reason patients were unable to complete the trial was due to toxicities, namely neuropathy, constipation, fatigue, and fluid retention at a dose beyond 200 mg a day. For 10 of the 16 responders, the median time to response was 16–20 weeks, and the majority of responders had lower risk disease: refractory anemia (RA) or refractory anemia with ringed sideroblasts (RARS), or a low or int-1 IPSS.

The North Central Cancer Treatment Group study, N998B, was a phase II multicenter trial with more aggressive dose escalation to 1000 mg/day of thalidomide, and was closed early due to excessive grade III

toxicities in more than 85% of patients at a median interval of less than 2.5 months.⁴⁵ In those patients who tolerated treatment, median time to response was once again not reached until 16 weeks. A national, randomized phase III, placebo-controlled trial to assess overall clinical benefit of low-dose thalidomide in MDS patients with low-risk disease is nearing completion.

Thalidomide analogs

Lenalidomide (Revlimid) A more potent analog of thalidomide, CC-5013 or lenalidomide, is currently under investigation. CC-5013 is an oral immunomodulatory derivative (ImiD) of thalidomide that lacks the neurotoxicity of its parent compound, but shows 100-fold higher anti-TNF activity and 50–2000-fold higher potency for stimulating T-cell proliferation. In addition, CC5013 has antiangiogenic and antiapoptotic properties. It inhibits VEGF signaling in endothelial cells and myeloblasts, increasing adhesion of hematopoietic progenitors to bone marrow stroma, which results in sustained growth arrest and preferential extinction of myelodysplastic clones.⁴⁶ It also downregulates adhesion molecules and apoptosis inhibitory proteins, thereby increasing receptor-induced apoptosis.

The safety and efficacy of lenalidomide was studied in 45 patients with MDS with RBC transfusion-dependent disease or symptomatic anemia.⁴⁷ Patients received treatment with one of three CC5013 doses: 10 or 25 mg daily or 10 mg/day for 21 days every 4 weeks. Patients were assessed at 8 and 16 weeks according to IWG criteria. Thirty-three patients were evaluable for response after completing 8 weeks or more of therapy. Most patients (88%) were in the low/int-1 risk group. Twenty-one (64%) patients achieved an erythroid response, 19 of which were major responses; major cytogenetic responses (>50%) were achieved in 11 of 17 informative patients, with restoration of normal cytogenetics in 10. Erythroid responses were higher in those with RA or low/int-1 IPSS score or del(5q31-33). In this subset of patients with del(5q), there was also resolution of megakaryocytic dysplasia, but not a significant reduction in bone marrow blast percentage. MVD as well as bone marrow and plasma VEGF levels were decreased in responders. Multicenter phase II trials have completed in patients with 5q– syndrome and non 5q– low/int-1 MDS.

Soluble TNF α receptor (etanercept)

Etanercept is a dimer formed of the two monomers of the extracellular p75 TNF receptor fused to the Fc portion of human type 1 immunoglobulin. It neutralizes the TNF α levels by competitive binding.⁴⁸

Raza et al. administered etanercept at a dose of 25 mg twice weekly for 12 weeks to 20 patients.⁴⁹ Eighteen patients were evaluated, and while the drug was well tolerated there were no complete responders. Improvements in absolute neutrophil count (ANC) and platelets were seen in some patients, especially those with normal

cytogenetics and a hypercellular bone marrow, but no improvement in the erythroid series could be documented with this approach. However, etanercept combined with thalidomide was effective in improving the cytopenia of some patients with MDS. Once again, the responses were restricted to 30–40% of MDS patients.

Infliximab

Infliximab is a chimeric human–murine monoclonal antibody capable of neutralizing both free and membrane-bound TNF α . It has been used as a TNF suppressor in MDS patients.⁵⁰ Infliximab was given to 37 low-risk MDS patients in two cohorts: 5 and 10 mg/kg intravenously every 4 weeks for four cycles. Twenty-eight patients completed the four cycles. Infliximab successfully produced a variety of responses in about 20% of low- to intermediate-risk MDS patients, including multilineage responses.

Matrix metalloprotease inhibitors (MMPis)

These compounds result in antiangiogenesis by inhibiting the matrix metalloproteases (zinc-dependent endopeptidases) of the extracellular matrix, thereby altering integrin-mediated cell adhesion. MMPis also promote local release of the proteoglycan-(membrane)-bound forms of VEGF, TNF α , and soluble Fas ligand. AG3340 is a potent, oral selective MMPi.

AG3340 (Prinomastat) was administered to 34 MDS patients of all subtypes in a phase II multicenter randomized trial.⁵¹ Patients were given either 5 mg or 15 mg daily and those who responded after 16 weeks were continued on therapy. Of 28 evaluable patients, 4 had major erythroid responses, with a median time to response of 12 weeks and median duration of response of 29+ weeks, being sustained for over a year after the end of treatment. The higher dose caused increased arthralgias and myalgias and the benefit appeared to be more significant in those patients with a lower risk disease.

Bevacizumab

Bevacizumab is a recombinant, anti-VEGF, humanized monoclonal antibody recently approved for the treatment of metastatic colon cancer. Neutralization of VEGF has also been shown to inhibit TNF α production by the bone marrow. There is only limited experience in MDS, with a phase II study⁵² in which bevacizumab was given at a dose of 10 mg/kg every 2 weeks for 4 months, with major hematologic responses occurring in 2 of 10 evaluable patients, after 4 months of treatment.

CYTOPROTECTIVE AGENTS

Aminothiols

Organic thiols neutralize free radicals generated in tissues exposed to cytotoxic drugs. Amifostine is a phosphorylated aminothiol initially developed as a radioprotective agent at the Walter Reed Army Institute in the 1970s. Following administration, amifostine is phosphorylated by tissue alkaline phos-

phatase, an enzyme with greater activity in normal tissue than in tumor tissue. Active free thiol thus accumulates in the normal tissue, neutralizing the destructive free radicals. Thus, amifostine has been used as a radio- and cytoprotective agent for the treatment of solid tumors. In addition, amifostine protects primitive hematopoietic progenitors from chemotherapy-induced toxicity and stimulates hematopoiesis in pre-clinical models and in vitro studies.⁵³

List et al. conducted a phase I/II study of 18 MDS patients with dose escalation of amifostine up to 400 mg/m² three times a week or 740 mg/m² weekly for 3 weeks.⁵⁴ Single or multilineage responses were seen in 83% of patients receiving three times weekly doses, which were optimized at 200 mg/m²: 14 patients had a neutrophil response, 6 had improvement in thrombocytopenia, and 5 patients had a 50% reduction in red cell transfusion requirements. Raza et al. reported the use of amifostine in combination with pentoxifylline (P), ciprofloxacin (C), and dexamethasone (D) in 35 MDS patients.⁵⁵ Pentoxifylline is a xanthine derivative that interferes with the activity of proapoptotic cytokines, such as TNF α , IL-1 β , and tumor growth factor β (TGF β). Ciprofloxacin was added as a pharmacologic inhibitor of the hepatic metabolism of pentoxifylline and dexamethasone to downregulate mRNA translation of TNF α . Twenty-nine patients completed at least 12 weeks of treatment; most patients had low- to intermediate-risk MDS. Pentoxifylline was given at 800 mg three times a day, ciprofloxacin 500 mg twice a day, and dexamethasone 4 mg a day for 4 weeks was added to partial and nonresponders at 12 weeks. Amifostine was given at 200, 300, and 400 mg/m² (i.v. or s.q.) doses three times a week along with daily PCD therapy. An improvement in cytopenias was observed in 76% of patients, and 50% of patients had a >50% decrease in transfusion requirements. However, there was no correlation seen between response rate and the dose of amifostine given.

VITAMIN D

Vitamin D is a potent inhibitor of proliferation and induces cellular differentiation and maturation in vitro. Low levels of vitamin D have been found in some cases of AML and MDS. Bone marrow biopsies of several MDS patients with low normal levels of vitamin D showed depressed bone turnover without osteoporosis or osteomalacia. These findings are suggestive of osteoclast dysfunction, with a decrease in osteoblast recruitment and function.

There have been reported cases of improvement in blood counts after treatment with vitamin D, with some benefit reported in AML patients, accompanied, however, with toxic levels of vitamin D and hypercalcemia.⁵⁶ Vitamin D may also induce cell differentiation through oncogene regulation, as leukemia cell lines showed a decrease in c-myc RNA levels after exposure to the drug calcitriol (a vitamin D derivative) in vitro. Blockage of cell differentiation is not characteristic

of low-risk MDS, and vitamin D response in these patients is thought to be mediated by antiapoptotic effects, as observed in neoplastic cell lines.⁵⁷

Nineteen patients with low- to intermediate-risk MDS were treated with vitamin D analogs: 5 patients received 266 µg of calcifediol three times a week, and the other 14 received calcitriol (1,25(OH)2D3), the most active analog of this hormone, with escalating doses from 0.25 to 0.75 µg/day.⁵⁸ With a mean follow-up of 26 months, there was 1 response in the calcifediol group and 10 responses (2 major responses) on calcitriol. Hypercalcemia was not observed, but no correlation was found between baseline levels of vitamin D levels and the presence of response.

IMMUNOMODULATION

Antithymocyte globulin/cyclosporine

Antithymocyte globulin (ATG) is derived from the serum of either rabbits or horses immunized with human thoracic duct lymphocytes. ATG suppresses cytotoxic and potentially inhibitory T lymphocytes, and also has an indirect effect on hematopoiesis through augmentation of hematopoietic growth factor release from T cells and stromal cells. ATG stimulates cellular differentiation, and has been successfully used to treat patients with aplastic anemia (AA).

Hypoplastic MDS, although a distinct entity from AA, has some pathophysiologic similarities, specifically T-cell-mediated immune suppression of hematopoiesis. There is evidence of an increase in cytotoxic T-cell activity, a higher percentage of CD8+ cells, as well as skewing of T-cell receptor Vβ complementarity-determining region 3 (CDR3). This immune dysfunction in MDS is also found in low-risk MDS patients, with fewer than 10% blasts. It is reasonable, therefore, to treat hypocellular MDS patients with the same immunomodulation therapy that has been used for patients with AA, i.e., ATG and cyclosporine. These patients showed favorable responses, especially patients with HLA-DR2, HLA-DR15, or those with a paroxysmal nocturnal hemoglobinuria (PNH) phenotype (i.e., CD55 and CD59 negative). Other factors that are predictive for response to ATG are thought to be bone marrow cellularity <30%, shorter duration of red cell transfusions, and age <60 years. This therapy has recently been extended to RA and RAEB-1 patients in several small trials.

In a trial by Molldrem et al., unselected MDS patients with RA and refractory anemia with excess blasts (RAEB) were given rabbit ATG 40 mg/kg/day for 4 days, with an overall response rate of 44%.⁵⁹ Higher responses of 64% were seen in patients with RA, 81% of whom maintained transfusion independence for a median of 36 months. This included 48% of those with severe thrombocytopenia and 55% of those with severe neutropenia. A follow-up with a total of 61 patients was reported in 2002, with an overall response of 34%.⁶⁰

Subsequently, in a study of a select group of 30 patients with low-risk MDS and <10% blasts, horse ATG 1.5 vials/10kg/day was given for 5 days.⁶¹ Ten of

20 evaluable patients responded and became transfusion independent, with a median duration of response of 15.5 months, and 62% of the RA patients responded. Only one patient had normal counts at the 6-month follow-up, and there was no relationship between age, gender, cytogenetic clone, bone marrow cellularity, and response.

In a trial of 32 unselected MDS patients (RA, RAEB/RAEB-T, or CMMoL) treated with ATG, cyclosporine, and prednisone, only one CR and four PRs were achieved (OR 16%).⁶² Another small phase II trial of eight MDS patients treated with ATG and prednisone showed no responses; although three patients had the HLA-DR15 allele, this did not improve responses, and toxicities were significant.⁶³ The role of ATG therefore remains limited to patients with hypocellular MDS, especially those with specific phenotypic features, as described above.

FUTURE OF EXPERIMENTAL THERAPY IN MDS

A number of single agents belonging to different classes of drugs have now been found to be of benefit for subsets of MDS patients. Targeted therapies, such as imatinib for patients with fusion proteins resulting from abnormalities of 4(q12) or t(5;12), and lenalidomide in patients with 5q-, are likely to remain restricted to small subsets of MDS patients. For the vast majority of both low- and high-risk patients, the challenge is to match the right drug with the individual needs of the patient. While ever-evolving biologic insights are providing a better and more healthy rationale for specific therapies, the ability to administer a single drug as a result of such insights is still a faraway dream. In AML, both ara-C and anthracyclines as single agents produced complete responses in approximately 30% of patients. It was only when the two drugs were combined in the so-called 7 + 3 regimen that we began to see the synergy and additive effects, with remission rates in the 60–70% range. Applying the same lessons to MDS, it is clear that while we are finally starting to witness responses to single-agent therapy in subsets of patients, the future lies in developing combination trials. As a general rule, it would be worthwhile to consider combining agents that target the clone of MDS cells with those that target the bone marrow microenvironment, so that both the seed and the soil are simultaneously affected. Examples of future combination trials would be the use of agents like DNA methyltransferase inhibitors, FTIs, TKIs, and arsenic with antiangiogenic, anti-TNF, and immunomodulatory drugs. In the final analysis, it is an exciting time to be involved in translational research in MDS as the last two decades have taken us from having nothing to offer our patients save supportive care, to having almost an embarrassment of riches. One drug has already been approved for use in this disease, and several others are approaching approval.

CHRONIC MYELOPROLIFERATIVE DISEASES

Chapter **45**

EPIDEMIOLOGY, RISK FACTORS, AND CLASSIFICATION

Hanspreet Kaur, Deepjot Singh, and Alan Lichtin

INTRODUCTION

Chronic myeloproliferative disorders (CMPDs) are characterized by the chronic proliferation of one or more of the three hematopoietic cell lines or by marrow stromal cells, in various proportions. Polycythemia vera (PV), idiopathic myelofibrosis (IMF), chronic myelogenous leukemia (CML), and essential thrombocytosis (ET) have been traditionally classified as “chronic myeloproliferative disorders.”¹ These disorders are believed to originate from a clonal transformation of a multipotent hematopoietic progenitor cell, resulting in an overproduction of one or more of the myeloid (i.e., granulocytic, erythroid, and megakaryocytic) lineages in the absence of a defined stimulus.² In contrast to the ineffective erythropoiesis observed in the myelodysplastic syndromes, the proliferating cells show relatively normal maturation, with a resultant increase in granulocytes, red blood cells, and/or platelets in the peripheral blood. Other features shared by these disorders include splenomegaly and hepatomegaly from extramedullary hematopoiesis; marrow hypercellularity, megakaryocytic hyperplasia, and dysplasia; chromosomal abnormalities of chromosomes 1, 8, 9, 13, and 20; leukemic skin infiltrates, and spontaneous transformation into acute blast phase or bone marrow failure due to myelofibrosis or ineffective erythropoiesis.^{3–6} The diagnosis of

individual entities is therefore complicated by their overlapping features. The presence of the *BCR/ABL* fusion gene in association with characteristic morphologic and clinical findings permits an unequivocal diagnosis of CML. However, no specific chromosomal or molecular markers exist uniformly for the other conditions. Diagnosis of the other conditions is made on the basis of clinical, laboratory, and morphologic findings, which can be misleading. For example, approximately 10% of patients in one study of IMF actually had PV, while many patients initially diagnosed as ET had PV, instead.^{7–8}

As CML is discussed in detail in Chapters 16–22, we will concentrate on the Philadelphia (Ph)-chromosome-negative CMPDs.

CLASSIFICATION

The classification of CMPDs is based on the lineage of the predominant proliferating cells and the prominence of marrow fibrosis, taken together with a constellation of clinical and laboratory features.

The World Health Organization (WHO) classification system⁶ identifies seven conditions under the category of CMPDs, as shown in Table 45.1.

Tefferi⁹ classified ET, PV, and IMF as CMPDs. The CMPDs, in turn, are members of a broader class of

“clonal” stem cell processes operationally designated as the chronic myeloid disease groups (CMDs).

The classification of chronic myeloid disorders is shown in Table 45.2. The classification system is somewhat arbitrary, as features may overlap between myelodysplastic syndrome (MDS) and CMPD. The identification of specific disease-causing mutations similar to the Ph chromosome in CML is hoped to pave the path toward a molecular classification system of CMDs.

EPIDEMIOLOGY

The CMPDs are primarily seen in the adult population, with a peak in the fifth to seventh decades of life. The combined annual incidence of the CMPDs is approxi-

mately 6–9/100,000 people.⁶ The first epidemiologic data were based on a large population study published by Prochazka and Markowe.¹⁰ The incidence of PV in Europe and North America is similar, with eight to ten cases per million individuals per year.¹¹ PV varies from 2 cases per million individuals per year in Japan to 13 per million per year in Australia.⁶

In a population-based study in Olmsted County, Minnesota, from 1935 to 1989, the age- and sex-adjusted incidence rate of PV was 1.9/100,000 person-years.¹² In the same county, in another population-based study from 1976 to 1995, the authors reported an approximate annual incidence of 2.5, 2.3, and 1.3 per 100,000 for ET, PV, and de novo agnogenic myeloid metaplasia (AMM), respectively. In a report from the United Kingdom, from 1984 to 1993, 2376 cases of CMPDs, including ET, PV, and AMM, were reported.¹³ The standardized incidence rate was 2.27/100,000 person-years for all three conditions. The incidence rate per 100,000 for PV, ET, and AMM was 0.92, 0.79, and 0.57, respectively. Although in adults the true incidence of chronic idiopathic fibrosis is not known, it is estimated to be between 0.5 and 1.5 per 100,000 individuals per year.^{9,14} The true incidence for chronic neutrophilic leukemia (CNL) is unknown, as fewer than 100 cases have been reported.⁶ In a study of 660 cases of chronic leukemias of myeloid origin, not one single case of CNL was observed.¹⁵ Chronic eosinophilic leukemia (CEL) and hypereosinophilic syndrome (HES) are rare diseases. As it is often difficult to distinguish between the two, the true incidence of these conditions is unknown. It appears that approximately 10–20% of all cases of CPMDs may be unclassifiable.⁶

PV appears to be more common in men than in women, with reported male-to-female ratios ranging from 1.2 to 2.2 in various studies.^{11–13,16} In the 1000 cases of ET in a study by McNally et al., there was no difference between the sexes. An age-specific (30–50 years) female preponderance in ET was seen, however. More males were affected by AMM. Males are more commonly affected by CEL and HES than females, with a male-to-female ratio of around 9:1 in HES.⁶

CMPDs are diseases of older individuals, with low rates until age 50, and a peak in incidence from 60 to 80 years of age.^{11,13,16} The maximum incidence of PV exceeded 20/100,000 person-years in the Olmsted County data. The median age of presentation is similar in ET, PV, and AMM, being 55–65 years. The mean age at diagnosis of PV has been increasing steadily since the 1920s.^{13,16,17} A few cases of PV diagnosed under the age of 40 have been reported.¹⁸ The age-specific mortality calculated by Prochazka and Markowe¹⁰ showed a sharp increase beginning in the early 40s, with the age-specific mortality reaching a maximum in the 75- and 84-year age group. CNL has been reported in both adolescents and older adults.^{19,20} HES may present at any age, though its peak incidence is in the fourth decade of life.²¹

Racial and ethnic factors influence the incidence of PV. PV is significantly less common in blacks than in whites. It is also more common in individuals of Jewish origin (Ashkenazi) than of non-Jewish origin.^{11,22,23}

Familial occurrence of PV has been reported, with a 6% incidence of patients enrolled in the protocols of the Polycythemia Vera Study Group, and in some sporadic cases.^{24,25}

RISK FACTORS

There is no strong evidence that supports the association of the CMPDs with environmental exposures. A number of toxic agents, including lead, saponin, and

benzene, and the Rauscher and feline leukemia virus, antigen–antibody complexes, and ionizing radiation have been shown to cause AMM in experimental animals.²⁶ The extramedullary hematopoiesis is believed to be a result of a normal response of mesenchymal cells to tissue injury. Some reported associations with AMM include exposure to toluene and benzene.^{27,28} An increased incidence of AMM was seen in patients receiving thorotrast.²⁹ The victims of the atomic bombing in Hiroshima had an 18 times more risk of AMM than that of the remainder of the Japanese population, with symptoms appearing at an average age of 6 years after the exposure, lending credence to the thought that radiation or nuclear exposure is a risk factor for developing AMM.³⁰

Chapter 46

MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS

Claire N Harrison

INTRODUCTION

The term myeloproliferative disease (MPD) was first used in 1951 by Dameshek¹ to unify the conditions chronic myeloid leukemia (CML), polycythemia vera (PV), and idiopathic myelofibrosis (MF). This group of entities later included essential thrombocythemia (ET). The revised WHO classification² also includes some newer entities and recognizes an overlap between myeloproliferative and myelodysplastic disorders (MPD/MDS) (Table 46.1). The WHO classification of these disorders interestingly does not include systemic mastocytosis, which now resides in a new group “mast cell diseases.” All these disorders have a predisposition to developing acute leukemia (usually myeloid) and/or MF to a variable extent.

This chapter focuses upon the chronic MPDs, with the exception of CML, and the overlap between

MPD/MDS disorders and mastocytosis. For each disorder in turn pathology, cytogenetics, and molecular biology will be discussed. The molecular basis of many of these conditions is becoming increasingly apparent and this has the potential to revise diagnostic pathways and to force the review of classification. For example, the V617F JAK2 mutation discovered in 2005 is present in up to 95% of PV and 50% of ET and MF, respectively.³⁻⁷

The WHO classification places more emphasis, than do previous diagnostic criteria, upon pathology, in particular on features of the bone marrow trephine most especially megakaryocyte morphology (Figure 46.1). This remains to be fully validated, and although it is currently undergoing revision, a more substantial revision may be required in the light of rapid advances in molecular knowledge (this is reviewed in detail in the Idiopathic Myelofibrosis Molecular Biology section and Figure 46.2). When all MPDs (excluding CML) are considered, cytogenetic abnormalities in order of frequency are $-Y$, $+8$, $+9$, -7 , $del(20)(q11q13)$, $del(13)(q12q14)$, $del(5)(q13q33)$, and $del(12)(p12)$. Conventional cytogenetics remain the evaluation of choice, but for rarer specific abnormalities (e.g., FIP1L1 PDGFR α) either RTPCR or FISH would be required. Deletion of chromosome 20q is probably one of the best characterized abnormalities in MPD and although a minimal common deleted region has been identified, no genes have yet been classified. For the common Philadelphia negative MPDs as discussed in this chapter, the most consistent and highly prevalent molecular abnormality akin to *BCR/ABL* for CML is V617F JAK2.³⁻⁷ The discovery of thrombopoietin triggered further interest in this and other cytokines in MPDs, and much molecular research has relatively fruitfully focussed in this field. Indeed a recent mutation in the cognate receptor cMPL has been identified in a small proportion of patients with ET and MF but thus far not PV.^{8,9} A pathogenic theme for the common MPDs in particular is that somatic mutations at a stem cell level result in at least two key events—hypersensitivity

Table 46.1 WHO classification of chronic myeloproliferative diseases

Chronic myeloproliferative disease
■ Chronic myeloid leukemia
■ Chronic neutrophilic leukemia
■ Chronic eosinophilic leukemia (and hypereosinophilic syndrome)
■ Polycythemia vera
■ Chronic idiopathic myelofibrosis (with myeloid metaplasia)

■ Chronic myeloproliferative disease unclassifiable
Mixed myelodysplastic/myeloproliferative disorders
■ Chronic myelomonocytic leukemia
■ Atypical chronic myeloid leukemia
■ Juvenile myelomonocytic leukemia
Myelodysplastic/myeloproliferative disease, unclassifiable

Figure 46.1 Examples of marrow pathology features. (A) Large megakaryocyte typical of ET with distinct nuclear morphology; (B) Scanty reticulin in such cases; (C) Megakaryocyte morphology said to be more in keeping with MF indistinct nuclear morphology and clustering; (D) Dense reticulin formation; (E) Large megakaryocytes demonstrating emperipolesis.

to proliferative signals and resistance to inhibitory ones.

POLYCYTHEMIA VERA

The dominant feature of polycythemia vera (PV), also termed polycythemia rubra vera or primary proliferative polycythemia, is the excessive production of erythrocytes frequently accompanied by increases in other hematopoietic lineages. To achieve a diagnosis of PV it is important to exclude potential causes of a secondary erythrocytosis. Clinical evaluation, pathology, cytogenetics, and the determination of erythropoietin levels or demonstration of spontaneous erythroid colonies are all potentially useful. Probably the most important diagnostic feature is now the presence of detectable V617F as it is only detected in myeloid disorders (principally MPDs and occasionally leukemias¹⁰) and an elevated hematocrit.

PATHOLOGY OF PV

The blood film may show evidence of iron deficiency, neutrophilia, and basophilia and occasionally immature myeloid precursors are seen. The aspirate is usually hypercellular with increases of erythroid, granulocytic, and megakaryocytic lineages. The megakaryocytes are bigger and nuclear lobation is increased. The trephine biopsy (Figure 46.1) demonstrates a similar extent of hypercellularity. Often reticulin is increased and may

be significantly increased in 10%¹¹ Erythropoiesis is morphologically normal but abnormalities of megakaryocyte morphology are common. Megakaryocytes are not only increased but they also have abnormal morphology. Both large and small forms are seen and emperipolesis is prominent.¹² Iron stores are commonly reduced or absent. Up to one-third of patients with PV progress to florid MF in the later stages of their disease, and the pathological features are then indistinguishable from primary MF.

CYTOGENETICS

The most common cytogenetic result in PV at diagnosis is a normal study; less frequently, the following abnormalities may occur: +8, +9 (may occur concurrently); del(20)(q11q13) is also relatively common. A number of other abnormalities occur more rarely—del(1)(p11), del(3)(p11p14), t(1;6)(q11,p21), and t(1;9)(q10p10).¹³ Recent studies suggest that abnormalities of chromosome 9p may be the most common abnormality in PV.¹⁴ This may arise due to uniparental disomy resulting in loss of heterozygosity and occurs in up to 30% of PV.¹⁵ This is the location of the *JAK2* gene and mitotic recombination is the mechanism for progressing from heterozygous to homozygous V617F *JAK2*.^{3,5}

MOLECULAR BIOLOGY

The marked prevalence of the mutation V617F in *JAK2* kinase in PV (85–95%)^{3–7} implies that it is most likely to be involved in the pathogenesis of this condition.

Figure 46.2 Proposed scheme for molecular pathogenesis and classification of chronic MPDs. A primary hit or hits affect a hematopoietic stem cell and may cause a “pre-MPD stem cell.” Second hits are likely to include V617F *JAK2* and *MPLW515L/K* and other as yet unidentified mutations. A continuum through ET to advanced disease is proposed where a potential drive to progression is load of V617F *JAK2* due to mitotic recombination and clonal dominance but is likely to also include other genetic events.

This is also supported by transplantation studies in mice who rapidly develop the phenotype of PV and later also develop fibrosis.⁴ Here a single point mutation converts a highly conserved valine to a bulky phenylalanine which is thought to stoichiometrically affect the interaction between the kinase and pseudokinase domains of JAK2 (reviewed in Refs. 16 and 17). Studies⁴⁻⁶ have shown that the JAK2 mutation causes cytokine independent activation of JAK-STAT, P13K-AKT and ERK pathways, these are involved in erythropoietin receptor signaling. The current status of knowledge in relation to the role of Janus kinases in hemopoiesis and hematological malignancy has recently been reviewed.¹⁶ This mutation potentially explains many of the features previously reported in PV including hypersensitivity to a number of other cytokines, granulocyte-macrophage colony-stimulating factor, stem cell factor, interleukin-3 and insulin-like growth factor 1, and reduced expression of cMPL.¹⁸ In addition to the constitutive activity of STAT3 reported in a proportion of PV patients,¹⁹ the mRNA for polycythemia rubra vera 1 (PRV-1) is elevated in granulocytes of PV patients²⁰; overexpression of PRV-1 correlates strongly with endogenous colony formation in PV, ET, and MF^{21,22} and also with V617F.²³

ESSENTIAL THROMBOCYTHEMIA

The predominant feature of ET is a marked, otherwise unexplained, thrombocytosis accompanied in a proportion of patients by thrombotic and/or hemorrhagic features. In the long term, a proportion of patients develop MF (less commonly than PV) and acute myeloid leukemia. The evaluation of patient involves excluding other conditions such as the other MPDs, MDS, or a reactive thrombocytosis especially for those 50% of the patients in whom the V617F JAK2 mutation is not detectable.

PATHOLOGY

It is important to scrutinize the blood film when establishing a diagnosis of ET. Here platelets are increased and often larger, hypogranular forms are seen as are megakaryocyte nuclei; a neutrophilia may also be present. Features of MDS, MF, iron deficiency, or hyposplenism (may be present in ET due to splenic infarction) should be excluded. The aspirate shows increased numbers of large, hyperlobated megakaryocytes and platelet drifts may be prominent. Trephine biopsy appearances are variable in ET; the marrow is not always hypercellular but megakaryocytes are always increased (Figure 46.1). The extent to which megakaryocyte morphology can be used to ascertain a definitive diagnosis of ET, where the megakaryocytes are enlarged and mature, or furthermore to discriminate between

true ET and a prefibrotic phase of MF²⁴ (a subgroup with a worse prognosis)²⁵ is unclear. The atypical features include immature megakaryocytes with clustering, cloud-like nuclei, erythroid hypoplasia, and increased and dysplastic granulopoiesis (Figure 46.1). It would be very attractive to be able to further subdivide patients prognostically; however, megakaryocyte morphology is notoriously difficult to reproducibly assess, and thus far there has been no evaluation of interobserver variation. The prognostic and diagnostic significance of varied reticulin density or scoring in ET remains similarly unclear.

CYTOGENETICS

Almost 95% of ET patients will have normal cytogenetics.²⁶ Abnormalities when present are highly variable; MF or progression to leukemia is reported in association with del(13)(q12q14)²⁷ but it is not clear that this abnormality is predictive of progression. It is important to use FISH or RTPCR at diagnosis in ET to exclude the presence of *BCR/ABL*, where the correct diagnosis would be CML.

MOLECULAR BIOLOGY

ET is a clinically heterogeneous disorder which is reflected in molecular analyses in these patients. Indeed a significant proportion of ET patients do not have clonal hemopoiesis as assessed using X-chromosome inactivation patterns and this subgroup may be at a lower risk of thrombotic complications.^{28,29} These findings may also reflect technical limitations or a low disease burden undetectable against a polyclonal background.

The V617F JAK2 mutation is detected in 50% of patients with ET^{3,30,31} and painstaking analysis of progenitors suggests that in ET it is highly unusual to detect homozygosity for V617F JAK2.³² The majority of ET patients negative for V617F JAK2 mutation have features characteristic of an MPD.³³ The V617F positive ET patients share features in common with PV patients including higher hemoglobins and white cell counts^{30,34} but have features that constrain erythropoiesis such as low erythropoietin levels and iron stores.³⁴ A small proportion of ET patients appear to have one of two mutations in cMPL in the juxtamembrane domain of the intracytoplasmic tail^{9,35} in mouse models this recapitulates the clinical features of ET and MF.⁹

Most patients with V617F JAK2 negative ET or MF will continue to be V617F JAK2 negative as suggested by most published data thus far^{36,37}; potential candidates for molecular aetiology in V617F JAK2 negative ET are manifold.

There is an emerging evidence for a V617F JAK2 negative subclinical pre-MPD phase most powerful of which is that in patients previously noted to be V617F JAK2 positive when a leukemic clone emerges it is

frequently V617F negative.³⁶ An alternative explanation for V617F JAK2 negative leukemia occurring in these patients is that V617F JAK2 must be lost to induce a block upon differentiation; however, experiments to investigate loss of heterozygosity in the appropriate chromosomal region suggest this is not the case. Most of these patients had received hydroxyurea alone not multiple therapies so transformation of a normal stem cell seemed improbable. Further data suggesting a disparity between size populations of clonal myeloid cells (as judged by X-chromosome inactivation patterns) and V617F JAK2 positive cells also suggests a pre-V617F clone^{38,39}; where clonality is judged by loss of heterozygosity at 20q this data is most convincing³⁸ as there are significant problems in interpreting clonality using XCIPs in V617F JAK2 positive disease.³⁶

CHRONIC IDIOPATHIC MF

Chronic idiopathic MF or MF with myeloid metaplasia is a rare condition in which myeloproliferation is associated with increased fibroblast proliferation neoangiogenesis and extramedullary hemopoiesis. MF may occur in later phases of the other MPDs namely ET, PV, and CML and this reflects the continuum and substantial overlap of clinical features in the MPDs, and given the prevalence of V617F JAK2 mutation adds weight to the need to reconsideration of disease classification as discussed later.

PATHOLOGY

Bone marrow features of this condition are variable. Cellularity ranges from being increased to markedly reduced or near absent normal hematopoiesis. Fibrosis ranges from a focal increase of reticulin to coarse parallel reticulin, the presence of collagen, and osteogenesis or new bone formation (Figure 46.2). Dense fibrosis is also associated with dilated marrow sinusoids and intrasinusoidal hematopoiesis. Variable systems of reticulin grading are in routine use and a unified system is required to inform future studies. Megakaryocyte morphology is a key to identify the newly proposed diagnostic entity prefibrotic MF. In prefibrotic MF there is at most a borderline increase in reticulin, reduced erythropoiesis, and increased granulocytic and megakaryocyte proliferation, and reactive lymphoid follicles may also be apparent. Significant megakaryocyte abnormalities (as discussed in ET)⁴⁰ are a key to differentiating this entity from ET. Yet to be delineated is whether or not this is a distinct disease entity and whether hematopathologists can reliably establish this diagnosis. The spleen is a common site of extramedullary hematopoiesis in MF and variable patterns of infil-

tration by myeloid precursors are identified, from diffuse to nodular or a predominance of myeloid precursors.⁴¹

Blood film appearances are important in making the diagnosis of MF. The most characteristic include leucoerythroblastic features with teardrop poikilocytes; dysplastic features may be present in granulocytes and platelets. In the early stages of MF, these features may be either absent or not prominent.⁴² Increased CD34⁺ cells and an elevated LDH may also be demonstrated.

CYTOGENETICS

Conventional cytogenetic evaluation of patients with MF often fails presumably because of marrow fibrosis precluding obtaining sufficient cells on aspiration. Fibrosis was shown to be a secondary process as fibroblasts in culture were either cytogenetically normal or had clones that differed from the marrow.⁴³ A normal karyotype is at least as frequent as an abnormal one; furthermore some studies suggest an associated prognostic significance.⁴⁴ In a larger study reported by Tefferi⁴⁵ 90% of abnormalities were either +8, +9, del(20)(q11q13), del(13)(q12q14), and del(12)(p12) or involved chromosomes 1 or 7. Here only +8 or del(12)(p12) appeared to be independent prognostic indicators.

Of interest is the fact that chromosome 13 abnormalities (del(13)(q12q14) or translocations involving this region) appear to be consistently present both in primary MF and, most likely, as a second event in MF which evolves in the other MPDs.^{46,47} The del(13)(q12q14) potentially results in the loss of *RB*, a well-characterized tumor suppressor gene, and this has indeed been demonstrated but only in a proportion of patients with MF.⁴⁸

MOLECULAR BIOLOGY

The cause of markedly enhanced fibroblast proliferation and collagen synthesis in MF could relate to an array of humoral factors that may be released from hemopoietic cells, including both the megakaryocytes and monocytes. The fibroblasts themselves rarely display intrinsic alteration and are hence regarded as "effector cells." Megakaryocytes and platelets may influence fibroblast proliferation by virtue of their increased content, release, and abnormal packaging of alpha granule contents PDGF, PF-4, TGF β , b-FGF, and calmodulin.⁴⁹ The subcellular location of P-selectin in megakaryocytes and platelets is abnormal and may correlate with emperipoiesis, which causes disruption of the megakaryocyte organelles and causes the leakage of α -granule contents.⁵⁰ Monocytes have also been implicated in the stimulation of fibrosis. They are activated following contact with protein components of the extracellular matrix via adhesion

molecules, particularly CD44, subsequently resulting in enhanced monocyte CD25 expression and increased production of TGF β and interleukin-1. The potential role for monocytes or macrophages or indeed other genetic factors in the pathogenesis of MF is supported by animal models. At a cellular level attention has focused upon growth factor pathway anomalies and the recent identification of V617F JAK2 and MPLW515L/K^{8,9} is in keeping with this. The aetiology of MF without JAK2 or cMPL mutations is unclear but the patients have all the features associated with MPD and while one publication⁵¹ suggests they may have superior prognosis this has not been identified in all studies.⁵²

Probably the next major issue in MPDs is whether it is still relevant to subdivide V617F JAK2 positive or indeed negative disease into the three different entities (PV, ET, or MF) or is it preferable to regard the MPDs as a continuum of conditions akin to the different phases of CML. Here advanced MF or AML would represent advanced phase and ET with PV chronic phase. Unlike CML the rate of progression, if at all, of patients along this continuum is slow and patients may of course present at any point of the spectrum.

This proposal is contentious but is recently strengthened by several pieces of evidence from translational research. For example, Scott et al.³² found that none of the patients studied with ET had V617F JAK2 homozygous colonies, while such colonies were detected in all the PV patients ($p < 0.0001$) and two ET patients after polycythemic transformation. This suggests that a fundamental difference between ET and PV might be the mitotic recombination events that generate daughter cells homozygous for V617F JAK2. Evidence that total "load" of V617F JAK2 increases between the entities ET, PV, and MF (and post-polycythemic MF) has also been reported by other groups. For example Moliterno⁵³ reports the median neutrophil JAK2 V617F allele percentage was greater in PV than in ET ($p = <0.001$), and that allele percentages greater than 63% were restricted to PV and MF. Similarly, Passamonti⁵⁴ recently reported in 66/90 MPD patients that significant differences in quantity of V617F JAK2 occur between PV and ET ($p = 0.01$), or PV and pre-fibrotic MF ($p = .005$); fibrotic MF and pre-fibrotic MF ($p = 0.001$) and post-polycythemic MF having higher levels than PV ($p < 0.001$). This data accords with data from the group at the Mayo Clinic groups.⁵⁵

These findings could be extrapolated to a model of the relationship between the V617F JAK2 positive MPDs and disease progression as shown in Figure 46.1. The challenges for this model are why the majority of ET patients do not transform to PV, which may relate to a genetic predisposition to undergo mitotic recombination, as well as to elucidate the additional genetic hits causing disease progression and why some

patients progress more rapidly than others who do not progress at all.

CHRONIC EOSINOPHILIC LEUKEMIA/ HYPEREOSINOPHILIC SYNDROME

Myeloproliferative hypereosinophilic diseases are defined by a persistent (>6 months) unexplained eosinophilia greater than $1.5 \times 10^9/L$, a hypercellular bone marrow with eosinophilia, and tissue damage. They are discriminated from idiopathic hypereosinophilic syndrome by the presence of tissue damage, although this may indeed be artificial as tissue damage may be subclinical or occur in the future. While investigating these patients, a reactive cause of eosinophilia such as allergies, parasitic infections, and other malignancies (e.g., on detection of phenotypically abnormal T lymphocytes⁵⁶) should be assiduously excluded. Eosinophil morphology varies from normal to include abnormalities such as degranulation, cytoplasmic vacuolation, hypolobulation, or hyperlobulation. The presence of Chronic eosinophilic leukemia (CEL) is suggested by increased proportion of blasts, hepatosplenomegaly, raised serum tryptase, vitamin B12, and a cytogenetic abnormality. In some patients the diagnosis will only be apparent after transformation to acute myeloid leukemia.

The detection of cytogenetic abnormalities is useful in discriminating CEL from a reactive eosinophilia. Abnormalities involving 5q33 or 8p11 are most frequent and clonality has been demonstrated even in patients with normal cytogenetics by X-chromosome inactivation patterns.⁵⁷ Abnormalities of 5q33, especially t(5;12)(q33;p13), produce the fusion oncogene *TEL-PDGFR β* with constitutive activation of the kinase domain of PDGFR β originally cloned by Golub.⁵⁸ Variable morphological features have been described from chronic myelomonocytic leukemia (CMML)-like to atypical CML, as reviewed by Bain.⁵⁹ Two other translocations involving the *PDGFR β* gene are t(5;7)(q33;q11.2) and t(5;10)(q33;21.2). Rarer translocations associated with 8p11 involve the fibroblast growth factor receptor-1 (FGFR1) most commonly fusing with the *ZNF198* gene of 13q12 generating t(8;13)(q11;q12); they are frequently associated with non-Hodgkin's lymphomas and have a particular tendency to leukemic transformation.⁶⁰⁻⁶³

Recently, a novel tyrosine kinase, FIP1L1-PDGFR α , has been described in 9/16 patients with hypereosinophilic syndrome⁶⁴ and 3/5 with systemic mastocytosis.⁶⁵ This is generated by microdeletion of CHIC2 and is only detectable by RTPCR or FISH; conventional cytogenetics is unhelpful. Patients with FIP1L1-PDGFR α and eosinophilia have been reported to show a dramatic response to imatinib mesylate^{64,66} as have several with activated PDGFR β fusion tyrosine kinases.^{67,68}

CHRONIC NEUTROPHILIC LEUKEMIA

Chronic neutrophilic leukemia is a very rare disorder; just over 140 cases are reported but many of these may not fulfil the diagnostic criteria.⁶⁹ It is characterized by a leucocytosis in excess of $25 \times 10^9/L$ (lack of eosinophilia, basophilia, and few myeloid precursors), absent *bcr/abl*, and bone marrow myeloid hyperplasia without prominent blasts. A rarer form of CML bears some morphological similarities for CNL but has a variant *bcr/abl* (BCRe19/ABLa2). Hepatosplenomegaly may be present and in 20% of the cases an associated neoplasm has been reported. Cytogenetics are normal in the majority (90%). There have been no comprehensive studies of molecular biology. One of the difficulties in making a diagnosis of CNL is in differentiating it from a leukemoid reaction, here clonality may be helpful in females who have normal cytogenetics. As a leukemoid reaction is reported in association with myeloma or monoclonal gammopathy of uncertain significance, it would be wise to exclude these entities.

MASTOCYTOSIS

There is a spectrum of MPDs described by the term mastocytosis in which the characteristic feature is the presence of mast cells with abnormal growth kinetics and their accumulation in organs (Table 46.2). A detailed discourse of all these mast cell disorders is beyond the scope of this chapter; the reader is directed to a recent chapter/review for further information.⁷⁰

PATHOLOGY

The major feature of systemic mastocytosis is the finding of compact dense multifocal mast cell infiltrates in a bone marrow trephine biopsy. These are most usefully identified by means of staining for mast cell tryptase. Such infiltrates may also be identified in other organs and lymph nodes. The individual morphology of the mast cells is also important. Typically they are spindle shaped, but may demonstrate atypia, including nuclear lobulation, smaller or absent

granules, and a primitive nuclear chromatin pattern; they also aberrantly express CD2 and CD25.^{32–35,37} Reticulin is usually increased, and collagen and new bone formation may be seen. “Pseudo-granulomas” may also be apparent and commonly are associated with eosinophils, lymphocytes (sometimes lymphoid nodules), and plasma cells in addition to the mast cell infiltrate.

The determination of serum tryptase level may be a useful index of burden of mast cells and is usually elevated in systemic mastocytosis. For patients with mast cell leukemia, the infiltrate comprises immature mast cell precursors which may also be identified in the blood film. It is perhaps somewhat of an anomaly that this entity appears with the MPD in the WHO classification rather than with the acute myeloid leukemias.

CYTOGENETICS AND MOLECULAR BIOLOGY

The most important cytokine in mast cell development from CD34⁺ progenitors is stem cell factor, or KIT ligand. In a high proportion of cases of systemic mastocytosis, a mutation Asp-816-Val is often detectable in *c-kit*, which is the receptor for stem cell factor and is a valuable diagnostic marker.^{71–73} This mutation is not always confined to mast cells but is sometimes demonstrable in other hematopoietic cells, including CD34⁺ cells. Cytogenetic abnormalities are variable and include +8, +9, del (5)(q), del (7)(q), monosomy 7, and del(20)(q).⁷⁴

CHRONIC MPD, UNCLASSIFIABLE

These patients have an MPD but cannot readily be classified with an individual disease entity sometimes as they display distinctive features of two MPD. This is a very heterogeneous group.

MYELOPROLIFERATIVE/MYELODYSPLASTIC DISORDERS

CHRONIC MYELOMONOCYTIC LEUKEMIA

CMML has features both of myelodysplasia and myeloproliferation. In the WHO classification it has migrated from the MDS category into the MPD/MDS disorders. To differentiate CMML from atypical CML, evaluation of the proportion of granulocytic precursors and the blood film to identify abnormal monocytes are useful. The bone marrow is hypercellular and displays varying degrees of dysplasia and a monocytic infiltrate. Cytogenetic abnormalities are common (20–50%) but again none are specifically associated with CMML. Those patients with abnormal karyotypes are more likely to have advanced disease and to transform to acute leukemia.⁷⁵

Table 46.2 WHO classification of mast cell disorders

- Cutaneous mastocytosis
- Indolent systemic mastocytosis
- Systemic mastocytosis with associated clonal haematologic non-mast cell lineage disease (including AML, MDS, MPD, CMML, NHL)
- Aggressive systemic mastocytosis
- Mast cell leukemia
- Mast cell sarcoma
- Extracutaneous mastocytoma.

Monosomy 7 is common, as are +8, der(12p) presenting as a terminal deletion or translocation, -Y.⁷⁵ Abnormalities of chromosome 5 (-5, 5q-, t(5;12)(q31p13)) are less common in CMML than in myelodysplasia.

JUVENILE MYELOMONOCYTIC LEUKEMIA

This condition usually occurs in children less than 5 years old and encompasses conditions previously termed "juvenile chronic myeloid leukemia," infantile monosomy 7 syndrome, and other myelodysplastic/myeloproliferative diseases of childhood.

Juvenile myelomonocytic leukemia is particularly associated with monosomy 7.⁷⁶ In approximately 25–33%, other cytogenetic abnormalities (+8 and abnormalities of chromosome 7) also occur. Furthermore, there is an increased incidence in Down's syndrome and neurofibromatosis. Some 15% of children with JMML have features of neurofibromatosis, these and others without these features have abnormalities of the *NF 1* gene. Mutations of the *RAS* oncogene are present in 15–30%, but these patients do not, to date, have *NF 1* abnormalities.⁷⁷ A further factor of genetic interest includes an occasional tendency for familial cases and increased expression of hemoglobin F.

ATYPICAL CML

Atypical CML is a rare condition that occurs in older patients and has a worse prognosis than CML. The blood film demonstrates a neutrophilia and an increase in myeloid precursors sometimes with dysplastic features; monocytosis is more pronounced than either eosinophilia or basophilia. The bone marrow

features resemble CML, but an increase in monocytes is the feature which suggests atypical rather than typical CML. In common with CMML, karyotypic abnormalities are frequent in atypical CML, occurring in 30–80%,⁷⁸ +8 being the most frequent. Interestingly, a fusion gene between *PDGFRβ* and *H4* has been reported in at least one patient.⁷⁹

MYELOPROLIFERATIVE/MYELOYDYSPLASTIC UNCLASSIFIED

Patients who display features of both myeloproliferative and myelodysplastic conditions are assigned to this diagnostic entity. A proportion will evolve and change diagnostic category with time. No specific cytogenetic abnormalities are reported in this diagnostic entity other than those already discussed for the other MPDs.

SUMMARY

The MPDs and MDS/MPDs are an expanding population of largely clinically defined disorders for which thus far we lack a clear understanding of their pathogenesis and molecular biology. It seems hopeful that we may be able to expand our knowledge greatly in the future by harnessing emerging sophisticated technologies such as proteomics and microarray methods. A global culture of cooperation, identifying and sharing data from rare kindreds with apparently clonal inherited MPDs, is also likely to significantly advance knowledge in this field.

Chapter 47

CLINICAL FEATURES AND MAKING THE DIAGNOSIS

Richard T. Silver

INTRODUCTION

Under normal circumstances, the marrow progenitor cells respond selectively to differing but specific stimuli. Examples include the rise in white blood cell (WBC) count that occurs during a bacterial infection or the elevation of the platelet count after hemorrhage. Reactions such as these are self-limited, for the marrow reverts to its normal status once the stimulus subsides. Myeloproliferative disorders (MPDs), on the other hand, comprise a group of diseases in which pluripotent stem cells proliferate more or less *en masse*, at least at the onset of the illness. In the hematology literature, opinions differ as to which diseases should be included in the MPD group, but based upon improvements in clinical diagnosis and refinements in cytogenetics, and molecular biology, the diseases of major clinical importance include chronic myeloid leukemia (CML), polycythemia vera (PV), essential thrombocythemia (ET) and agnogenic myeloid metaplasia (AMM). In general, the diagnostic difficulties associated with the MPDs relate to their clinical symmetry ("clinical mimicry") and, except for CML, the lack of clinically applicable clonal markers. Thus, they share similar clinical and hematologic features. Their origin from a multipotent hematopoietic stem cell leads to clonal dominance over normal hematopoietic progenitor cells, giving rise to increased production of one or more of the formed elements of the blood. As examples, in PV, although an increased red blood cell (RBC) mass is the *sine qua non* at diagnosis, such patients often have an increase in the WBC count and/or platelet count. Physical examination of a patient with an MPD often reveals an enlarged spleen and biochemical abnormalities such as elevation in the serum values of uric acid, vitamin B₁₂, and B₁₂-binding protein. A biochemical marker that can be of value in distinguishing one MPD from another is the concentration of leukocyte alkaline phosphatase found in the cytoplasm of neutrophils. It is typically absent in patients with CML, increased in PV and ET,

and variably increased, normal, or decreased in AMM. Although cytogenetic abnormalities are seen in all patients with the MPDs, the only consistent cytogenetic abnormality, the Philadelphia (Ph) chromosome, occurs in CML, sharply distinguishing it from the others. To a varying degree, increased reticulin fibers are present in the bone marrow in all the MPDs, and as the disease progresses, fibroblastic proliferation becomes evident (probably a reactive phenomenon).

Only recently has it been appreciated that the megakaryocytes are morphologically abnormal in the myeloproliferative diseases, and biologically, are central to the genesis of the fibrosis that occurs in the marrows of patients with MPDs. An experienced hematopathologist may suspect the appropriate clinical diagnosis by studying the structural characteristics of the megakaryocytes in a bone marrow biopsy from a patient with an MPD, as their appearance differs among the four diseases.

Acute leukemia develops as an end result of all the MPDs. In decreasing order of frequency, it occurs in CML, AMM, PV, and rarely in ET.^{1,2} Acute leukemia may be a natural evolution of the disease, as is seen most often in CML, or it may also be related to the drugs used in treating the primary illness.^{1,2}

CHRONIC MYELOID LEUKEMIA

CML develops with an insidious onset of symptoms and signs, which may include fatigue, anemia, splenomegaly, and leukocytosis marked by an increase in neutrophils, eosinophils, and basophils. The median age of onset is 50 years^{1,2} the peak incidence occurs between 50 and 60 years.^{1,2} The frequency increases with age. CML occurs equally in males and females.¹

There are three phases of the disease: the first, a chronic phase, lasts 30–40 months; the second is a transitional phase called the accelerated phase; and the terminal blast or acute ("blast crisis") phase, in which the disease resembles acute leukemia. In some patients, there is no transitional phase, and the disease transforms abruptly into an acute phase.

CHRONIC PHASE OF CML

In the chronic phase, the WBC count approximates 200,000/dL. The myelocyte is the predominating cell in both peripheral blood and marrow. Myeloblasts are rare. Basophilia and eosinophilia are common. There may be slight anemia, which is normocytic and normochromic. The platelet count may be normal, decreased, or increased, but more than half of the patients have platelet counts greater than 1 million/ μL ;² however, thrombotic phenomena are rare.³ The bone marrow is hypercellular, with a striking increase in granulocytic cells. Cells resembling Gaucher cells (sea-blue histiocytes) are observed in about 10% of cases.⁴ Megakaryocytes are smaller than normal. Reticulin, in biopsy sections, is increased. Collagen stains may show fibrosis. Of unique importance is the presence of the Ph chromosome, demonstrated in approximately 95% of all CML patients. Those patient with phenotypic characteristics of CML but lacking the ph chromosome must have marrow or blood specimens examined for the molecular abnormality, the BCR-ABL oncogene, which is present in all cases. By definition, those patients in whom the BCR-ABL oncogene cannot be found are considered to have an “atypical myeloproliferative disease” or “atypical CML.”

The blast crises are divided into two general types, myeloid and lymphoid. Biphenotypic or mixed lymphoblastic–myeloblastic crises also have been observed.⁵ Lymphoid blast crisis occurs in 20–30% of patients. The cells often resemble those seen in acute lymphocytic leukemia and contain terminal deoxynucleotidyl transferase.⁶ (Terminal deoxynucleotidyl transferase is found mainly in poorly differentiated normal and malignant lymphoid cells of T-cell and B-cell origin and is lost as these lymphocytes differentiate and mature). Myeloid blast crisis may mimic acute myeloid leukemia. Megakaryoblastic⁷ and erythroblastic⁸ transformations and blast crises marked by basophilia also have been reported.

MAKING THE DIAGNOSIS

Although the complete blood count and bone marrow findings in CML cases may be classic, less marked phenotypic presentations may mimic other myeloproliferative diseases, especially AMM. The diagnosis rests on the demonstration of the Ph chromosome in the bone marrow, the (9;22) translocation in the marrow or peripheral blood by FISH (fluorescent *in situ* hybridization) studies, or by reverse transcriptase analysis by polymerase chain reaction (RT-PCR) of the marrow or blood for the molecular abnormality, the BCR-ABL oncogene.

POLYCYTHEMIA VERA (PV)

Polycythemia is defined as an increase in the volume of circulating RBCs per kilogram of body weight or, equivalently, an increase in the RBC mass. Clinically,

this is expressed as an absolute increase in the number of RBCs, usually but not always accompanied by corresponding increases in the hemoglobin and hematocrit (though the hematocrit may be affected by plasma volume). Polycythemia may occur as a primary disease of unknown cause (polycythemia vera) or as a secondary manifestation of other illnesses. The diagnosis of PV is made only after other causes of secondary polycythemia have been excluded (Table 47.1).

The terms *erythremia* and *erythrocytosis* are often used to refer to primary and secondary polycythemia, respectively. Others use erythremia as a classification for patients whose only abnormality is an increased RBC volume. Both terms are superfluous and confusing, and therefore are not recommended. The term “relative” polycythemia is also a misnomer and its use should be discontinued. Similarly, “false” polycythemia is a confusing term; it is not polycythemia because the RBC volume per kilogram of body weight is normal. In this instance, the increased hematocrit is related to a decrease in plasma volume (whereas in true polycythemia, the plasma volume is usually increased, but it may also be decreased). Other terms referring to false or relative polycythemia include

Table 47.1 Clinical classification of the polycythemias*Secondary polycythemia*

- (1) Related to inadequate oxygen delivery to tissues with respect to need
 - (1.1) Due to decreased arterial oxygen tension
 - (1.1.1) With physiologic or anatomic cardiopulmonary abnormalities:
 - abnormalities of lungs, chest bellows, or ventilatory control mechanisms
 - right-to-left vascular shunts
 - (1.1.2) Without physiologic or anatomic cardiopulmonary abnormalities:
 - low oxygen tension, i.e., high altitudes
 - impaired oxygen-carrying capacity of hemoglobin
 - (1.2) Due to decreased blood flow—congestive heart failure
- (2) Unrelated to inadequate oxygen delivery and need, and associated with benign or malignant lesions of the following:
 - kidney—cysts, hydronephrosis, adenoma, hyper-nephroma
 - cerebellum—hemangioblastoma
 - uterus—myoma
 - liver—hepatoma, hamartoma
 - other—adrenal (pheochromocytoma), lung

Familial polycythemias (normal hemoglobin function)

Primary polycythemia (polycythemia vera)

Table 47.2 Relation of absolute erythrocytosis (AE) to hematocrit (Hct)¹⁰

Hct (%)	% of patients with AE
50–52	18
56–58	65
>60	100

stress polycythemia, stress erythrocytosis, pseudopolycythemia, and benign polycythemia. Likewise, these terms should be discarded. As it is not possible to predict an increased RBC mass by a single hematocrit determination, particularly in the lower range of increased hematocrit values, a chromium-51 RBC mass (volume) determination is mandatory. For hematocrit values more than 60%, it is not necessary to determine a Cr⁵¹ RBC mass^{2,9} (Table 47.2).

Polycythemia vera is a disease characterized not only by proliferation of erythroid progenitors (which results in the increased RBC mass), but also by early myeloid cells and megakaryocytes. An increasing number of cases are now being detected prior to the development of symptoms through the use of routine screening blood counts. The median age in one series of more than 100 patients is about 50 years, and nearly 40% of the patients are seen while in their 30s and 40s.¹⁰ Other series report an older age group.^{12,13} Symptoms related to hypervolemia and hyperviscosity are usually accentuated by an increase in platelet count. Headaches, lightheadedness, vertigo, and blurred vision may occur. A most troublesome symptom is pruritus, worse after a hot bath or shower, and called “aquagenic pruritis.” Spontaneous bruising, peptic ulcers, and gastrointestinal hemorrhage are seen as the disease progresses. Secondary gout and uric acid kidney stones are relatively frequent, occurring in about 10% of the patients.¹¹

Untreated patients are also at risk for both thrombotic and hemorrhagic events,¹⁴ but in our series, thrombosis predominates (cerebrovascular, cardiovascular, and lower extremity, especially). Erythromelalgia (painful fingertips and toes) is frequent. A serious thrombotic event occurring in about 10% of patients with PV is the Budd–Chiari syndrome, due to hepatic vein thrombosis.¹⁴ This is marked by hepatosplenomegaly, ascites, edema of the lower extremities, and other consequences of portal vein obstruction.

On physical examination, about 60% of the patients in our series have had an enlarged spleen, usually 1–2 cm below the left costal margin. The complexion is usually normal, but in more advanced cases it may be dusky.

Laboratory studies reveal, in addition to the increased RBC mass (for men, RBC $\geq 36\text{cm}^3/\text{kg}$; in women $\geq 32\text{cm}^3/\text{kg}$), an elevated WBC (above 10,000/ μL) in approximately 60% of patients and an increased platelet count above 400,000/ μL in 75% of patients.⁹ Examination of the peripheral blood smear shows a

higher percentage of neutrophils, and an increased number of basophils and eosinophils. Evidence of iron deficiency exists, particularly in the bone marrow. Because of occult gastrointestinal or other internal bleeding, anemia may initially mask the diagnosis of polycythemia. Iron deficiency is manifested by a low serum iron and increased ferritin values.

As the disease progresses, extramedullary hematopoiesis (i.e., hematopoiesis in sites other than the bone marrow) occurs, often accompanied by myelofibrosis in the bone marrow. The end stage of PV is morphologically indistinguishable from that of AMM [primary myelofibrosis with myeloid metaplasia (MMM)].

Unlike CML, in PV there is no unique or specific cytogenetic marker of the disease. However, the recently, repeated molecular, abnormality, the V617F (JAK2), is of great importance. SNCE 95% or more patients abnormality.¹⁴ However, newer and more easily performed laboratory tests have demonstrated monoclonality in a number of patients with PV. Certain karyotypic changes are seen in approximately 20% of patients with PV. The most common abnormalities involve chromosomes 20 (20q⁻), or 9, trisomy of chromosome 8, and deletions of chromosomes 5 or 7¹⁵ (see Chapter 46).

Recently, it has been shown that there is impaired expression of the thrombopoietin receptor, Mpl, in the platelets of patients with PV and ET.^{16,17} Another genetic marker, the *PRV-1* gene, has been reported to be overexpressed in the RNA of peripheral blood granulocytes of both patients with PV and patients with ET.¹⁸ Testing of these markers may also be valuable for diagnosis in the future, though it is too early to use these genetic markers in practice. A schema suggested for the evaluation of patients suspected of PV is shown in Table 47.3.

Table 47.3 Suggested evaluation of a patient with polycythemia

History (family history important to exclude hemoglobinopathies and familial polycythemias)
Physical examination, including neurologic and pelvic examinations
Complete blood count, reticulocyte count, platelet count, serum uric acid
Urinalysis
Red blood cell volume with Cr ⁵¹
JAK2 determination
Serum erythropoietin
Arterial oxygen saturation
Bone marrow aspiration and biopsy with stains for iron, reticulin, and collagen
Chest X-ray, electrocardiogram
Optional:
– Leukocyte alkaline phosphatase determination
– Hemoglobin electrophoresis
– Vitamin B ₁₂ and vitamin B ₁₂ -binding capacity

Table 47.4 Criteria for the diagnosis of polycythemia vera (Polycythemia Vera Study Group Criteria)

A ₁ Increased RBC mass Men ≥ 36 cm ³ / kg Women ≥ 32 cm ³ /kg	B ₁ Thrombocytosis, platelets >600,000/cells/mm ³
A ₂ Arterial oxygen $\geq 92\%$	B ₂ WBC count $\geq 12,000/\text{mm}^3$ in absence of fever or infarction
A ₃ Splenomegaly	B ₃ Leukocyte alkaline phosphatase score >100 B ₄ Elevated serum vitamin B ₁₂ (>900 pg/mL) or elevated unsaturated vitamin B ₁₂ - binding capacity >2200 pg/mL
The diagnosis is acceptable if A ₁ , A ₂ , and A ₃ are present: (1) A ₁ + A ₂ + A ₃ or, in the absence of splenomegaly, (2) A1 1 + A2 and any two of column B	

Until recently, the diagnosis of PV was made after all causes of secondary polycythemia had been excluded (Table 47.1). The most commonly used criteria for the diagnosis of PV had been those of the Polycythemia Vera Study Group (PVSG).¹¹ These criteria were established for diagnosing patients with active polycythemia entering a therapeutic trial comparing the value of phlebotomy only, chlorambucil, or P-32.¹¹ For historical purposes, the PVSG diagnostic criteria are shown in Table 47.4. Note that the RBC mass determination was used *both* for establishing the existence of polycythemia per se and as a criterion for diagnosing PV. Categories B₂, B₃, and B₄ all reflect an increase in WBCs and their progenitors. (Yet in our series, only 60% of patients had a leukocytosis).

There are many other limitations of these criteria, which were, in fact, appreciated by the PVSG. Nevertheless, in the ensuing 40 years they have been used, and/or cited in the literature, for diagnosing patients with PV at least 270 times.^{11,18} Other limitations of the criteria include the following: (1) the increase in RBC mass should be used to establish whether or not a patient is polycythemic, and not as a diagnostic criterion; (2) the abnormalities seen on bone marrow biopsy characteristic of PV are not mentioned: these are panhyperplasia, absent iron stores, increased reticulin fibers, and morphologic abnormalities of the megakaryocytes¹⁹; (3) determination of the serum erythropoietin level is not required.

MAKING THE DIAGNOSIS

A more contemporary approach to the diagnosis of PV is outlined in Table 47.5. It includes the demonstration of an increased RBC mass, particularly for

Table 47.5 Suggested diagnostic criteria, polycythemia vera

Must have*
(a) Increased RBC mass or Hct $\geq 60\%$ in men, 58% in women
(b) Absence of any cause of secondary erythrocytosis or familial polycythemia (assumes serum erythropoietin level not increased)
And any three of the following:
(c) Palpable splenomegaly
(d) serum erythropoietin <5U/mL
(e) Platelets $\geq 400,000/\mu\text{L}$
(f) WBC $\geq 12,000/\mu\text{L}$
(g) Bone marrow biopsy
(i) Cellularity, reticulin, fibrosis
(ii) Megakaryocyte abnormalities

* Please see text regarding JAK2 expression

patients with only a modest increase in hematocrit. It is not possible to predict an increased RBC mass from a single hematocrit value, except for a hematocrit more than 60% in men and 58% in women. A careful history, physical examination, and screening laboratory studies, including oxygen saturation values, should exclude polycythemia due to inadequate oxygen delivery to tissues with respect to need; a serum erythropoietin value should be elevated in those cases where the polycythemia is associated with a benign or malignant tumor. As always, an accurate history is important. It should exclude familial polycythemias.

A proactive approach to the diagnosis of PV is shown in Table 47.5. Splenomegaly occurs in about 60% of patients, an elevated WBC in 60%, increased platelets in 75%. In PV, the serum erythropoietin most often, but not always, is less than 5U/mL. A bone marrow biopsy is helpful, both for establishing the diagnosis and for baseline purposes in order to follow the progress of the disease. Due attention should be paid to cellularity (panhyperplasia), iron stores (which should be diminished or absent), reticulin content and fibrosis, and abnormal megakaryocyte morphology.

ESSENTIAL THROMBOCYTHEMIA (ET)

By far the most common cause of thrombocytosis in general medical practice is a reactive or secondary process. This is related to acute or occult bleeding, infection, or malignant diseases. Thus, a careful history, physical examination, and appropriate laboratory studies should establish the cause of secondary thrombocytosis in the majority of cases.

Thrombocytosis may be associated with the myelodysplastic 5q- syndrome, which is characterized by deletion of the long arm of chromosome 5 (see Chapter X). In addition to thrombocytosis, these

patients will often have anemia and immature granulocytes including myeloblasts in the peripheral blood and/or bone marrow. Thus, cytogenetic studies are crucial in excluding this diagnosis.

In the absence of causes of secondary thrombocytosis, a diagnosis of ET may be considered when a patient is found with an increased platelet count ($\geq 400,000/\mu\text{L}$), symptoms of thrombosis (usually), or hemorrhage. ET is a disease characterized by an increased platelet count owing to proliferation of an abnormal clone of megakaryocytes unresponsive to normal control mechanisms governing platelet production.

ET affects young and middle-aged women and men. Recurrent thromboses and, paradoxically, bleeding are the cardinal features. Although some patients, particularly younger ones, remain asymptomatic for long periods, approximately 50% of patients with ET are first seen as emergencies because of an episode of vascular occlusion that may be either arterial, venous, or both.

In our center, most younger patients present with thromboses rather than hemorrhage. Variable symptoms and signs include transient ischemic attacks, stroke, thrombosis of the splenic and/or hepatic veins, and evidence of peripheral circulatory impairment characterized by digital cyanosis, erythromelalgia, and pain and burning owing to microvascular clogging of small vessels by platelets. Clinical bleeding is manifested by easy bruising, bleeding of mucosal surfaces, epistaxis, unexplained hemorrhage, and postoperative hemorrhage.

Aside from the physical findings related to the aforementioned, physical examination of the asymptomatic patient is usually unremarkable. About one third of asymptomatic patients have splenomegaly, which is only modest in degree (1–3 cm below the left costal margin).

The peripheral smear shows clusters and clumps of megakaryocytes and giant platelets. Granulocyte and RBC morphology is essentially normal. The WBC is slightly increased in a minority of patients. Cytogenetic abnormalities (not related to the Ph chromosome diagnostic of CML) are present in only a few patients with ET. The overall significance of cytogenetic abnormalities in terms of clinical course and prognosis is unclear.

Sometimes, an often unrecognized and curious laboratory abnormality may lead to the diagnosis of ET in asymptomatic patients. When a routine electrolyte panel is submitted for analysis, an artificially abnormal high potassium value may be found. This is due to loss of potassium released from large numbers of platelets, which occurs during clotting *in vitro*. This abnormality is not associated with any deleterious clinical effect. This spuriously high potassium value is known as pseudohyperkalemia. If a potassium determination is required from a patient with ET, a plasma sample, wherein unclotted blood is submitted for laboratory analysis, will avoid this problem.

As in PV, abnormalities of the MpL receptor abnormality^{16,17} and the *PRV-1* gene occur in ET.¹⁸ As yet, the practical clinical use of these two tests remains to be established. Abnormal JAK2 expression has been observed in approximately 50% of patients with ET. It has been suggested that the course of JAK2 (+) patient may be more aggressive than JAK2 (–) patients but it is too soon to rely in this statement as fact.¹⁹ Thus, ET is largely based on exclusion of secondary reactive causes of thrombocytosis.

Recently, in ET, the morphologic changes in marrow megakaryocytes have been appreciated.²⁰ Thus, all patients with a presumptive diagnosis of ET should have a marrow biopsy performed. In reactive thrombocytosis, the number of megakaryocytes is slightly-to-moderately increased, but size and nuclear lobulation remain normal; there is no tendency for megakaryocytes to cluster together. Megakaryocytes in ET, increased in number, are scattered or loosely grouped within the bone marrow. ET megakaryocytes are characterized by large, giant-sized megakaryocytes and exhibit deeply lobulated staghorn-like nuclei. Sheets and clumps of platelets may be associated with masses of platelet debris.

The platelet abnormality occurring in ET cannot be quantified by any measure of platelet dysfunction; despite a great deal of research, the pathophysiologic basis for excessive bleeding and thrombosis is not clearly understood. The results of *in vitro* platelet function tests are variable and show impaired or absent epinephrine-induced platelet aggregation. There is no exact correlation between the platelet count and thrombosis or hemorrhage, although in general, the higher the platelet count, the greater is the likelihood of these events occurring.

The diagnostic criteria for ET are shown in Table 47.6. These criteria are based on modified criteria proposed originally by the Polycythemia Vera Study Group (PVSG) and the World Health Organization.²¹ All criteria must be fulfilled to make a diagnosis of ET. Note that collagen fibrosis of the marrow in 1/3 of the marrow was allowed by the PVSG. Permitting this degree of fibrosis may confuse ET with early cases of AMM (MMM).

MAKING THE DIAGNOSIS

The platelet count of reactive thrombocytosis accompanying inflammation, bleeding, cancer, or infection is rarely elevated to the degree seen in ET. A Serum, ferritin level is helpful in excluding iron deficiency (bleeding as a cause of thrombocytosis). Thrombosis never occurs in secondary thrombocytosis. All patients considered to have ET should have cytogenetic or molecular studies performed to exclude CML, a disease that can present in a patient with an increased platelet count and only a modest elevation of the WBC. For patients with borderline or moderately elevated RBC values, a Cr⁵¹ RBC mass study is mandatory to exclude PV. JAK2

Table 47.6 Suggested diagnostic criteria, essential thrombocythemia

1. Sustained platelet count greater than $400 \times 10^3/L$
2. No cause for a reactive thrombocytosis due to inflammation, infection, bleeding, neoplasia, prior splenectomy
3. Hematocrit less than 40% or normal red blood cell (RBC) mass
4. Stainable iron in the marrow or normal RBC mean corpuscular volume
5. No Ph chromosome or <i>bcr/abl</i> gene rearrangement
6. Bone marrow biopsy specimen showing proliferation—mainly of the megakaryocytic lineage with increased numbers of enlarged, mature megakaryocytes with nuclei resembling staghorns
7. Collagen fibrosis of the bone marrow absent. Reticulin fibrosis minimal or absent
8. No significant splenomegaly or leukoerythroblastic blood film
9. No evidence of a myelodysplastic syndrome

positivity is helpful in diagnosis in about half the patient seen.

AGNOGENIC MYELOID METAPLASIA (AMM)—MYELOFIBROSIS WITH MYELOID METAPLASIA (MMM)

AMM (also known as idiopathic MMM), is characterized initially by a hypercellular bone marrow, extramedullary hematopoiesis, splenomegaly, and a leukoerythroblastic peripheral blood picture. The disease can be defined as the causally unknown (agnogenic) proliferation of hematopoietic cells (myeloid cells) in organs or tissues that are not usually involved in blood cell formation (metaplasia). *Extramedullary hematopoiesis* is a term meaning that this blood cell formation occurs outside the medullary or bone marrow cavity. Leukoerythroblastic anemia means that WBCs and RBCs of varying degrees of immaturity are seen in the peripheral blood.

AMM occurs primarily in older patients. Nearly two thirds of the cases occur between the ages of 50 and 70, about equally in men and in women. Symptoms and signs depend upon the stage of disease when the patient is first encountered. Most often, symptoms are related to anemia and/or an enlarged spleen. Otosclerosis, which can be a presenting symptom in advanced cases, causes deafness in about 10% of patients.

Symptoms and signs depend upon the stage of disease when the patient is first seen. Classically, the spleen is enlarged, the degree depending upon the severity and/or duration of the disease. About a fourth

of the patients are asymptomatic and seek medical attention solely because an enlarged spleen is found on routine physical examination, or because of an abnormal peripheral blood smear. Those patients who become symptomatic suffer from fatigue, symptoms related to an enlarged spleen, gout due to elevated uric acid levels, and constitutional symptoms such as weight loss, night sweats, fatigue, and peripheral edema. The latter represent advanced symptoms. Pressure of a large spleen on the stomach may lead to delayed gastric emptying and early satiety.²¹ Myeloid metaplasia may occur in unusual sites, such as the pulmonary, gastrointestinal, and central nervous systems. Although extramedullary hematopoiesis occurs frequently in the lymph nodes, it rarely accounts for significant nodal enlargement.

Splenomegaly may be found only on radiographic or sonographic examination when it cannot be appreciated clinically.

The hemoglobin ranges between 9 and 13 g/dL. The WBC count is elevated in about half of the patients, normal in one third, and low in the remainder. Examination of the peripheral blood smear discloses a shift toward granulocytic immaturity, including a few myeloblasts and promyelocytes. Significant changes in the RBCs include variation in size and shape and teardrop-shaped forms (though teardrop forms are not specific for AMM). Large fragments and clumps of megakaryocytes and large platelets may be seen. Nucleated RBCs are noted in advanced cases. The platelet count may be increased, normal, or low, depending upon the stage of disease.

The bone marrow aspirate in almost every patient yields a “dry tap,” even when the marrow biopsy is highly cellular. Recently, a prefibrotic stage of AMM without splenomegaly has been defined, with the diagnosis based on bone marrow findings (see below). Thus, unless a marrow examination is performed when the patient is initially seen, the clinical diagnosis may be confused with ET. A bone marrow biopsy shows panhypercellularity in the early stages of the disease and, most strikingly, increased numbers of morphologically atypical megakaryocytes appearing in clusters.^{18,22} These changes occur when there is little fibrosis, and have been labeled “the prefibrotic state.”²² Previously, such patients had been incorrectly thought to have ET.²² Often the nuclear segmentation with hypolobulation of the megakaryocytes gives rise to a bulbous or open nuclear appearance. Megakaryocytes in AMM are more atypical than those in other subtypes of MPDs, and consequently present the major discriminating diagnostic hallmark. As the disease progresses, there is a striking increase in reticulin and collagen fibrosis. In advanced stages, overt collagen and fibrous osteosclerosis is noted. Special silver stains demonstrate an increase in the amount of reticulin fibers even before the classic increase in collagen tissue occurs.

Obviously, the true morphologic diagnosis of myeloid metaplasia (or equivalently, extramedullary hematopoiesis) rests upon the demonstration of this process in the spleen and/or the liver; however, rarely are the risks justified to make the diagnosis by biopsy of either of these organs.

As the disease progresses, the spleen gradually enlarges, as may the liver. Anemia becomes more severe and is complicated both by iron deficiency owing to bleeding from esophageal varices and by relative folic acid deficiency. The high portal blood flow due to the enlarged spleen may cause “forward liver failure,” portal hypertension, and ascites. Thrombosis of the hepatic vein and development of the Budd–Chiari syndrome have been recognized. Eventually, the spleen may occupy the entire abdomen. Ascites may develop.

Chapter 48

TREATMENT APPROACH TO POLYCYTHEMIA VERA AND ESSENTIAL THROMBOCYTHEMIA

Steven M. Fruchtman and Celia L. Grosskreutz

POLYCYTHEMIA VERA

INCIDENCE AND CLINICAL PRESENTATION

The incidence of polycythemia vera (PV) is slightly higher in men than in women (2.8 vs 1.3 cases per 100,000 per year).¹ The mean age at diagnosis is 62 years (range, 20–85).²

The clinical presentation of patients with PV can be nonspecific, and may include headaches (48%), weakness (47%), dizziness (43%), pruritus (43%), and excessive sweating (33%). Most patients are asymptomatic and come to a hematologist's attention based on a "routine" complete blood count (CBC).

Erythromelalgia (burning pain in the feet and hands accompanied by erythema, pallor, or cyanosis) is common in PV and is considered to be secondary to microvascular thrombotic complications (also seen in essential thrombocythemia, ET). It is more common when platelet counts are above 400,000/ μ L.³

Venous and arterial thrombosis are also common in PV patients and are related to increased blood viscosity and other unknown factors. Major thrombotic events can happen in 15% of the patients and include cerebrovascular accidents, myocardial infarction, superficial thrombophlebitis, deep venous thrombosis, pulmonary emboli, Budd–Chiari syndrome, and mesenteric thrombosis.⁴

Gastrointestinal symptoms of peptic ulcer disease are common and can be attributed to histamine release from tissue basophils and from *Helicobacter pylori*.⁵

On physical exam, patients often will have splenomegaly (70%), facial plethora (67%), and hepatomegaly (40%).

Laboratory abnormalities may include elevated hematocrit and red blood cell mass in almost all patients, platelet count >400,000/ μ L (in 60%), and a white blood cell (WBC) count >12,000/ μ L (in 40%). Bone marrow cellularity is increased in 90% of cases, and iron storage is absent in 95%.

SURVIVAL

Survival in symptomatic patients without treatment is estimated to be between 6 and 18 months, and with appropriate therapy >10 years. However, the mean survival is influenced by the age at diagnosis. Thus, younger patients diagnosed and managed appropriately can have longer survivals. The main causes of death are thrombosis (29%), hematologic malignancies in those treated in previous eras with alkylating agents (23%), nonhematologic malignancies (16%), hemorrhage (7%), and myelofibrosis with myeloid metaplasia (3%).⁶

DIAGNOSIS

The diagnosis of PV can be made with great confidence if the proposed modified criteria are used, as shown in Table 48.1.⁷ Despite its inclusion in Table 48.1, the need for routine red cell mass determination

Table 48.1 Proposed modified criteria for the diagnosis of polycythemia vera

A1	Raised red cell mass (>25% above mean normal predicted value, or PCV \geq 0.60 in males or 0.56 in females)
A2	Absence of cause of secondary erythrocytosis
A3	Palpable splenomegaly
A4	Clonality marker, i.e., acquired abnormal marrow karyotype
B1	Thrombocytosis (platelet count >400 \times 10 ⁹ /L)
B2	Neutrophil leucocytosis (neutrophil count >10 \times 10 ⁹ /L; >12.5 \times 10 ⁹ /L in smokers)
B3	Splenomegaly demonstrated on isotope or ultrasound scanning
B4	Characteristic BFU-E growth or reduced serum erythropoietin

A1 + A2 + A3 or A4 establishes PV; A1 + A2 + two of B establishes PV.

Table 48.2 Common causes of secondary erythrocytosis**Congenital**

Mutant high-oxygen-affinity hemoglobin
 Congenital low 2,3-diphosphoglycerate
 Autonomous high erythropoietin production

Acquired

Arterial hypoxemia (high altitude, cyanotic congenital heart disease, chronic lung disease)
 Other causes of impaired tissue oxygen delivery (smoking)
 Renal lesions (renal tumors, cysts diffuse parenchymal disease, hydronephrosis, renal artery stenosis, renal transplantation)
 Endocrine lesions (adrenal tumors)
 Miscellaneous tumors (cerebellar hemangioblastoma, uterine fibroids, bronchial carcinoma)
 Drugs (androgens)
 Hepatic lesions (hepatoma, cirrhosis, hepatitis)

is controversial. Its major utility is in the evaluation of border line elevations of hematocrit. It is important to exclude secondary causes of erythrocytosis (Table 48.2) related to increased erythropoietin, which may be physiologically appropriate (e.g., high altitude, smoking) or physiologically inappropriate (e.g., erythropoietin-secreting tumors). Thus, the measurement of serum erythropoietin is helpful in the differential diagnosis. PV patients have low or normal erythropoietin production secondary to a negative feedback mechanism. In contrast, patients with secondary erythrocytosis typically have elevated erythropoietin levels.

TREATMENT

The aim of treatment is to prevent thromboses by reducing the elevated red cell mass, often with phlebotomy. Some patients require cytoreductive drugs to control the number of circulating blood elements, while others benefit from low-dose aspirin. The only potentially curative therapy is allogeneic stem cell transplantation. This is a consideration only in patients who develop high-risk postpolycythemic myeloid metaplasia with myelofibrosis, or transformation to acute leukemia.

Phlebotomies

Phlebotomies of 250–500 mL as frequently as every other day should be performed until a hematocrit of between 40 and 45% is obtained. In older adults and in those with compromised hemodynamic status, only 250–300 mL should be removed each session, with a frequency of not more than twice a week. Once a normal hematocrit is achieved, a blood count should be checked every 4–8 weeks, and phlebotomy should be performed whenever the hematocrit is greater than 45% in men and 42% in women.⁸

Myelosuppression

Phlebotomy will not be able to control leukocytosis, hyperuricemia, hypermetabolism, pruritus, and the complication of splenomegaly that are seen in PV

patients. Patients treated with phlebotomy alone have a higher incidence of serious thrombotic complications during the first 3 years of therapy when compared to patients treated with myelosuppression.⁶ Thus, older patients who are more prone to thrombotic disease should be treated with myelosuppression in addition to phlebotomy. Recent data from the European Collaboration Low Dose Aspirin Trial in PV (ECLAP) suggest that low-dose aspirin may also prevent certain thrombotic complications.⁹

Hydroxyurea HU is an antimetabolite that prevents DNA synthesis by inhibiting ribonucleoside reductase. The initial dose is 15 mg/kg daily orally, and subsequent adjustment of the dose is based on initial weekly blood counts for a month, to control the hematocrit without causing leukopenia or thrombocytopenia. If the WBC count falls below 3500 cells/mm³ or the platelet count falls to less than 100,000/mm³, HU is withheld until these elements normalize, and then is reinstated at 50% of the prior dose. When the peripheral blood count is maintained within an acceptable range on a stable dose of HU, the interval between blood counts is lengthened to every 2 weeks, and then to every 4 weeks.

For patients who require frequent phlebotomies or who have platelet counts greater than 600,000/mm³, the dose of HU can be increased by 5 mg/kg daily at monthly intervals, with frequent monitoring until control is achieved. The majority of patients will be controlled with doses between 500 and 1000 mg daily. Supplemental phlebotomy is preferable to increased myelosuppression to control the hematocrit.

In emergency situations, particularly in those presenting with signs of decreased cerebral perfusion in the setting of an elevated hematocrit or marked thrombocytosis, more rapid control of disease may be crucial.

In these emergency situations, daily phlebotomy to a hematocrit of 45% should be accompanied by a loading dose of HU of 30 mg/kg/day for 7 days, followed by a maintenance dose of 15 mg/kg daily. Besides the requirement for close observation to prevent excessive marrow suppression, acute toxicity of HU is rare; occasionally, rash, fever, nausea, and oral or lower extremity ulcerations may be seen. The leukemogenic potential of HU is an issue that remains unsettled, though most evidence indicate it has little or no potential to induce leukemia.^{10,11} This has prompted trials with other agents considered safe for long-term use, such as interferon- α (IFN- α) and anagrelide.

Interferon- α IFN- α is a biologic response modifier that suppresses the proliferation of hematopoietic progenitors. In PV patients, IFN- α reduces the hematocrit to below 45% in 60% of the patients. It is also highly effective in controlling the platelet counts. The initial dose of IFN- α is 3 million units three times per week subcutaneously. Full response usually requires 6 months to a year of treatment. The major side effects

are flu-like symptoms, fever, and joint pain that can be controlled with acetaminophen. Liver function abnormalities and depression are also seen. IFN- α does not cross the placenta, and thus may be used in pregnant women who have a need for myelosuppression, although the majority of pregnant women do not have an indication for marrow suppression and the CBC may normalize during pregnancy. It can aid in the treatment of pruritus.¹²

Anagrelide It is an oral quinazoline derivative that has a profound effect on the maturation of megakaryocytes, resulting in a reduction of platelet production. It controls thrombocytosis in 66% of patients with PV or ET. Time to response is between 17 and 25 days. It is also reported to cause a minimal decrease in hematocrit. The initial dose should be 0.5 mg orally twice daily. Typically, steady state doses are 2.2–2.5 mg daily. The most significant side effects include palpitations, fluid retention, dizziness, and headaches; these are related to the drug's vasodilatory and inotropic properties. They can be minimized by initially starting with a low dose, such as 0.5 mg twice daily, and gradually increasing the dose until control of the platelet count is achieved. Patients with lactose intolerance may have diarrhea due to packaging of anagrelide with lactose. Patients with PV treated with anagrelide in one study developed acute leukemia at a rate of 2.6% (13 of 455). However, all the patients were previously exposed to other cytoreductive agents. There were no patients who transformed to acute leukemia who were exposed only to anagrelide.¹³

Antithrombotic therapy

Low-dose *aspirin*, 80–100 mg daily, seems reasonable to recommend, in addition to cytoreduction, for patients who have a prior history of thrombosis or cardiovascular disease.⁹ In addition, aspirin is effective for the treatment of erythromelalgia and other microvascular, neurologic, and ocular disturbances.

In patients with PV who continue to have thrombotic or vascular symptoms, despite aspirin and good control of the hematocrit and platelet count with phlebotomy and myelosuppression, *clopidogrel* 75 mg daily or *ticlopidine* 250 mg orally twice daily should be considered.¹⁴

ESSENTIAL THROMBOCYTHEMIA

INCIDENCE AND CLINICAL PRESENTATION

The incidence of essential thrombocythemia (ET) has been reported to be 2.38 patients/100,000 population/year. ET and PV appear to have approximately a 1:4 relative incidence,¹⁵ but ET may have been underdiagnosed until the recent introduction of routine platelet counts included in the CBC. ET affects primarily middle-aged people, with an average age at diagnosis of 50–60 years. In several reports, a higher prevalence in females has been noted.

The presenting symptoms of patients with ET are variable. Many patients (12–67%) reach medical attention fortuitously, as a result of an extreme degree of thrombocytosis detected when obtaining a routine blood cell count. Most patients present with symptoms related to small- or large-vessel thrombosis or minor bleeding. Neurologic complications are common, with headaches being the most common and paresthesias of the extremities second.^{16,17} Transient neurologic symptoms seen in ET include unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine-like symptoms, syncope, and seizures.

Erythromelalgia refers to a syndrome of redness and burning pain in the extremities, and is usually preceded by paresthesias. It is caused by microvascular circulatory insufficiency. Cold is reported to provide relief to these symptoms, while heat intensifies them.

Symptoms related to coronary artery disease or transient ischemic attacks may precede or accompany the onset of erythromelalgia.¹⁶ Thrombosis of large veins and arteries in patients with ET still occurs commonly,¹⁸ particularly in the arteries of the legs (30%), the coronary arteries (18%), the renal arteries (10%), and splenic and hepatic veins (Budd–Chiari syndrome) (7%).

Spontaneous abortion during the first trimester of pregnancy was found in 43% of ET patients, compared with 15% expected in the general population, and is due to placental thrombosis leading to placental infarction.¹⁹

Hemorrhagic problems plague some patients with ET; the primary site of bleeding is the gastrointestinal tract. Other sites of bleeding may be the skin, eyes, urinary tract, gums, tooth sockets (following extraction), or brain. The syndrome of hemorrhagic thrombocythemia is closely correlated with a significant increase of platelet counts in excess of $1000 \times 10^6/L$, and is associated with pseudohyperkalemia.^{3,16} It is also associated with the development of acquired von Willebrand deficiency due to the adsorption of von Willebrand multimers by the platelets and megakaryocytes.

Constitutional symptoms, such as weight loss, sweating, low-grade fever, and pruritus, can occur in 20–30% of the patients, and can be improved with the initiation of myelosuppressive therapy. Splenomegaly is detectable in 40–50% of patients, and 20% have hepatomegaly.

CRITERIA FOR DIAGNOSIS OF ET

1. Platelet count $>600,000/mm^3$ on two different occasions, separated by a 1-month interval.²⁰
2. Hemoglobin level ≥ 13 g/dL or normal red cell mass (males <36 mL/kg and females <32 mL/kg).
3. Stainable iron in marrow or normal iron studies.
4. Collagen fibrosis of marrow:
 - (a) absent or

- (b) <1/3 biopsy area without both splenomegaly and leukoerythroblastic reaction.
5. Absence of the Philadelphia chromosome or the fusion *bcr/abl* gene by polymerase chain reaction; absence of clonal cytogenetics abnormalities associated with myelodysplastic disorders.
 6. Absence of identifiable cause of reactive thrombocytosis.

LABORATORY FINDINGS

Laboratory findings include platelet count in the range of 450,000–1,000,000/mm³, leukocytosis, basophilia, and the presence of megathrombocytes in the peripheral smear. Marrow cellularity is increased in 90% of the patients, with bizarre megakaryocytes with nuclear pleomorphisms and clustering of megakaryocytes. Enlargement of megakaryocytes with multilobulated nuclei, and their tendency to cluster in small groups along sinuses, is the hallmark of ET.²¹ The bone marrow may also appear normal.

Bleeding times are prolonged in 10–20% of the patients. Platelet aggregation studies are frequently abnormal, most often demonstrating impaired aggregation in response to epinephrine, ADP, and collagen, but not to arachidonic acid and ristocetin.²² Laboratory features of acquired von Willebrand syndrome (simulating type II vW factor deficiency) are associated with a platelet count >1000 × 10⁹/L. An enhanced thrombotic risk in ET patients has been associated with a reduction in the concentration of protein S, antithrombin III, protein C, and resistance to activated protein C resulting from an associated genetic defect in factor V,²³ along with patients who have both ET and acquired anticardiolipin antibodies.

TREATMENT

The optimal therapy for patients with ET remains uncertain. Certain concepts, however, apply to all patients. One is that the precise and correct diagnosis is of utmost importance, and that all patients with ET should stop smoking to minimize the risk factors associated with atherosclerotic disease and thrombosis. Indiscriminant use of high doses of nonsteroidal anti-inflammatory drugs, especially in those patients with extreme elevations in platelet numbers ≥1,500,000, should be avoided because this practice can lead to an increased risk of hemorrhage. Use of such agents is particularly common in the older age group in which ET is common. Finally, cytoreductive agents such as those that have been used in the past and have more recently been shown to increase the rate of leukemic transformation must be avoided.²⁴

In a randomized trial of high-risk patients, cytoreductive therapy has been shown to lessen the chance of developing additional thrombotic events.²⁵ High-risk patients include patients older than 60 years and patients with a history of a previous thrombotic episode,

including erythromelalgia, transient ischemic attacks, or large vessel thrombosis. Until a pharmacologic agent is available that is well tolerated and is proven safe for long-term use, no myelosuppressive therapy is an acceptable alternative in asymptomatic patients younger than 60 years. If a patient has a platelet count ≥1,500 × 10⁹/L and the acquired von Willebrand syndrome, platelet reduction therapy is also indicated to avoid the high risk of hemorrhage. Patients with this syndrome should avoid the use of aspirin.

In those patients requiring platelet reduction therapy, the choice between the use of anagrelide, IFN-α, and HU therapy is based upon patient age, ease of administration, comorbidities, and drug-related toxicity. In patients older than 60 years, HU therapy is the treatment of choice, while in younger patients, who may require myelosuppression, we prefer to initiate therapy with anagrelide. If a patient cannot tolerate anagrelide, we then start therapy with HU. Although we remain concerned about the leukemogenic potential of HU, whether or not there is an increased risk is controversial; clearly, the risk is less than that with alkylating agents or ³²P. Those patients who initially receive HU and no longer respond to this agent or suffer toxicity and require another agent should not receive long-term ³²P or melphalan therapy. This sequence of administration is associated with an extremely high risk of leukemic transformation. Those patients who have had a trial of HU and require further treatment should receive either anagrelide or IFN-α. Doses of each of these agents required for disease control will, of course, be dependent on the target platelet level.

Strict control to a platelet count ≤450 × 10⁹/L may lead to greater protection from thrombosis than merely reduction to a level ≤600 × 10⁹/L. There are no randomized trials to support this approach, but the available anecdotal information is compelling, and this objective may be easier to achieve with anagrelide or IFN-α than agents from previous eras, as neutropenia can be avoided.²⁶ Our success in achieving this goal is dependent on the ability of the patient to tolerate the agents used. In the younger patient, if such strict control is not achievable due to poor compliance or toxicity associated with the agents used, we are satisfied with continuing therapy and accepting a higher platelet number in the 600 × 10⁹/L range. In these patients, the addition of low-dose aspirin (81 or 100 mg/day) should be considered; it is less clear to us if those patients who achieve better platelet control with cytoreductive therapy should also be so treated. However, if one examines recent studies from Europe in PV trying to address this question, the approach of combining aspirin with cytoreduction in patients requiring cytoreduction appears to minimize thrombotic complications.⁹ In patients who suffer from thrombotic episodes, particularly episodes involving the microcirculation or large vessels, we administer low-dose aspirin (81 mg/day). This dose of aspirin may

increase the number of bleeding episodes to a modest degree, but is effective in treatment of thrombotic events, which are the major cause of mortality.

HU can be started at a dose of 1 g/day and then adjusted to achieve a target platelet count ($<350 \times 10^9/L$), with care to avoid the development of significant leukopenia. Anagrelide is initiated at 0.5 mg b.i.d. and increased by 0.5 mg/day every 5–7 days, if platelet counts do not begin to drop. The usual dose to achieve platelet number control is 2.0–2.5 mg/day. There are patients who do not tolerate either HU or anagrelide. In this patient group, IFN- α therapy is initiated at 3 million units three times per week subcutaneously. Another choice for therapy is busulfan at 4 mg/day for 2-week courses every time the platelet count rises above the normal range. Busulfan therapy is reserved for patients older than 60 years, and those refractory or intolerant to other approaches. Busulfan can precipitously drop platelet numbers, and thus patients receiving this therapy should be monitored closely.

We do not routinely treat patients younger than 40 years with cytoreduction, unless they already have had thrombohemorrhagic symptoms, have significant risk factors for atherosclerotic disease, or have other comorbidities. Serious complications even in young, otherwise healthy, patients with prolonged platelet counts of $>2.0 \times 10^6/mm^3$ are unusual. However, these marked elevations of platelet numbers can be anxiety-provoking situations for both patient and clinician; thus they may receive cytoreduction with anagrelide.

In certain situations, even in young, low-risk patients, treatment should be instituted. Surgery can increase the risk of thrombosis and use of anti-inflammatory agents can increase the risk of bleeding post-operatively. Under these circumstances, the platelet count should be lowered to the normal range. In pregnant patients with ET, low-dose aspirin therapy is the first treatment option, except in the third trimester of pregnancy, when prostaglandin inhibitors should be avoided. If the patient develops symptoms as a result of thrombosis within the vasculature, platelet reduction therapy is necessary and IFN- α therapy is the treatment of choice. As IFN does not cross the placenta, it likely will not be terato-

genic. HU, anagrelide, and busulfan have been successfully used to treat myeloproliferative disorders during pregnancy, but they are probably teratogenic if used during the first trimester. If such agents are needed, they should be instituted after the first trimester, but ideally should be avoided.

In a patient with ET and a serious acute hemorrhagic event, the site of bleeding should be immediately determined and antiplatelet aggregating agents stopped. Although the platelet count may be high, these platelets should be considered to be qualitatively abnormal, leading to defective hemostasis. The patient may be suffering from acquired von Willebrand syndrome. In patients with acquired von Willebrand syndrome, DDAVP or Factor VIII concentrates containing von Willebrand factor can be used in the setting of a bleeding episode. If acquired von Willebrand syndrome is not present, the transfusion of normal platelets is suggested. In those patients with persistent hemorrhage, immediate reduction of the platelet count can be achieved by plateletpheresis. HU at 2–4 g/day for 3–5 days should be administered immediately, then reduced to 1 g/day. Any patient receiving HU should be monitored for the onset of granulocytopenia and/or thrombocytopenia. Reduction of platelet counts is usually observed within 3–5 days of HU treatment. Anagrelide can also be employed in this scenario, at a dose of at least 2 mg/day, and increased as required to control platelet numbers.

In contrast, patients with acute arterial thrombosis require immediate institution of platelet antiaggregating agents. Aspirin at a dose of 81 mg/day is suggested. Patients with erythromelalgia or transient ischemic attacks will have a rapid cessation of symptoms following the use of low-dose aspirin. In a patient with a life-threatening arterial thrombosis, the platelet count should be lowered with either a combination of apheresis and HU or with HU alone, depending on the severity of the event. Surgical intervention may also be required. If the arterial thrombosis involves the microcirculation and is not life threatening (transient ischemic attacks or erythromelalgia), immediate low-dose aspirin therapy is indicated and platelet reduction therapy (HU, anagrelide, or IFN- α) can be initiated using standard dose and schedule.^{13,27–35}

Chapter 49

APPROACH TO CHRONIC IDIOPATHIC MYELOFIBROSIS (WITH EXTRAMEDULLARY HEMATOPOIESIS)

Ruben A. Mesa and Ayalew Tefferi

Chronic idiopathic myelofibrosis (CIMF) is a chronic myeloproliferative disorder first described in 1879 by Gustav Heuck¹ with a report of two patients with massive splenomegaly, constitutional symptoms, and intramedullary fibrosis. This disorder was further defined as a distinct entity in the twentieth century as agnogenic myeloid metaplasia² (AMM). AMM was subsequently categorized as a subset of myelofibrosis with myeloid metaplasia (MMM).³ The diagnosis of MMM includes patients with a de novo presentation (i.e., AMM) as well as those who progressed from a previous chronic myeloproliferative disorder (specifically essential thrombocythemia or polycythemia vera⁴) to the disorders of postthrombocytopenic (PTMM) and postpolycythemic myeloid metaplasia (PPMM), respectively.³ As the clinical presentation, prognosis, and management are indistinguishable for both de novo CIMF and the secondary states of PTMM and PPMM, we will refer to MMM as one disease.

MMM is a clonal⁵ hematopoietic stem disorder, resulting in two major processes. The first process is a myeloproliferation that is manifest by an intramedullary expansion of one or more myeloid lineages, resulting frequently in either leukocytosis and/or thrombocytosis. Additionally, an increase in circulating immature myeloid cells is observed which can accumulate in the spleen, liver, or other organs and lead to extramedullary hematopoiesis. The second is a prominent, polyclonal reactive process within the marrow, which leads to fibroblast proliferation, deposition of collagen (types I and III) and other connective tissues (i.e., fibronectin and proteoglycans), neoangiogenesis,⁶ osteosclerosis, reticulin fibrosis, and ineffective hematopoiesis.

INITIAL ASSESSMENT

CLINICAL PRESENTATION

Patients with MMM have a tremendous degree of variability in symptoms, exam findings, and laboratory abnormalities. Typically, patients present in the seventh decade of life (median age 67⁷), although MMM can be diagnosed at any age. Symptoms related to MMM can be broken down into one of three main categories.

MYELOPROLIFERATIVE SYMPTOMS

Increases in circulating mature (i.e., neutrophils) and immature (i.e., myelocytes, metamyelocytes, myeloblasts, etc.) myeloid cells occur in varying degrees in MMM. These cells have a propensity for accumulation in the reticuloendothelial system, particularly in the spleen and liver.⁸ These organs expand to accommodate the burden of myeloid cells, and the resulting hepatosplenomegaly may lead to pain, early satiety, sequestration of erythrocytes and platelets, and portal hypertension.⁹ Extramedullary hematopoiesis also can occur in the lungs (leading to pulmonary hypertension¹⁰), abdomen, spine,¹¹ and pericardium.¹²

CYTOPENIAS

Cytopenias of varying severity are characteristic of MMM and are multifactorial. Anemia is the most common cytopenia and can be caused by (1) ineffective hematopoiesis, (2) decreased marrow production capability because of the severity of the reactive fibrosis, (3) splenic sequestration, (4) myelosuppression from MMM therapy (i.e., from hydroxyurea), (5)

hemolysis, or (6) bleeding from the gastrointestinal tract (e.g., from varices resulting from portal hypertension). Thrombocytopenia also occurs in MMM, although it is less common than anemia at presentation, and may result from the same factors that cause anemia, as well as from consumption through disseminated intravascular coagulation.

CONSTITUTIONAL SYMPTOMS

These include hypermetabolic symptoms of fever, night sweats, and unintentional weight loss. In addition, mild-to-overwhelming fatigue may occur frequently in excess of what would be anticipated with respect to the degree of the patient's anemia. Lastly, bone pain (thought to result from intramedullary expansion from myeloproliferation) may occur and may be severe.

EVALUATION OF PROGNOSIS

MMM is a disease with a wide degree of prognostic variability, with most patients eventually expiring from their disease in the absence of leukemic transformation (LT). Several prognostic factors have been examined, with the most useful being the Lille criteria for MMM,¹³ which include the presence or absence of anemia (hemoglobin <10 g/dL) or extremes of leukocyte count (<4 or >30 × 10⁹/L). The Lille criteria modeled median survival in MMM patient groups of 93, 26, and 13 months, respectively, based on the presence of 0, 1, or 2 abnormalities. Additional negative prognostic factors include increasing age,¹⁴ increased circulating myeloblasts at diagnosis,¹⁵ increased peripheral blood CD34⁺ cell count,¹⁶ and abnormal karyotypic analysis¹⁴ (especially trisomy 8 and deletions of the "p" arm of chromosome 12).

HEMATOPOIETIC STEM CELL TRANSPLANTATION

MYELOABLATIVE ALLOGENEIC STEM CELL TRANSPLANT

Allogeneic hematopoietic stem cell transplantation is the only therapy that has the potential to be curative in MMM (see Table 49.1). Guardiola and colleagues²⁶ performed myeloablative allogeneic transplants in 55 MMM patients (median age 42). The 5-year survival was approximately 50%, with a 27% 1-year transplant-related mortality and 33% experiencing grade III–IV acute graft-versus-host disease (GvHD). Subsequent trials have confirmed the potential for long-term complete response with allogeneic stem cell transplant, but at the cost of significant short- and long-term risk, particularly in older patients (see Table 49.1).

Deeg and colleagues²³ reported data on 56 patients with MMM receiving allogeneic stem cell transplantation (with a range of mainly busulfan-based conditioning regimens) and showed a 3-year survival of 58% (highest with "targeted" busulfan conditioning). Several patients demonstrated sustained absence of obvious features of diseases (splenomegaly or intramedullary fibrosis). Nonrelapse mortality was 18/56 (32%), with 68 and 59% incidences of acute (grades II–IV) and chronic GvHD (extensive in 90% of those afflicted), respectively. Posttransplant mortality was highest in those with poor Lille prognosis,¹³ karyotypic abnormalities, and severe marrow fibrosis.

NONMYELOABLATIVE STEM CELL TRANSPLANT IN MMM

Allogeneic transplant with reduced intensity conditioning regimens have recently shown promise in the therapy of MMM.²¹ A series by Rondelli and colleagues²⁴ of 20 "high-risk" MMM patients (by Lille criteria²⁷) with a median age of 54 years underwent reduced intensity conditioning allogeneic transplant. Survival was 90% at 18 months, with a 10% transplant-related mortality (both from complications of GvHD). Chronic GvHD (>grade II) was present in 50% of evaluable patients. Significant clinical improvement was noted in many, but extent and duration of remission have not yet been published.

AUTOLOGOUS STEM CELL TRANSPLANT IN MMM

Autologous stem cell transplantation has the advantage of use in (1) older patients, (2) those without an HLA match, and (3) those who would not tolerate an allogeneic transplant. A multicenter, pilot, study of 21 MMM patients who received an autologous stem cell (mobilized with granulocyte colony-stimulating factor) transplant²⁵ was recently published with several interesting findings. The procedure was overall surprisingly well tolerated (transplant-related mortality 3/21; 1 < day 100), with improvements seen in both cytopenias and myeloproliferative symptoms.

MEDICAL SURGICAL AND RADIOTHERAPEUTIC OPTIONS IN CIMF

No therapy, other than perhaps stem cell transplant, has been shown to impact the survival of MMM patients. Thus, nontransplant management strategies are palliative in orientation and goal. When palliative therapy is appropriate, it is necessary to identify which disease manifestations truly affect quality of life (see Figure 49.1). Currently, there has been only modest success with palliating myeloproliferative and cytopenia-associated symptoms, with no real success in either improving MMM-associated constitutional symptoms or preventing blastic transformation.

Table 49.1 Published results for hematopoietic stem cell transplantation in MMM

Reference	Disease	Graft	N	Age median (range)	Conditioning	Mortality <Day 100	NRM	GvHD	Results

THERAPY OF CYTOPENIAS

TRANSFUSIONS

Direct replacement of red blood cells through transfusion is the cornerstone of palliating anemia-related symptoms in MMM. Currently, there are no data to support the routine use of iron chelation therapy for prevention of secondary iron overload in these transfusion-dependent individuals. Indeed, there are no data demonstrating definitive end-organ toxicity from iron overload in MMM patients. Unfortunately, the

poor prognosis associated with transfusion dependence in MMM results in a short survival duration, making concerns over long-term effects of iron overload moot.

Platelet transfusions in MMM are less frequently required, but lead to alloimmunization more rapidly than erythrocyte transfusions. Therefore, platelet transfusions in MMM should be limited to hemorrhagic episodes or thrombocytopenia severe enough that risks of spontaneous bleeding are unacceptable (platelet counts $<10 \times 10^9/L$ or higher in clinical scenarios, such as fever).

Symptomatic Management of Myelofibrosis with Myeloid Metaplasia

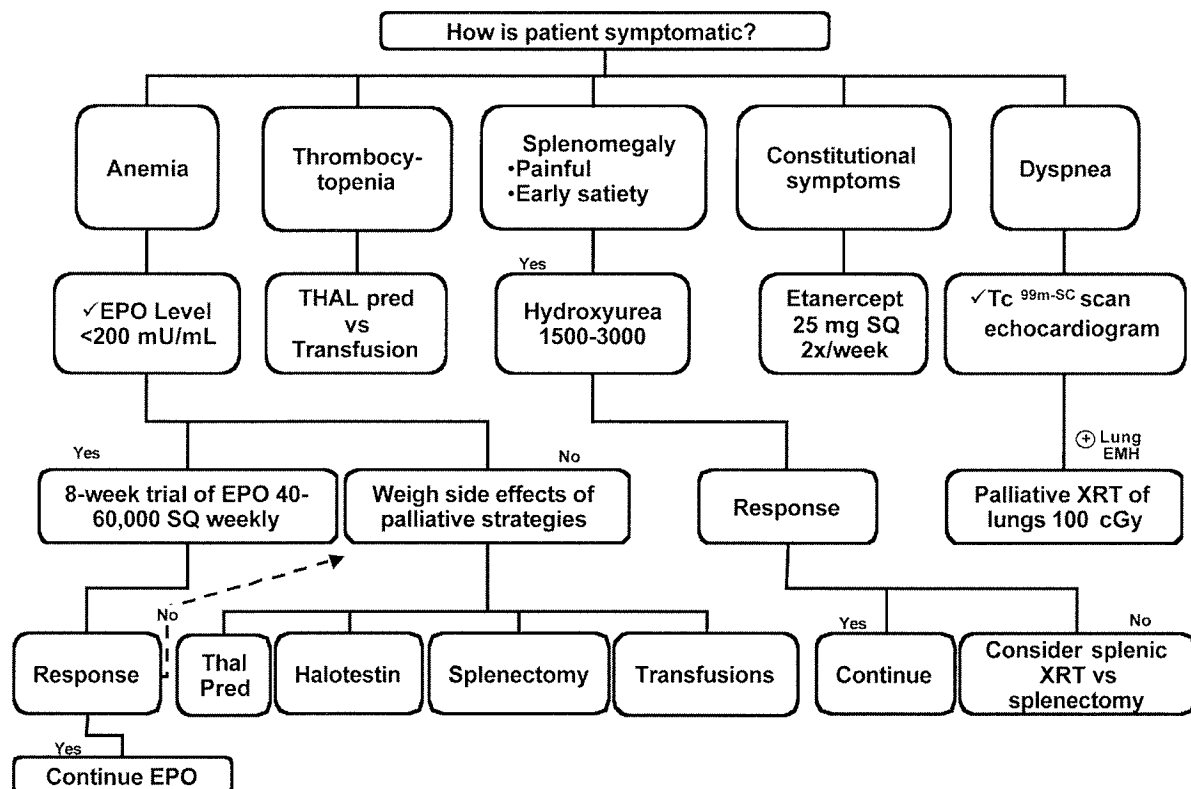

Figure 49.1 Symptomatic approach to implementing palliative therapies in patients with MMM

ERYTHROPOIETIN

The administration of exogenous erythropoietin has been occasionally helpful for MMM-associated anemia. Rodriguez et al.²⁸ described their experience and conducted a meta-analysis of patients with MMM treated with erythropoietin. A response rate of 33% was seen, with doses of up to 600 units/kg/week being required. Patients with serum erythropoietin levels of <125 mU/mL had the highest likelihood of response. Responses to exogenous erythropoietin most frequently occurred within 2–3 months, with responses ranging from mild decreases in transfusion dependence to complete transfusion independence.

ANDROGENS

Androgens have been beneficial for the treatment of MMM-associated anemia. Various androgen formulations have been used in MMM patients, including nandrolone,²⁹ oxymetholone, and danazol.^{30,31} Doses of danazol in the range of 600–800 mg/day led to responses in four out of seven patients (treated from 3 to 6 months) with MMM anemia in a report by Cervantes et al.³⁰ In this study, responders had either previously been splenectomized, or had only modest splenomegaly. In addition, it has been suggested that MMM patients with karyotypic abnormalities are less likely to respond to palliative androgen therapy.²⁹

THALIDOMIDE

Initial pilot studies with thalidomide in MMM were dose escalating, starting with 100 mg of thalidomide

per day^{32–40} (see Table 49.2). The published trials of thalidomide as single-agent therapy in MMM had several interesting findings. First, the activity observed in these trials was mainly manifest in the improvement of cytopenias (anemia and thrombocytopenia), with less frequent improvement in splenomegaly. In addition, patients with MMM did poorly with dose escalation, and in fact did not tolerate the agent well even at doses of 200 mg/day of thalidomide. Finally, a subset of MMM patients can experience unwanted myeloproliferation with thalidomide therapy.⁴³ Interestingly, myeloproliferation has even been observed in patients without prior identified myeloproliferative disorders.⁴⁴

In excess of 100 patients with MMM have been reported in the literature to have received thalidomide as single-agent therapy for their disease. These trials (outlined in Table 49.2) demonstrate that thalidomide does appear to be reproducibly active in improving anemia and thrombocytopenia in approximately 30–40% of patients, with more modest relief from symptomatic hepatosplenomegaly. Subsequent trials using low-dose thalidomide (50 mg/day) appear to retain the activity but with less toxicity (see Table 49.2). Additionally, the combination of 50 mg/day of thalidomide with a corticosteroid taper⁴¹ has resulted in improvements in the toxicity profile, decreases in toxicity dropout, and equivalent if not superior efficacy. Responses, when obtained, to thalidomide can be durable even after discontinuation of the drug. In a recent report⁴⁵ of long-term outcomes with thalidomide among initial responders, 35% (7 of 20 patients)

maintained a hematologic response for 16–31 months after discontinuation of thalidomide and keeping off all other therapies for MMM. Recent trials with linalidomide show similar results with less toxicity.

THERAPY OF MYELOPROLIFERATIVE SYMPTOMS

The palliation of symptomatic extra-medullary hematopoiesis (EMH) in MMM is accomplished through either nonspecific myelosuppressive drug therapy (in an attempt to decrease the contributory circulating myeloid progenitor pool) or targeted cytoreduction, using either radiotherapy or surgery.

SPLENOMEGALY

The surgical removal of the spleen is one of the oldest acknowledged therapies for MMM⁴⁶ (see Table 49.3), yet has only been palliative in benefit with significant risks (bleeding and infection) of perioperative and long-term complications (i.e., thrombocytosis). If splenectomy is only palliative and risky in MMM, should any MMM patient be splenectomized? In a recent retrospective review from our institutional experience with 223 splenectomized MMM patients, we found that patients with certain surgical indications were more likely to experience clinical benefit.⁹ Specifically, patients whose primary indication for splenectomy was painful splenomegaly experienced durable symptomatic relief and occasional improvement in refractory anemia. However, we found only marginal benefit in patients splenectomized to ameliorate portal hypertension, and adverse outcomes in patients splenectomized for thrombocytopenia. The latter group also experienced increased morbidity and mortality with the procedure. Additionally, postoperative risks of significant thrombocytosis were associated with increased preoperative platelet counts. Therefore, our current recommendations are to offer palliative splenectomy to individuals with refractory, severely symptomatic, splenomegaly (unresponsive to hydroxyurea) with aggressive postoperative control of thrombocytosis (with platelet-lowering agents +/- platelet apheresis).

Hydroxyurea

Hydroxyurea is a useful, oral, well-tolerated, nonspecific myelosuppressive agent that can reduce the leukocytosis and occasional thrombocytosis associated with MMM.⁷⁷ The reduction of leukocytosis in MMM is clinically useful only if it is extreme and symptomatic, or if the reduction in leukocytosis leads to a significant reduction in splenomegaly (seen in approximately 25% of patients). Occasionally, substantial doses of hydroxyurea (2–3 g/day) are needed to achieve a meaningful reduction in splenomegaly. Hydroxyurea may potentially exacerbate anemia or thrombocytopenia (if present), but supplemental exogenous erythropoietin may

be used to ameliorate the associated anemia. Complications of hydroxyurea may include lower extremity ulceration⁷⁸ and undesired myelosuppression exacerbating underlying cytopenias.

Alkylating agents

Melphalan is an orally bioavailable alkylating agent with myelosuppressive properties. The action of alkylating agents in MMM includes a direct, nonspecific myelosuppression, and therefore they may potentially palliate symptoms associated with myeloproliferation.⁷⁹ A clinical trial was recently reported in MMM using low doses of melphalan.⁸⁰ Over a 7-year period, 104 patients with MMM were treated with 2.5 mg of oral melphalan three times a week. The agent was active, with 66% of patients achieving a response after a median of 7 months of therapy. The greatest impact was on myeloproliferative manifestations. However, the major reason for study discontinuation was blastic transformation in 26% of the study cohort, as high as 48% in pretreated patients. Thus, the long-term use of melphalan in MMM may increase the risk of LT and should be used only in appropriate circumstances (e.g., the older patient who needs myelosuppression and is not a candidate for/ or has not responded to hydroxyurea).

2-Chlorodeoxyadenosine

Therapeutic splenectomy in MMM may result in extreme thrombocytosis, leukocytosis, and accelerated hepatomegaly.⁸¹ Palliative benefit from the purine nucleoside analog 2-chlorodeoxyadenosine (2-CdA) has been reported to provide beneficial cytoreduction in such instances.⁸¹ The agent has been used successfully in MMM in either of two common schedules (0.10 mg/kg intravenously by continuous infusion for 7 days or 5 mg/m² intravenously over 2 h for five consecutive days per cycle). 2-CdA (after a median of one to two cycles) responses were observed in 55, 50, 55, and 40% of patients for hepatomegaly, thrombocytosis, leukocytosis, and anemia, respectively. Cytopenias were frequent, but usually transient and without clinical consequence. Responses were sustained for a median of 6 months after discontinuation of the treatment.

Other agents

Recent clinical trials with novel therapies, such as lenalidomide (Revlimid®), the farnesyltransferase inhibitor tipifarnib⁸² and the oral vascular endothelial growth factor inhibitor PTK787⁸³ have demonstrated preliminary benefits in reducing MMM-associated organomegaly. Durability and overall efficacy of these agents for the disorder have not yet been reported.

Splenic Radiation

Several reports (see Table 49.4) have described the palliative benefit to external beam radiation in improving symptomatic splenomegaly in MMM.^{88,89} The Mayo Clinic experience⁸⁸ described a group of 23 MMM patients who received a median radiation course of 277 cGy in a median of eight fractions. An objective decrease in spleen size was noted in 94% of patients; however, 44% of patients experienced posttreatment cytopenias (26% were severe and 13% fatal). In addition,

splenic radiation seemed to increase morbidity and mortality of subsequent splenectomy when undertaken. Splenic radiation is effective for palliating MMM-associated splenomegaly but should be limited to patients with adequate platelet counts, and to those who are not likely to be splenectomized.

NONSPLENIC EXTRAMEDULLARY HEMATOPOIESIS

Myeloid progenitors are sensitive to the cytotoxic effects of external beam radiotherapy (XRT); therefore, it is reasonable to hypothesize that judicious use of radiotherapy may reduce symptomatic aggregations of extramedullary hematopoiesis. Indeed, palliative radiotherapy has been used successfully in a variety of settings in MMM (see Table 49.4).

LUNGS

The sequestration of myeloid precursors into the pulmonary parenchyma can lead to symptomatic pulmonary hypertension in MMM.¹⁰ We have recently reported our experience with single-fraction, low-dose (100 cGy) external beam radiation to the lungs for palliating MMM-associated pulmonary hypertension.⁹⁴ A total of seven patients at our institution have experienced a palliative benefit from pulmonary XRT demonstrated by improved performance status, decreased pulmonary artery pressures on echocardiography, and less EMH on lung ^{99m}Tc sulfur colloid scans.

LIVER

The experience with palliative radiotherapy for MMM-associated hepatomegaly has been less positive than for the spleen.⁹¹ Though responses can be achieved with irradiating the liver, they are not durable. In addition, the exacerbation of underlying cytopenias (which are invariably present) are problematic. Indeed, routine irradiation of the liver is not recommended, and if cytoreduction is required then medical therapy (i.e., hydroxyurea) should be considered.

THERAPY OF CONSTITUTIONAL SYMPTOMS

MMM is variably associated with a wide range of constitutional symptoms. The most common of these is fatigue, which can range from mild to debilitating. Patients may also suffer from hypercatabolic symptoms, manifested as night sweats, fevers, and significant loss of lean body mass. Lastly, patients occasionally suffer from bone pain that can be severe. There have not been many therapeutic agents, either tested or reported, to significantly palliate these problems. Indeed, these symptoms frequently can be the most debilitating and frustrating to arise in MMM patients.

Table 49.4 XRT for palliating extramedullary hematopoiesis in patients with MMM

Reference	Patients (n)	Dose (cGy)	Fractions	Response/Comments

Tumor necrosis factor α (TNF- α) is a cytokine implicated both in the pathogenesis of MMM, as well as in being profibrogenic⁹⁶ and potentially a direct inhibitor of hematopoiesis,⁹⁷ and a cause of MMM-associated constitutional symptoms (fatigue and cachexia).⁹⁸ Etanercept (Enbrel, Immunex, Seattle, WA) is an inhibitor of TNF- α . Based on its activity and safety, it was piloted in MMM.⁹⁹ Twenty-two patients with MMM were prospectively treated with twice-weekly subcutaneous injections of etanercept (25 mg per injection) for up to 24 weeks. The drug was well tolerated and was successful in improving MMM-associated constitutional symptoms in 60% of those enrolled. However, only modest benefit was observed in either improving peripheral cytopenias or reducing splenomegaly (20%).

LEUKEMIC TRANSFORMATION OF MMM

Leukemic transformation of MMM occurs in approximately 10–15% of patients,¹⁰⁰ and is usually fatal. A recent series of 91 consecutive MMM patients¹⁰¹ who underwent LT reported that transformation was usually

clinically heralded by organomegaly, worsening constitutional symptoms, anemia, thrombocytopenia, and leukocytosis. At the diagnosis of MMM, these patients had frequently presented with typical disease-related features, but about half had an increase in circulating myeloblasts. All episodes of LT were acute myeloid leukemia, with all French–American–British subtypes represented except M3. Additionally, 91% of patients displayed an abnormal karyotype. LT from MMM was usually fatal, with 89 patients (98%) having expired of disease or therapy a median of 2.6 months (range 0–24.2) after LT. Supportive care alone or noninduction chemotherapy had similar outcomes in 48 patients and 19 patients, respectively (median survival <3 months in both groups). Induction chemotherapy in 24 patients (26%) had a 33% mortality with no complete remissions achieved [median survival 3.4 months (range 0.9–24.3)]. However, a subset of patients ($n = 10$; 41%) reverted their marrow to a chronic phase of MMM after induction. Salvage regimens for nonresponders were overall unsuccessful. The outcome of LT in MMM with current therapies is dismal. Either supportive care alone or appropriate clinical trials should be considered.

ESTABLISHING A THERAPEUTIC PLAN FOR MMM

The wide range of prognosis and symptomatology in MMM is a significant issue as we decide on the aggressiveness of therapy. Management of this complex disorder should diminish short-term morbidity from the disease with an eye on long-term goals.

SHORT-TERM MANAGEMENT GOALS

In the short term, our goal with MMM is to diminish the immediate possible morbidities at presentation, with the least amount of expense and toxicity from therapy. Therefore, the patient who presents with asymptomatic or minimally symptomatic disease may most appropriately be observed (see Figure 49.1). To date, no survival benefit has been demonstrated for reduction of asymptomatic splenomegaly, reduction of asymptomatic leukocytosis, or improvements in mild anemia (i.e., hemoglobin >11 g/dL).

LONG-TERM MANAGEMENT GOALS

Establishment of a long-term plan is again crucial in this disease. Specifically, upon presentation, it is reasonable to assess whether a stem cell transplant will ever be

appropriate for a particular patient. If the patient is a transplant candidate, but currently is stable and at low risk, observation or minimally toxic therapies may be used as short-term interventions, with consideration of the transplant at time of progression.

SUMMARY

The current management of MMM is problematic, as there are limited options that have been shown to impact survival and disease course. Allogeneic stem cell transplantation, although potentially curative in some patients, is not an option for many patients because of older age, lack of donors, and comorbidities. Useful palliative options exist for treating symptoms from the disease, but have overall not improved survival for the disease. Active investigations into novel agents for the therapy of MMM with thalidomide analogs such as lenalidomide and others ongoing. Improved understanding of pathogenetic mechanism of disease or disease progression may hopefully yield therapeutic targets of greater specificity and efficacy.

Chapter 50

MANAGEMENT OF CHRONIC MYELOMONOCYtic LEUKEMIA AND OTHER RARE MYELOPROLIFERATIVE DISORDERS

Miloslav Beran

CHRONIC MYELOMONOCYtic LEUKEMIA

INTRODUCTION

Chronic myelomonocytic leukemia (CMML) is a clonal bone marrow disorder of stem cells. The distinguishing feature is a persistent absolute monocytosis (blood monocytes greater than $1 \times 10^9/L$). Studies of the disease's natural history reveal heterogeneity in pathology, clinical features, and the outcome of untreated patients, as measured by duration of survival. The recent World Health Organization (WHO) reclassification of CMML and its inclusion as a separate entity in the groups of myeloproliferative/myelodysplastic disorders reflects two major pathologic features that appear with varying prominence in individual patients: cellular proliferation, which involves predominantly white blood cell (WBC) lineage and is often associated with organ infiltration and organomegaly, and maturation defects characterized by marrow dysplasia, which may involve all cell lineages, and result in anemia, thrombocytopenia, and rarely neutropenia.¹ Either proliferative or dysplastic features may predominate in the clinicopathologic profile of individual patients, and the predominance may change during the course of the disease, usually from dysplastic to proliferative. Whether CMML should be categorized into dysplastic and proliferative entities based on the arbitrarily chosen "cutoff" for WBC at $13 \times 10^9/L$, or whether these features could be viewed as various stages of the same disease, is still being discussed^{2,3} and was recently reviewed.³ It is tempting to speculate that different cellular regulatory pathways may be activated as a consequence of the presence of different primary or secondary molecular lesions. However, as will be discussed later in this chapter, these basic features do have some relevance in the current treatment of individual patients. These features are only marginally associated with prognosis and survival.^{3,4}

ASSESSMENT OF PROGNOSIS

Because optimal CMML management is still being developed and a multitude of investigational options are available, the ability to assess the risk-to-benefit ratio of any particular treatment for individual patients is important. This assessment has been facilitated by the identification of both disease- and patient-related variables associated with outcome, as measured by survival. In turn, these variables have led to the development of prognostic scoring systems for CMML that allow identification of patients with various life expectancies and risks of succumbing to the disease if untreated.⁴

The most significant variables negatively associated with survival, as determined by a multivariate analysis of a large number of patients with well-defined CMML, are the degree of anemia; the presence of circulating immature WBC; the absolute blood lymphocyte count; an increased percentage of bone marrow blasts; and an abnormal karyotype.⁴ Although age was not a significant prognostic variable in that multivariate analysis, the goals of optimal management are modified by age-related considerations (e.g., quality of life vs potentially limited prolongation of survival), and age should always be considered, along with auxiliary medical problems and patients' wishes, in choosing the approach for optimal management.

PRETREATMENT EVALUATION

Continuous development of investigational treatments, identification of prognostic variables, and the recent success of targeted therapy with imatinib mesylate in selected CMML patients with specific chromosomal alterations associated with activation of receptor tyrosine kinases (RTKs, see below), all support the need for an extended initial evaluation. In addition to clinical assessment and the standard laboratory tests used to

establish a diagnosis, the pretreatment workup should include bone marrow aspiration, biopsy, and cytogenetic analysis. Information on β_2 -microglobulin and plasma lactate dehydrogenase (LDH) concentrations are useful because high plasma levels are associated with a worse prognosis.⁴ In patients up to 65–70 years old, HLA tissue typing of patients and their siblings should be considered, given the possibility of a reduced-intensity conditioning regimen and allogeneic stem cell transplantation (SCT). Both karyotyping and molecular screening for the BCR/ABL translocation are therapeutically relevant, as they have prognostic implications and are necessary to exclude BCR/ABL-positive disease with monocytosis and to identify rare cases with specific translocations involving genes coding for RTK.^{5–8} (This is discussed in detail elsewhere.) Cells from patients with translocations involving platelet-derived growth factor receptor (PDGFR) β may be further evaluated by molecular assays to verify such molecular abnormalities, and result in abnormally functioning RTK sensitive to TK inhibitors, such as imatinib mesylate.^{5–8} In myeloproliferative disorders (MPD), including CMML, translocations involving PDGFR β [such as t(5;12)] frequently appear to be associated with marrow dysplasia and blood eosinophilia.⁸ In the absence of an abnormal karyotype, the possibility of a cryptic translocation involving the 5q33 region may mandate further molecular screening using, for example, polymerase chain reaction (PCR) and specific primers.

Ideally, the final therapeutic decision is made on the basis of both the patient's clinical status and the prognostically significant features of the disease.⁴ With the exception of SCT in certain patients, however, the available treatment modalities rarely, if ever, result in the eradication of CMML. The relative rarity of the disease, lack of agreement on a "standard of care," and lack of uniform criteria for patient response hamper initiation of well-designed randomized clinical trials needed to answer such questions. This said, numerous treatment modalities, which are all by definition investigational, provide various levels of disease control and improvements in quality of life.

TREATMENT OPTIONS

Traditionally, the management of CMML has focused on disease-associated clinical symptoms, symptoms associated with marrow failure (i.e., anemia and thrombocytopenia), and symptoms of increased myeloproliferation (i.e., increased WBC count, organomegaly, and hypermetabolic state). For this purpose, an intuitive stratification into "dysplastic" CMML, resembling myelodysplastic syndrome (MDS), and "proliferative" CMML, resembling MPD, seems practical.^{2–4} MDS CMML is primarily managed with supportive care, and cytotoxic therapy is added when signs of proliferative disease, characterized by an increased WBC count and/or organ involvement or constitutional symptoms, appear. MPD CMML is managed with cytotoxic therapy plus supportive care.

Supportive care

In elderly patients who have low-risk or intermediate-1-risk CMML at the time of diagnosis, as assessed with the MD Anderson Prognostic Score (MDAPS),⁴ the median survival times from presentation are 24 and 18 months, respectively.⁴ For such patients, supportive care similar to that given for patients with low-risk MDS and participation in clinical trials using low-toxicity agents are recommended. Severe anemia (hemoglobin concentration <10 g/dL) or transfusion-dependent anemia may be treated with weekly doses of erythropoietin of 40,000–60,000 units for a trial period of 6–8 weeks, with pretreatment assessment of endogenous erythropoietin levels and monitoring of treatment by weekly evaluation of reticulocyte count and hemoglobin concentration. Unlike in MDS,⁹ the benefit of such treatment in CMML is not well documented. Growth factors such as granulocyte-colony-stimulating factor and granulocyte-macrophage colony-stimulating factor should be used cautiously because of their propensity to induce an unwanted monocytic response. Their use should be limited to febrile patients, particularly those with documented infection and severe neutropenia, not responding to antibiotics. To avoid allosensitization, platelet transfusions should be administered on the basis of symptoms of clinically significant hemorrhage rather than on platelet counts; an exception to this rule is the use of prophylactic transfusions in patients enrolled in clinical trials. Routine use of prophylactic platelet transfusions is not recommended. Whether associated with leukocytosis or not, severe thrombocytopenia usually signals advanced disease and indicates a need for reassessment of the patient's risk status and change in therapeutic strategy.

Established single-agent oral chemotherapy

In patients who have CMML with a significant myeloproliferative component, high WBC count, or organomegaly, treatment with single-agent chemotherapy has been the standard of care. Oral agents such as busulfan, 6-mercaptopurine, hydroxyurea, and oral etoposide have been used empirically with some success, but a prospective randomized study conclusively determined the superiority of hydroxyurea over etoposide in terms of overall survival in patients with mostly advanced proliferative disease (i.e., splenomegaly, mild thrombocytopenia, and increased bone marrow blasts): 24 months for hydroxyurea versus 9 months for etoposide.¹⁰ This is the only prospective randomized study to date that has compared two treatment regimens in patients with CMML. Although neither regimen induced complete remission (CR) or affected the natural history of the disease, the results supported the idea of using hydroxyurea plus supportive care as the "standard-of-care" arm in any future randomized trials. No randomized study comparing "treatment" with supportive care has ever been reported in CMML.

Agents currently approved by the Food and Drug Administration for the management of CMML (defined as a subcategory of MDS by FAB classification) are 5-azacytidine (Vidaza®) and 2'-deoxy-5'-azacytidine (Dacogen®). One major reason for the lack of clinical trials specifically designed for CMML is the French–American British classification which recognized CMML as a subcategory of MDS, and guided the enrollment of patients with CMML into MDS trials. The identification of CMML as a separate disease entity,¹ together with the availability of a prognostic risk assessment developed specifically for CMML,⁴ should facilitate future design of CMML-specific trials.

Other chemotherapeutic agents

Not much is known about the effectiveness of other cytoreductive agents in managing CMML as assessed in phase I/II trials. For example, three separate studies with the anthracycline idarubicin suggested that it has limited activity, with no significant responses observed in CMML patients who were treated daily with intermediate dosages.^{11,12}

In the first trial of *oral etoposide (VP-16)*, 10 consecutive patients with CMML were treated with 100 mg of etoposide orally, daily for 3 days (50 mg in “nonproliferative” disease), followed by a “maintenance” dose of 50 mg twice weekly. Clinical benefit, observed in seven patients, included improvement of anemia, thrombocytopenia, and extramedullary disease. Diminished benefit was noted in patients with increased blasts in the blood and bone marrow.¹³ A second etoposide trial used 50 mg orally, daily for 21 days every 4 weeks.¹⁴ Twelve of 17 patients with CMML experienced hematologic responses, three after failing treatment with hydroxyurea. The median duration of hematologic responses was 9+ months (range 4–49+ months). Responses consisted of control of leukocytosis in 12 patients, normalization of platelet counts in 2 thrombocytopenic patients, and resolution of anemia in 1 case. Two of six patients with splenomegaly had >50% reduction in spleen size.¹⁵

The use of *cladribine (2-chlorodeoxyadenosine-2 CdA, or 2-CdA)* to manage CMML was prompted by the drug's proven efficacy in indolent lymphoproliferative disorders and by the observation of decrease in monocyte counts in patients with lymphoproliferative disorders treated with cladribine. An initial trial of cladribine at 0.1 mg/kg/day for 5–7 days in four patients¹⁵ resulted in a rapid decrease in monocyte counts. These results were subsequently confirmed in seven patients given cladribine in a dosing schedule of 0.2 mg/m² daily for 5 days every 3 weeks for a total of three cycles.¹⁶ With this regimen, one patient attained a CR lasting 4 months and three patients exhibited partial responses (PRs) lasting 3–6 month. Although the overall response of 55% was encouraging, no further trials were conducted.

Cytarabine (cytosine arabinoside, or ara-C), administered subcutaneously at low dosages of 10–20 mg daily

for 10–21 days, was studied extensively in the management of MDS and to a lesser degree of CMML during the 1980s and early 1990s. The initial enthusiasm was sparked by speculation on the ability of cytarabine to induce terminal differentiation of malignant hematopoietic cells. Although the contribution of differentiation to the treatment outcome was never proven and the effect was attributed to the cytotoxic action of the drug, the effectiveness of the regimen was well documented. In small studies using cytarabine to manage CMML, the CR rates varied from 0 to 25%, and a review of data from 80 patients noted 9 CRs and a calculated CR rate of 14%.¹⁷ Thus, the efficacy of cytarabine was modest and, ultimately, the treatment outcomes were viewed skeptically. Because of the small numbers of patients in the reported trials, the associated myelosuppression, and the lack of information on response durations, the value of cytarabine in the management of CMML is poorly documented. However, the activity of low-dose cytarabine is probably comparable to that of other single agents, such as 5-azacytidine, decitabine, and topotecan, in terms of effect on the bone marrow and CR rates. Its future use may more likely lie in combination with other agents, as documented for high-dose cytarabine plus topotecan.¹⁸

Topoisomerase I inhibitors

Among studies using recently developed agents, encouraging results have been obtained with the topoisomerase I inhibitor topotecan in a phase II study of 30 patients with diagnosis of CMML, both previously treated and untreated. Topotecan was given as a continuous intravenous infusion at the maximal tolerated dosage (MTD) of 10 mg/m² over 5 days every 4–8 weeks.^{19,20} Topotecan induced a CR in almost one-third of the patients, and for the first time, CRs due to a single agent were characterized by karyotypic conversion of bone marrow from abnormal to diploid.^{19,20} This result suggested that topotecan has a differential effect on normal and CMML cells. The median CR duration was 7.5 months (range 1–31 months), and median survival was 10.5 months.²⁰ In this single-arm study, the impact on survival could not be documented.^{19,20}

An oral preparation of topotecan with satisfactory bioavailability was investigated in two studies using three regimens.^{21–23} Given over 17 days at dosages varying from 0.8 to 1.9 mg/m²/day, 5 days on, 2 days off for three cycles, oral topotecan induced CRs in two of seven patients with CMML.²¹ The dose-limiting toxicity was nausea and vomiting, and the MTD was 1.4 mg/m²/day. In a phase II study, 1.2 mg/m² of topotecan was given orally either twice daily for 5 days or once daily for 10 days, and both schedules delivered the same total dose.^{22,23} Ten patients with CMML were included. Although no patients achieved a CR, seven exhibited a response.²³ The duration of responses was not reported, and the impact of the treatment with

oral topotecan on the natural history of the disease is unknown.

Another orally bioavailable topoisomerase I inhibitor, 9-nitro-20-(S)-camptothecin, was studied in a phase II study as a continuous daily administration at doses adjusted according to each patient's tolerance. The study group included 23 patients with CMML; responses were observed in 10 (1 CR, 4 PRs, and 5 hematologic improvements [HI]).⁶⁰

The optimal administration schedule for increasing the rate and duration of responses remains to be defined for both topotecan and 9-nitro-20-(S)-camptothecin. At present, topotecan administered intravenously at the MTD appears to be the more effective agent against CMML, with the highest documented frequency of complete hematologic and cytogenetic remissions.^{19,20} The potential value of these topoisomerase I inhibitors would be best appreciated in a randomized trial comparing them with hydroxyurea, analogous to the trial that compared hydroxyurea and etoposide.¹⁰ The use of topoisomerase I inhibitors to manage CMML might be more effective in combination therapy than as single agents.¹⁸

2-Deoxycytidine analogs (hypomethylating agents)

The role of 5-azacytidine and 5-aza-2'-deoxycytidine (decitabine) in the treatment of MDS and, to a lesser degree, in MPD has been investigated for well over a decade. Besides their cytotoxic activity, these agents induce hypomethylation of genes involved in regulating proliferation and differentiation, particularly tumor suppressor genes that are frequently hypermethylated in malignant disorders and presumably also in CMML.²⁴ This hypomethylating effect is believed to be particularly active at relatively low doses. The effectiveness of both 5-azacytidine²⁵ and decitabine^{26,27} in managing MDS is well documented, but their efficacy and usefulness in managing CMML are less clear.

In the randomized trial comparing subcutaneous 5-azacytidine (75 mg/m²/day for 7 days every 4 weeks) with supportive care, seven patients with CMML were included in each group.²⁵ The responses were not analyzed in detail by disease category, but the responses of CMML patients were reported to be "similar" to those with high-risk MDS [refractory anemia with excess blasts (RAEB) and refractory anemia with excess blasts in transformation (RAEBt)]: 8% CR, 15% PR, and 38% HI. Three monthly courses were needed to obtain the best response. Compared with supportive care, the 5-azacytidine regimen provided a significant delay in the disease progression and some survival advantage in patients with MDS; whether these benefits also applied to the small cohort with CMML is unknown.²⁵

The effectiveness of decitabine in managing CMML can be assessed from European clinical trials of this agent. In one study of 66 patients with high-risk MDS,²⁶ subjects were treated with decitabine (15 mg/m² given as an intravenous infusion over 4 h every 8 h for 3 days,

for a cumulative dose of 135 mg/m² over 3 days) every 6 weeks for a maximum of six courses. The study included nine patients with CMML; the cases were classified by the International Prognostic Scoring System, suggesting that all nine belonged to the category of MDS CMML.^{2,4} Four (44%) of the nine patients responded: 1 CR, 1 PR, and 2 HI.²⁶ The actuarial median response duration for the entire study cohort of 66 patients was 31 weeks, and it increased from 26 weeks in patients with HI to 39 weeks for patients with a PR to 36 weeks for those with a CR; no information was provided specifically for the nine patients with CMML.²⁶ In a subsequent review, the results of three separate studies of 124 patients, including 16 with CMML, revealed cytogenetic CR in two patients with CMML.²⁷ The response rates and durations were not specifically reported for the CMML patients, however.²⁷ Together, these results suggest a role for both 5-azacytidine and decitabine in managing CMML, but because reports on their effectiveness in treating CMML are sporadic, no conclusion can be reached. Further study and new assessments based on larger and more formal investigations are required before an accurate evaluation can be made.

Agents targeting fusion RTKs

Discovery of unique chromosomal abnormalities and underlying molecular changes of RTKs causatively associated with CMML or atypical chronic myelogenous leukemia (aCML)⁵⁻⁸ suggested potential therapeutic agents targeting the molecular basis of these disorders. The proof of principle was provided by documentation of activity of imatinib mesylate in the management of MPD, including CMML, characterized by activation of the *PDGFRβ* gene by its fusion to *tel* oncogene, a process rendering the *PDGFRβ* TK permanently activated and responsible for the dysregulated cell growth.⁷ After the publication of encouraging results on the in vitro inhibitory activity of imatinib mesylate on *PDGFRβ* TK,²⁸ four patients with t(5;12)(q33;q13) and *PDGFRβ* fused with either *TEL*(*ETV6*) (three patients) or an unknown partner (one patient), all with elevated WBC counts and eosinophilia, were treated with 400 mg of imatinib orally, daily. All four patients achieved a CR and the levels of fusion transcripts decreased significantly, even becoming negative in one patient.⁵ Responses occurred as early as 1 month, but could be delayed up to 9 months, suggesting disease heterogeneity and the need for prolonged treatment in some cases. Similar responses to imatinib were reported for a CMML patient with the *RAB5EP/PDGFRβ* fusion gene underlying a t(5;17)(q33;p13.3) who achieved a molecular CR 6 weeks after the start of imatinib therapy.⁶ Further CRs were reported for a CMML patient with t(5;12)(q33;p13)²⁹ and for a patient with aCML and a t(5;10)(q33;q22).³⁰ This concept supported a trial in which imatinib was given to patients with CMML in the expectation of potential activity through

as-yet-undetected imatinib-sensitive pathways. So far, the results have been uniformly negative in 19 patients with CMML,^{31,32} seven with aCML,³¹ and eight with MDS.³² Thus, imatinib continues to be indicated for trial use in patients with documented rare karyotypic abnormalities that lead to production of imatinib-sensitive fusion TKs. Most patients achieved response within 6 weeks of the initiation of treatment with 400 mg imatinib mesylate daily and continued the treatment in remission. With only preliminary experience, duration of the responses and the optimal treatment schedule are unknown. Although data on the association between the progression of CMML and aCML into more aggressive disease and decreased effectiveness or loss of response to imatinib have been restricted to those from single-case observations (M. Beran, personal observation), this association is analogous to the limited activity of imatinib in advanced BCR-ABL-positive CML.³³

Farnesyltransferase inhibitors

The *ras* oncogene is positioned at the crossroads of cellular signaling pathways, and its role in the neoplastic process is well appreciated.^{34,35} Mutations in codons 12, 13, or 62 of *ras* significantly affect its physiological role and result in a permanently activated state, causing dysregulated proliferation. CMML is the hematologic malignancy with the highest frequency of *ras* mutations; in the largest reported cohort of patients, the prevalence of the *N-ras* and *K-ras* mutations was 38%,⁴ and the presence of the mutation appeared to negatively influence patients' prognosis and response to therapy.³⁶ These findings made CMML an attractive target for treatment that blocks *ras* activity by inhibiting the enzyme farnesyltransferase, which is essential for posttranslational *ras* modification and attainment of its functional state.^{34,35}

Of several farnesyltransferase inhibitors being investigated, tipifarnib (R115777, Zarnestra) and lonafarnib (SH66366, Sarasar) were explored in studies that included a limited number of patients with CMML. In a phase I study, an oral preparation of tipifarnib was administered to 10 patients; two showed a PR and one exhibited an HI, although those responses were transient.^{37,38} In a phase I/II study, tipifarnib was given to patients with MPD, including seven patients with aCML and two with CMML.³⁹ At an initial oral dosage of 300 mg twice daily for 21 days every 4 weeks, clinical responses were noted in three of the seven patients with aCML and none of the patients with CMML.³⁹ Finally, in the phase II study, lonafarnib, administered orally at 200–300 mg daily until disease progressed or unacceptable toxicity occurred, was investigated in 35 patients with CMML.⁴⁰ Among the 25 patients evaluable for response, one achieved a CR and seven exhibited HI, mostly in a single lineage; one patient became independent of red blood cell transfusions.⁴⁰

Orally administered farnesyltransferase inhibitors represent a new category of “targeting” agents; they

are only in the early stages of clinical investigations in CMML. However, because the responses to treatment in the malignancies investigated so far, including CMML, do not appear to be influenced by the *ras* mutational status, and because the responses have correlated poorly with the degree of inhibition of farnesyltransferase,^{37,38} processes other than farnesylation may be targeted by these agents. Their role as single agents in the treatment of CMML remains uncertain.

Miscellaneous agents

The presence of increased angiogenesis in CMML⁴¹ stimulated interest in the potential use of angiogenesis inhibitors for managing this disease. A limited number of patients with CMML have been treated with thalidomide. Of seven patients with CMML treated with 100–400 mg thalidomide orally, daily in two studies,^{42,43} only one experienced a minor and transient improvement in platelet counts. Because of its poorly predictable adverse effects and the seeming lack of activity, future use of thalidomide in treating patients with CMML is unlikely. Other antiangiogenic and immunomodulating agents, including derivatives of thalidomide that have both antiangiogenic and immunomodulatory properties, are in early stages of clinical development. Phase I/II studies are including patients with CMML.

Intensive chemotherapy using combination regimens

The first patients with CMML who were treated with combination chemotherapy used to manage acute myelogenous leukemia (AML) were probably those whose initial diagnosis was AML that was later reclassified as MDS or CMML. In later trials in patients with AML, patients with CMML were occasionally included, along with RAEB and RAEBt, as all three categories were considered high-risk MDS. More often than not, little information was given on the clinical and hematologic status of CMML patients, and in such prospective studies, selection bias toward treating younger patients with advanced disease was likely. With few exceptions, treatment regimens consisted of cytarabine (given at standard dosages for 5–7 days) plus anthracycline or anthracenedione antibiotics (daunorubicin, mitoxantrone, or idarubicin). A review of six such studies conducted between 1980 and 1995 identified only 35 patients with CMML, 11 (31%; 95% confidence interval 15.9–47.0%) of whom achieved a CR.¹⁸ Duration of remission and overall survival, when reported, tended to be short and there was no convincing evidence that addition of anthracyclines to cytarabine improved the outcome.

Unfortunately, in most clinical trials, the responses of the CMML cohort were not evaluated separately, further clouding their interpretation. From the results of studies with at least some data available, it may be concluded that such treatments are feasible and that in a portion of patients with CMML, a CR can be obtained, although at the expense of substantial morbidity and even mortality.

Further information on the role of intensive combination chemotherapy was obtained from a series of clinical trials that used chemotherapy of increasing intensity to manage CMML. One such trial used a combination of two single agents with documented effectiveness in CMML and low cardiotoxicity: topotecan, administered as a continuous intravenous infusion at 1.25 mg/m² over 24 h, daily for 5 days, and cytarabine, as a 2-h infusion at a dosage of intermediate intensity, 1 g/m²/day, for 5 days.¹⁸ Patients who did not experience a CR after the first course of therapy received a second course and a dose adjustment when indicated. Patients who experienced a CR were eligible for postremission chemotherapy. In this prospective phase II study, patients with CMML, RAEB, and RAEBt were registered separately, and treatment outcome was evaluated separately for each disease. Among the 27 patients with CMML who enrolled in the study, 12 (44%; 95% confidence interval 25–65) achieved a CR.¹¹ Analysis by disease stage showed a CR rate of 62% in CMML patients with <5% bone marrow blasts (corresponding to CMML I by WHO criteria) and 29% in those with >5% bone marrow blasts (CMML II by WHO criteria). As was the case for the RAEB and RAEBt patients, the response rates were not affected by the presence of diploid or abnormal karyotypes, or by primary or secondary CMML. In most CMML patients with an abnormal karyotype, conversion to diploid status was observed. Responses did not differ in patients treated immediately on diagnosis and in those with up to 6 months' history of antecedent hematologic disorder. At a median follow-up of 7 months, the median duration of CR was 33 weeks and the median survival time was 42 weeks.¹⁸ Although the presence of an abnormal karyotype had no significant effect on the response rate, its presence appeared to be associated with a shorter response duration. As with any myelosuppressive treatment, neutropenia-associated fever and infections were the most frequently reported complications during treatment and were observed in 50% of the patients. With supportive care and close surveillance, the mortality rate in the CMML cohort was 10%; all deaths were related to infectious causes.¹⁸

Most, if not all, combination chemotherapy regimens used to manage CMML included cytarabine as the most active agent. In an attempt to develop an alternative treatment and explore the reported effectiveness of etoposide in CMML,^{13,14} a group of 17 patients with CMML was treated with a combination of etoposide (100–200 mg/m² daily for 5 days) and carboplatinum (continuous intravenous infusion, 200 mg daily for 3–5 days). Of the 17 patients enrolled, 14 were classified by WHO criteria as having CMML I and 3 as having CMML II; 14 had platelet counts of <100 × 10⁹/L, all 17 were anemic (10 with hemoglobin concentrations less than 10 g/dL), 13 had “proliferative” CMML, and 10 had an abnormal karyotype. Despite the severe myelosuppression and marrow aplasia characteristically caused by

this regimen, five (29%) CMML patients achieved a CR with a median duration of 16 weeks (range 3–22 weeks),⁴⁴ indicating that although intensive combination chemotherapy without cytarabine resulted in a CR in one-third of patients, the benefit, as measured by CR duration, was not durable. Achieved at the price of high toxicity and risk of death, the results were not better than those obtained in another study by the same institution with the single-agent topotecan.^{19,20} This conclusion led to questioning of the benefit of intensification of chemotherapy in managing CMML.

One comparison of chemotherapy regimens of various intensities used to manage CMML over a 15-year time period⁴⁴ included 23 CMML patients treated with a combination of various high-intensity regimens containing high-dose cytarabine plus fludarabine, anthracycline antibiotics (idarubicin and liposomal daunorubicin), or both. Compared with a less intensive topotecan plus cytarabine regimen, no further improvement in the CR rate was achieved, likely because the more intensive regimens induced higher mortality. CR duration remained short, as did overall survival.⁴⁴ Because of the limited size of the CMML cohorts treated with various regimens, identification of covariates associated with response and response duration was inconclusive so far. A trend for lower CR rates was noted for patients with more than 5% marrow blasts (CMML-II and for patients with abnormal karyotype).¹⁸ A recent update of the results from the topotecan plus cytarabine regimen, then including 39 patients with CMML, confirmed the earlier results, as did a review of high-dose cytarabine-based regimens updated to 30 patients.⁴⁴

Taken together, these results indicate that although complete hematologic and cytogenetic responses can be obtained in up to 40% of CMML patients, response durations are limited. Only occasional patients remain disease free at 3 years. Further intensification of induction chemotherapy appears to increase mortality and morbidity without leading to an improved response rate and response duration. Topotecan plus cytarabine yields the best results in terms of morbidity, mortality, response rates, and response durations. Whether similar results could be obtained with less intensive regimens (e.g., standard- or low-dose cytarabine plus topotecan, or anthracycline antibiotics at presumably lower toxicity) remains to be investigated in controlled clinical trials. The benefit of postremission chemotherapy, in terms of both intensity and duration, remains unanswered. Responding patients enjoy a better quality of life and prolonged survival, but the effect of the treatment on survival may be related to the natural history of the disease. To date, no treatment regimen positively impacts the natural history of the disease or extends expected survival. As is the case with every management approach in CMML, the value of combination chemotherapy on patient survival will be determined only in a randomized trial against best standard

of care; e.g., supportive care (plus hydroxyurea in patients with proliferative disease).

Should chemotherapy be considered at all in the management of CMML, and if so, which regimen should be chosen? No consensus is currently available, but several observations may guide such decision making. At present, the regimen of topotecan plus cytarabine appears to be the best studied, most effective, and least toxic. More than 80% of patients who achieve a CR do so after a single course of this treatment. Although additional complete responses may be achieved with further courses, these responses are obtained with an increased risk for complications, at a higher cost, and tend to be shorter. Thus, one course of this regimen (and possibly other combination regimens) may segregate patients who will likely benefit from additional chemotherapy from those who will not. Supportive care or investigational treatment in the setting of clinical trials may be an alternative option, particularly for high-risk CMML patients. Thus, CMML patients with clinical symptoms or a high-risk prognostic score (e.g., MDAPS)⁴ may be candidates for such trials. Another candidate group for chemotherapy may be patients with HLA-matched donors who are considered for allogeneic SCT. Because CMML is resistant to chemotherapy, the frequency of relapses in patients with active disease who receive SCT is high.^{46–48} Cytoreduction, and particularly induction of CR, before the SCT may improve the outcome.

Allogeneic stem cell transplantation

Only two studies report results obtained with allogeneic SCT in adult patients with CMML.^{46,47} The outcome of such patients was traditionally included in studies of allogeneic SCT in patients with MDS, of which CMML has been considered a subcategory. Recent WHO classification established CMML as a separate category¹; the effect of the reclassification on the prognostic impact of SCT is not yet appreciated.

In a European study,⁴⁶ 50 patients with CMML underwent SCT at 43 centers; 44 of the donors were HLA matched (38 siblings, six unrelated donors, and one nonsibling relative), and six were partially mismatched. At a median age of 44 years (range 19–63 years), this patient group was clearly selected with respect to age; 40% had karyotypic abnormalities and 36% had between 5 and 29% marrow blasts at the time of transplantation. The median time from diagnosis to SCT was 9 months. Two patients (4%) failed to engraft, and the treatment-associated mortality was high (47%). Median follow-up was 29 months (range 1–59 months); the 5-year estimated overall survival rate was 21%, the disease-free survival rate 16%, and the 5-year estimated probability of relapse 61%.⁴⁶ No significant associations with outcome were identified, although transplantation early in the disease might have had a positive influence.⁴⁶ The probability of relapse was higher in patients without graft-versus-host disease

(51%) than in those with this disease (29%), and the probability of relapse was higher in patients who received T-cell-depleted grafts (61%) than in those who did not (45%), suggesting a favorable graft-versus-leukemia effect.

Another study⁴⁷ reported results for 21 patients with de novo CMML (12 with “proliferative” disease and nine with nonproliferative disease) who underwent SCT. The cohort consisted of both adults and children (median age 47 years). Twelve of the donors were HLA-identical siblings, four were matched unrelated donors, and five were mismatched donors. Before SCT, only two patients had received intensive combination chemotherapy after progression to AML. After SCT, five patients died of organ failure, two died of chronic graft-versus-host disease, and five relapsed and died. The cumulative relapse rate at 3 years was 25%, and 0.7–8.1 years after transplantation (median 6.9 years), nine (43%) of the patients were still alive.⁴⁷ The small size of the patient cohort limited the significance of covariates associated with outcome. SCT later in the course of disease and signs of disease acceleration (e.g., more than 5% marrow blasts), but not abnormal karyotype or proliferative disease, appeared to influence the outcome negatively: four of the five patients who relapsed had an increased percentage of marrow blasts at the time of transplantation.

Finally, a European study of SCT in 43 patients with childhood CMML⁴⁸ revealed a 5-year event-free survival rate of 31% (38% in patients who received cells from HLA-matched siblings). However, the relapse rate of 58% suggested resistant disease. The major obstacles of the few studies that have examined the effect of SCT on patients with CMML were the toxicity of the procedure and resistant disease. Additional results, including those for a few CMML patients in reports on MDS, are scattered in the literature, and no critical review is currently available. References to some recent studies are found in a review on the role of SCT in MDS⁴⁹ and MPD.^{50–52} The conclusion that can be drawn is that SCT is feasible and occasionally “curative” only in younger patients, even though the procedure is associated with considerable morbidity and mortality, and young people make up a small proportion of patients with CMML. This interpretation is compromised by the small number of study patients to date and the heterogeneity of CMML.

Newer transplantation approaches attempt to avoid the excessive toxicity of current conditioning regimens by using lower doses of immunosuppressive drugs (e.g., fludarabine or antithymocyte globulin) and myelosuppressive drugs.^{53,54} In patients with MDS, the reduced-intensity regimen results in full engraftment and recovery with less immediate toxicity,⁵³ thereby extending eligibility for SCT to older persons. The approach relies on the graft-versus-leukemia effect more than ablation of malignant cells by the conditioning regimen, though its success in patients

with relatively resistant high-risk CMML is unclear. Because of the high frequency of relapses⁴⁶ in patients receiving standard cytoreductive regimens,⁴⁶ it seems reasonable, at least for patients with high-risk CMML, to attempt induction of CR immediately before transplantation. The claimed advantage of SCT in low-risk patients and those transplanted early after diagnosis is based on results of retrospective studies or phase II clinical trials with small numbers of CMML patients who are highly selected,^{46,47} which complicates interpretation of the results. The absence of randomized studies leaves open the question of whether a delay of transplantation until disease progression would compromise the outcome. For MDS, modeling of the expected outcome of early transplantation suggested an advantage for patients with high-risk disease, whereas patients with low-risk disease benefited from delayed transplantation.⁵⁵ In both situations, delay until progression to leukemia resulted in the worst outcome.⁵⁵ Thus, patients with low-risk and intermediate-risk disease (by, e.g., MDAPS) may be best treated by supportive care and can be encouraged to participate in investigational clinical trials. Patients with intermediate-risk and high-risk CMML should be considered for SCT if a suitable donor is available. Although many treatment centers prefer a direct transplant procedure, an induction attempt followed by SCT may be a better choice in light of the high relapse rate in such patients and the availability of effective and safe induction therapy.

ATYPICAL CHRONIC MYELOGENOUS LEUKEMIA

INTRODUCTION

This category was recently introduced by the WHO classification into the subgroup of myelodysplastic/myeloproliferative disorders.¹ To some extent, it is still a diagnosis of exclusion and includes patients with predominantly overproduction of neutrophils and various degrees of dysplasia in one or more hematopoietic lineages. The most important feature, differentiating aCML from CML is the absence of the BCR/ABL translocation or any variant translocations present in CML. This makes the diagnostic category of aCML similar, if not identical, to that of BCR/ABL-negative CML.⁵⁶ Minor distinguishing features include absence of basophilia, older age, more frequent presentation with lower WBC counts, thrombocytopenia, and anemia.^{56–60} Separation from CMML is less stringent: Both disorders share the proliferative and dysplastic marrow feature, high median age, and a lack of distinguishing cytogenetic or molecular features. The presence of absolute monocytosis ($>1 \times 10^9/L$ monocytes) in CMML in association with relative monocytosis (>8 – 10% monocytes on blood smear^{2,56,58,60}) separates CMML from aCML. aCML is a rare disease, and in the past cases were included in the category of Ph-negative CML. As about one-half

of Ph-negative CML cases are BCR/ABL positive,^{60,61} it was difficult to assess characteristic features, prognosis, and response to therapies. Assuming that BCR/ABL-negative cases of CML and aCML are, if not identical, then clinicopathologically very similar entities, information on characteristics, prognostic variables, and outcome of this rare disorder(s) can be based on an analysis of 76 patients.⁵⁶ The median survival of patients was 24 months and progression into acute leukemia occurred in 30%. Chromosomal abnormalities were found in 30% of patients, with trisomy 8 being the most frequent, while monosomy 7 was not observed. Complex chromosomal abnormalities were rare. Multivariate analysis identified age >65 years, hemoglobin <10 g/dL, and WBC $>50 \times 10^9/L$ as variables associated with poor survival. Younger patients with better blood counts had a median survival of 38 months, compared to 9 months for older patients with compromised counts.⁵⁶ The overall prognosis is worse and survival shorter in patients with a CML (Bcr/Abl-negative CML) compared to Ph'-positive CML.^{58,59,61} In at least one study, the survival seems not significantly affected by treatment.⁵⁶

The outcome is, however, similar to that in CMML.^{3,4,56,59,61} No study has demonstrated the importance of the single objective distinguishing feature of monocytosis as being associated with a different outcome. A detailed analysis of factors associated with outcome in 485 patients (CMML, 304; BCR/ABL-negative CML, 74; Ph-negative, BCR/ABL unknown, 107) found that a diagnosis of CMML indeed confers a significantly shorter median survival (12.6 months) than BCR/ABL-negative CML [21.4 months and Ph-negative, BCR/ABL unknown CML (18.3 months)]. This finding provided, for the first time, the empirical support for separating aCML from CMML.⁴⁵

TREATMENT

Similar to patients with CMML, the most therapeutically relevant diagnostic tests are karyotype analyses, which should be completed with additional testing for the presence of *BCR/ABL* fusion gene or gene transcripts by fluorescence in situ hybridization (FISH) and, preferably, by molecular testing using PCR. The BCR/ABL-negative CML/aCMLs are rare and only recently defined diseases. No clinical trial has ever been conducted to assess the effectiveness of any specific treatment. Traditionally, the primary goal of therapeutic interventions has been to control myeloproliferation manifested by leukocytosis, or thrombocytosis, and amelioration of anemia, thrombocytopenia, and systemic clinical symptoms associated with the disease (i.e., fatigue, weight loss, night sweats, cough, bone pain, and organomegaly). In asymptomatic patients with moderate leukocytosis without anemia or thrombocytopenia, it may be prudent to observe the patient with appropriate hematologic follow-up to assess the rate of disease progression.

Younger patients who may be potential candidates for allogeneic SCT should initiate tissue typing of family members and search for a potential stem cell donor. Exceptions to this “observe-and-wait” approach are the rare patients with documented balanced translocations involving RTKs, who are amenable to treatment with TK inhibitors, such as imatinib mesylate, as discussed in the Section “Chronic Myelomonocytic Leukemia”.

Cytoreductive agents

Hydroxyurea and busulfan are the agents most frequently reported as treatment choices in patients with diseases resembling aCML.⁶² Both can be used either on a daily schedule with the dose adjusted to the desired leukocyte blood count, or alternatively, on a cyclical schedule aiming initially for resolution of systemic symptoms and reduction of the leukocyte count. Due to its more rapid onset of action and lack of delayed effect on the bone marrow, hydroxyurea is more suitable for continuous, daily maintenance treatment. Busulphan's effects on the bone marrow are less predictable and may be delayed and cumulative, resulting in a prolonged bone marrow suppression. Therefore, its cyclical use is preferable. Although not formally documented in clinical studies, anemia and thrombocytopenia often persist in aCML patients with well-controlled leukocytosis, either as a consequence of the disease itself, treatment-associated myelosuppression, or both. Careful dose titration is therefore recommended for hydroxyurea and particularly for busulphan. An unfavorable response of these patients to busulfan has been considered by some a characteristic feature of aCML,⁶² and even treatment with hydroxyurea often yields only partial and transient disease control.^{62,63} The effectiveness of both agents is particularly limited in the management of organomegaly.

Analysis of the impact of the effects of various treatments after referral to a tertiary cancer center failed to document significant differences in the survival of treated and untreated patients.⁵⁶

In patients with splenomegaly, splenectomy may result in a temporary alleviation of anemia and thrombocytopenia, provided that the bone marrow remains functional and the cytopenias are not a consequence of disease evolution. Therefore, a bone marrow aspiration, biopsy, and karyotyping should be part of the preoperative evaluation. A recent report on the value of splenectomy in 12 patients with CMML showed improvement of thrombocytopenia in 4 of 11, and a modest improvement of anemia in 2 of 9 patients. None of the anemic patients achieved transfusion independence.⁶⁴ There are no reports in aCML, but it is reasonable to expect similar results. Thus, splenectomy should be viewed as a palliative measure, particularly in patients with clinical symptoms, including pain due to splenomegaly. Of the remaining options to reduce

splenomegaly, splenic irradiation is ineffective in myeloid malignancies and intensive intravenous chemotherapy using, e.g., cytarabine, although effective as a palliative treatment, it is invariably associated with bone marrow suppression. (M. Beran, unpublished observation, 2003).

The effectiveness of both oral drugs is particularly limited in control of hepatosplenomegaly. Analysis of the impact of treatment after referral to one tertiary cancer center failed to document significant differences in the survival between treated and untreated patients.

Interferon α

There are no prospective data on the efficacy of interferon α (IFN- α) in treating aCML. IFN- α has been used, however, in Ph-negative CML, and a retrospective analysis of some of these patients revealed the absence of the BCR-ABL abnormality, rendering the diagnosis similar to aCML. In one report, two of six patients with BCR-ABL-negative CML achieved a CR, while four patients failed to respond.⁶³ In another study involving Ph-negative CML, 21 patients were treated with a daily subcutaneous dose of up to 5 million units/m² of IFN- α .⁶¹ Seven of seven (100%) patients with BCR/ABL-positive disease responded, while five of six (83%) patients with BCR/ABL-negative CML and six of eight (75%) patients with CMML failed to respond. The outcome of the two latter groups was worse as well.⁶¹ This experience suggests a limited role for IFN- α in aCML. In patients presenting with low platelet counts, the known platelet-lowering effect of IFN- α treatment may further aggravate thrombocytopenia.

Recent availability of pegylated IFN, a pharmacologic formulation providing a slow release of the agent with weekly administration, has renewed interest in reexamining the efficacy of IFN- α in MPD, including aCML. In the absence of better choices, this treatment may be offered as an investigational alternative to hydroxyurea or for patients failing hydroxyurea therapy.

Combination chemotherapy

In individual cases, complete responses to combination chemotherapy that included cytarabine have been reported. Although limited information is available, it appears that responses are lower than in CMML and that this approach should be saved for cases evolving into AML. Complete responses may be obtained in a minority of patients with such “secondary” AML or blast phase of aCML and, as in similar cases of AML secondary to MDS and CMML, the responses are short, and long-term disease-free survival is rarely obtained. Intensive chemotherapy may be considered as a cytoreductive approach before allogeneic SCT.

Allogeneic stem cell transplantation

There are no reports summarizing the experience with SCT in aCML, and the lack of experience is reflected in

a recent review of the results of SCT in MPD.⁶⁵ With no curative option and generally poor control of aCML with currently available modalities, SCT should be considered in younger patients with available HLA-matched donors and particularly in those presenting with unfavorable risk factors.⁵⁶ As with other rare disorders, the preferable use of investigational treatment modalities should be in the context of clinical trials.

HYPEREOSINOPHILIC SYNDROME AND CHRONIC EOSINOPHILIC LEUKEMIA

INTRODUCTION

Recognition of heterogeneity in hypereosinophilic syndrome (HES) is important as identification of the exact pathologic mechanisms becomes relevant to the design of treatment strategies and the overall management of individual patients. This importance is best illustrated by seminal discoveries of the unique therapeutic efficacy of imatinib mesylate in a subset of patients with HES⁶⁶⁻⁷² and by the identification of the FIP1L1-PDGFR α TK as the molecular basis in a subpopulation of patients and as a therapeutic target of imatinib^{69,73} and potentially other small-molecule TK inhibitors.⁷⁴

Although hypereosinophilia may have any number of causes, the clinical symptoms and organ damage appear to be related to the pathologic consequences of the chronically elevated eosinophils.^{75,76} Because the benign and malignant disorders are not yet always distinguishable, treatment of patients with hypereosinophilia is aimed primarily at suppressing eosinophil counts (particularly in symptomatic patients); the ultimate goal is to prevent or limit organ damage.

A therapeutically relevant classification of HES plus chronic eosinophilic leukemia (CEL) is emerging, still largely under development and dictated by the exclusion criteria spelled out in the most recent WHO classification⁷⁶ and by other criteria. Eradication of symptoms and prevention of eosinophil-triggered organ damage remain the primary overall concerns, but in a subcategory of patients, the choice of treatment is now based on the likely underlying molecular mechanism(s). Recognition of therapeutically important features of HES suggests a need for closely integrated diagnostic workup with therapeutic decision making.

DIAGNOSTIC AND TREATMENT PARADIGMS

The diagnosis of HES or CEL requires exclusion of reactive causes of eosinophilia. According to WHO criteria,⁷⁶ reactive causes include infections, hypersensitivity and allergic diseases, immune system disorders, metabolic abnormalities, and diseases of the connective tissue, heart, lungs, skin, and gastrointestinal systems. CEL remains, to a degree, a poorly defined entity.⁷⁷ The most characteristic feature distinguishing CEL from HES is the presence of karyotypic abnormalities in the myeloid cells or presence of increased blast cells in the bone mar-

row (5–19%) or blood (more than 2%).⁷⁶ Differential diagnoses further include malignant disorders in which eosinophilia is either reactive (e.g., secondary to tumor-producing hematopoietic growth factors) or where eosinophils are part of the hematopoietic malignant clone [e.g., CML, AML with inv(16) or t(8;21), MDS with t(1;7), hematologic malignancies involving rearrangement of transcription factor ETV6, MPD with t(5;12)(q33;p13), hematologic malignancies associated with rearrangement of 5q chromosome in the area coding for genes regulating eosinophilic growth factors, and other rare hematologic malignancies].

For the remaining cases which fulfill the original criteria for HES,⁷⁸ the WHO criteria,⁷⁶ and other criteria,^{77,79} further screening should include complete bone marrow examination, including histologic examination, karyotype analysis, FIP1L1-PDGFR α by PCR or FISH, and documentation of disease and eosinophil clonality by FISH or molecular methods. Abnormal T-lymphocyte subsets may be identified immunophenotypically as immature T cells (CD3⁺, CD4⁻, and CD8⁻) or aberrant T cells (CD3⁻ and CD4⁺),^{80,81} with or without rearrangement of T-cell receptor genes.⁸⁰⁻⁸³ The usefulness of determining interleukin 5 (IL-5) and other cytokines plasma concentrations is unknown. Association of eosinophilia with systemic mastocytosis^{84,85} supports the determination of plasma tryptase concentrations. Assessment of splenomegaly, hepatomegaly, abnormal marrow function (e.g., anemia, thrombocytopenia, marrow fibrosis, and dysplasia), and elevated plasma concentrations of tryptase helps define “myeloproliferative variant” and thus influences therapeutic decisions.⁸⁶ The final pretreatment assessment should focus on identifying and grading the involvement of cardiovascular, pulmonary, neurologic, dermatologic, and other systems known to be involved in patients with hypereosinophilia, and should help guide the risk-to-benefit ratio of a particular therapeutic approach. This consideration is particularly important with the use of novel, investigational treatments that were pioneered using imatinib mesylate.

MANAGEMENT

Because the eosinophils produce end-organ damage through their activation, regardless of the cause of eosinophilia,⁷⁵ the primary aim of hypereosinophilia management is to reduce the number of eosinophils. The secondary, though no less important, goal is to reduce or correct the already incurred damage. The treatment selected is dictated by the status of the disease at diagnosis and identification of the cause of hypereosinophilia, and consists of nonspecific measures as well as treatment tailored to patients with a particular subcategory of HES.

End-organ damage does not always correlate with the degree of eosinophilia^{75,87}; therefore, assessment of successful therapy should not be limited to monitor-

ing eosinophil counts, but should also involve regular evaluation of organ status and function (e.g., echocardiograms every 6 months to assess the presence and extent of cardiac disease). The same approach applies to reassessment of the original diagnosis because the evolution of the disease (e.g., clonal evolution in HES) may require timely changes in the management strategy.

Corticosteroids

For patients with symptomatic HES and evidence of end-organ damage or clinical symptoms, such as cough, dyspnea, myalgia, or neurologic deficits, the first treatment of choice is the daily administration of systemic corticosteroids (1 mg/kg). In most cases, this treatment results in a rapid reduction of eosinophilia, organ infiltration with eosinophils, suppression of the inflammatory process, and prevention of further organ damage. Whether such treatment ameliorates existing organ damage is uncertain.^{88–91} In patients positive for FLIP1-PDGFR α , imatinib mesylate would be an alternative and probably preferable treatment. Documentation of clonal HES (FLIP1-PDGFR α , abnormal karyotype), CEL, or clonal hematologic disorder with eosinophilia on the diagnostic sample or on a subsequent follow-up examination would require reconsideration of this approach plus additional agents or change of therapy.

Hydroxyurea and other single-agent chemotherapy

For steroid-resistant HES patients and particularly in patients with “myeloproliferative” HES or CEL, hydroxyurea is a first-line agent that effectively reduces eosinophil counts, organ infiltration, and hepatosplenomegaly, and thus likely delays end-organ damage.^{89–91} The initial dose of 1–2 g of hydroxyurea per day is often sufficient to bring the eosinophil count to within the normal range. Subsequent maintenance dosing requires monitoring to avoid myelosuppression and cytopenias.

Other cytotoxic agents have occasionally been used empirically, mostly for patients with proliferative HES and evidence of end-organ damage. Case reports of successful treatment include use of cyclophosphamide in HES with recurrent eosinophilic colitis,⁹² vincristine,^{78,93,94} and, in hydroxyurea-resistant HES, cytosine arabinoside (100 mg/m² given subcutaneously or intravenously) daily for 5 days plus prednisone 100 mg orally, daily, for 5 days, every month (M. Beran, unpublished observations, 2003). Ameliorated clinical symptoms and suppressed eosinophilia were reported with each of the above treatments. The effect of chemotherapy on the natural course of the disease remains unknown.

Immunosuppressive agents

The use of hydroxyurea may be less effective in managing T-cell-mediated HES than other types of HES. T-cell-mediated HES is characterized by the expansion of immunophenotypically abnormal T cells (CD3⁺, CD4⁻,

CD8⁻, or CD3⁻, CD4⁺) and, in some cases, by a clonal rearrangement of the T-cell receptor genes.^{81,82} Development of T-cell lymphoma and Sezary syndrome in this group of HES patients indicated the neoplastic potential of such T cells.⁸² These T-cells have a helper type 1 or 2 cytokine profile, and secretion of eosinophil production-stimulating factors may be a pathogenetic mechanism underlying the “lymphocytic” variant of HES.⁸³ Some patients respond well to treatment with T-cell suppressive agents, such as cyclosporin A^{95,96} or cladribine in combination with steroids.⁹⁷

Interferon α

The success of using IFN- α in managing Ph-positive CML⁹⁸ and clinicopathological similarities between CML and HES (particularly its proliferative variant) have prompted trials of IFN- α in the management of HES. The first report of a successful response in a patient with HES was followed by a series of mostly case reports, some associated with literature reviews.^{99–107} The initial dose of IFN- α varied between 1 and 5 million units/m² subcutaneously, daily, 5 days/week, and was adjusted according to the patient's tolerance. As with most of the trials in this patient population, the estimations of response rates, duration of responses, and the effect on existing end-organ damage or prevention of its development were plagued by the limited size of the treated population, the disease's heterogeneity, the limited follow-up, and the lack of a control population treated with the “standard of care” (i.e., steroids plus hydroxyurea).

Imatinib mesylate

The pathologic features of some cases of HES are reminiscent of those of other MPD, such as BCR/ABL-positive CML. The groundbreaking success of targeted treatment of CML with imatinib mesylate²⁸ prompted its empirical use in patients with HES who failed other therapies. The first reported patient treated with imatinib mesylate achieved a complete response after only 2 weeks of treatment at 100 mg a day,⁶⁶ a fraction of the standard dose used for treatment of CML.²⁸ This observation, followed by reports of similar responses in additional patients with HES,^{67–72} ushered in what appears to be a new era of HES management and reclassification.

This clinical success prompted a search for an imatinib mesylate target in patients with HES, leading to the seminal discovery of a new fusion gene, the product of which is the molecular basis of HES in some patients. Deletion of an 800-kilobase part of the *PDGFR α* gene leads to fusion of its 5' end to the 3' end of a new gene *FIP1L1* on chromosome 4.^{69–73,77,79,86,108} The FIP1L1/*PDGFR α* gene product, an intracellular protein with TK function, is unique because it is autophosphorylated due to deletion of the portion of *PDGFR α* gene coding for the juxtamembrane portion of the *PDGFR α* receptor known to inhibit phosphorylation of the ATP-binding site, and thus promotes uncontrolled growth. The most convincing documentation

that the FIP1L1-PDGFR α TK is a target of imatinib was imatinib's loss of inhibitory action in cells with acquired mutation (T671I) in the TK domain of the *FIP1L1/PDGFR α* fusion gene, which implies that the mutation confers resistance to imatinib mesylate.^{69,74}

The clinical experience with imatinib mesylate in managing HES and CEL can be summarized as follows: In most responding patients, daily oral doses of 100 mg effectively induced complete responses. The median time to response was 4 weeks, but responses were seen within the first 2 weeks of treatment. In only a few cases, increasing the imatinib dose to 400 mg was required for response.⁷¹ The adverse effects were minimal and similar to those experienced by patients with Ph-positive CML.^{28,33} The exceptions were two cases of congestive heart failure, both in responding patients, ensuing shortly after initiation of imatinib treatment.^{72,108} Administration of steroids resulted in the resolution of symptoms in both cases, raising the question of whether steroids should be used during initial therapy with imatinib (with or without monitoring of troponin levels), particularly in patients with existing cardiac involvement. All HES and CEL patients with the FIP1L1/PDGFR α abnormality responded regardless of the disease stage, and no cases of primary resistance have been reported.^{69,109} In one study, however, four of nine patients who achieved a complete response with imatinib had no detectable FIP1L1-PDGFR α .⁶⁹ This observation not only indicated the presence of other imatinib targets but also argued in favor of an empirical trial of imatinib in patients with HES or CEL. Such a trial would ensure that no patient missed a potential therapeutic benefit, contribute further to a therapeutically meaningful classification of HES and CEL, and provide clinical feedback and guidance for ongoing translational research.

The complete responses were associated with normalization of eosinophil counts and normalization of hematologic parameters with resolution of clinical symptoms.^{69,109} Among 41 patients with HES or CEL included in seven reports, 29 (71%) achieved CRs and one achieved a PR.¹⁰⁹ Of six patients monitored for FIP1L1-PDGFR α transcripts, molecular remissions were documented in five after 1–12 months of treatment with 400 mg imatinib daily.⁷¹ The treatment effect on end-organ damage is unknown because the experience is limited. No amelioration of cardiac disease was noted in three patients at the time they achieved CR,⁷¹ but the clearing of interstitial pulmonary infiltrates,^{71,110} normalization of pulmonary function tests,⁷¹ and a major improvement in the bone marrow fibrosis of responding HES patients was encouraging.^{71,109}

What is the optimal treatment strategy for patients with HES and CEL and FIP1L1/PDGFR α ? Although the clinical experience with imatinib mesylate is limited, these disease categories are clearly highly sensitive to the

agent. Thus, the starting daily dose of 100 mg is recommended after the expression level of the fusion transcripts has been determined, if possible with PCR. In HES patients with cardiac disease, use of prophylactic oral steroids during the first week of treatment should be considered. Because the median time to optimal response was 4 weeks, failure to respond should prompt consideration of dose escalation. The benefit of dose escalation is supported by experience in a limited number of HES cases and is corroborated by extensive experience on dose response to imatinib in patients with Ph-positive CML.^{111,112} For patients who achieve CRs, the treatment strategy developed for CML should be adapted; they could continue on the same daily dose and be monitored for minimal residual disease by PCR every 3–6 months and for degree of end-organ damage (e.g., heart damage every 6 months with cardiac sonography). In patients with CRs but positive for minimal residual disease, after 6–12 months, dose escalation according to clinical tolerance is an option worth to investigate.

A similar treatment approach should be used for imatinib-mesylate-responsive patients lacking FIP1L1/PDGFR α . Hematologic status, and end-organ damage and function must be monitored.

Recently, a lemtuzumab (Campath-1HTM) has shown remarkable activity in patients with FIP1L1/PDGFR α -negative HES. Normalization of absolute eosinophil counts was observed in 8 of 9 patients within 4 weeks of treatment with weekly cycles of alemtuzumab.¹¹³ The mechanism of action is likely by direct interaction with CD52 target antigen on eosinophils. Although dosing and maintenance must be optimized and safety of the treatment documented, the preliminary results justify further clinical investigation.

Allogeneic stem cell transplantation

The use of allogeneic SCT in patients with HES or CEL remains at the exploratory stage and is limited to selected cases with aggressive disease. Successful engraftment using standard myeloablative regimens and disease-free survival between 8 months and 5 years have been reported.^{114–117} Recently, the concept of nonmyeloablative SCT has been applied to a few HES patients, who achieved engraftment after reduced-intensity conditioning.^{118,119} Follow-up of those patients has not exceeded 12 months, so the potential advantage of this less toxic approach is not yet evident. Nonmyeloablative SCT is worth attempting in selected symptomatic patients who fail standard treatments, including imatinib mesylate. Because of transplantation-related complications (e.g., serious infections and acute or chronic graft-versus-host disease), and the likely bias inherent in patient selection, the major challenge will be to determine the benefit of SCT in a limited number of candidates for this treatment.

NON-HODGKIN'S LYMPHOMA

Chapter **51**

THE CLASSIFICATION OF NON-HODGKIN'S LYMPHOMA

P.G. Isaacson

INTRODUCTION

The aim of a lymphoma classification is to provide a means of communication between those with a special interest in this group of diseases. The classification must be reproducible and clinically relevant, so that the results of treatment can be compared worldwide, and sufficiently flexible to allow the incorporation of new data. Finally, the classification should be histopathologically based since it is the histopathologist who, almost always, makes the initial diagnosis. Traditionally, Hodgkin's disease (Hodgkin's lymphoma) and non-Hodgkin's lymphomas have been classified separately. This is a reflection of the specific identifying cell and limited morphological range of Hodgkin's disease as well as its distinctive clinical features. In comparison, the clinicopathological features of the non-Hodgkin's lymphomas are much more wide ranging and less distinct for any given entity. Not surprisingly, therefore, there have been only two classifications of Hodgkin's disease proposed since 1925 compared to more than 25 classifications of non-Hodgkin's lymphoma that have appeared in the same period.

To the early pathologists, the histological appearances of all non-Hodgkin's lymphomas were alike, consisting of replacement of the normal lymph node architecture by sheets of small or sometimes larger cells with dark-staining nuclei. It was clear, however, that not all cases behaved alike; the survival of patients

with non-Hodgkin's lymphoma varied from a few months to many years. Pathologists were, therefore, under an increasing pressure from their clinical colleagues to predict the natural course of an individual case. Initial therapeutic success with Hodgkin's disease was followed by the emergence of more effective means of therapy for the non-Hodgkin's lymphomas. These therapies were not homogeneously effective in all the non-Hodgkin's lymphomas and the results clearly varied according to their histology. Consequently, clinicians began to demand much more precise and clinically relevant histological diagnoses. In 1966, in response to this, Rappaport formulated the first clinically relevant histological classification of non-Hodgkin's lymphomas. Broadly speaking, the Rappaport classification divided lymphomas into those composed of small cells and those composed of large cells. Each of these groups could be further subdivided into those with a follicular (or nodular) growth pattern and those that were diffuse. The follicular and small-celled tumors were clinically less aggressive; a better survival could, therefore, be predicted and, importantly, less potent and less toxic therapy was suitable for these cases. The converse applied to cases with a diffuse growth pattern, especially if composed of large cells. As histological techniques improved, allowing finer morphological discrimination between cells, more detailed classifications emerged. In parallel with these improvements it was becoming possible to

establish the immunophenotype of lymphoma cells using immunohistochemical techniques. It soon became evident that the lymphoma cells were closely related to normal lymph node cells and that the cells of many non-Hodgkin's lymphomas recapitulated the cytology of normal lymphocytes, particularly the B cells of the follicle center. It was also clear, however, that there were an alarmingly wide variety of lymphoid neoplasms and a whole host of classifications based on these new concepts soon emerged. This caused so much confusion that a series of special international meetings were convened to decide on a single clinically relevant classification that could be used throughout the world. In the absence of any consensus, The United States National Cancer Institute convened a study to evaluate the competing classifications and the result was the compromise "Working Formulation for Clinical Use."¹ It was stressed at the time that this "formulation," although based on histopathology, was a system for translation between the competing classifications and not a classification in its own right. However, it was rapidly accepted as such by pathologists, particularly in the United States where it became the classification of choice. The working formulation divided lymphomas into three grades based on their clinical behavior, according to their response to therapy prevalent in the late nineteen sixties and early seventies. Imprecise collective morphological terms such as "large cell" and "mixed small and large cell" were used to characterize individual entities. The result was that different clinicopathological entities were lumped together and as new entities were described, they merely became absorbed into this rather rigid system. The Working Formulation was incapable of incorporating the rapidly expanding amount of immunophenotypic data on which pathologists were, nevertheless, increasingly relying for lymphoma diagnosis. The Working Formulation thus soon lost its main reason for existence, namely its clinical relevance.

The majority of European pathologists never accepted the Working Formulation and preferred to use the Kiel classification. This classification and its updated editions² were based on immunophenotypic data dividing lymphomas into B- and T-cell types and, thereafter, into individual entities based principally on the similarity of their cells to normal lymphocyte variants. The lymphomas were designated low or high grade according to their cytological characteristics, rather than their predetermined clinical behavior and in keeping with established schemes for other tumors. Unlike the Working Formulation, the Kiel Classification had a sound biological basis and could easily be updated and maintain its clinical relevance. Criticisms that could be leveled at the Kiel Classification included overreliance on establishing the normal cell counterpart for each type of lymphoma, illogical oversplitting of some entities, and failure specifically to include extranodal lymphomas.

The use of different lymphoma classifications on either side of the Atlantic and the inherent defects in each contradicted the basic requirement of a classification, namely that it should provide a language for international communication, and threatened a return to the chaos of the 1970s. Moreover, new techniques and new concepts were emerging that urgently required incorporation into the principles underlying lymphoma classification. Developments in immunohistochemistry meant that a cell lineage could confidently be assigned to most lymphomas and that many distinctive functional properties of the neoplastic cells could be determined. Distinctive molecular genetic properties of the different disorders also began to emerge and some of these could be identified using simple immunohistochemical techniques. Another important development was the recognition that many lymphomas arose in extranodal sites and that the site of origin was often a significant clinical determinant.

THE REVISED EUROPEAN AMERICAN LYMPHOMA CLASSIFICATION

In 1991 a group of pathologists from both sides of the Atlantic and the Far East formed an International Lymphoma Study Group that met annually to discuss research. Not surprisingly, this group soon began to address issues of lymphoma classification as outlined above and the need for a new approach to classification soon became evident. Of three alternative approaches that emerged, to update either the Working Formulation or the Kiel classification or to produce an entirely new classification, a decision was made to adopt the latter course. The basis for what was to become the Revised European American Lymphoma (REAL) Classification³ was the construction of a list of neoplastic lymphoproliferative disorders each defined as far as possible according to a set of five properties, namely morphology (histology), immunophenotype, genotype, normal cell counterpart, and clinical features. The degree to which these properties contribute to the classification of each entity varies. In some cases, such as mantle cell lymphoma, each property is highly distinctive, perhaps reflecting its basic distinctive genotype,⁴ while for others such as nasal-type natural killer (NK)-cell lymphoma⁵ clinical features together with immunophenotype are the most important.

THE WORLD HEALTH ORGANIZATION CLASSIFICATION

In 1995, the World Health Organization (WHO), the Society for Hematopathology and the European Association for Haematopathology undertook a joint project to produce a comprehensive classification of all

hematologic neoplasms including those of myeloid lymphoid and histiocytic lineage. Since the REAL classification had only recently been proposed and was in the process of clinical evaluation, the task proposed for lymphoid neoplasms was to update and revise the REAL classification with input from additional experts in order to broaden the consensus. The formation of the steering committee and 10 subcommittees, each charged with the review of a specific group of neoplasms, involved 52 expert histopathologists and hematologists. In recognition of the importance of clinical relevance, a clinical advisory committee of 35 experts in the fields of leukemia and lymphoma from around the world was convened. The subcommittees and the clinical advisory committee met separately, the former on many occasions, and recommendations were fed to the steering committee prior to a joint meeting of all committee members that was held in November 1997 at Airlie House in Virginia. The aim of this final meeting was to reach agreement on particular controversies most of which had arisen consequent to actual use or, in effect, field testing of the REAL classification, to ensure that there was common ground between pathologists and clinicians and to agree on the final format. The agenda of the Airlie House meeting comprised a series of topics and questions that had been proposed by members of the subcommittee and the clinical advisory committee. In the case of the lymphomas, discussion of these topics served to refine and update the REAL classification, which could then be subsumed into the WHO scheme.

THE BASIS OF THE REAL AND WHO CLASSIFICATIONS

MORPHOLOGY

Morphology remains the mainstay of lymphoma diagnosis since it is, in effect, the collective expression of the immunophenotype, genotype, and normal cell counterpart. Once an entity has been defined on the basis of its collective properties, morphology on its own is often sufficient for a definitive diagnosis. However, lymphomas of identical morphology, but arising in different sites, may constitute different disease entities and some single disease entities may be morphologically heterogeneous. For example, anaplastic large cell lymphoma (ALCL) arising in lymph nodes behaves much more aggressively than the morphologically identical tumor arising in the skin,⁶ while the cytological features of enteropathy-type T-cell lymphoma are highly variable and do not influence its clinical behavior.⁷ Histological grade alone, which should not be confused with clinical aggressiveness, is no longer considered a basis for the separation of lymphomas into broad groups. Many entities may transform from low- to high-grade morphology as part of

their natural history and can present de novo as either low- or high-grade lesions.

IMMUNOPHENOTYPE

The immunophenotype of lymphomas was first used in the Kiel classification for broad grouping of lymphomas into B-cell and T-cell types. With the inclusion of the NK-cell lymphomas into the T-cell group, this distinction remains a fundamental consideration in the REAL classification and serves as a primary step in the separation of the lymphomas into two broad groups. Within these broad groupings the detailed immunophenotype is useful in helping to define individual entities but in only a few instances does a combination of immunophenotypic properties alone serve to define an entity that cannot be distinguished by other means. This is true of mantle cell lymphoma where the defining genotype, t(11;14), results in expression of cyclin D1, the defining immunophenotype.

GENOTYPE

With increasing recognition that cancer is a genetic disease, the genotype of lymphomas is assuming greater significance in their classification. For some entities such as follicular lymphoma, [t(14;18)], and mantle cell lymphoma, [t(11;14)], the genotype is indeed the defining property. However, genotyping is beyond the capability of most laboratories and, fortunately, the genotype finds expression as reproducible morphological and/or immunophenotypic features that allow confident and reproducible diagnoses.

NORMAL CELL COUNTERPART

The normal cell counterpart, although not always known, is a useful aid to classification as it helps to characterize the morphology and phenotype of the lymphoma and, importantly, to understand its clinical behavior which may relate to the physiologic pathways of the normal cell. This property is more significant for B-cell lymphomas than for T-cell lymphomas largely because more is known about the B-cell subtypes and their functional characteristics.

CLINICAL FEATURES

The inclusion of clinical features, including the site of origin, aggressiveness, and prognosis as an integral and practical part of the definition of lymphomas as distinct diseases is one of the more novel aspects of the REAL and WHO classifications.

SITE OF ORIGIN

Neither the Working Formulation nor the Kiel classification acknowledged that a significant percentage of lymphomas do not arise in lymph nodes. Extranodal lymphoma accounts for some 25% of all cases in the United States,⁸ while in the Far East the percentage is much higher amounting to 45% in Japan and 60% in Korea.⁹ The site of origin of lymphomas is of considerable

importance and the distribution of lymphoma types shows a markedly different bias in different sites. Thus, extranodal Hodgkin's disease is altogether rare and follicular lymphoma, one of the commonest nodal tumors, occurs only infrequently as a primary tumor in the gastrointestinal tract despite its high content of native lymphoid tissue.¹⁰ In some organs and/or tissues, such as the skin, gastrointestinal tract and, to a lesser extent the spleen, lymphomas specifically characteristic of that site alone occur. Examples include cutaneous follicle center cell lymphoma,¹¹ enteropathy-type T-cell lymphoma,¹² and splenic marginal zone lymphoma (SMZL).¹³ For clinical purposes it is sometimes useful to group together the lymphomas that arise in specific sites and to approach the diagnosis of lymphoma arising in those sites in this way rather than in the purest sense of an overall lymphoma classification. This is best exemplified by lymphomas arising in the gastrointestinal tract¹⁰ and the skin.¹¹ However, the use of entirely separate classifications for lymphomas arising at different extranodal sites is to be discouraged.¹⁴

CLINICAL AGGRESSIVENESS

The REAL and WHO classifications clearly distinguish between histological grade and clinical aggressiveness. Histological grade is based on cell and especially nuclear size, density of nuclear chromatin, and the proliferation fraction determined by immunostaining with Ki-67. Low-grade lymphomas are composed of small cells with dense nuclear chromatin and a low proliferation fraction; the converse is true for high-grade tumors. The REAL and WHO classifications, unlike the Kiel classification, do not separate lymphomas according to grade in recognition of the fact that low-grade lymphomas may transform to high-grade tumors without changing the disease "entity." Histological grade mostly correlates with clinical aggressiveness, but this is not always the case. Mantle cell lymphoma is histologically low grade but clinically aggressive¹⁵ as are some T-cell lymphomas such as angioimmunoblastic T-cell lymphoma.¹⁶ The Working Formulation and the Kiel classification both stressed the fundamental importance of "grade" in determining treatment, although using the term to mean different things. The REAL and WHO classifications instead stress the disease entity. Thus, not all "low-grade" B-cell lymphomas are necessarily treated alike as exemplified by hairy cell leukemia, for which highly specific therapy has evolved.¹⁷ It is likely that as the different entities become more sharply defined and are recognized clinically, more disease-specific therapies will emerge.

PROGNOSIS

Clinical aggressiveness is often confused with prognosis but does not have the same meaning. For example, ALCL, a high-grade neoplasm, is clinically aggressive

but has a good prognosis since it responds excellently to therapy.¹⁸ A variety of prognostic factors within each disease influence the clinical outcome. One of these is histological grade, but clinical features are also important. The more important of these have been collected together to form the International Prognostic Index (IPI),¹⁹ the measurement of which is a powerful predictor of clinical outcome in any given patient.

THE STRUCTURE OF THE WHO CLASSIFICATION

As in the Kiel classification, the lymphomas, defined according to the principles described above, are firstly divided broadly into B- and T-cell groups (Table 51.1). A modification is the inclusion of lymphomas with a NK-cell phenotype in the T-cell group. In each of these two groups the precursor cell, or lymphoblastic, lymphomas are separated from the larger group of peripheral cell tumors. The order in which the different entities are cited is not fixed and can be changed according to the convenience of the user. For example, the B-cell lymphomas can be grouped into those with peripheral blood involvement, plasma cell neoplasms, extranodal lymphomas, nodal lymphomas, and lymphoproliferative disorders of uncertain malignant potential. The T/NK-cell lymphomas are often similarly grouped into those that tend to involve the peripheral blood, cutaneous lymphomas, other extranodal lymphomas, nodal lymphomas, and a single entity of uncertain lineage.

HODGKIN'S LYMPHOMA

Given the increasing evidence that Hodgkin's disease is a B-cell neoplasm,^{20,21} the authors of the REAL classification took the decision to include Hodgkin's disease in the lymphoma classification albeit as a separate table. This concept was continued in the WHO classification with the modification that Hodgkin's disease is now designated as Hodgkin's lymphoma (HL). There is, however, still a preference for maintaining the "Hodgkin" eponym since in this way, the unique features of HL, including, importantly, its specific therapy and good prognosis will continue to be recognized. Not surprisingly, the classification of this disorder is little changed from those of Jackson and Parker, and Lukes and Collins. The only changes in its classification are the implicit recognition that lymphocyte-predominant HL is a different disorder from classical HL and the addition of the entity "lymphocyte-rich HL." The intention is that the inclusion of this new category will serve to prevent misdiagnosis of these cases as lymphocyte-predominant HL especially when they present with nodular or follicular histology.²² It could be argued that Hodgkin's lymphoma eventually will be listed in the table of B-cell lymphomas.

Table 51.1 The World Health Organization classification of lymphoid malignancies

<i>B-cell neoplasms</i>	<i>T and putative NK-cell neoplasms</i>
Precursor B-cell neoplasm	Precursor T-cell neoplasm
B-cell lymphoblastic lymphoma/leukemia	T-lymphoblastic lymphoma/leukemia
Mature B-cell neoplasms	Mature T-cell and NK-cell neoplasms
Chronic lymphocytic leukemia/small lymphocytic lymphoma	T-cell prolymphocytic leukemia
Prolymphocytic leukaemia	T-cell large granular lymphocytic leukemia
Lymphoplasmacytic lymphoma	Aggressive NK-cell leukemia
Splenic marginal zone lymphoma	Adult T-cell lymphoma/leukemia (HTLV-1+)
Hairy cell leukaemia	Mycosis fungoides and Sezary syndrome
Plasma cell myeloma	Extranodal T/NK-cell lymphoma, nasal type
Monoclonal gammopathy of undetermined significance	Enteropathy-type T-cell lymphoma
Solitary plasmacytoma of bone	Angioimmunoblastic T-cell lymphoma
Extraosseous plasmacytoma	Peripheral T-cell lymphoma unspecified
Primary amyloidosis	Hepatosplenic T-cell lymphoma
Heavy chain diseases	Subcutaneous panniculitis-like T-cell lymphoma
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)	Blastic NK-cell lymphoma
Nodal marginal zone lymphoma	Angioimmunoblastic T-cell lymphoma
Follicular lymphoma	Peripheral T-cell lymphoma, unspecified
Mantle cell lymphoma	Systemic anaplastic large cell lymphoma
Diffuse large B-cell lymphoma	T-cell proliferations of uncertain malignant potential
Mediastinal (thymic) large B-cell lymphoma	Primary cutaneous CD30 positive lymphoproliferative disorders
Intravascular large B-cell lymphoma	
Primary effusion lymphoma	<i>Hodgkin's lymphoma</i>
Burkitt lymphoma	Nodular lymphocyte predominance
B-cell proliferations of uncertain malignant potential	Classical
Lymphomatoid granulomatosis	Nodular sclerosis
Posttransplant lymphoproliferative disorder, polymorphic	Lymphocyte rich (nodular)
	Mixed cellularity
	Lymphocyte depletion

REPRODUCIBILITY AND CLINICAL RELEVANCE

The value of any lymphoma classification is only as good as its histopathological reproducibility and its clinical relevance. In this respect, the validity of the REAL and WHO classifications had already been tested to a certain extent prior to their publication since many of the entities had been subject to detailed clinicopathological analysis in the medical literature. Shortly after its publication, moreover, the reproducibility and clinical relevance of the REAL classification were formally evaluated.

THE LYMPHOMA CLASSIFICATION PROJECT

Shortly after its publication, an international study was convened to determine whether the REAL classification could be readily applied by a group of six expert hematopathologists who, with one exception, were not associated with the original proposal.²² The aims of the project were to judge whether the classification could be used in practice, to test its interobserver reproducibility, to assess the need for immunophenotyping in making a diagnosis (one of the criticisms following its publication having been that the REAL classification was not cost effective in this respect!), to determine whether the constituent diseases were clinically distinctive either at presentation or in terms of clinical

outcome, and to determine the relevant frequency of these diseases in the study populations. The participating pathologists, assisted by clinicians and statisticians, studied 1400 cases of lymphoma comprising 80–210 cases in each of eight centers in North America, Europe, Asia, and Africa.

The participants found that the REAL classification was highly practical, allowing the ready classification of 95% of cases. Interobserver reproducibility was greater than 85% for most entities, which was a substantial improvement over previous studies using other classifications where reproducibility was frequently in the region of only 60% or less. Immunophenotyping was not necessary for the classification of certain diseases including follicular lymphoma and small lymphocytic lymphoma/chronic lymphocytic leukemia but essential for the classification of T-cell lymphomas and particularly helpful for some B-cell disorders including mantle cell lymphoma and diffuse large B-cell lymphoma (DLBCL).

In undertaking clinicopathological correlation, the Lymphoma Classification Project showed that the different diseases recognized by the REAL classification did indeed differ in terms of clinical presentation and survival, supporting the contention that they were distinct biological entities. However, an important finding of the study was that classification is not the only

predictor of clinical outcome of any individual case. In this respect, the power of the IPI was confirmed. For example, patients with follicular lymphoma and an IPI score of 1–3 have a median survival of 7–10 years, while the median survival for the minority with an IPI of 4 or 5 is significantly reduced to 1.5 years.²³

THE RELATIVE FREQUENCY OF THE DIFFERENT LYMPHOMAS

Inevitably, in any discussion of lymphoma classification there tends to be greater emphasis on the rare and difficult conditions than is necessarily warranted by their frequency. Because of epidemiologic differences and regional bias, it is difficult to generalize about the distribution of different lymphomas. Extrapolating from previous studies that preceded the REAL classification, and the results of the Lymphoma Classification Project (Table 51.2), it is possible to obtain some sort of perspective. Thus, in North America and Europe, B-cell lymphomas account for approximately 85% of all lymphomas. The Lymphoma Classification Project found that, together, large B-cell lymphoma (30.6%), follicular lymphoma (22.1%), mucosa-associated lymphoid tissue (MALT) lymphoma (7.6%), lymphocytic lymphoma/chronic lymphocytic leukemia (6.7%), and mantle cell lymphoma (6.0%) comprised 73% of all lymphomas. Given that Asian and African patients were represented by only two of the eight centers, these relative incidence figures are less valid for Asia or Africa where overall there is a much lower frequency of follicular lymphoma and, in parts of Asia, a higher frequency of T-cell lymphoma.

UPDATING THE WHO CLASSIFICATION

Previous experience, especially with the Working Formulation, has shown that lymphoma classification is necessarily a constantly moving target. New con-

cepts and consequently newly recognized diseases are constantly arising and demand to be included in current classifications. The REAL classification recognized this both tacitly and overtly by the inclusion of provisional entities. The question of how to address the problem of updating the classification was left hanging, however. In this respect it was a fortunate coincidence that, shortly after the publication of the REAL classification, the WHO commenced the ambitious project with the aim of formulating a new comprehensive classification of both lymphoma and leukemia. In terms of the lymphomas, the WHO classification project has essentially addressed the immediate problem of updating and refining the REAL classification. However, the problem of continuous updating of the WHO classification still remains to be addressed.

GENE EXPRESSION PROFILING

The profound effect of the advent of immunohistochemistry on lymphoma classification, outlined above, is likely to be repeated once the new gene array techniques²⁴ move out of the academic research area into diagnostic pathology laboratories. This technique permits automated, semiquantitative comparative analysis of the expression of thousands of genes (the entire human genome) from RNA extracted from a small sample of fresh tissue. By simultaneous analysis of a large number of cases of lymphoma, those with identical and distinctive patterns of either overexpression or underexpression of certain genes can be identified and recognized (i.e., classified) as distinctive diseases. The power of this technique, with regard to lymphoma classification, was first demonstrated in a series of DLBCLs²⁵ (see below) and it is likely that as more studies are completed considerable changes in lymphoma classification will follow. Unlike previous changes in lymphoma classification, however, the broad principles of the WHO classification are unlikely to change.

ISSUES RELATING TO INDIVIDUAL ENTITIES IN THE WHO CLASSIFICATION

As with any new classification, when the WHO lymphoma classification was presented to the hematologists and oncologists²⁶ who would be using it in the clinic, several contentious issues arose that deserve special consideration and clarification.

PRECURSOR CELL NEOPLASMS

With respect to the relationship of the solid precursor cell tumors with the leukemias, the FAB terms L1, L2, and L3 are no longer relevant, since L1 and L2 do not predict immunophenotype or clinical behavior and L3 is equivalent to Burkitt lymphoma (BL) in a leukemic phase. Lymphoblastic lymphomas and leukemias are the same disease in different stages.

Table 51.2 Relative incidence of non-Hodgkin's lymphomas (Non-Hodgkin's Lymphoma Classification Project)

Diffuse large B cell	30.6%
Follicular	22.1%
Marginal zone B-cell of MALT type	7.6%
Peripheral T cell	7.0%
Small B lymphocytic	6.7%
Mantle cell	6.0%
Primary mediastinal large B cell	2.4%
Others	17.6%

THE MATURE B-CELL LEUKEMIAS

The term "mature" is preferable to "peripheral" to describe the majority of the lymphomas. Chronic lymphocytic leukemia and lymphocytic lymphoma are clearly the same disease although they tend to be seen by different clinicians. However, prolymphocytic leukemia is distinctly different.

FOLLICULAR LYMPHOMA

Grading of follicular lymphoma is a contentious issue but it is now agreed that grading should be carried out according to the method proposed by Berard,²⁷ which described 3 grades based on the number of large cells (centroblasts) per high-power field. Grade 3 follicular lymphoma is divided into 3a and 3b, the latter used for tumors comprising sheets of centroblasts. In practice, only grade 3 (greater than 15 centroblasts per high-power field) is clinically significant being indicative of more aggressive disease that may require doxorubicin-containing therapy.²⁸ The presence and percentage of diffuse areas should also be commented on although the clinical significance of this point is not yet clear.

CUTANEOUS FOLLICLE CENTER LYMPHOMA

This controversial and poorly defined skin tumor²⁵ tends to occur in the upper half of the body and appears to be unrelated to follicular lymphoma but is, rather, a variant of DLBCL. Its importance lies in its remarkably indolent clinical behavior.

MARGINAL ZONE LYMPHOMAS

Three separate entities comprise this group of lymphomas. The first two, marginal zone lymphoma of MALT and nodal marginal zone lymphoma +/- monocytoid B cells, are closely related but the third, "SMZL," is a quite different disease.

MARGINAL ZONE LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE

This type of lymphoma arises in extranodal sites and recapitulates the histology of the Peyer's patch.²⁹ The stomach is the commonest site. MALT lymphomas are, by definition, low grade. Transformation to a diffuse large B-cell (high-grade) lymphoma can occur and this phenomenon is clinically significant and should be documented in the histology report. However, the term "high-grade MALT lymphoma" should not be used for these cases. In particular, DLBCLs arising de novo at extranodal sites where MALT lymphomas occur, such as the stomach, should not be called high-grade MALT lymphomas since this terminology may bias the clinician toward inappropriate therapy.

NODAL MARGINAL ZONE LYMPHOMA +/- MONOCYTOID B CELLS

The lymph node histology of this entity is identical to that of the lymph nodes involved by MALT lymphoma³⁰ so that the possibility of a cryptic MALT lymphoma

should always be born in mind when a diagnosis of nodal marginal zone lymphoma is entertained.

SPLENIC MARGINAL ZONE LYMPHOMA

The constituent cells of SMZL bear only passing resemblance to splenic marginal zone cells and do not share their immunophenotype.³¹ Patients typically present with splenomegaly often accompanied by anemia and thrombocytopenia. Peripheral blood involvement is often, but not always, present and in some of these cases the circulating neoplastic lymphocytes have a villous appearance. These cases were previously termed "splenic lymphoma with villous lymphocytes."³² The use of this somewhat imprecise term will not only fail to include those cases without circulating villous lymphocytes but, more importantly, tends to include other cases of B-cell lymphoma with peripheral blood spillover since the cells of various lymphomas may sometimes adopt a villous appearance, either real or artifactual, in the peripheral blood. This is an important consideration since SMZL tends to respond favorably to splenectomy alone in contrast to its poor response to chemotherapy.³³

DLBCL AND BURKITT-LIKE LYMPHOMA

The classification of large B-cell lymphomas as a single group has been controversial. Various morphologic subtypes have been recognized including centroblastic, immunoblastic, anaplastic, and T-cell rich but the clinical significance of subclassifying DLBCL in this way is of doubtful significance and they do not appear to constitute separate diseases. There are, however, three rare large B-cell lymphomas that do appear to merit the designation as distinct diseases namely primary mediastinal (thymic) large B-cell lymphoma,³³ intravascular lymphoma,³⁴ and primary effusion lymphoma.³⁵ There is little doubt that within the category of DLBCL there are at least several more distinct entities that might benefit from different therapies. Their recognition is one of the challenges faced by hematopathologists, and gene profiling techniques have already shown great promise in this area. The original study using this technique²⁵ showed that it was possible to recognize two major clinically significant groups of DLBCL, those derived, respectively, from germinal center cells and so-called activated B cells. Subsequently, a third group has been recognized³⁶ and a further study has vindicated the separate classification of mediastinal large B-cell lymphoma.³⁷

The borderline between DLBCL and BL is not always clear-cut. The WHO clinical advisory meeting took the decision that those DLBCL with Burkitt-like morphology that did not strictly conform to that of BL, but with c-myc rearrangement and a proliferation fraction of 100%, are best termed "atypical BL" and should receive therapy tailored for BL. Thus, they represent a subtype of BL, the others being endemic BL, nonendemic BL, and immunodeficiency-associated BL.

MATURE T- AND NK-CELL LYMPHOMAS

Clinical syndromes rather than cytomorphological features form the principal basis for the identification of real diseases within this difficult group. Several provisional disorders listed in the REAL classification are now recognized as defined entities but, despite many attempts to recognize distinct diseases, most T-cell lymphomas end up being classified as "T-cell lymphoma unspecified." This is clearly unsatisfactory and is partly due to the rarity of T-cell lymphomas as a whole. It is to be hoped that the adoption of the new principles of classification will, as new data accumulate perhaps with the aid of gene profiling, lead to the rationalization of this group.

ANAPLASTIC LARGE-CELL LYMPHOMA

Previously defined on the basis of its cytology and expression of CD30, it has become clear that more than one "real" disease can exhibit these features. The discovery of the t(2;5) translocation, which results in the expression of anaplastic lymphoma kinase (ALK) protein, has helped to define a form of T/null-cell ALCL that tends to occur in children and young adults and which, although aggressive, carries a good prognosis with appropriate therapy.³⁸ It seems likely that the somewhat similar, but t(2;5) (ALK) negative, cases are a different disorder, but this awaits confirmation. Again, gene profiling is likely to give us the answer. It is clear, however, that primary cutaneous ALCL,³⁹ which is always ALK negative and, moreover, lacks a cytotoxic phenotype, is an entirely different entity.

Cutaneous ALCL is closely related to the benign disorder lymphomatoid papulosis and the term "cutaneous lymphoproliferative disorder"⁴⁰ has been suggested for those cases with overlapping features. Whether such a term is appropriate in a lymphoma classification is a moot point and in recognition of this, this entity is included under the subheading "T-cell neoplasm of uncertain malignant potential."

CONCLUSIONS

The WHO classification of lymphoid neoplasms represents a major step forward in our understanding of these tumors. Moreover, in building on the REAL classification, it has pointed the way to practical methods of further updating, which will be essential if the classification is to endure and to continue to serve the needs of clinicians. Implicit in the classification are signposts for further research, particularly with respect to DLBCL and T-cell lymphoma, unspecified. The formulation of the WHO classifications must be counted as a considerable achievement. By contrast with previous attempts to classify this difficult group of tumors, a large number of pathologists, 19 for the REAL classification and over 50 for the WHO scheme, have been involved, and to have achieved consensus within this group is remarkable! Perhaps even more remarkable is to have maintained this consensus in presenting such radically new concepts to the clinicians who treat patients with lymphoma.

Chapter 52

PATHOLOGY AND MOLECULAR GENETICS OF NON-HODGKIN'S LYMPHOMA

James R. Cook and Eric D. Hsi

B-CELL LYMPHOMAS

INTRODUCTION

The B-cell lymphomas can be thought to arise from normal B-cell counterparts and therefore can be placed in the context of normal B-cell development. This model serves as a framework for understanding the origin of these lymphomas (Figure 52.1). In this section,

we will present the typical histopathologic, immunophenotypic, and molecular genetic features of the B-cell lymphomas.

SMALL LYMPHOCYTIC LYMPHOMA

General: Small lymphocytic lymphoma (SLL) represents approximately 7% of non-Hodgkin's lymphomas (NHLs)¹ and presents in adulthood with a median age

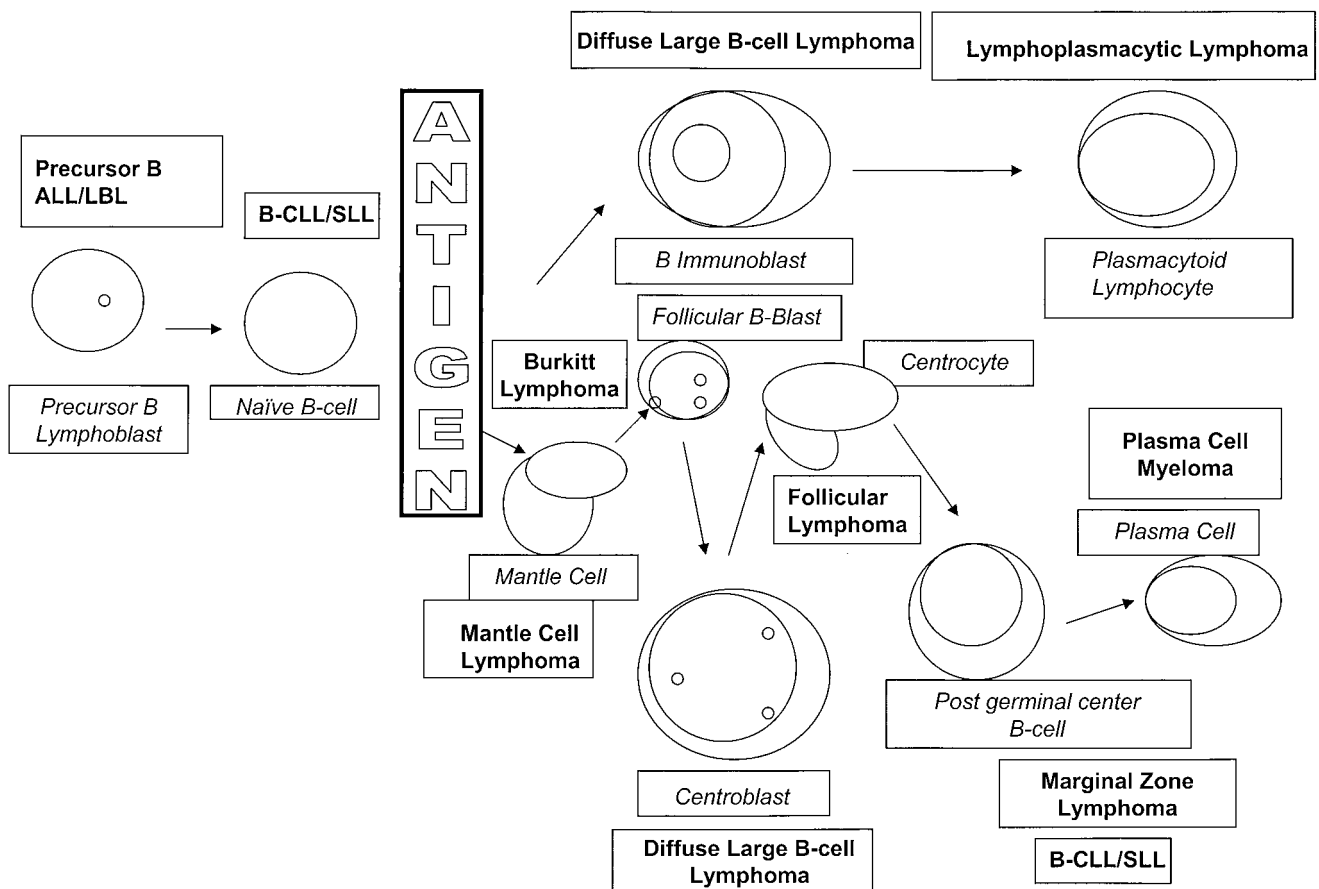

Figure 52.1 Schema of B-cell development and lymphoma. (Modified from Ref. 109, with permission of the International Agency for Research on Cancer.)

Figure 52.2 SLL, low magnification shows a diffuse infiltrate of small lymphocytes with a central pale area representing a proliferation center

of 65 years and a 2:1 male predominance. It is the tissue equivalent of chronic lymphocytic leukemia (CLL).

Pathology: SLL is a diffuse process that effaces lymph node architecture with a small lymphoid infiltrate. The cells have condensed chromatin, round nuclear contours, and scant cytoplasm. As in CLL, intermediate-sized lymphocytes with slightly open chromatin and a small central nucleolus (paraimmunoblasts) are always present and oftentimes aggregate to form proliferation centers (Figures 52.2 and 52.3). Increased numbers of paraimmunoblasts can be seen in biopsies and this does not constitute a transformation of SLL. Only when sheets of large cells are present does one consider a large cell transformation of SLL to diffuse large B-cell lymphoma (a form of Richter syndrome)

Figure 52.3 SLL, high magnification shows the detail of a proliferation center. Nucleolated cells (paraimmunoblasts) are present in increased numbers

Table 52.1 Frequency of chromosomal abnormalities^a

Aberration	Percentage of cases
13q deletion	55
11q deletion	18
Trisomy 12	16
17p deletion	7
6q deletion	6
Trisomy 8q	5
t(14q32)	4
Trisomy 3q	3
Normal	18

^aDefined by FISH, some cases may have more than one abnormality.

Immunophenotype: The immunophenotype of SLL is identical to CLL and the cells express CD5, CD19, CD20, CD23, and restricted surface immunoglobulin.

Molecular genetics: SLL has monoclonally rearranged immunoglobulin heavy (*IGH*) chain genes, which can be detected by PCR or Southern blot methods. Much has been learned regarding the cytogenetic abnormalities that have prognostic significance.² Table 52.1 shows the most common abnormalities and their frequency. Cases with del 13q and trisomy 12 have relatively good prognosis compared to those cases with del 11q or del 17p.² *IGH* mutational status has also been shown to be an important predictor of outcome. Cases of CLL with unmutated *IGH* have a relatively poor prognosis compared to those with mutated *IGH* (>2% deviation from germline sequences).^{3,4} Recent expression arrays studies have shown excellent (but not 100%) correlation between *ZAP-70* expression (present in unmutated SLL/CLL) and *IGH* mutational status.

MANTLE CELL LYMPHOMA

General: Mantle cell lymphoma (MCL) represents approximately 6% of lymphomas.¹ It generally presents in middle-aged to older adults with a median age of approximately 60 and a male predominance. Stage 3 or 4 involvement is common at presentation and bone marrow involvement is seen in more than half the patients at presentation. Although nodal disease is most common, primarily extranodal disease involving Waldeyer's ring or the gastrointestinal tract does occur.⁵

Pathology: Nodular, mantle zone, and diffuse architectural patterns of infiltration can occur. In the mantle zone pattern, the lymphomatous infiltrate surrounds reactive germinal centers. In the nodular pattern, the infiltrate replaces normal follicles. The diffuse pattern is most common. The infiltrate is very monotonous and is composed of small lymphocytes with slightly irregular nuclei, condensed chromatin, and inconspicuous cytoplasm (Figure 52.4). Mitotic

Figure 52.4 MCL, low magnification shows a diffuse infiltrate of small lymphocytes. Inset (upper right) shows the high magnification appearance with an epithelioid histiocyte in the center. The lower inset show cyclin D1 expression

figures, unusual in other low-grade B-cell lymphomas, are commonly seen in MCL. Epithelioid histiocytes are frequently admixed in the infiltrate, imparting a “mottled” look at low to intermediate magnification.

The blastoid variant is an aggressive variant of MCL and is characterized histologically by intermediate-sized cells. A fine blast-like chromatin can be seen in some cases resembling lymphoblastic lymphoma. Other cases have a more pleomorphic appearance and more closely resemble large cell lymphoma.⁶ Mitotic figures (>20/10 hpf) are seen and associated with a poor prognosis.⁵

Immunophenotype: The characteristic immunophenotype of MCL is CD5+, CD10–, CD19+, CD20+(bright), CD23–, FMC7+, surface Ig light chain restricted, and cyclin D1+.⁷

Molecular genetics: Expression of cyclin D1 is seen in the vast majority of cases and is a consequence of the t(11;14)(q13;q32) that helps define this lymphoma. Only rare cases of MCL may lack this translocation.⁸ This translocation can be detected by standard cytogenetics or FISH. PCR assays exist but because of the variability in breakpoints these are not as widely used in clinical laboratories as FISH. Blastoid mantle cell lymphomas have characteristic (although not specific) additional genetic abnormalities such as TP53 mutation, deletion of P16, deletion of P21, and tetraploidy.^{9–11}

FOLLICULAR LYMPHOMA

General: Follicular lymphoma is the second most common NHL after diffuse large B-cell lymphoma and comprises approximately 22% of lymphomas.¹ It occurs in older adults with a median age of 59 years and female predominance.¹ Most patients have disseminated disease at presentation, with only 33% of patients having stage 1 or 2 disease. Bone marrow is involved in 40% of patients. This lymphoma generally has a long relapsing and remitting disease course with

Figure 52.5 Follicular lymphoma demonstrating a nodular architecture. The inset shows the cytologic features with predominantly small cleaved cells in this case

a 5 year overall survival of 72% but a failure-free survival of only 40%.¹

Pathology: The hallmark of follicular lymphoma is the follicular architecture. The follicles are occupied by neoplastic cells recapitulating the normal lymphoid follicle. The lymphoma cells are neoplastic centrocytes (cleaved cells) and centroblasts (large noncleaved cells) in varying proportions, which determines the cytologic grade (Figure 52.5). Lymphoma cells are also seen between the neoplastic follicles when these areas are closely inspected and can also be a useful diagnostic feature. Cytologic grades are determined according to Mann and Berard (Table 52.2).¹²

The WHO classification suggests that overall and failure-free survival does correlate with cytologic grade, although conflicting data exists.^{13,14} Evolution of treatment regimens will likely impact the importance of grading.

Diffuse areas can be seen in follicular lymphoma in varying proportions. The WHO recommends reporting the proportion of diffuse areas (see Table 52.1). The amount of diffuse component may indicate a worse prognosis, particularly with grade 3 lymphoma,¹⁵ and any diffuse component of sheets of large cells is best considered diffuse large B-cell lymphoma. A diffuse

Table 52.2 Cytologic grading of follicular lymphoma

Grade	Centroblasts/hpf (average of 10 fields, 0.159 mm ² /hpf = 40 × objective, 18 mm ocular field of view)
1	0–5
2	6–15
3	>15
3a	Centrocytes admixed with centroblasts
3b	Sheets of centroblasts

Diffuse areas are reported as follows: Follicular = greater than 75% follicular pattern; follicular and diffuse = 25–75% follicular; focally follicular = less than 25% follicular.

Figure 52.6 Immunostains in the case shown in Figure 52.5 demonstrate expression of CD20 (left) and *bcl-2* (right). The case also expressed CD10 and *bcl-6* (not shown)

variant of low-grade follicular lymphoma is recognized by the WHO classification.

Immunophenotype: Follicular lymphomas are CD5⁻, CD10⁺, CD19⁺, and CD20⁺ B-cells. Light chain restriction can usually be demonstrated; however, a minority of cases may lack detectable surface immunoglobulin.¹⁶ Bcl-6 is also expressed in a great majority of follicular lymphomas and is a useful marker when the differential includes other B-cell lymphomas with a nodular pattern such as that may occur in nodular mantle cell lymphoma.¹⁷ Bcl-2 is overexpressed in 85% of follicular lymphomas and expression can be useful in distinguishing follicular hyperplasia (negative) from follicular lymphoma (positive) (Figure 52.6). Expression levels depend on cytologic grade, with nearly 100% of grade 1 lymphomas expressing *bcl-2*, while only 75% of grade 3 lymphomas express this oncoprotein.¹⁸

Molecular genetics: Follicular lymphoma is typically characterized by t(14;18)(q32;q21). It can be found in approximately 80–90% of follicular lymphomas.¹⁹ This brings the *BCL2* gene under the influence of *IGH* and results in overexpression of this antiapoptotic protein. The breakpoints in the *BCL2* gene are clustered in the major and minor breakpoint regions of *BCL2*.²⁰ Thus, PCR assays can be designed to detect this translocation. These can detect t(14;18)(q32;q21) in approximately 60–70% of cases of follicular lymphoma.¹⁹ Additional probe sets can be used to detect other less common breakpoints and improve detection of this translocation.²¹ FISH probes flanking breakpoints have a higher detection rate and are a preferred method for detection of this translocation.²²

Variant follicular lymphomas

Primary cutaneous follicular lymphomas have been somewhat controversial, probably due to lack of consistent definition. Many studies, when adhering to WHO classification criteria, report a low percentage

(<30%) of cases harboring a t(14;18)(q32;q21) and also low rate of expression of *bcl-2* protein, compared to nodal follicular lymphoma. These lymphomas are very indolent and have an excellent prognosis.²³ Pediatric follicular lymphomas are also a peculiar subset of follicular lymphomas. Although histopathologic features are essentially identical to adult cases, those occurring in children are usually *bcl-2* protein negative and lack a *BCL2/IGH* translocation.²⁴

EXTRANODAL MARGINAL ZONE B-CELL LYMPHOMA OF MUCOSA-ASSOCIATED LYMPHOID TISSUE

General: Mucosa-associated lymphoid tissue (MALT) lymphomas are extranodal lymphomas that commonly involve mucosal sites in adults with a median age of 61 years.¹ These are often associated with autoimmune disorders such as Sjögren syndrome and Hashimoto thyroiditis. These lymphomas comprise approximately 7.6% of NHLs. The most common site is the gastrointestinal tract (51%) with the stomach accounting for the great majority of those cases. Other common sites include lung (10%), orbit (12%), skin (9%), salivary gland (6%), and thyroid (5%).²⁵

Gastric MALT lymphomas can serve as a prototype of antigen driven lymphomas with *Helicobacter pylori* present in up to 90% of cases.²⁶ Subsequent studies have shown the organism is responsible for antigen stimulation of the lymphoma, which is dependent on T-cell help while B-cells react to autoantigens.^{27–29} Treatment for *Helicobacter* is now part of the therapy in gastric MALT lymphomas and can, in some cases, cause regression and cure of disease.³⁰

Most (66%) patients present with low stage (1 or 2) disease but up to 30% may have disseminated disease at diagnosis.^{1,31} This is an indolent lymphoma with a 5 year survival of 85%.³¹

Pathology: MALT lymphomas recapitulate normal MALT in that they can have an organized architecture in mucosal sites with hyperplastic germinal centers, expansion of marginal zone cells, and superficial plasma cell differentiation. Occasionally, the plasma cell differentiation can be extreme, mimicking a plasmacytoma. Using a gastric MALT lymphoma as the example, the mucosa is infiltrated by a dense lymphoid infiltrate consisting of small lymphocytes with round to slightly irregular contours and moderate amounts of pale cytoplasm (marginal zone cells or “centrocyte-like” cells). Nucleoli are inconspicuous. There are admixed larger centroblastic cells present and plasma cells vary in number

The marginal zone cells can infiltrate epithelium and destroy the glandular structures. These are termed lymphoepithelial lesions (LELs) and are a hallmark of this disease (Figure 52.7). Marginal zone cells can invade the reactive germinal centers in a process termed follicular colonization.

Figure 52.7 Gastric MALT lymphoma with LELs (left center). The inset shows *H. pylori* organisms in Giemsa staining

Immunophenotype: MALT lymphoma cells express CD19, CD20, and surface immunoglobulin. They lack CD5 and CD10. CD43, an antigen not normally expressed on B-cells can be seen in up to approximately 60% of cases.³² Cytoplasmic immunoglobulin can be detected in minority (20%) of cases. Cases with t(11;18)(q21;q21) and t(1;14)(p22;q32) express nuclear bcl-10.³³

Molecular genetics: Much has been learned about the molecular genetics of MALT lymphomas. A t(11;18)(q21;q21) is the most common recurrent cytogenetic abnormality in MALT lymphomas, occurring in approximately 20% of MALT lymphomas. The frequency varies by site, being most common in lung (38%) and stomach (25%) and uncommon in the salivary gland and thyroid (Table 52.3).^{34,35}

This translocation results in a fusion of the *API2* and *MLT1* genes that appears to activate NFκB.³⁶ Detection of this translocation has clinical significance since those cases of gastric MALT lymphoma with the t(11;18)(q21;q21) do not respond to anti-*Helicobacter* therapy and are associated with infection by CAG-A+ strains of the organism. A t(14;18)(q32;q21) resulting in an *IGH/MLT1* translocation has also been recently described in MALT lymphomas, particularly in those MALT lymphomas with low incidence of *API2/MLT1*.³⁷

Another recurrent translocation is seen in MALT lymphomas. The t(1;14)(p22;q32) is an uncommon translocation in MALT lymphoma. It juxtaposes *IGH*

and *BCL10* genes, resulting in nuclear expression of bcl-10. Recently, bcl-10 has been shown to interact with MLT1 protein. These two proteins are also capable of activating NFκB via IKK kinase (IKK) activation. Thus, it appears that both these translocations have a common mechanism of action, namely to activate NFκB, which may play a major role in lymphomagenesis.³⁸

SPLENIC MARGINAL ZONE LYMPHOMA

General: Splenic marginal zone lymphoma (SMZL) is an uncommon lymphoma and probably accounts for less than 3% of lymphomas. The median age at diagnosis is 68 years with a slight male predominance.³⁹ It presents with splenomegaly and peripheral blood involvement is common. The appearance in the peripheral blood accounts for the term splenic lymphoma with villous lymphocytes. Adenopathy is uncommon and a small monoclonal gammopathy is present in up to two-thirds of patients.⁴⁰

Pathology: Peripheral blood morphology is variable. The cells are small with moderate amounts of pale cytoplasm and short cytoplasmic projections that may aggregate at opposite ends of the cells. Nucleoli are inconspicuous. At times the cells lack noticeable projections and have a more monocytoïd or plasmacytic appearance.

In the spleen, there is expansion of the white pulp. Marginal zones may be expanded and a nodular appearance can be seen from replacement of the pre-existing follicles. The cells have a variable appearance with small lymphocytes having scant cytoplasm often seen at the centers of the nodules and monocytoïd B-cells with more abundant cytoplasm present at the edges of the nodules (Figures 52.8 and 52.9). Transformed centroblastic cells are present and there may be plasmacytic differentiation. There is always extension into red pulp that can be highlighted by immunohistochemistry. Hilar lymph nodes are usually

Figure 52.8 Splenic marginal zone lymphoma. Low magnification shows expansion of the white pulp with prominent marginal zones. The inset (upper left) shows a circulating lymphoma cell with villous cytoplasmic projections

Table 52.3 Frequency of *API2/MLT1* translocation in MALT lymphoma

Site	Frequency
Lung	38%
Stomach	24%
Conjunctiva	19%
Orbit	14%
Skin, salivary, thyroid	Rare

Figure 52.9 Splenic marginal zone lymphoma. High magnification shows the characteristic cytologic features of small cells with abundant pale cytoplasm. The upper right corner shows part of a germinal center surrounded by a thin rim of mantle cells

involved with replacement of the germinal centers but patent sinuses.^{41,42} Bone marrow involvement is often in a sinusoidal distribution but the pattern is not entirely specific.^{43,44}

Immunophenotype: The immunophenotype is CD5⁻, CD10⁻, CD19⁺, CD20⁺, CD22⁺, CD25^{-/+}, CD103⁻, bcl-2⁺, bcl-6⁻, surface Ig⁺.^{17,45,46}

Molecular genetics: Recent studies have show frequent deletion of 7q31-32 in SMZL.⁴⁷ Other common abnormalities include gain of 3q and abnormalities of chromosomes 1, 8, and 14.⁴⁸ Note that translocations of *MLT1* seen in extranodal marginal zone lymphomas of MALT type are not seen in SMZL, thus further supporting the contention that these are unrelated disorders.⁴⁹ Cases with chromosomal losses, including del 7q, may identify cases with a poor survival.⁵⁰ *IGH* mutational analysis shows, as in CLL, heterogeneity within SMZL and cases. Unmutated SMZL appeared to have a shorter overall survival and del 7q31 was over-represented in this group.⁵⁰

NODAL MARGINAL ZONE LYMPHOMA

General: Nodal marginal zone lymphoma is an uncommon lymphoma, comprising approximately 2% of NHL. There is a slight female predominance (M:F = 0.7) and the median age at diagnosis is 58 years. Forty percent of patients have marrow involvement at presentation and the overall survival is approximately 55% at 5 years.¹ In order to make this diagnosis, patients should not have previous or concurrent extranodal marginal zone lymphoma of MALT type.

Pathology: The lymph node is altered by an infiltrate of marginal zone cells. These cells are small with condensed chromatin, slightly irregular nuclei, and variable amounts of pale cytoplasm. The cells, therefore, can vary between centrocyte-like cells and monocytoid B-cells. Plasmacytic differentiation can be seen in some cases. The infiltrate expands the interfollicular areas with preservation of reactive germinal centers

Figure 52.10 Nodal marginal zone B-cell lymphoma showing a germinal center (arrows) that is ill-defined and being infiltrated by lymphoma cells

(Figures 52.10 and 52.11). Colonization of the follicles can occur and impart a nodular appearance to the lymphoma. Two subtypes have been suggested, a MALT type and splenic type, based on resemblance to these two lymphomas.⁵¹

Immunophenotype: This lymphoma expresses CD19, CD20, and surface immunoglobulin. CD5 or CD10 are not expressed. Some cases express IgD and this has been suggested as a differentiating characteristic between the splenic type (positive) and the MALT type (negative).⁵¹

Molecular genetics: Little is known regarding the molecular genetics of this lymphoma. It has been shown that these lymphomas do not contain *MLT1* translocations, supporting the concept that these lymphomas are distinct from MALT lymphomas.³⁴

LYMPHOPLASMACYTIC LYMPHOMA

General: Lymphoplasmacytic lymphoma (LPL) is an uncommon lymphoma (1% of lymphomas) that presents equally in men and women. The median age at diagnosis is 63 years.¹ A subset of patients, approximately 25%, present clinically with Waldenström macroglobulinemia. The overall survival at 5 years is 59%.¹

Figure 52.11 Nodal marginal zone B-cell lymphoma. At high magnification, the cytologic features of the lymphoma cells surrounding the follicle in Figure 10

Figure 52.12 Lymphoplasmacytic lymphoma consisting of a diffuse infiltrate of small lymphocytes and plasma cells

Pathology: The morphologic features of LPL are variable. Cytologically, the lymphoma is composed of small lymphocytes with plasmacytoid features and plasma cells that are part of the neoplasm. Dutcher bodies (intranuclear cytoplasmic intrusions) can be seen. Recently, three morphologic patterns have been described. In one, there are open sinuses with small follicles. In the second, there are hyperplastic germinal centers, and in the third there is diffuse effacement of the lymph node (Figure 52.12). Epithelioid histiocytes are commonly seen.

Immunophenotype: The lymphoma cells express CD19 and CD20 with surface immunoglobulin. Cytoplasmic immunoglobulin is expressed in the plasmacytic cells and heavy chain is usually IgM, although other can be seen uncommonly. Presence of CD5 should prompt consideration of CLL/SLL.

Molecular genetics: Relatively little is known regarding the molecular genetics of LPL. Immunoglobulin genes are clonally rearranged. Initial studies have suggested a t(9;14)(p13;q32) translocation; however, recent studies suggest this is not a common occurrence.⁵²

DIFFUSE LARGE B-CELL LYMPHOMA

General: Diffuse large B-cell lymphoma (DLBCL) is the most common NHL. It occurs most commonly in adults with a median age of 64 years and a slight male predominance. Unlike indolent lymphomas, only 17% of patients have bone marrow involvement.¹ This lymphoma is potentially curable with a cure rate of approximately 35% with anthracycline-based therapies.⁵³

Pathology: DLBCL is characterized by a diffuse infiltrate of large cells. Size can be gauged by histiocyte or endothelial cells within the tissue. DLBCL cells are typically larger than these cells. The cytologic features can be variable. Many cases have a predominance of centroblasts with vesicular chromatin and multiple small nucleoli. The nucleus can be round or lobulated. Some cells resemble immunoblasts with prominent central nucleoli. Cytoplasm is generally moderate in amount.

Occasional cases are composed of large centrocytes with open chromatin. Mitotic figures are variably prominent. In some case, partial involvement of the lymph node can be seen. Rare cases will involve interfollicular areas.

Extranodal DLBCLs appear similar to nodal cases. Some may represent transformation of MALT lymphomas. A variant of DLBCL, primary mediastinal DLBCL, typically has lobulated cells and sclerosis. Another variant, intravascular DLBCL involves vessels only.

Immunophenotype: The vast majority of DLBCLs express pan-B-cell antigens such as CD19 and CD20. Surface immunoglobulin is expressed in most cases but may be lacking in some.⁵⁴ Expression of bcl-2 and high Ki-67 index have been associated with poor prognosis in DLBCL.^{55,56} Bcl-6 expression has been suggested to be indicative of a more favorable outcome.⁵⁷ Recent expression array studies have shown that phenotyping with CD10, Bcl-6, and MUM-1 can help identify the germinal center type of DLBCL (Figure 52.13).⁵⁸

Molecular genetics: Rearranged B-cell receptor genes are present. Recurrent genetic abnormalities can be found. For example, the t(14;18)(q21;q32), characteristic of FL, can be seen in approximately 20% of DLBCL.⁵⁹ BCL6 rearrangements are also common and can be found in approximately 30% of cases.⁶⁰ Much progress has been made in understanding gene expression patterns in DLBCL by using microarrays.⁶¹⁻⁶³ These studies have allowed distinction of prognostic subgroups within DLBCL, which are independent of the International Prognostic Index. Germinal center-like DLBCL (having expression patterns similar to germinal center B-cells) appear to have a favorable prognosis compared to the activated B-cell like DLBCL (having expression patterns similar to activated B-cells). Distillation of this complex data to practical clinical laboratory assays is beginning. Genetic expression models

Figure 52.13 Diffuse large B-cell lymphoma. Sheets of centroblastic cells are present. Immunostains show the cells lack CD10 (top inset), but express bcl-6 (middle inset) and MUM1 (bottom inset). This phenotype is consistent with a nongerminal center-type DLBCL, associated with a worse outcome compared the germinal center-type DLBCL

using expression data from just a few genes^{62–64} or immunohistochemical staining for three genes⁵⁸ have been shown to be prognostically significant. Using a model of weighted gene expression, investigators showed that just six genes yielded prognostic information independent of the IPI in two independent data sets. Three genes (*BCL2*, *SCYA3*, and *CCND2*) were associated with worse prognosis and three genes (*LMO2*, *BCL6*, and *FN1*) were associated with good prognosis.⁶⁴

BURKITT LYMPHOMA

General: Burkitt lymphoma (BL) is a highly aggressive B-cell lymphoma that can present as a lymphoma or acute leukemia. It often occurs in extranodal sites. Three clinical variants are recognized. The endemic form occurs in Africa, where it is the most common childhood malignancy. Epstein–Barr virus (EBV) is present in virtually 100% of cases. The sporadic form occurs in the developed world and children and younger adults. It is uncommon and represents about 1% of lymphomas with a median age of 31 years and male predominance.¹ EBV is present in approximately 30% of cases. Immunodeficiency-associated BL is seen typically in HIV infected patients, where it often occurs early in the course of infection (sometimes as the AIDS defining illness). Its incidence appears to be decreasing in the era of more effective retroviral therapy.⁶⁵ EBV is seen in approximately 40% of cases.⁶⁶

Pathology: Burkitt lymphoma shows a starry sky pattern at low magnification because of the numerous tingible body macrophages that are present in the infiltrate containing apoptotic debris. The lymphoma cells are intermediate in size and uniform in appearance with vesicular chromatin and multiple inconspicuous nucleoli. There is a thin rim basophilic cytoplasm. The individual cells may show a retraction artifact around the cells. Mitoses are frequent and apoptosis of individual cells is present (Figure 52.14). Imprint morphol-

Figure 52.14 Burkitt lymphoma. Sheets of intermediately sized cells (compared to tingible body macrophage nuclei in left center) are seen with multiple inconspicuous nucleoli. The upper right inset shows lymphoma cells with basophilic cytoplasm and distinct vacuoles. The bottom inset is a Ki-67 antigen immunostain showing an extremely high proliferative fraction

ogy shows uniform cells with deeply basophilic cytoplasm and cytoplasmic vacuolization, which stains positively with oil-red O. In HIV-associated cases, plasmacytoid differentiation may be seen.

Immunophenotype: The immunophenotype is that of a mature B-cell expressing CD19, CD20, CD10, and surface immunoglobulin. The cells are negative for precursor-B-cell blast markers such as CD34 or TdT. Bcl-2 is also absent in most cases. Ki-67 is expressed in more than 90% of cells as a result of the underlying molecular genetic abnormality (described below).

Molecular genetics: Burkitt lymphoma is defined by the presence of a *C-MYC* translocation with immunoglobulin genes. Cytogenetically, this can be t(8;14)(q24;q32) or the variant translocations t(2;8)(p11;q24) or t(8;22)(q24;q11). These can be detected by FISH techniques and place *C-MYC* under the control of the immunoglobulin gene promoters, which leads to overexpression of *C-MYC*. This, in turn, causes expression of genes important in cell cycle such that virtually 100% of cells are cycling. Breakpoints in the immunoglobulin genes appear to vary depending on the type of BL. In endemic cases, the breakpoint is in the joining region suggesting transformation at the early B-cell stage, while in sporadic cases it involves the heavy chain switch region, suggesting a later B-cell stage of development at transformation.⁶⁷ EBV viral genome can be detected in EBV positive cases and is clonally integrated, consistent with infection prior to malignant transformation.⁶⁸

While *C-MYC* translocations are present in BL, it should be noted that it is not specific for this lymphoma since *C-MYC* translocation can occur as a secondary event in other types of lymphomas.

LYMPHOMATOID GRANULOMATOSIS

General: Lymphomatoid granulomatosis (LYG) is a rare lymphoproliferative disorder typically involving lung and other extranodal sites such as skin, kidney, and central nervous system. It is an angi-destructive and angioproliferative lesion that only recently has been understood to be an EBV driven B-cell lymphoproliferative disorder. A previous term in the literature that likely represent LYG is angioimmunoproliferative lesion. Patients present with respiratory symptoms such as cough, chest pain, and dyspnea. Constitutional “B” symptoms are also common. This presents in adults with a median age of 40 years and a male predominance.⁶⁹ Patients with immunodeficiency states are at increased risk for LYG.^{70–72} The clinical course is variable and spontaneous regression of some low-grade lesions may occur. Treatment with multiagent chemotherapy and interferon has been used with some success.⁷³

Pathology: LYG appears as a polymorphous lymphoid infiltrate with necrosis. The cells are, for the most part, small to intermediate in size with angulated nuclei. The infiltrate is angiocentric and infiltration of

the vasculature occurs. Destruction of the vessels may contribute to the necrosis. Rare larger atypical transformed cells are present with the appearance of immunoblasts or sometimes demonstrating more atypia. Mitotic figures are present to varying degrees. A three-tier histologic grading scheme has been proposed⁷⁴ based upon the number of proliferating large B-cells.⁷⁵ Grade 3 lesions correspond to an overt large cell lymphoma.

Immunophenotype: Immunophenotyping shows the majority of small lymphocytes are T-cells with a CD4 predominance compared to CD8. The large cell are now shown to be CD20+ B-cells.

Molecular genetics: In situ hybridization (ISH) shows that the large B-cells are EBV-positive in the higher grade lesions.^{69,76} Gene rearrangement studies are often negative due to the low level of neoplastic B-cells in the infiltrate. Higher grade lesions more frequently have monoclonal *IGH* rearrangements. Grading is aided by EBER ISH. Grade 1 lesions have less than 5 cells/hpf. Grade 2 has 5–20 cells and grade 3 tumors have numerous EBV-positive cells that can form sheets.

PRIMARY EFFUSION LYMPHOMA

General: Primary effusion lymphoma is a rare type of large B-cell lymphoma that occurs most frequently in HIV-infected patients. It usually presents in patients as an effusion in the absence of lymphadenopathy or mass. Pericardial, pleural, or peritoneal cavities may be involved. The lymphoma is highly associated with HHV-8 and most, but not all, cases are EBV-positive. It is an aggressive lymphoma with short survival.^{77,78}

Pathology: On Wright stain the cells are pleomorphic. Some cells may have features of immunoblasts with large nuclei and prominent nucleoli. Others are more anaplastic with multilobated nuclei and/or multinucleation. The cytoplasm is deeply basophilic. Vacuoles may be present. Histologic sections, when a mass is present, show similar cells.^{77,78}

Immunophenotype: The cells are usually negative for pan B-cell antigens such as CD19 and CD20 but show expression of plasmacytic differentiation such as CD38 and CD138. CD30 is often expressed as epithelial membrane antigen. Surface and cytoplasmic immunoglobulin are not detectable.^{77,78}

Molecular genetics: *IGH* is rearranged, as expected. The HHV-8 viral genome encodes for several genes that may be involved in lymphomagenesis such as cyclin genes, cytokines, and molecules important in regulating apoptosis and nuclear transcription factors.^{79–82}

T-CELL AND NK-CELL MALIGNANCIES

INTRODUCTION

Like their B-cell counterparts, several types of T-cell and NK-cell lymphomas are currently recognized as distinct clinicopathologic entities. Importantly,

approximately half of T-cell lymphomas do not appear to represent any of the currently defined clinicopathologic categories, and are instead classified as members of a heterogeneous group of lymphomas designated “peripheral T-cell lymphoma, unspecified” (see below). Establishing a diagnosis of a specific type of T-cell or NK-cell lymphoma is heavily dependent upon integration of the associated clinical data. Knowledge of the clinical findings is especially important for the cutaneous T-cell lymphomas. Close cooperation between the clinician and pathologist is therefore essential for the most precise diagnosis.

PERIPHERAL T-CELL LYMPHOMA, UNSPECIFIED

General: The designation “peripheral T-cell lymphoma, unspecified” (PTCLU) encompasses a heterogeneous group of mature T-cell neoplasms that do not meet criteria for one of the more distinct clinicopathologic entities described below. Overall, PTCLU accounts for approximately half of all mature T-cell lymphomas.⁸³ In most cases, patients present primarily with nodal disease, although extranodal presentations also occur, including those with primary cutaneous disease.

Pathology: The histologic findings in PTCLU are very diverse. There is usually extensive effacement of the normal lymph node architecture by a diffuse proliferation of the malignant cells (Figure 52.15). Some cases consist of small- to intermediate-sized cells with only minimal cytologic atypia, such that distinction from T-zone hyperplasia can be difficult by morphology alone. In most cases, however, the malignant cells are intermediate to large in size, with irregular nuclear contours and vesicular chromatin.⁸³ Frequently, the malignant cells exhibit prominent pale to clear cytoplasm. A subset of cases will include large, Reed–Sternberg-like cells, creating a differential diagnosis that includes Hodgkin's lymphoma.

Immunophenotype: In general, cases of PTCLU will express one or more T-cell antigens. Frequently,

Figure 52.15 Peripheral T-cell lymphoma, unspecified. This case displays a diffuse infiltrate of small- to intermediate-sized cells with pale cytoplasm admixed with occasional large transformed cells

however, the phenotype is aberrant, with loss of at least one T-cell antigen. Such cases often require extensive immunophenotypic studies with numerous antibodies to confirm a T-cell lineage. CD30 may be expressed on a subset of the malignant cells in some cases.⁸³

Molecular genetics: Clonal T-cell receptor rearrangements are usually detectable by PCR and/or Southern blot studies. Most cases of PTCLU will display a complex karyotype by classical cytogenetic studies, but specific, recurrent karyotypic abnormalities have not been identified. Genomic profiling studies have identified a complex pattern of recurrent chromosomal gains and losses,⁸⁴ but the diagnostic significance of such changes remains to be determined.

ANAPLASTIC LARGE CELL LYMPHOMA

General: Anaplastic large cell lymphoma (ALCL) represents approximately 3% of all NHL in adults, but 10–30% of NHL in childhood.⁸⁵ Typically, the disease presents in systemic fashion with involvement of lymph nodes and possibly extranodal sites, including skin, bone, soft tissue, and other sites. This systemic form of disease must be distinguished from cases that present with disease limited to the skin (see section on CD30+ lymphoproliferative disorders of the skin below). Most patients will present at advanced stage (stage 3 or 4). Detection of ALK rearrangements (see below) are of importance due to the superior outcome of ALK+ ALCL compared to ALK – ALCL.⁸⁶

Pathology: Although the morphologic features of ALCL are variable, essentially all cases will contain varying numbers of large cells with eccentrically placed, band- or horseshoe-shaped nuclei, often with a punctate area of eosinophilic cytoplasm located adjacent to the nucleus.⁸⁵ These large cells are known as “hallmark cells,” because their morphology is characteristic of ALCL (Figure 52.16). Variants of ALCL, termed “lymphohistiocytic variant ALCL” and “small cell variant ALCL,” have also been described.

Figure 52.16 Anaplastic large cell lymphoma. Sheets of large, pleomorphic cells are present. The inset shows a characteristic “hallmark cell” with a band-shaped nucleus and central, punctate eosinophilic cytoplasm

Figure 52.17 Anaplastic large cell lymphoma. Immunostains of the case shown in Figure 52.16 demonstrate the large cells to be positive for CD30 (left panel) and ALK (right panel)

The marked nuclear pleomorphism seen in routine histologic sections of ALCL leads to a wide differential diagnosis. In some cases, the malignant cells resemble the Reed–Sternberg cells of Hodgkin’s lymphoma. In other cases, the cells resemble metastatic carcinoma, especially in cases with only partial effacement, where the malignant cells may be confined to the lymph node sinuses.

Immunophenotype: The large cells will be strongly positive for CD30 and recent studies have indicated the vast majority of cases will express clusterin.^{87,88} Most cases will also express cytotoxic proteins such as granzyme B or TIA1. The expression of other T-cell antigens is quite variable, although most cases will express at least one T-cell antigen. In some cases, no detectable T-cell antigens will be identified, leading to the designation “null cell.” The T-cell origin of these latter cases is only revealed by the presence of monoclonal T-cell receptor rearrangements. In the majority of cases, ALK protein can be detected by immunohistochemistry as a result of a balanced translocation involving the ALK gene at 2p23 (Figure 52.17) The ALK-positive cases are also typically positive for EMA.

Molecular genetics: In approximately 60–80% of cases overall, and in an even greater percentage of cases arising in childhood, a balanced translocation is present involving the ALK gene at 2p23.^{85,89} In roughly 75% of such cases, the translocation is t(2;5)(p23;q35) involving ALK and NPM. In the remaining 25% of translocations, one of a large number of other translocation partner genes is involved instead of NPM, such as TPM3 (1q25), TFG (3q35), ATIC (2q25), or CLTC (17q23). Other translocation partner genes have also been described.

Translocations involving the ALK gene generally lead to aberrant expression of the ALK protein, which can be detected by immunohistochemistry. ALK translocations are best detected at the molecular level

FISH probes, which are capable of detecting rearrangement of the ALK gene, regardless of the partner gene present.⁹⁰

ANGIOIMMUNOBLASTIC T-CELL LYMPHOMA

General: Angioimmunoblastic T-cell lymphoma (AITL) accounts for 1–2% of NHL.⁹¹ Initially thought to represent an abnormal immune reaction, molecular studies have demonstrated this process to represent a clonal malignancy.⁹² Patients typically present at high stage with adenopathy, hepatosplenomegaly, and, often, bone marrow involvement. Systemic symptoms such as fever and pruritis are common. Laboratory abnormalities such as circulating immune complexes and hemolytic anemia are also seen.

Pathology: Lymph nodes involved by AITL show architectural effacement by a proliferation of small- to intermediate-sized lymphocytes with pale to clear cytoplasm and variable numbers of large transformed cells.⁹² Regressively transformed germinal centers are often present and there is a characteristic proliferation of arborizing vessels (Figure 52.18). Increased numbers of follicular dendritic cells are characteristic of AITL, often associated with the vascular proliferation.

Immunophenotype: The malignant cells are typically CD4+, and recent studies have shown most cases of AITL to coexpress CD10.^{93,94} Expression of other T-cell antigens is variable. Most cases also display scattered large, EBV-positive B-cells that may give rise to secondary B-cell lymphomas in a subset of patients.

Molecular genetics: Clonal T-cell rearrangements are detectable by PCR or Southern blot studies in at least 75% of cases. Clonal B-cell populations may also be detected in some cases, likely corresponding to accompanying EBV-positive B-cells.⁹¹ Recurring cytogenetic abnormalities include trisomy 3, trisomy 5, and gains

Figure 52.18 Angioimmunoblastic T-cell Lymphoma. The lymph node is effaced by a diffuse proliferation of intermediate to large lymphocytes with pale cytoplasm. There is an accompanying vascular proliferation

of the X chromosome, although none of these represent specific findings.⁹⁵

ENTEROPATHY-TYPE T-CELL LYMPHOMA

General: Enteropathy-type T-cell lymphoma (ETL) is a neoplasm of intraepithelial lymphocytes that is often associated with celiac disease. While in some cases there is a history of celiac disease since childhood, in most cases of ETL, celiac disease is diagnosed either concurrently with or shortly before diagnosis of the lymphoma.⁹⁶ Prior to diagnosis of an overt lymphoma, some patients will experience a period of refractory celiac disease and/or intestinal ulcers (ulcerative jejunitis). Establishing a diagnosis from small endoscopic mucosal biopsies can be very difficult, and excision of a full-thickness intestinal biopsy specimen may be required for a definitive diagnosis.

Pathology: One or more ulcerating mass lesions are present in the jejunum or ileum. Occasionally, other parts of the GI tract may also be involved. Histologically, the tumor cells display a variable appearance. In most cases, the infiltrate is composed of medium-sized lymphocytes with round to irregular nuclei, vesicular chromatin, and variable amounts of cytoplasm.⁹⁷ Small cell variants and cases with markedly anaplastic features have also been described. Areas of uninvolved intestinal mucosa often show features of celiac disease (villous blunting, crypt hypertrophy, and increased numbers of intraepithelial lymphocytes).

Immunophenotype: The neoplastic cells in ETL typically demonstrate expression of CD3, CD7, CD103, and cytotoxic proteins such as TIA1 or granzyme B.^{96,98} The tumor cells are usually negative for CD5, CD4, and CD8, although in some cases a CD8 positive, CD56 positive phenotype is present.⁹⁹

Molecular genetics: A monoclonal T-cell population is present, and may be detected by PCR or Southern blot studies. Biopsies of refractory sprue or ulcerative jejunitis may contain monoclonal T-cell populations with clonal rearrangements identical to the overt lymphoma, suggesting these may represent precursor lesions.¹⁰⁰ PCR studies alone therefore are not sufficient to distinguish between refractory sprue and ETL. Interestingly, most patients display the HLA DQA1*0501, DQB1*0201 genotype that is associated with celiac disease.¹⁰¹

EXTRANODAL NK/T-CELL LYMPHOMA OF NASAL TYPE

General: Extranodal NK/T-cell lymphoma of nasal type (or “NK/T-cell lymphoma”) is most prevalent in Asia, Mexico, and South America, but occurs in other ethnic groups as well.^{102,103} The term “NK/T-cell” reflects the finding that while the majority of cases appear to represent neoplasms of NK cells, a subset are thought to be of T-cell type. In some cases, it may not be possible to distinguish with certainty whether the neoplastic cells represent T-cells or NK-cells. Most commonly, this

lymphoma arises within the nasal cavity, but essentially identical cases may occur at other extranodal sites including skin, testis, soft tissue, and GI tract.

Pathology: The morphologic findings in NK/T-cell lymphoma are somewhat variable. In most cases, a diffuse proliferation of small- to intermediate-sized lymphoid cells are present, but some cases display numerous large, even anaplastic, lymphoid cells.¹⁰²⁻¹⁰⁴ A characteristic feature of this neoplasm is that the proliferation often centers around and infiltrates vessel walls. There is often associated vascular destruction and extensive necrosis, which in some cases can obscure the malignant infiltrate.

Immunophenotype: The malignant cells in NK/T-cell lymphoma typically display a CD2+, CD56+, surface CD3-, and cytoplasmic CD3ε+ phenotype. There is consistent expression of cytotoxic proteins such as granzyme B and TIA1.^{102,105} Nearly all cases are EBV-positive, especially those arising in the nasal cavity, and in Asian patients. The association with EBV may be somewhat less strong in Western populations and in cases arising at nonnasal sites.¹⁰⁵⁻¹⁰⁷

Molecular genetics: Most cases represent malignancies of true NK cells and so lack clonal rearrangements of the T-cell receptor genes. In a subset of cases, however, clonal rearrangements may be detected, consistent with a true T-cell origin. In EBV positive cases, clonality of the episomal EBV DNA can also usually be demonstrated. The most frequent cytogenetic abnormality is del(6q), although this abnormality is also found in many other forms of lymphoma. There is currently little information available regarding other possible recurrent cytogenetic abnormalities.¹⁰⁸

HEPATOSPLENIC T-CELL LYMPHOMA

General: Hepatosplenic T-cell lymphoma (HSTL) is a rare systemic lymphoma that generally presents with involvement of the liver, spleen, and bone marrow.¹⁰⁹ Initially described as a lymphoma of $\gamma\delta$ -type T-cells, it is now known that some otherwise identical cases consist of $\alpha\beta$ T-cells. Importantly, it should be realized that other types of T-cell lymphoma may consist of $\gamma\delta$ -type T-cells and such cases should not be categorized as HSTL solely because of the type of T-cell receptor expressed.

Pathology: There is typically splenomegaly, and histologic sections of the spleen display prominent red pulp infiltration by a proliferation of intermediate-sized lymphoid cells. The white pulp is characteristically uninvolved.^{109,110} Similarly, the liver displays a striking infiltrate of the hepatic sinusoids by similar appearing cells, with sparing of the portal tracts. The bone marrow is also usually involved, and displays clusters of intermediate-sized lymphoid cells within the sinusoids.^{110,111}

Immunophenotype: Typical cases display an immature cytotoxic T-cell phenotype with expression of TIA1, but not perforin or granzyme B. Most cases are

positive for CD2 and CD3, but are negative for CD4, CD5, and CD8.^{109,110} Expression of other T-cell associated antigens is variable. Most cases express the $\gamma\delta$ T-cell receptor, although occasional $\alpha\beta$ T-cell receptor positive cases are well described.^{109,112} Many cases show co-expression of CD56. There is no association with EBV.

Molecular genetics: Many cases appear to be associated with a recurrent cytogenetic abnormality, isochromosome 7q.^{109,110} The exact incidence of i(7q) in HSTL has not yet been clarified, although it is clear that not all cases contain this abnormality. Monoclonal T-cell receptor rearrangements may be detected by PCR or Southern blot studies.

MYCOSIS FUNGOIDES/SÉZARY SYNDROME

General: Mycosis fungoides (MF) is defined as a primary cutaneous T-cell lymphoma that clinically presents with patches and plaques and histologically displays an epidermotropic infiltrate of small- to intermediate-sized cells with atypical, cerebriform nuclei.¹¹³ Although some have used the term "cutaneous T-cell lymphoma (CTCL)" synonymously with MF, this practice is to be strongly discouraged because many other types of T-cell lymphoma may also present with primary cutaneous disease. Within the spectrum of MF is a clinical variant condition designated "granulomatous slack skin" characterized by folds of atrophic skin, usually within the axilla or groin. Sezary syndrome is also regarded as a variant of MF and is characterized by peripheral blood involvement by malignant T-cells with cerebriform nuclei, usually associated with adenopathy and erythroderma.

Pathology: The skin lesions of MF are histologically characterized by an epidermal infiltrate of small- to intermediate-sized cells with irregular, cerebriform nuclei. The presence of such cells in small clusters, known as "Pautrier's microabscesses," is very characteristic of the disease, but in most cases the epidermal infiltrate is present predominantly as scattered, single atypical cells.¹¹⁴ The dermal component may be variable, ranging from a sparse, often band-like, infiltrate in earlier lesions to an extensive collection of malignant cells filling the dermis in advanced stages (Figures 52.19 and 52.20). In a variant form of MF, known as "pagetoid reticulosis," the dermal component is characteristically absent. Some cases of MF are associated with follicular mucinosis, a condition of mucinous changes within a hair follicle accompanied by an infiltrate of malignant cells within the follicular epithelium. The variant known as granulomatous slack skin typically shows a granulomatous infiltrate within the infiltrate, where the admixed lymphocytes include a population of cerebriform cells, similar to those seen in typical MF. In Sezary syndrome, cerebriform malignant cells are present within the peripheral blood.

Figure 52.19 *Mycosis fungoides*. At low power, a band-like lymphocytic infiltrate is seen in the upper dermis

In more advanced disease, there is frequently involvement of lymph nodes, and several schemes have been proposed to grade the extent of nodal involvement. The WHO classification recommends a modification of earlier criteria^{113,115,116} to divide cases into three grades of lymph node involvement. In grade I cases, there is no definitive morphologic evidence of nodal involvement. Such cases may show dermatopathic lymphadenopathy and scattered cerebriform cells, but clusters of atypical cells are not present. In grade II cases, clusters of atypical, cerebriform cells focally efface the lymph node architecture. Lastly, grade III cases demonstrate complete effacement of the nodal architecture by a diffuse infiltrate of malignant cells. Importantly, this scheme is intended to quantify lymph node involvement with a previous diagnosis of MF, and should not be definitively applied to patients without prior, biopsy-proven MF.

Figure 52.20 *Mycosis fungoides*. At high power, collections of atypical lymphocytes are identified in the epidermis

Immunophenotype: Typically, the malignant cells of MF are positive for T-cell antigens including CD3, CD2, CD5, and, usually, CD4. Occasional cases may lack CD4 and express CD8, especially in the variant form known as pagetoid reticulosis. Most cases display aberrant loss of the CD7 antigen. The finding of CD7 loss must be interpreted with caution, however, as some inflammatory dermatoses also contain significant populations of CD7⁻ T-cells.

Molecular genetics: T-cell receptor gene rearrangements are generally detectable by PCR and/or Southern blot studies. Information regarding the cytogenetic findings in MF is limited by the difficulties of successful karyotypic analysis of small skin biopsies. Analysis of peripheral blood lymphocytes in patients with Sezary syndrome generally display complex karyotypes,¹¹⁷ but specific recurrent abnormalities have not been identified. Recent comparative genomic hybridization studies have suggested losses of chromosomes 1p and 17p may be common.¹¹⁸

PRIMARY CUTANEOUS CD30-POSITIVE LYMPHOPROLIFERATIVE DISORDERS

General: The category of primary cutaneous CD30⁺ lymphoproliferative disorders includes a spectrum of cases that range from primary cutaneous anaplastic large cell lymphomas (C-ALCL) at one end to cases of lymphomatoid papulosis (LYP) at the other.^{119,120} Cases designated as C-ALCL are clinically characterized by single or localized skin lesions and are histologically composed of sheets of large, atypical CD30 positive lymphocytes. There may be partial or complete spontaneous regression, but frequent cutaneous relapses generally occur. In contrast, cases designated as LYP present clinically as multiple papules that display spontaneous regression and histologically contain an inflammatory infiltrate with varying numbers of atypical CD30 positive lymphocytes. The clinical course is benign, but chronic, often lasting over many years. Lastly, some cases are designated as “borderline lesions” because there is a discrepancy between the clinical and histologic findings (e.g., a clinical appearance most consistent with LYP, but histology displaying sheets of CD30⁺ cells, suggestive of C-ALCL). In the absence of complete clinical information, many pathologists prefer to designate these disorders simply as “CD30⁺ lymphoproliferative disorder.”

Pathology: In C-ALCL, there is a diffuse dermal infiltrate of intermediate to large lymphoid cells that resemble those found in cases of systemic ALCL.^{119,121} In some cases, multinucleate or binucleate cells are present, creating a differential diagnosis that includes Hodgkin's lymphoma. Any accompanying inflammatory infiltrate is usually quite mild.

The histologic findings in LYP are quite variable.^{119,120} The most frequent pattern, which has been

designated type A LYP, consists of a wedge-shaped dermal infiltrate composed of varying numbers of large, atypical lymphoid cells admixed with neutrophils, eosinophils, histiocytes, and small lymphocytes. Much less commonly (<10% of LYP), the histologic findings may resemble those of mycosis fungoides (so-called type B LYP). In these latter cases, an infiltrate of cerebriform small lymphocytes is present. Some individuals may display a mixture of both Type A and Type B lesions.

Immunophenotype: In both C-ALCL and LYP, the neoplastic cells are CD30+ and display variable loss of associated T-cell antigens. Most cases are CD4+, although occasional CD8+ cases may also occur. The majority of cases will also express cytotoxic proteins, such as TIA1 and granzyme B. Expression of ALK protein, if it occurs at all in these disorders, is rare. The finding of ALK expression therefore strongly suggests secondary cutaneous involvement by a systemic ALCL rather than primary cutaneous disease.

Molecular genetics: Clonally rearranged T-cell receptors may be identified in the majority of cases of both C-ALCL and LYP. Genotypic studies therefore do not assist in differentiating between C-ALCL and LYP. In some patients, different T-cell receptor clones may be identified in different lesions of LYP.¹²² In other LYP patients, however, the same T-cell receptor clone can be identified in multiple lesions over time. For example, in one report, single-cell analysis identified the same T-cell receptor clone in different biopsies taken over 4 years apart.¹²³ There is currently little data available regarding cytogenetic abnormalities within C-ALCL and LYP.

SUBCUTANEOUS PANNICULITIS-LIKE T-CELL LYMPHOMA

General: Subcutaneous panniculitis-like T-cell lymphoma (SPTCL) is an uncommon form of lymphoma (<1% of all NHLs) composed of cytotoxic T-lymphocytes.¹²⁴⁻¹²⁶ Patients typically present with multiple subcutaneous nodules, most commonly on the extremities and trunk. Frequently, SPTCL may be accompanied by a hemophagocytic syndrome with associated fevers, cytopenias and hepatosplenomegaly.¹²⁵ This area is undergoing change in definitions depending on whether the tumor cells express $\gamma\delta$ -type or $\alpha\beta$ -type T-cell receptor.

Morphology: There is typically a diffuse infiltrate of small- to intermediate-sized lymphocytes throughout the subcutaneous tissues, often without sparing of the lobular septae.^{125,126} The infiltrate may extend into the dermis as well, although the dermal component is usually relatively minor (particularly in the $\alpha\beta$ -type). Areas of vascular invasion may be present, and there is

frequent necrosis (particularly in the $\gamma\delta$ -type). Characteristically, the malignant cells tightly ring individual adipocytes. There may be accompanying histiocytes, especially in areas of fat necrosis.

Immunophenotype: The malignant cells express cytotoxic molecules including TIA1, granzyme B and perforin. Most cases are CD8+ and express the $\alpha\beta$ T-cell receptor.^{124,125} Approximately 25% of cases, however, express the $\gamma\delta$ T-cell receptor. Many of these latter cases lack expression of both CD4 and CD8 and are positive for CD56. There is no association with EBV. It is these $\gamma\delta$ -type lymphomas that appear to have an aggressive clinical course. The $\alpha\beta$ -type appears to have an indolent course and is currently the only type accepted as SPTCL in the recently published WHO-EORTC classification of cutaneous lymphomas.¹²⁷ The $\gamma\delta$ -type is now classified as a provisional entity (primary cutaneous $\gamma\delta$ -T-cell lymphoma).

Molecular genetics: Rearrangements of the T-cell receptor are usually detectable by PCR and/or Southern blot studies. EBV is absent. Currently, no characteristic cytogenetic abnormalities have been identified.

BLASTIC NK-CELL LYMPHOMA

General: Blastic NK-cell lymphoma is a rare neoplasm characterized by a blastoid morphology and tendency to involve the skin and peripheral blood. There may also be systemic nodal involvement.^{126,128} The cell of origin and most appropriate nomenclature for this neoplasm have been subjects of controversy, and this malignancy is incompletely characterized at present. This neoplasm is classified as a natural killer lymphoma in the WHO system, due largely to the characteristic expression of CD56. More recently, however, studies have suggested this neoplasm is derived from DC2 cells, a type of dendritic cells.¹²⁹⁻¹³¹

Pathology: In cutaneous blastic NK-cell lymphoma, there is typically a diffuse infiltrate of intermediate-sized cells with dispersed chromatin. In many cases, the tumor cells infiltrate the dermis in a single-file pattern.^{126,128}

Immunophenotype: The neoplastic cells are characteristically positive for CD56, CD4, and CD123. Some cases may be at least partially positive for CD34, TdT, and/or CD68.^{126,128} Other T-cell associated antigens are typically negative. There is no association with EBV.

Molecular genetics: The T-cell receptor genes are in the germline configuration. Characteristic, recurrent cytogenetic abnormalities have not been identified to date.

Chapter 53

TREATMENT APPROACH TO FOLLICULAR LYMPHOMAS

Bruce D. Cheson

CLASSIFICATION AND PROGNOSIS

The follicular lymphomas are the second most common subtype of indolent non-Hodgkin's lymphoma (NHL), representing about 25–30% of NHL. In the working formulation, these tumors were subclassified into follicular small cleaved cell, follicular mixed small and large cell, and follicular large cell, based on the number of larger cells per high-powered field.¹ In the more recent Revised European American Lymphoma² and the subsequent, universally adopted World Health Organization (WHO) classifications,^{3,4} the nomenclature became grade I, grade II, and grade III, respectively. Grade III has been further subdivided into grade III A or grade III B, reflecting the presence of centroblasts (III A) or sheets of centroblasts (III B). A clinically meaningful difference in outcome between grade I and II has not been uniformly demonstrable.^{5–8}

The conduct of clinical trials has been facilitated by the availability of prognostic scoring systems^{9,10} and standardized response criteria.¹¹ The International Prognostic Index, originally developed for diffuse large B-cell lymphoma,⁹ can distinguish risk groups in patients with follicular lymphoma as well.^{12,13} However, better separation among the prognostic subsets may be afforded by the new Follicular Lymphoma International Prognostic Index¹⁰ that uses stage, age, number of involved nodal sites, lactate dehydrogenase (LDH), and hemoglobin to identify low- (0–1 adverse factor), intermediate- (2 factors), or high-risk (≥ 3 factors) patients.

THERAPY

LIMITED-STAGE DISEASE

Only about 10–15% of patients present with limited-stage (stage I and nonbulky stage II) disease. For these patients, radiation therapy may result in prolonged disease-free survival. Whether or not they are cured is controversial, since relapses occur even after 10–20 years.¹⁴ Prolonged progression-free survival without

therapy in some series suggests that watchful waiting may be an appropriate option.¹⁵

ADVANCED-STAGE DISEASE

Patients with advanced follicular NHL are characterized by an indolent clinical course with a median survival of 6–10 years.^{16,17} Nevertheless, early intervention with treatment in patients with asymptomatic, nonbulky disease has not been associated with a prolongation of survival.^{18,19} As a result, a watch-and-wait approach has been routinely recommended until treatment is clinically indicated on the basis of disease-related symptoms, massive or progressive lymphadenopathy or hepatosplenomegaly, potential organ compromise, or bone marrow involvement resulting in peripheral blood cytopenias.

Standard chemotherapy

When treatment is indicated, no particular chemotherapy regimen has clearly prolonged the survival of patients with advanced-stage follicular NHL compared with another. Extensive experience with single alkylating agents alone or combined with vincristine and prednisone [e.g., cyclophosphamide, vincristine, and prednisone (CVP)], or CVP with adriamycin [cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin (vincristine), and prednisone (CHOP)] failed to demonstrate a major difference in outcome.^{17,20} Thus, until recently, a single alkylating agent or CVP was the standard. The use of CHOP is often reserved for patients for whom there is a concern of histologic conversion, or at the time of such conversion. Single-agent fludarabine is an active agent in previously treated and untreated patients,^{21–26} and fludarabine-based combinations with cyclophosphamide or mitoxantrone demonstrated high response rates in phase II trials.^{27,28} The regimen of fludarabine plus mitoxantrone has been reported to induce a higher complete response rate than that of CHOP, and with more molecular remissions, but with a similar overall response rate and time to progression.²⁹

Interferon therapy

Interferon (IFN) has modest single-agent activity in the treatment of patients with low-grade NHL,^{30–32} leading to a series of phase III trials. IFN was approved by the Food and Drug Administration (FDA) for “low-grade” NHL in combination with aggressive chemotherapy largely based on a study from the Groupe d’Etude Lymphomes Folliculaire,³³ including 242 evaluable patients with follicular NHL and a high tumor burden. They were treated with doxorubicin, cyclophosphamide, teniposide, and prednisone for a year either alone or with concurrent IFN, which was continued out to 18 months. There was an advantage in response rate for the combined modality arm (85% vs 69%). At a median of 6-year follow-up, the progression-free survival was 2.9 years and 1.5 years, and the overall survival was not reached versus 5.6 years for the IFN-containing arm and the chemotherapy-alone arm, respectively.³⁴

However, at least 10 randomized trials have evaluated the role of IFN either during induction,³⁵ as a maintenance,^{36–39} or in both settings^{33,40–43} with remarkably inconsistent results.

Rohatiner and colleagues⁴⁴ conducted a meta-analysis of these trials. In the five studies in which chemotherapy was considered to be “less intensive,” defined as not including an anthracycline or anthracene agent,^{38,40–43} there was no evidence of any benefit from IFN. In the five trials of “more intensive” treatment,^{34–37,39} there was no improvement in the response rate when IFN was added to chemotherapy, but there was an overall prolongation of time to disease progression and survival, limited to patients with either a complete or partial response to their induction regimen. The conclusion was that IFN played a role in responsive patients who were receiving more intensive chemotherapy.

Nevertheless, given the disparate results of the various trials, the toxicity of this agent, and the availability of effective monoclonal antibodies, there is no clear role for IFN in the current management of follicular lymphoma.

Monoclonal antibody therapy

An increasing number of monoclonal antibodies are either commercially available or available in clinical trials for follicular NHL (Table 53.1).

Single-agent rituximab therapy The treatment paradigm for the approach to indolent B-cell malignancies has been revolutionized by the availability of active monoclonal antibodies and related agents. Rituximab has become an integral component of the therapy of most patients with follicular NHL. The original studies of this chimeric anti-CD20 monoclonal antibody were conducted in patients with relapsed and refractory follicular and low-grade NHL. In the pivotal trial including 166 patients treated with a dose of 375 mg/m²

Table 53.1 Unconjugated monoclonal antibodies for follicular NHL

Antibody	Target	Status
Rituximab	CD20	Commercial
Alemtuzumab	HLA-DR	Commercial
Galiximab (IDEC-114)	CD80	Phase II
Humanized anti-CD20	CD20	Phase I/II
Bevacizumab (Avastin)	VEG-F	Commercial*
Anti-CD40	CD40	Phase I
Anti-TRAIL	Trail 1,2	Phase I
Epratuzumab	CD52	?
Apolizumab (Hu1D10)	CD22	?

“*”, for colorectal cancer; “?”, future uncertain.

weekly for 4 weeks,⁴⁵ responses were induced in 48% of patients, including 6% complete remissions, with an about 13-month duration of response. This antibody has been widely adopted because of its activity and favorable toxicity profile. Most adverse reactions occur during the infusion and consist primarily of fevers, chills, with occasional hypotension. Premedication includes acetaminophen and diphenhydramine. Demerol may be indicated for rigors. Hydrocortisone may also help ameliorate these toxicities. Delayed myelosuppression, especially neutropenia, has been observed, although the etiology of this phenomenon is unclear.

Attempts to improve on the activity of rituximab have included increasing the dose, dose density, or number of infusions, using it earlier in the course of the disease, combining it with chemotherapy or other biologics, maintenance therapy, and identifying patients more likely to experience a response. Administration of eight weekly infusions instead of the standard four neither increased the response rate nor clearly prolonged the time to progression.⁴⁶ In chronic lymphocytic leukemia, administration of higher doses or schedules involving three doses per week was not clearly associated with meaningful clinical benefit.^{47,48} Pursuing such an approach is, therefore, not warranted in follicular NHL.

The activity of rituximab correlates with the extent of prior treatment. When rituximab is used as initial therapy, response rates have been greater than 70% compared with the 50–58% in relapsed/refractory patients^{49,50}; however, the duration of response has been disappointing.

Rituximab and chemotherapy combinations The large number of studies that have been conducted with rituximab in combination with chemotherapy suggest that results with the combination are superior to what would be expected with either chemotherapy or rituximab alone. These observations support the *in vitro* studies suggesting that monoclonal antibodies such as rituximab can sensitize lymphoma

Table 53.2 Rituximab + chemotherapy regimens, for follicular NHL

Author	Patients	Other drug(s)	RR (CR)%
Czuczman ⁵³	38	CHOP	100(63)

Rummel ⁶³	35	Bendamustine	97(71)

cells to the effects of subsequent chemotherapy.^{51,52} Czuczman et al.⁵³ were the first to report a combined modality experience with 38 patients, 31 of whom were previously untreated, who received CHOP plus rituximab. The overall response rate was 100% with 58% complete remissions and a median time to progression of 8.3 years.⁵⁴ However, comparable response rates can be achieved with a variety of other chemotherapy-rituximab regimens (Table 53.2).^{55–63} Any differences in complete or overall response rates among the various regimens may be explained by a number of factors including patient selection or the point in time when response is assessed, as maximal responses may occur several months following therapy. Nevertheless, the relative duration of responses among these various regimens has not been compared.

Recent randomized trials have shown superiority for rituximab-containing regimens over chemotherapy alone. However, the optimal approach to such combinations is unknown. In some of these studies, the antibody has been combined with the chemotherapy. The German Low Grade Lymphoma Study Group conducted a randomized study of 394 patients who were allocated to either CHOP or rituximab plus CHOP (R-CHOP), with a secondary randomization to a variety of postremission therapies including INF or stem cell transplantation (SCT).⁵⁵ There was no advantage from rituximab in overall response rate (97% vs 93%), but the combination was associated with a longer event-free survival and a trend toward a longer overall survival. The variety of postremission therapies makes these data difficult to interpret. Marcus and coworkers⁵⁶ randomized 322 patients with either intermediate- or poor-risk follicular NHL to either CVP alone or with rituximab (CVP-R). The dose of drugs was lower than usually used at only 750 mg/m² with prednisolone 40 mg/m². The overall response rates and complete response rates were significantly higher with CVP-R at 81 and 40% versus 57 and 10% for CVP alone. The median time to treatment failure with CVP-R was 27 months compared with 7 months for CVP at a median follow-up of 18

months. In addition, the median time to progression was not reached for CVP-R compared with 113 months for CVP alone.

Maintenance therapy with rituximab Maintenance rituximab therapy has also been evaluated in an attempt at prolonging the time to disease progression and, possibly, survival.^{50,64,65} In several trials, rituximab has been used as a single-agent for induction followed by the same agent as maintenance. Hainsworth et al.⁵⁰ treated 62 patients with follicular and low-grade NHL, using four weekly doses of rituximab followed by four additional doses every 6 months for 2 years. The time to progression of 32 months was longer than expected. In a randomized trial, Ghielmini et al.⁶⁴ reported previously treated ($n = 128$) and previously untreated patients ($n = 57$) who received four weekly doses of rituximab followed by a randomization to no further therapy or to maintenance consisting of a single infusion of rituximab every 2 months for a total of 8 months. At a median follow-up of 35 months, the median event-free survival was 23 months for the prolonged treatment group compared with 12 months in those allocated to no further treatment. This advantage was greatest in the chemotherapy-naïve patients.

About 40% of patients who have experienced an initial response to rituximab lasting at least six months respond a second time with a duration at least as long as the initial response.⁶⁶ Thus, whether maintenance is associated with an outcome that is superior to retreatment is an important question. Hainsworth et al.⁶⁷ conducted a study in which patients who were treated with an initial 4 weeks of rituximab were then randomized to maintenance therapy as previously published⁵⁰ or retreatment upon recurrence; although response rates and time to progression favored the maintenance arm, the time to which another treatment other than rituximab was required was similar (31 months vs 27 months). The ongoing Eastern Cooperative Oncology Group (ECOG) “RESORT” trial is comparing treatment until relapse with retreatment at the time of recurrence. Therefore, at the present time, the preferable approach is not clear.

Investigators from ECOG recently presented the early results from a trial exploring the role of rituximab maintenance following induction chemotherapy.⁶⁵ The initial study design had included a randomization during induction between CVP (cyclophosphamide 1000 mg/m² with prednisone 100 mg/m² every 3 weeks for six to eight cycles, determined by the rapidity of the response) and fludarabine plus cyclophosphamide; however, the latter arm was discontinued because of excessive toxicity. Rituximab maintenance was started 4 weeks after the completion of the chemotherapy, and four weekly infusions were delivered every 6 months for 2 years. After CVP, approximately 15% of patients attained a

CR with an overall response rate of 79%. Rituximab improved the response rate in 22% of patients, while an improvement in response was noted in 8% of patients receiving no further therapy. Progression-free survival was 4.5 for the maintenance arm versus 1.5 years for observation at a median follow-up of only 1.2 years, with a trend in favor of the maintenance arm in overall survival ($p = .06$). Van Oers et al. randomized 461 patients with relapsed or refractory follicular lymphoma to CHOP or R-CHOP with a secondary randomization to rituximab maintenance or observation. Maintenance was associated with a longer time to progression with a suggestion of a survival advantage.^{67a}

Patient selection for antibody therapy

In the future, the optimal treatment may be determined by clinical and biological characteristics of individual patients. Patient characteristics that appear to predict those patients more likely to respond to rituximab therapy include polymorphisms for FcRgammaIII, which represents the binding site on natural killer cells for the rituximab antibody,⁶⁸ and DNA microarray signatures.⁶⁹ Moreover, in large B-cell NHL the benefit of rituximab appears to be limited to patients whose tumors overexpress the *bcl-2* gene.⁷⁰ Whether these observations will determine which patients will receive rituximab remains to be seen.

Other monoclonal antibodies

A number of other unconjugated antibodies are being evaluated in clinical trials for follicular NHL (Table 53.1).

Alemtuzumab Alemtuzumab (Campath-1H) is a humanized anti-CD52 monoclonal antibody with activity in chronic lymphocytic leukemia as well as T-cell lymphomas; however, its single-agent activity in indolent B-cell NHL has been disappointing.^{71,72}

Epratuzumab Epratuzumab is a humanized IgG1 monoclonal antibody directed against the CD22 antigen, expressed on a variety of lymphomas. In a dose-escalation study of epratuzumab in 55 patients with indolent NHL, no dose-limiting toxicities were identified.⁷³ The overall response rate was 24% in those with follicular histologies. In a subsequent trial, both epratuzumab and rituximab were administered using an empiric schedule with each weekly for 4 weeks. The response rate and duration were disappointing, suggesting that a inferior dose and schedule of this combination was used.⁷⁴

Anti-CD80 (Galiximab) CD80 is an immune costimulatory molecule present on the surface of NHL cells. Galiximab (IDEC-114) is a macaque-human chimeric anti-CD80 antibody with *in vivo* antilymphoma properties. In phase I trials, the antibody was well

tolerated except for mild fatigue, nausea, and headaches. Moreover, single-agent activity was approximately 15%.⁷⁵ Based on preclinical data suggesting synergy, a phase I/II study of the combination of galiximab and rituximab was conducted, and a response rate of 58.3% was reported.⁷⁶ This combination has been evaluated as the initial therapy for patients with follicular lymphoma in a Cancer and Leukemia Group B phase II trial and results are pending.

Apolizumab Apolizumab (Hu1D10, Remitogen) is a humanized monoclonal antibody directed against a polymorphic determinant of HLA-DR, found on both normal B-cells and in about half of patients with lymphoid malignancies. Limited activity and excessive toxicities have halted its development (U. Hegde, T. White, M. Stetler-Stevenson et al., unpublished data, 2002).^{77,78}

Humanized anti-CD20 Several humanized anti-CD20 monoclonal antibodies are in clinical trials.⁷⁹ Potential advantages are activation of different pathways enhancing cell kill, and a shorter infusion time. Whether there will be any clinical benefit remains to be determined.

Radioimmunotherapy (RIT)

Two radioimmunoconjugates are currently commercially available; Y-90 ibritumomab tiuxetan (Zevalin) and I-131 tositumomab (Bexxar). The clinical trials thus far conducted with radioimmunoconjugates have demonstrated greater activity than their cold antibody, and are useful in patients who have relapsed after or who are refractory to rituximab.

Y-90 ibritumomab tiuxetan Y-90 ibritumomab tiuxetan has a murine rituximab conjugated to the isotope.⁸⁰ The Y-90 ibritumomab tiuxetan regimen takes about 8 days to administer. On the first day, a dose of cold rituximab at 250 mg/m² is administered to bind nontumor CD20 sites and to facilitate better biodistribution. Because Y-90 is a beta emitter, it cannot be used for imaging; thus, indium-111-labeled ibritumomab is substituted for biodistribution studies performed at days 2–3, and if needed, 6–7 to ensure appropriate localization of the isotope. On days 7–8, another low dose of cold antibody is delivered followed by 0.4 mCi/kg of Y-90 ibritumomab tiuxetan (not to exceed 32 mCi) for patients with platelet counts of at least 150,000/mm³. The dose is reduced to 0.3 mCi in patients with a platelet count of 100–149,000/mm³.⁸¹

In the initial phase I/II trial,⁸² the overall response rate in 32 patients with follicular/low-grade NHL was 82%, including 26% complete remissions. Response could be predicted by tumor grade, tumor burden, whether or not the bone marrow was involved with lymphoma, and the extent of that

bone marrow involvement. The median time to progression was 12.9+ months with a median response duration of 11.7+ months. The major toxicity was myelosuppression, with median granulocyte and platelet nadirs of 1100/mm³ and 49,500/mm³, respectively.

The additive benefit of the radioisotope is supported by the activity of radioimmunotherapy in rituximab failures. Y-90 ibritumomab tiuxetan induces responses in 74% of these patients with 15% complete remissions.⁸³ How radioimmunotherapy compares with unconjugated antibody therapy has been addressed in a randomized trial in which 143 patients, with relapsed CD20-positive NHL without previous rituximab exposure, received either rituximab or Y-90 ibritumomab tiuxetan.⁸⁴ Whereas the response rates were higher with Y-90 ibritumomab tiuxetan (80%) than with rituximab (56%), there was no difference between the arms in time to disease progression. Responses to this agent may be quite durable with 24% of responders having a time to progression longer than 3 years and some responses in excess of 5 years.⁸⁵

I-131 tositumomab I-131 tositumomab is a conjugate of the murine anti-CD20 antibody tositumomab and I-131. It is approved for use in patients with relapsed/refractory follicular or transformed NHL. As with Y-90 ibritumomab tiuxetan, treatment occurs over about a week. Thyroid protection is required with I-131 tositumomab because of the radioactive iodine. I-131 is a gamma emitter, and dosimetry is required to provide patient-specific dosing. In a multicenter pivotal trial,⁸⁶ 65% of the 60 heavily pretreated patients with NHL responded including 20% CR. The response rate in the subset with follicular histologies was 81%. Response rates and response duration were significantly higher than from the last chemotherapy. The response rate has been 63% with 29% complete responses in rituximab-refractory patients.

Newer approaches to radioimmunotherapy

A number of approaches are under investigation to increase the activity of radioimmunotherapy. Multiple dosing and retreatment are being studied in clinical trials. Radioimmunotherapy is also being used earlier in the course of the disease. I-131 tositumomab has been administered to 76 previously untreated patients, of which 97% responded, including 63% complete remissions, and with almost 59% free of progression at 5 years for all patients, and this endpoint was not yet reached for those who achieved a CR.⁸⁷ A similar study is under way with Y-90 ibritumomab tiuxetan. I-131 tositumomab can be safely administered after CHOP chemotherapy, and it converts some partial responses to complete responses.⁸⁸ A randomized phase III of R-CHOP followed by I-131 tositumomab compared to R-CHOP is ongoing within

the Southwest Oncology Group and the Cancer and Leukemia Group B. A variety of sequences of chemotherapy and radioimmunotherapy are under investigation.

RIT has also been used in the stem cell transplant setting. Gopal and coworkers compared their results with follicular lymphoma patients who received high-dose I-131 tositumomab with those treated using various high-dose chemotherapy regimens and found better overall survival and progression-free survival, with lower toxicity in the RIT-treated population.⁸⁹

Toxicities of radioimmunotherapy

The major complications of radioimmunotherapy are infusional reactions during the administration of the cold antibody, especially the rituximab, and myelosuppression that occurs around 7–9 weeks after therapy. Febrile neutropenia or infections that require hospitalization are uncommon events. There is little in the way of alopecia, nausea, vomiting, or mucositis. Because of the radioactive iodine, I-131 tositumomab therapy is associated with hypothyroidism in fewer than 10% of patients.

As a result of the treatment associated with myelosuppression, exclusionary criteria for the use of radioimmunotherapy include >25% bone marrow involvement, a hypocellular bone marrow (<15% cellular), platelets <100,00/mm³, neutrophils <1500/mm³, extensive prior radiation therapy, and prior stem cell transplant, the latter because the safety in this setting is unknown, and pregnancy or lactation. Thus, review of a bone marrow biopsy is essential prior to radioimmunotherapy.

One of the major concerns with RIT is the potential for the development of secondary acute myelogenous leukemia or myelodysplastic syndrome. The reported risk is about 1.5% with Y-90 ibritumomab tiuxetan, and 6.3% with I-131 tositumomab. However, the development of this secondary malignancy likely relates to the type and extent of prior treatment, as many patients have cytogenetic abnormalities suggestive of myelodysplasia prior to receiving radioimmunotherapy. In addition, there have been no cases of myelodysplastic syndrome in patients receiving radioimmunotherapy as their initial treatment.⁸⁷ Moreover, based on reviews of the literature, the risk may not be greater than expected from chemotherapy alone.^{86,90,91}

Whether these myelotoxic agents will compromise the ability to safely deliver subsequent therapies has been another area of concern. Preliminary reports with both Y-90 ibritumomab tiuxetan and I-131 tositumomab suggest that patients can tolerate additional therapies; however, response and toxicity data are not yet available.^{92,93}

Y-90 ibritumomab tiuxetan and I-131 tositumomab appear to have comparable activity, and their relative toxicity is being tested in a large phase III trial. Current

research is directed at trying to combine or sequence radioimmunotherapy with chemotherapy and other biologicals.

NEW AGENTS

ANTISENSE OLIGONUCLEOTIDES

Antisense oligonucleotides are chemically modified single-strand DNA molecules with a nucleotide sequence that is complementary to the target mRNA and, therefore, are capable of inhibiting expression of the target gene. Bcl-2 upregulation is thought to be responsible for maintaining the viability of tumor cells, as well as inducing a form of multidrug resistance. The *bcl-2* gene is a rational target in follicular NHL because it is overexpressed in most tumors.

Oblimersen sodium (Genasense, Genta Incorporated, Berkeley Heights, NJ) is a phosphorothioate oligonucleotide consisting of 18 modified DNA bases (i.e., 18-mer) that targets the first six codons of Bcl-2 mRNA to form a DNA/RNA duplex. This agent is the first antisense molecule to be widely tested in the clinic for the treatment of human tumors.

In the single phase I study of oblimersen in 21 patients with NHL,⁹⁴ one patient attained a complete response, which lasted unmaintained for longer than 3 years. Combinations of oblimersen with fludarabine, bortezomib, rituximab, and other agents are in development.

VACCINES

Several vaccines are currently in clinical trials for follicular NHL. Most of these are directed against the idiotype of the hypervariable region of the immunoglobulin light chain. Interest in this approach has been stimulated by a number of nonrandomized studies, such as one from Stanford in which 49% of patients with follicular NHL reacted to their own idiotype conjugated to keyhole limpet hemocyanin (KLH) by exhibiting a cellular and humoral immune response. Those patients capable of mounting such a response had a time to tumor progression of 7.9 years compared to 1.3 years for those who could not.⁹⁵ The results of the three randomized trials will determine if there is clinical benefit from this approach.

NEW CHEMOTHERAPY DRUGS

Bendamustine

Bendamustine is a bifunctional compound with both an alkylating nitrogen mustard group and a purine-like benzimidazole ring. It was first synthesized in 1963 in the German Democratic Republic and has been used extensively in Germany since then. Bendamustine has demonstrated activity in indolent and aggressive NHL, Hodgkin's lymphoma, chronic

lymphocytic leukemia, and multiple myeloma.⁹⁶⁻⁹⁹ In vitro and clinical data also support a beneficial interaction with rituximab. In a study of 63 patients with relapsed/refractory indolent NHL or mantle cell lymphoma, the response rate to this combination was 94% with 71% complete remissions.⁶³ This combination was extremely well tolerated. To better characterize the activity of this agent and to provide broader experience with the agent, it is now being studied alone and in combination with rituximab in phase II trials in the United States.

Bortezomib

Bortezomib (PS-341; Velcade) is a potent, reversible inhibitor of the 26S proteasome, an enzyme important in the intracellular degradation of proteins including those involved in cell cycle regulation, transcription factor activation, apoptosis, and cell trafficking. A primary target for this agent is nuclear factor kappa B (NF- κ B). Bortezomib is the first proteasome inhibitor to be studied in the clinic, and has recently been approved by the FDA for the treatment of relapsed/refractory multiple myeloma.¹⁰⁰ The rationale for a study in NHL is that NF- κ B is overexpressed in a number of histologies. In reports from Goy et al.¹⁰¹ and O'Connor et al.,¹⁰² responses were noted in patients with follicular NHL and, notably, mantle cell lymphoma.

STEM CELL TRANSPLANTATION

The experience with SCT for low-grade NHL is limited because of the older age of the population, the relatively long natural history of the disease, the tendency for peripheral blood and bone marrow involvement, and the fact that most patients have already received extensive prior therapy at the time a transplant is considered. Autologous SCT for low-grade NHL has generally been disappointing with no evidence of cure.¹⁰³⁻¹⁰⁶ However, in a recently published study,¹⁰⁷ patients who responded to three cycles of salvage chemotherapy were randomized to either three more cycles or high-dose therapy with autologous stem cell support. Only 89 patients were randomized; nevertheless, a benefit for transplantation was observed in both progression-free and overall survival, but with no plateau on the survival curve.

Serious complications of autologous SCT for NHL include up to a 20% actuarial risk of myelodysplastic syndrome and acute myelogenous leukemia,¹⁰⁸⁻¹¹¹ and the outcome of those patients is extremely poor.

Allogeneic SCT has been used infrequently in follicular NHL because of an excessive treatment-related mortality.^{112,113} In an analysis of the 81 patients from the International Bone Marrow Transplant Registry,¹¹² transplanted at a median age of 41 years, 56% had never achieved a complete remission and the projected survival at 3 years was 46%, with 43% disease-free

survival. The median follow-up was only 23 months. However, the transplant-related mortality was 44%. Chemosensitivity prior to transplant was the strongest predictor of outcome.

As a result, the long-term outcome of autologous and allogeneic transplants have been comparable because of the early mortality with allogeneic transplants and the late relapses with autologous SCT.^{114,115} More recently, benefit has been suggested for submyeloablative SCT; however, longer follow-up is required to better assess the impact of this therapy.¹¹⁶⁻¹¹⁸

HISTOLOGIC TRANSFORMATION OF FOLLICULAR LYMPHOMA

Patients with a follicular lymphoma have a relatively constant risk over time of transforming into a more aggressive histology, most often a diffuse large B-cell lymphoma.^{16,119,120} The frequency of this occurrence varies among series from fewer than 20%¹⁶ to at least 30%.¹¹⁹ The difference among studies reflects a number of factors, including the duration of follow-up, the definition of what is called “transformed lymphoma,” and the method of surveillance. In studies in which patients had lymph nodes routinely rebiopsied, the likelihood of identifying transformation is greater. Patients with histologic transformation are a clinically diverse group; some exhibit no clinical effects at the time this diagnosis is identified by a lymph node biopsy, whereas others present with the recent onset of fever, sweat, weight

loss, rapidly progressive lymphadenopathy and splenomegaly, and a markedly elevated serum LDH. The outcome of patients with histologic transformation is better in patients identified prior to the development of these signs and symptoms.¹²⁰ In general, aggressive chemotherapy is recommended and, if a complete remission is achieved, autologous SCT is a potentially effective treatment option.¹²¹ Activity has also been reported with radioimmunotherapy.^{84,86}

SUMMARY

After decades of clinical research using various combinations of nonspecific cytotoxic drugs, there is now a wealth of new approaches for patients with follicular NHL. The availability of an expanding menu of novel targeted agents provides great promise for therapeutic advances. These include monoclonal antibodies such as rituximab, radioimmunotherapeutics, anti-idiotypic vaccines, antisense oligonucleotides, and proteasome inhibitors. Clearly, higher complete and overall response rates are achieved with antibody–chemotherapy combinations than with chemotherapy alone; however, whether an eventual prolongation in survival will be achieved remains to be demonstrated by longer follow-up. As there is still no consensus as to the optimal initial therapy, a clinical trial remains the preferred option (Figure 53.1). The potential for cure will result from the rational development of multiple targeted agents with individualized treatment selection based on specific molecular and biologic findings.

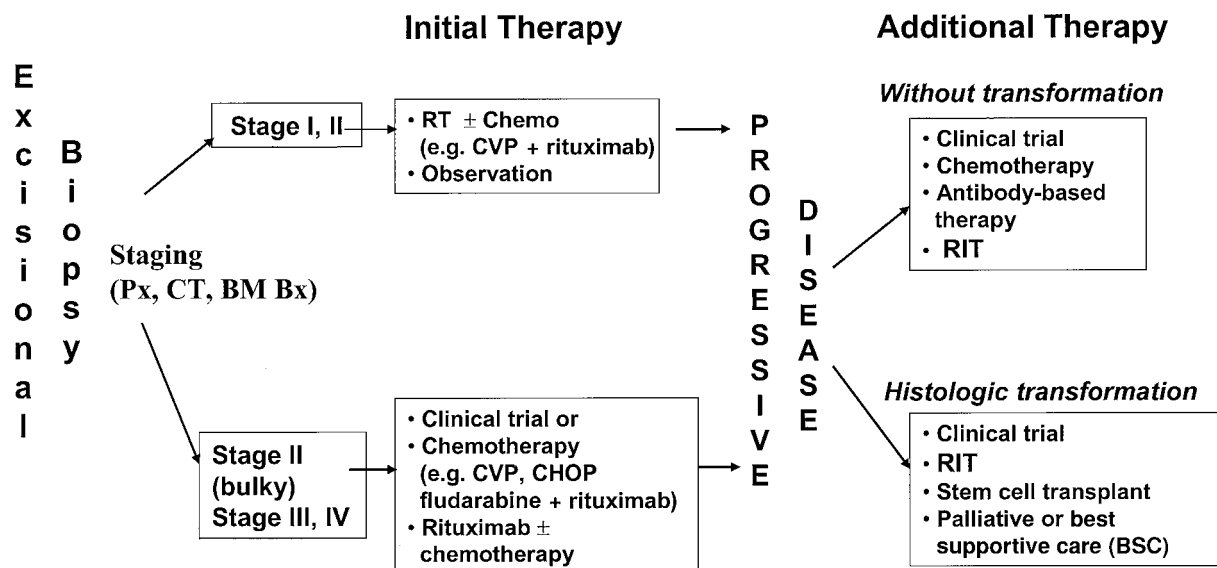

Figure 53.1 Suggested paradigm for the management of patients with follicular NHL

Chapter 54

TREATMENT APPROACH TO DIFFUSE LARGE B-CELL LYMPHOMAS

Sonali M. Smith and Koen van Besien

INTRODUCTION

Non-Hodgkin's lymphoma (NHL) is the fifth most common malignancy in the United States, with 53,400 new cases and 23,400 deaths in 2003.¹ The overall incidence of NHL rose by 80% over the past 3 decades, for reasons that are not entirely clear.^{2,3} Diffuse large B-cell lymphoma (DLBCL) is the most common histologic subtype of NHL. It accounts for almost one-third of cases and is considered the prototype for aggressive lymphomas.

DLBCL is a chemosensitive disease. Approximately half of the patients are cured with front-line anthracycline-based chemotherapy. However, many others will relapse after initial response and become candidates for potentially curative transplantation strategies. Patients with refractory disease, those who relapse following transplant and those who are not candidates for transplantation, have no true curative options and most will ultimately die of lymphoma. The factors determining clinical outcome are increasingly complex, and are discussed in detail below.

INITIAL PRESENTATION

DLBCL may occur in all age groups, but the incidence increases with age. The median age at presentation is 63 years, with a slight male preponderance.⁴ Children with DLBCL comprise only 700–800 cases per year in the United States, and tend to present with widespread disease, high-grade disease, and frequent extranodal involvement.⁵ Most adult patients with DLBCL also present with symptoms. Symptoms may include a rapidly enlarging lymph node, B symptoms (fevers, night sweats, >10% loss of body weight) or other constitutional symptoms, or paraneoplastic syndromes. Approximately 30–40% of the patients have an extranodal site of involvement,^{3,4} and DLBCL can occur in nearly every body site. Several sites merit their own

diagnostic categories in the WHO classification due to unique clinical and/or pathologic features. These include primary effusion lymphoma (PEL), intravascular DLBCL, and primary mediastinal lymphoma (PMBL); PMBL is discussed later. PEL and intravascular large B-cell lymphoma are extremely rare subtypes with a uniformly poor prognosis.⁶ PEL typically occurs in the setting of immunodeficiency and has been clearly linked to human herpesvirus 8 (HHV-8) infection. No mass can be identified, and the malignant cells instead accumulate in body cavities such as the pleural, peritoneal, or pericardial spaces. Intravascular diffuse large B-cell lymphoma is characterized by widely disseminated circulating malignant cells that frequently occlude small vessels. Diagnosis is often delayed due to heterogeneous presentations, and the pathologic features are often not appreciated until the time of autopsy.

DIAGNOSIS AND INITIAL EVALUATION

The diagnosis of DLBCL requires adequate tissue for histologic, flow cytometric, and immunohistochemical studies. Histopathologic examination reveals a diffuse growth pattern of medium- to large-sized cells that replace the normal nodal architecture. Several morphologic variants exist (centroblastic, immunoblastic, T-cell/histiocyte rich, anaplastic)⁶ but do not currently influence initial treatment strategies. The classic immunophenotype of DLBCL is CD20⁺, CD22⁺, CD19⁺, CD79a⁺, and with surface and cytoplasmic immunoglobulin expression in the majority of cases. Less commonly, CD5 or CD10 may be expressed,⁶ necessitating differentiation from other NHL subtypes. Molecular studies such as immunoglobulin gene rearrangement studies may be needed to confirm the diagnosis in cases with weak or absent surface markers or in cases with pleomorphic morphology. Other immunohistochemical stains for markers such as Pax5

and MUM1 can identify a B-cell process and a post-germinal center process, respectively.⁷ Cytogenetics may also be performed on lymph node or bone marrow biopsy samples. Three recurring chromosomal abnormalities have been described: t(14;18) in 30% of cases, 3q27 in 30–40% of cases, and t(8;14) in occasional cases. However, cytogenetic analysis is currently used merely to support a diagnosis of DLBCL and is not used to subclassify the disease or guide treatment.

Once the diagnosis is established, the initial evaluation consists of staging and clinical assessment. The initial staging procedures should include imaging (most commonly CT scan or MRI) of the chest, abdomen, and pelvis, and a bone marrow aspirate and core biopsy. In many centers, bilateral bone marrow biopsies are preferred, but a single biopsy of good quality may be acceptable. An international collaboration suggests that an aggregate bone marrow biopsy of at least 2 cm is sufficient if only one side is sampled.⁸ A test of cardiac function in anticipation of anthracycline-based therapy is usually recommended as well.

Gallium scintigraphy (Ga-67) or positron emission tomography (PET) with ¹⁸fluorine fluorodeoxyglucose provide complementary information. Although neither of these tests is part of the standard response criteria,⁸ they are commonly used to provide a baseline and to aid in the evaluation of residual masses following the end of treatment. Both are extremely sensitive imaging tools that can be used as part of routine staging to evaluate response to treatment, to evaluate residual masses following treatment, and to predict risk of relapse after completion of treatment. Gallium imaging has been used for many years, but, more recently, PET scanning has received increasing interest because of its convenience of use and its greater sensitivity. Several groups have used PET to assess residual masses in Hodgkin's lymphoma and NHL following treatment. It is now fairly well established that residual PET positivity after completion of treatment correlates with an increased risk for recurrence in aggressive lymphoma, and should at the very least lead to increased surveillance for relapse.^{9,10} The optimal management of patients who have residual PET positivity after completion of treatment is not determined. Other studies suggest that PET positivity midway through treatment is a strong predictor for treatment failure.^{11,12} Again, the optimal management of such patients remains undetermined.

In staging patients with newly diagnosed DLBCL, an important question is when to obtain a lumbar puncture and when to consider central nervous system (CNS) prophylaxis. In contrast to high-grade lymphomas such as Burkitt's or Burkitt-like subtypes, the risk of CNS involvement for intermediate grade lymphomas appears to be low at approximately 1–2%.^{13,14} However, CNS relapse carries a grim prognosis and is uniformly fatal with less than 25% of the patients sur-

living the first year following diagnosis.¹⁴ The median time to death following diagnosis is only 5 months.¹³ There are many reports linking clinical risk factors at diagnosis to an increased risk of CNS relapse, including blood and bone marrow involvement, testicular involvement, bulky retroperitoneal disease, sinus involvement, epidural involvement, and elevated lactate dehydrogenase (LDH). Therefore, we have recommended a lumbar puncture as part of the initial evaluation in patients with any of these characteristics.

PATHOLOGIC AND PROGNOSTIC FEATURES

Over the past several decades, DLBCL is increasingly understood to be a heterogeneous disease with widely variable clinical outcomes. The Ann Arbor staging system (Table 54.1) provides a measure of tumor burden, and is an essential, though no longer sufficient, determinant of prognosis and treatment. Approximately 40% of patients present with localized disease (stage I and II) and the rest have disseminated disease at initial presentation.¹⁵ In general, the prognosis of early-stage patients is better than that of patients with advanced disease. Still, the prognosis of individual patients is not accurately predicted by the Ann Arbor stage alone. In 1993, an international task force developed a model, called the International Prognostic Index (IPI), that can be easily implemented for individual patients, using readily available clinical, laboratory, and radiographic features.¹⁵ This study analyzed over 2000 patients receiving anthracycline-based treatment for clinical features potentially predictive of outcome and identified five that retained independent prognostic

Table 54.1 Ann Arbor (Cotswold revision) staging system for malignant lymphomas

Ann Arbor staging for malignant lymphomas	
Stage I	Involvement of a single lymph node region or a lymph node structure of a single extralymphatic site
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm or localized contiguous involvement of an extralymphatic site and lymph node organ
Stage III	Involvement of lymph node regions on both sides of the diaphragm
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement

A: absence of B symptoms

B: presence of B symptoms (fevers, night sweats, weight loss > 10% of body weight)

E: extranodal disease or extension from known nodal site of disease

X: bulky disease (> 1/3 widening of the mediastinum at T5-T6 or maximum size of nodal mass > 10 cm)

Table 54.2 The International Prognostic Index

Adverse factor	Risk group	Number of factors present	5-year DFS (%)	5-year OS (%)
Age > 60 years	Low	0–1	70	73
PS ≥ 2	Low/Intermediate	2	50	51
LDH > Normal	High/Intermediate	3	49	43
Extranodal sites ≥ 2	High	4–5	40	26
Stage III–IV				

significance. These include age ≥ 60 years, tumor stage, B symptoms, serum LDH level, and the presence of more than one extranodal site of involvement. The IPI is essentially a scoring system in which these five clinical features are tallied to categorize patients into one of four prognostic groups that correlate with both relapse-free survival (RFS) and overall survival (OS) (Table 54.2). Moreover, patients with low-risk disease consistently attain complete response more frequently than the patients with higher risk disease. In addition to providing prognostic guidance at an individual patient level, the IPI provides a common language for clinical trials to allow homogeneity when comparing patient groups. For now, the IPI remains the most clinically useful tool to predict prognosis.

Recent research highlights the clinical and molecular heterogeneity of this most common form of NHL even further, via gene expression profiles and microarray technology. Microarray analysis of gene expression involves the simultaneous evaluation of thousands of genes by hybridizing complementary DNA to the mRNA in a cell of interest. In an elegant pilot study by Alizadeh and colleagues,¹⁶ normal and malignant lymphoid cells were analyzed on a “lymphochip” microarray that included nearly 18,000 genes of interest. These genes were all of putative importance in normal B-cell development and/or in the progression to neoplasia. The authors identified two molecular signatures, germinal center B cell like (GC) and activated B cell like (ABC). They then applied the lymphochip to 40 patients with previously untreated DLBCL and compared the genetic signature with the clinical outcome. The OS for all patients at 5 years was 52%; however, the OS for patients with the GC pattern of gene expression was 76% as compared to only 16% for patients with the ABC pattern ($p < 0.01$). Even more powerful is their finding that patients within the low-risk IPI group could be further separated, in terms of prognosis, by the gene expression pattern. In summary, their data suggest that DLBCL comprises at least two distinct diseases differentiated by the expression pattern of hundreds of genes. A larger multicenter study confirms these findings, validates the significance of these two molecular signatures, and identifies a probable third signature (labeled “Type 3”) of genetic importance.¹⁷

Most recently, Lossos and colleagues evaluated 36 genes identified by microarray analysis that predicted

survival.¹⁸ Using quantitative real-time polymerase chain reaction (RT-PCR) in 66 frozen patient samples, they ranked the genes by their ability to predict survival and identified the six most powerful genes: *LMO2*, *BCL6*, *FN1*, *CCND2*, *SCYA3*, and *BCL2*. They then developed a prognostic model based on the weighted expression of these six genes, which is potentially a simpler approach to determine prognosis than is the use of microarrays. It is likely that similar reports will eventually allow further ability to predict survival at an individual patient level using readily available techniques such as immunohistochemistry or flow cytometry. In addition to its potential clinical utility, microarray technology also aids in the understanding of lymphoma biology by identifying genes and genetic pathways that determine growth rate, responsiveness to therapy, or other important clinical parameters.

INITIAL THERAPY OF LOCALIZED DLBCL

Approximately 30–40% of DLBCL patients present with stage I or II disease,¹⁵ often referred to as localized or limited-stage disease. Many localized cases involve extranodal sites with or without regional lymph node involvement. Historically, early-stage DLBCL was treated with irradiation alone. However, this led to unsatisfactory 5-year progression-free survival (PFS) rates of approximately 50% for patients with stage I disease and 20% for patients with stage II disease.^{19–21} A retrospective review with greater than 10 years of follow-up by the British National Lymphoma Investigation with subgroup analysis shows that the elderly fared especially poorly with radiation alone, underscoring the negative prognostic connotation of advanced age and supporting the need for systemic therapy even in clinically localized disease.²²

The most common current strategy is to use combined modality treatment with anthracycline-based chemotherapy followed by radiotherapy. However, the optimal number of chemotherapy cycles is unknown, and several investigators have questioned whether or not radiation therapy (RT) can be eliminated entirely. There are now several phase III studies addressing this issue. A Southwest Oncology Group (SWOG) trial²³ randomized 401 patients with nonbulky stage I and II diseases to cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP) $\times 8$ versus CHOP $\times 3$ plus RT; 75%

of the patients in this series had DLBCL, and 37% had primary extranodal disease. Initial results with a median follow-up of 4.4 years showed that combined modality therapy (CMT) was superior in terms of PFS (77% vs 64%, $p = 0.03$) and OS (82% vs 72%, $p = 0.02$). A recent update, however, shows that the PFS and OS curves of the chemotherapy only arm and the combined modality arm converge at 7–9 years.²⁴

The authors also introduced the application of a stage-modified IPI for early-stage DLBCL. This stage-modified IPI included four components: age >60 years, stage II (as opposed to stage I), increased LDH, and poor performance status. As in the IPI, a point was assigned for the presence of each of these parameters. They found that even apparently localized NHL has widely variable outcomes, and that a stage modified IPI provided important prognostic information. For example, patients with 0–1 risk factor had a 5-year PFS and OS of 77% and 82%, respectively, as compared to only 34% and 45% for patients with more than two risk factors. Using the stage modified IPI, the authors conclude that limited CHOP (three cycles) plus involved field radiation therapy is appropriate for patients with stage I or nonbulky stage II disease, but that patients with adverse risk factors may not benefit from shortened chemotherapy plus radiation.

Another phase III randomized study by the Eastern Cooperative Oncology Group (ECOG) compared CHOP times eight cycles with or without consolidative low-dose radiation (30 Gy) for patients achieving complete remission.²⁵ All partial responders received 40 Gy to residual masses. Nearly two-thirds of patients in this series had stage II or IIE disease. Sixty-one percent of eligible patients achieved a complete remission with CHOP and were subsequently randomized. With a median follow-up of 6 years, patients randomized to radiation enjoyed an improved disease-free survival (73% vs 56%, $p = 0.05$), failure-free survival (75% vs 56%, $p = 0.06$), and time to progression (80% vs 67%, $p = 0.06$). However, there was no difference in OS.

The Groupe d'Etude des Lymphomes de l'Adulte (GELA) also addressed the ability to eliminate RT entirely in a group of elderly patients with minimal risk factors.²⁶ In this study, presented in abstract form, 455 eligible patients older than 60 years were randomized to CHOP times four cycles with or without 40-Gy RT. All patients had good prognosis disease. In the preliminary presentation of this trial, there is no difference in event-free survival (EFS) or OS with 49 months median follow-up. Furthermore, in patients older than 69 years, radiotherapy actually increased toxicity. The authors suggest that CHOP times four cycles may be sufficient for this favorable subgroup.

In summary, combined modality therapy with limited cycles of anthracycline-based chemotherapy has been the accepted standard treatment for patients with limited-stage DLBCL. Newer information, such as the lack of a survival benefit with continued follow-up and

the potential to cure patients with prolonged chemotherapy, is challenging the role of radiation. Mature follow-up and final publication of the randomized controlled trials mentioned above are certain to guide future treatment selection. Our standard approach is to deliver three or four cycles of CHOP-rituximab (CHOP-R) chemotherapy followed by involved field radiation for patients with minimal risk factors (i.e., stage I or nonbulky stage II), and to deliver six cycles of CHOP-R for others with early-stage DLBCL. The results of the GELA study suggest that involved field radiation may not be necessary or beneficial for all patients. This study has only been reported in abstract form, and until its definitive publication, our treatment recommendations are not guided by its results. More recent data regarding the use of rituximab in patients with DLBCL will be discussed below.

INITIAL THERAPY OF ADVANCED DLBCL

Nearly 3 decades ago, CHOP chemotherapy was introduced: cyclophosphamide 750 mg/m² on day 1, adriamycin 50 mg/m² on day 1, vincristine 1.4 mg/m² on day 1 (maximum 2 mg), and prednisone 100 mg daily on days 1–5.²⁷ This early report, in the era prior to routine radiographic follow-up, demonstrated a previously undescribed overall clinical response rate of over 90% in a heterogeneous group of lymphoma patients. It quickly became the standard against which other regimens were measured. During the subsequent 2 decades, alternative combinations were proposed that appeared more intense and more effective than CHOP in phase II and/or single institution studies. These include combinations such as m-BACOD (low-dose methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, dexamethasone), ProMACE-CytaBOM (prednisone, doxorubicin, cyclophosphamide, etoposide alternating with cytarabine, bleomycin, vincristine, and methotrexate), and MACOP-B (methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin) among others. However, a definitive phase III, randomized, controlled trial conducted by the SWOG and the ECOG demonstrated that CHOP was equally efficacious and less toxic than these second-generation regimens.²⁸ Specifically, 899 eligible patients with bulky stage II, stage III, or stage IV aggressive lymphomas were randomized to either CHOP, m-BACOD, ProMACE-CytaBOM, or MACOP-B. There was no significant difference in either EFS (44% at 3 years) or OS (52–54% at 3 years). Furthermore, CHOP had the lowest number of deaths due to toxicity. With 6 years of follow-up, the PFS and OS curves continue to overlap for all treatment groups.²⁹ CHOP remained the gold standard during most of the nineties. A recent meta-analysis of nearly 2000 patients enrolled on randomized controlled trials of CHOP versus second-generation

regimens confirms these findings as well.³⁰ The authors report that newer regimens did not confer a statistically significant survival advantage at 5 years as compared to CHOP.

But several recently published randomized studies show that some dose-intensive regimens are indeed superior to CHOP and constitute one of the several exciting developments in the treatment of lymphoma. Promising strategies include the addition of targeted therapies to CHOP, the addition of other chemotherapeutic agents to CHOP, shortening the cycle length to increase dose intensity, and the use of infusional chemotherapy that allow dose escalation. The use of hematopoietic growth factors such as filgrastim and peg-filgrastim has substantially facilitated dose intensification in the modern era. Also, the IPI or similar prognostic models are routinely used in patient selection for recent trials. It is typically patients with high IPIs that are assigned to more dose-intensive strategies, and such patients may be destined to benefit more.

RITUXIMAB IN DLBCL

Perhaps the most radical change in the treatment of aggressive lymphomas has been the addition of the monoclonal antibody, rituximab. Rituximab is a murine/human chimeric monoclonal antibody against the CD20 antigen present on both normal mature and malignant B cells. The function of CD20 is unknown, but the binding of rituximab to its target leads to cell death via antibody dependent cell-mediated cytotoxicity, complement dependent cytotoxicity, and apoptosis. Rituximab has an excellent safety profile, with the most common adverse events (flushing, rash, pruritus, hypotension) being limited to the duration of infusion. Rarely, anaphylaxis has been described. Several phase II studies showed that rituxan had modest single agent activity in large cell lymphoma.^{31,32} On the basis of *in vitro* data suggesting that rituximab sensitizes cells to chemotherapy, several groups have pursued front-line therapy in combination with CHOP and reported promising response and survival rates.^{33,34} A pivotal phase III study performed by a French–Belgian cooperative group, the GELA, confirmed these promising findings.³⁵ This multicenter, randomized controlled trial compared CHOP versus CHOP-R in 399 patients older than 60 years with DLBCL. The median age was 69 years and nearly 90% of patients had diffuse large B cell as the presenting histology. The original report, with 2-year follow-up, showed CHOP-R to be superior in terms of complete remission rate (76% vs 63%, $p = 0.005$), 2-year EFS (57% vs 38%, $p < 0.001$), and 2-year OS (70% vs 57%, $p = 0.007$). Longer follow-up of 3 years continues to demonstrate an advantage for patients receiving rituximab: EFS 53% versus 35%, $p = 0.00008$ and OS 62% versus 51%, $p = 0.008$.³⁶ The GELA study was the first randomized study of large cell lymphoma in more

than 10 years to show an advantage for the investigational arm. This, as well as the extremely favorable safety profile for rituximab, resulted in a great degree of enthusiasm and widespread adoption of the CHOP-R regimen as the new standard.

More recent studies have confirmed these promising results in other subgroups of patients, such as those with early-stage disease and those younger than 60 years. In addition, considerable attention was devoted to an analysis of rituximab's contribution to clinical outcome by the British Columbia Cancer Agency.³⁷ Due to governmental regulation, rituximab was not approved for use in front-line aggressive lymphomas in British Columbia, until March 2001. Sehn and colleagues thus compared the 18-month survival of 142 patients treated prior to this date to 152 patients treated after this date. Only 9% of the patients treated for DLBCL prior to March 2001 had received rituximab with CHOP, and only 15% of the patients treated for DLBCL after March 2001 had not received rituximab. The results show an impressive improvement in PFS in the rituximab era in both elderly and young patients.

More recently, the enthusiasm over CHOP-R has been tempered somewhat by the results of a multicenter phase III randomized controlled trial in the United States. In this intergroup study, over 600 older patients with DLBCL were randomized to CHOP with or without rituximab.³⁸ The rituximab was scheduled to be given on five occasions during six cycles of CHOP therapy; in addition, a second randomization with maintenance rituximab (375 mg/m² weekly times four doses, repeated every 6 months times four) was incorporated. With a median follow-up of almost 3 years, there was no significant difference in overall response rate or OS. However, patients receiving rituximab, either as part of CHOP or as part of maintenance, enjoyed a prolonged time to treatment failure. Rituximab maintenance did not further improve time to treatment failure (TTF) in patients who had already received rituximab with their CHOP chemotherapy. There is considerable debate over how to interpret these results. Some claim that the study was flawed because of an insufficient intensity of rituximab administration. Others argue that the benefits of rituximab may not be as great as originally thought.

Finally, there may be subsets of patients who benefit to a greater magnitude with rituximab. In a follow-up analysis of the GELA data, Mounier and colleagues report that CHOP-R confers an improved OS in patients with bcl-2 overexpression (67% vs 48%, $p = 0.004$) but not in patients lacking bcl-2 overexpression (72% vs 67%, $p = \text{NS}$).³⁹ They also show that the benefit of rituximab is greater in patients with a low IPI score than in patients with higher-risk disease. Finally, some data suggest that genetic polymorphisms in the Fc γ IIIA receptor of lymphocytes predicts for inherent sensitivity versus resistance to rituximab.^{40,41}

Thus, the optimal incorporation of rituximab into existing therapies continues to be refined. All in all, it appears that the addition of rituximab improves the outcome of patients with large cell lymphoma with minimal toxicity. Despite remaining questions about the magnitude of its effect in specific subgroups of patients, it is likely to be widely used.

DOSE INTENSIFICATION

The GELA recently published results of a multicenter prospective phase III study comparing CHOP to a second-generation regimen that was initiated in 1993.⁴² Over 600 older patients were randomized to either ACVBP (intensified doxorubicin, intensified cyclophosphamide, vindesine, bleomycin, prednisone, intrathecal methotrexate) or standard CHOP treatment. All patients received growth factor prophylaxis. The complete remission rates did not differ between the two groups, and ACVBP was associated with a significant increase in hematologic and non-hematologic toxicity and treatment-related deaths. But with a median follow-up of 68 months, the ACVBP patients had a longer EFS (39% vs 29%, $p = 0.005$), longer disease-free survival (62% vs 44%, $p = 0.0002$), and an improvement in OS (46% vs 38%, $p = 0.036$) at 5 years. This study was conducted at the same time as the influential, but negative, SWOG randomized study comparing CHOP to second-generation regimens. Explanations for these discrepant results include the possibility that the ACVBP regimen is superior to the investigational regimens tested in the SWOG study, or that patient selection was more geared to patients with advanced disease in the GELA study.

VARIATIONS IN CYCLE LENGTH WITH DOSE INTENSIFICATION OF CHOP

The original cycle length of 21 days for CHOP was based on the average time needed for hematopoietic recovery. However, the introduction of effective hematopoietic stem cell growth factors such as filgrastim, sargramostin, and peg-filgrastim allow a shortening of cycle length with the goal of increased drug intensity. A phase II SWOG study demonstrated that the drugs in CHOP could be both intensified (CHOP-DI) and the cycle duration could be shortened safely in a group of over 100 patients with aggressive and high-grade lymphomas.⁴³ CHOP-DI led to an improved OS at 5 years as compared to a historical control group; however, the main endpoint of the study was PFS, and no difference between the CHOP-DI patients and historical control patients could be demonstrated.

Two large German multicenter phase III randomized studies (NHL-B1 and NHL-B2) also address the issue of cycle shortening with or without the addition of etoposide to CHOP. The design for each study was a four-armed randomized (2×2 factorial) controlled trial in both younger (18–60 years) and older (61–75

years) patients.^{44,45} The following regimens were delivered for a total of six cycles: CHOP-21 (the standard arm), CHOP-14, CHOEP-21 (CHOP with addition of etoposide 100 mg/m² on days 1 through 3), and CHOEP-14. All patients on the shortened cycle arms received growth factor support whereas for the 3-weekly regimens the growth factor support was at the physician's discretion. The NHL-B2 trial for older patients included both favorable prognosis patients (defined by normal LDH at diagnosis) and unfavorable prognosis patients (defined by an increased LDH at diagnosis). By contrast, the NHL-B1 study for younger patients included only favorable prognosis patients. Young patients with elevated LDH were enrolled on a competing trial. The NHL-B2 trial for older patients randomized 689 patients and, with a median follow-up of 58 months, shows that CHOP-14 significantly improved the EFS and OS compared with CHOP-21. The addition of etoposide did not improve these endpoints, and, when given in an every 14-day schedule, substantially increased the hematologic and non-hematologic toxicity. In the NHL-B1 study for young patients, shortening the cycle length did improve the OS at 5 years. The addition of etoposide substantially improved the complete response rate and the EFS; in contrast to the trial in older patients, CHOEP-21 and CHOEP-14 were successfully delivered without excessive toxicity. The authors suggest that CHOEP should be the preferred regimen for this population. However, these trials were designed before the routine addition of rituximab, and it remains to be seen if rituximab is able to overcome the need to intensify CHOP, either with or without etoposide.⁴⁶

INFUSIONAL REGIMENS

Another means of intensifying CHOP is the use of infusional administration. Infusional regimens are based on the premise that prolonged exposure of anti-neoplastic agents breeds less drug resistance as compared to brief, but higher, doses of chemotherapy. The infusional regimen EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, adriamycin) is highly active in aggressive lymphomas. It was first tested in a group of relapsed and refractory patients, all of whom had failed front-line CHOP-like regimens.⁴⁷ Despite the fact that all patients had previously received these same agents, the overall response rate exceeded 70% in patients with aggressive lymphomas. Furthermore, the authors discovered significant variability in serum drug concentrations between patients. This formed the basis for their subsequent investigation of dose-adjusted EPOCH (DA-EPOCH) in which chemotherapy drug doses are escalated or de-escalated each cycle based on the neutropenic nadir and neutropenic duration during the previous cycle; this type of patient-specific therapy could theoretically allow maximal use of each agent. In a group of 49 evaluable patients with previously untreated DLBCL, 92% achieved a complete

response, and there was a PFS of 70% and OS of 73% at 5 years.⁴⁸ Most recently, the addition of rituximab to DA-EPOCH was tested in a cooperative group setting. DA-EPOCH-R will be the investigational arm in a large, randomized, prospective Cancer and Leukemia Group B study for advanced lymphoma.

AUTOLOGOUS TRANSPLANTATION AS CONSOLIDATION TREATMENT IN NEWLY DIAGNOSED PATIENTS IN FIRST REMISSION

Transplantation in DLBCL is usually reserved for relapsed patients, but many have investigated its role in consolidation of response to first-line regimens. The results appear to be highly dependent on patient selection and timing of transplantation. Two prospective randomized trials evaluated autologous transplantation in patients with a slow response (i.e., less than a complete remission) to standard front-line regimens.^{49,50} A randomized Dutch study assessed 106 patients with previously untreated intermediate grade lymphoma receiving CHOP chemotherapy.⁴⁹ After three cycles, 69 patients had achieved a PR and were randomized to receive either three more cycles of CHOP or to proceed to an autologous stem cell transplantation. The authors found no advantage of high-dose chemotherapy with autologous transplantation over CHOP in terms of overall response rate, EFS, disease-free survival, or OS. The Italian study compared either DHAP (dexamethasone, cytarabine, cisplatin) versus high-dose chemotherapy with BEAC (carmustine, etoposide, cytarabine, cyclophosphamide) and autologous stem cell transplant in partial remitters following two-thirds of an anthracycline-containing regimen.⁵⁰ However, only 49 patients were randomized, which was insufficient to detect a statistically meaningful difference between the two arms. A third prospective randomized study, performed by the German High-Grade non-Hodgkin's Lymphoma Study Group, evaluated the role of high-dose chemotherapy in patients achieving at least a minor response following two cycles of CHOEP (CHOP plus etoposide) as compared to three more cycles of CHOEP followed by involved field radiation.⁵¹ It also failed to identify an advantage of transplantation following abbreviated induction. Furthermore, even patients with high-intermediate and high-risk lymphoma did not appear to benefit from early transplant in this trial.

In contrast, the French-Belgian LNH87-2 trial retrospectively applied the IPI and identified 236 high-intermediate and high-risk patients who were randomized to either more chemotherapy or autologous transplantation after achieving complete remission.⁵² Both DFS and OS favored the autologous arm (55% vs 39%, $p = 0.02$; and 64% vs 49%, $p = 0.04$, respectively) in these higher risk subgroups. A study from Milan also evaluated the benefit of autologous transplantation as part of initial treatment for

patients with adverse prognostic features (stage III/IV disease and large tumor bulk) in a prospective randomized trial.⁵³ This study was restricted to patients with classic DLBCL (no discordant lymphomas) and those without bone marrow involvement. With a median follow-up of 55 months, they found significantly improved CR rates, FFP, RFS and EFS, and borderline improved OS for those undergoing autologous transplantation compared to the control group who received MACOP-B. The most recent study in favor of consolidative autologous transplant in first remission was published by the GOELAMS in 2004.⁵⁴ Nearly 200 consecutive eligible patients were randomized to receive either standard CHOP for 8 cycles, or CEEP (cyclophosphamide, epirubicin, vindesine, prednisone) for 2 cycles followed by high dose methotrexate/cytarabine, and BEAM (BCNU, etoposide, cytarabine, melphalan) with autologous stem cell transplant. Patients randomized to the transplant arm enjoyed a prolonged PFS, but there was no statistical advantage in terms of complete remission rate or OS except for the high intermediate IPI risk group in which the transplant arm enjoyed a superior OS (74% vs 44%, $p = 0.001$). The authors conclude that high intermediate IPI risk group patients should receive an autologous transplant as part of front-line therapy.

In summary, the role of autologous transplantation as part of initial management in aggressive lymphomas remains unclear. A meta-analysis of 11 randomized trials concludes that there may be a benefit to transplant for patients with high-risk disease, who are younger and who are transplanted in complete remission.⁵⁵ It should be emphasized that none of the above studies included rituximab and that this may influence the outcome. Certain subgroups, such as those with intermediate and high-intermediate IPI scores, may derive benefit when transplanted in first complete remission, whereas a recent randomized multi-institutional investigation by the EORTC has convincingly shown that high-dose chemotherapy and autologous transplantation in first remission does not confer benefit for patients with low or low-intermediate IPI scores.⁵⁶ Autologous transplantation after shortened induction regimens and for patients in partial remission seems not to be of benefit. Dose intensification continues to be investigated in an ongoing intergroup randomized study in the United States.⁵⁷

CNS PROPHYLAXIS

It is not clear which, if any, subgroup of patients should receive CNS prophylaxis and exactly what that prophylaxis should consist of. Although the IPI correlates with a higher incidence of CNS recurrence, even patients with low-intermediate risk disease may have CNS relapse.⁵⁸ A French group has shown that CNS prophylaxis with systemic and intrathecal methotrexate

may decrease the incidence of CNS relapse compared with reported incidence in the literature,¹³ but most investigators agree that prospectively designed studies delineating the optimal prophylactic and treatment strategy are still needed.

OUR CURRENT APPROACH TO TREATMENT OF DLBCL

Patients with early stage (I–II) disease are treated with CHOP-R for three to six cycles, depending on the stage-adjusted IPI. Those with 0–1 risk factors are given three cycles of CHOP-R followed by radiation. This is generally a very well-tolerated approach. For those with a stage-adjusted IPI >1, we prefer to administer six cycles of chemotherapy with CHOP-R. Radiation therapy is not routinely administered for such patients, but is considered for those with residual masses, especially if those masses are PET positive.

Patients with advanced disease are staged with CT scans and a bilateral bone marrow biopsy. We include a PET scan in our initial staging work-up and will routinely restage patients after four cycles of treatment. Modifications in treatment strategy will be considered for those with residual PET positivity after four cycles. A lumbar puncture is a part of the staging work-up for those with IPI greater than 2, those with testicular lymphoma, those with lymphoma in the head and neck area, and those with large cell lymphoma in the bone marrow. We currently do not have guidelines for prophylactic intrathecal treatment. Our patients with advanced stage lymphoma are treated with CHOP-R for six cycles at 21-day intervals. We will consider CHOP-R-14 with G-CSF support for patients with an increased LDH. We do not usually recommend autologous transplant in first remission, unless there is major concern for residual disease after completion of treatment, usually based on the presence of residual PET positivity. Our recommendations are admittedly somewhat guided by empiricism. Continued accrual to prospective studies is indicated, especially for patients with unfavorable prognostic features.

PRIMARY MEDIASTINAL B-CELL LYMPHOMA

Primary mediastinal B-cell lymphoma (PMBL) is a distinct subtype of diffuse large cell lymphoma originating from thymic B cells. It was first described nearly 25 years ago^{59,60} and is now recognized as a unique entity based on clinical, immunophenotypic, and genotypic features. PMBL accounts for approximately 5% of all aggressive lymphomas and affects mainly young adults. The median age at presentation is in the third decade, with a slight female predilection. Most patients present with significant symptoms, including

shortness of breath, superior vena cava syndrome, phrenic nerve palsy, cough, or chest pain, all due to local aggressiveness and invasion of other mediastinal and thoracic structures. Up to 80% of patients have disease limited to the thorax at presentation⁶¹; the bone marrow is only rarely involved. Despite their young age and apparently localized initial presentation, only a third of patients are alive at 5 years, and recurrences typically involve distant extranodal sites such as the kidney or CNS.

Histologic examination reveals a massive diffuse proliferation along with significant fibrosis. Similar to other DLBCLs, PMBL expresses CD19, CD20, and CD45 with variable expression of surface immunoglobulin and HLA molecules. Cytogenetic analysis shows several recurring abnormalities: gains of chromosome 9p in 50% of cases,⁶² trisomy 12q31 in 31% of cases, and trisomy 2p in occasional cases.⁶³ Molecular features include amplification of the *rel* gene and overexpression of the *mal* gene, with absence of *bcl-2*, *bcl-6*, and *myc* expression. Recently, the gene expression pattern via microarray analysis of PMBL was shown to more closely resemble Hodgkin's lymphomas rather than NHLs.⁶⁴ The clinical implications of this finding are yet to be defined, and PMBL continues to be treated similar to other DLBCLs.

In addition to unique epidemiologic and pathologic features, PMBL presents its own treatment challenges. Despite the initial supradiaphragmatic localization, there is difficulty in assigning patients a stage. Some consider PMBL to be stage II, whereas others feel that IVE is more appropriate due to invasion of mediastinal or intrathoracic structures.⁶¹ This could lead to heterogeneity when comparing patient populations between trials and published reports. Regardless of the staging, a full course of anthracycline-based treatment is initially offered, similar to advanced stage, aggressive lymphomas. However, up to a third of patients have primary refractory disease, and consolidative measures should therefore be considered. Mediastinal irradiation to the primary mass is commonly used. A report from the MD Anderson Cancer Center suggests that RT prevents local relapse,⁶⁵ a finding supported by several European studies.^{66,67} In a multicenter Italian study, patients remaining gallium avid after MACOP-B converted to gallium negative after consolidative RT and few patients relapsed. However, other authors have shown that RT adds little to disease control. Lazzarino and colleagues retrospectively reported on 99 evaluable patients and found that the relapse rate did not significantly differ between patients receiving RT and those who did not.⁶¹ Furthermore, 11 of 12 relapses in the RT group were intrathoracic. A French group reported that patients achieving only a PR to front-line chemotherapy did not further respond to RT.⁶⁸ High-dose chemotherapy followed by autologous stem cell rescue in first remission has also been proposed, with very promising phase II data.⁶³

At relapse, patients with PMBL are considered for autologous stem cell transplantation. In general, this population may do better as compared to the general group of aggressive lymphoma patients, partly due to their younger age and partly due to less common bone marrow involvement. Popat and colleagues⁶⁹ report a series of patients with recurrent or refractory DLBCL treated with high-dose chemotherapy and found that having PMBL was a favorable prognostic feature. Sehn and colleagues⁷⁰ also performed a retrospective analysis of 35 patients with PMBL treated with high-dose cyclophosphamide, carmustine, and etoposide (CBV) plus autologous bone marrow transplant (ABMT). Patients with primary refractory disease had 58% long-term disease-free survival and patients with relapsed disease had 27% long-term disease-free survival. The strongest predictor of PFS was chemotherapy responsiveness immediately before transplant. But even in chemo-therapy-refractory patients, 33% long-term survival was observed.

TREATMENT OF RELAPSED AND REFRACTORY DLBCL

More than half of all DLBCL patients initially entering remission with combination chemotherapy will relapse. The standard treatment approach for such patients is to deliver salvage chemotherapy followed by consolidative autologous stem cell transplantation in patients demonstrating chemosensitivity.^{71a} Patients with chemorefractory disease and patients relapsing following an autologous stem cell transplant have an overall poor prognosis and should be considered for allogeneic stem cell transplantation or for clinical trials with investigational agents. The role of autologous and allogeneic transplant in the management of relapsed and refractory aggressive lymphomas is discussed elsewhere in chapters 64 and 65.

The optimal salvage regimen is not known, and there are no phase III, prospective, randomized trials comparing various combinations. Most of the data is from phase II trials, and the choice of treatment is often influenced by both patient features and physician preferences. Some commonly used regimens include DHAP,^{71a} ESHAP^{71b} (etoposide, methylprednisolone, cytarabine, cisplatin), ICE⁷² (ifosfamide, carboplatin, etoposide), IE⁷³ (ifosfamide, etoposide), MINE^{73,74} (mesna, ifosfamide, mitoxantrone, etoposide) and EPOCH^{48,75} (etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin), among others. The DHAP regimen is one of the first salvage regimens to be designed. In the Parma trial, patients with relapsed lymphomas receiving DHAP had an overall response rate of 58%, but the 5-year EFS and OS of patients not subsequently transplanted were only 12% and 32%, respectively.^{71a}

Ifosfamide-based regimens are gaining in popularity, partly due to the ability to dose-escalate the ifos-

famide, and also because they are excellent stem cell mobilizing regimens.^{72,73} Overall response rates are over 60%, although the complete response rate is only 24%.⁷³ The major advantage to improving salvage regimens is to demonstrate chemosensitivity, since this is arguably the most crucial characteristic-determining outcome following autologous stem cell transplantation in aggressive lymphomas. Of the ifosfamide-based salvage regimens for aggressive lymphomas, extensive data have been published on the ICE (ifosfamide, carboplatin, etoposide) regimen developed at the Memorial Sloan Kettering Cancer Center (MSKCC).⁷³⁻⁷⁸ In an initial publication, investigators at MSKCC treated 163 consecutive transplant-eligible patients with relapsed or refractory aggressive NHL with 3 cycles of the ICE regimen. The overall response rate was 66%, allowing 89% of patients to proceed to a planned autologous stem cell transplant. There was minimal nonhematologic toxicity, although a third of patients had greater than grade 3 thrombocytopenia. All patients received growth factor support during each cycle of treatment. There are several other high-dose ifosfamide-based regimens that are in widespread use,^{72,73} and all appear to be effective at stem cell mobilization. However, despite high activity, none of these regimens are curative unless followed by a consolidative transplant procedure.

The addition of rituximab to salvage regimens appears to substantially improve the response rate. For example, Kewalramani and colleagues show that the overall response rate and complete response rate increases to 81% and 55%, respectively, when adding rituximab to the ICE regimen.⁷⁹ Although not specifically demonstrated for large cell lymphoma, rituximab also serves as an “in vivo purge” during stem cell collection^{80,81} and is likely to be an important component of most pretransplant salvage regimens for CD20-positive malignancies.

There are a multitude of promising investigational agents being pursued for the treatment of lymphomas. These include proteasome inhibitors (bortezomib or Velcade), anti-Bcl-2 agents (oblimersen sodium or Genasense), antiangiogenic agents, liposomal formulations of standard chemotherapeutic agents (liposomal vincristine, liposomal doxorubicin), newer monoclonal antibodies (epratuzamab), and radiolabeled monoclonal antibodies (ibritumomab tiuxetan or Zevalin, tositumomab or Bexxar). Phase II and III studies are ongoing, and several of the most active agents in preliminary studies are being incorporated into front-line regimens.

SUMMARY

Significant advances in our understanding of DLBCL have been made in the past decade. Assessment of prognosis by use of the IPI is now in widespread use

and facilitates treatment decisions. More recently, microarray technology has refined our ability to formulate prognosis, has generated interesting hypotheses regarding the biology of the disease, and will hopefully allow the design of better treatment strategies for the various subgroups in the near future. DLBCL is a largely chemosensitive disease, and CHOP chemotherapy has long represented an acceptable standard. But relapses are still common and salvage regimens and transplantation are impor-

tant components of treatment for relapsed disease. The impact of the monoclonal antibody, rituximab, in both front-line and relapsed regimens is encouraging, and may change the long-term outcome of this disease. Recent data also has revived interest in dose intensity as a further way of improving treatment for large cell lymphoma. Ongoing research and development of new agents is critical, and the next decade promises to provide even more effective options for our patients.

Chapter 55

TREATMENT APPROACH TO MANTLE CELL LYMPHOMA

Ellie Guardino, Kristen N. Ganjoo, and Ranjana Advani

INTRODUCTION

Mantle cell lymphoma (MCL) is a distinct entity of lymphoma in the WHO classification¹ and represents approximately 5–6% of all non-Hodgkin's lymphomas.² The incidence of MCL is 2–3 per 100,000/year and occurs with at a median age of 65 years. Classical nodal and extra-nodal MCL is associated with overexpression of Cyclin D1 from the presence of the t(11;14) (q13; q32) translocation juxtaposing the *BCL1* gene and the immunoglobulin heavy chain locus.^{3–5} MCL exhibits a strong tendency toward extranodal involvement, especially the gastrointestinal tract,⁶ bone marrow, and spleen. The approach to staging is similar to aggressive lymphomas, and also includes colonoscopy due to a high incidence of lower GI tract involvement.⁷ MCL has moderate chemosensitivity, with complete responses to conventional chemotherapy ranging from 20% to 60%.^{8–10} Despite this, the disease has a dismal outcome and tends to recur following conventional therapy, with a median survival of 3 years.^{11–13}

HISTOLOGY

MCL comprises a group of lymphoma subtypes previously classified as centrocytic lymphoma, lymphocytic lymphoma, or diffuse small-cleaved cell lymphoma.^{14–16} Two morphologic subtypes of MCL are now classified: classic or typical MCL, which comprises 90%, and the blastoid variant, which is found in 10% of cases.¹⁵ The malignant cell type of the classic or typical MCL is composed of morphologically small- to medium-sized lymphocytes with irregular nuclei and condensed chromatin, while the blastoid variant resembles lymphoblasts with medium size rounded nuclei, dispersed chromatin, and scant cytoplasm.¹⁶ The blastoid variant has a high mitotic index compared to the classic MCL and has a worse prognosis than the classic form, with a median survival of <2 years.¹⁷ Architecturally, three different patterns are recognized: mantle-zone pattern with the malignant cells

surrounding normal germinal centers, nodular pattern, and diffuse pattern with loss of germinal centers.

IMMUNOPHENOTYPE

MCL is thought to arise from naïve pregerminal center B cells in the primary follicles or mantle zone of secondary follicles. It has an immunophenotype of a mature B cell,^{15,16,18–21} expressing CD19, CD20, CD22, CD79A, IgM, and/or IgD. MCL express lambda light chain more often than kappa light chain. Additionally, these malignant cells are CD5⁺, CD43⁺, but CD23⁻, and CD10⁻, which differentiates them from chronic lymphocytic leukemia. Most cases display an unmutated immunoglobulin chain locus.^{22,23} Recent studies have now shown that 25–30% of MCL carry mutations in the IgV_H, a feature of postgerminal center cells.^{22,24,25}

Some patients may present with peripheral lymphocytosis with a t(11;14) translocation, extra-nodal disease, and may have a different clinical course than that for classical MCL. In a study that looked at the clinical course in 80 MCL patients with circulating t(11;14) lymphocytes, IgV_H genes were unmutated in 90% of nodal MCL patients, while only 44% of the extra-nodal patients had unmutated IgV_H genes.²⁶ Interestingly, long-term survivors in this study were all found in the extra-nodal group with IgV_H gene mutation. The authors suggested that mutated IgV_H genes found in the extra-nodal asymptomatic MCL group may be of use to identify patients who have more indolent disease and for whom early intensive treatment is not indicated. Further studies are warranted before adopting this management approach for extra-nodal MCL.

GENETICS/CYTOGENETICS

MCL is associated with the t(11;14)(q13;q32) the ataxia telangiectasia mutation and the 11q deletion. The t(11;14) juxtaposes the Cyclin D1 gene to the B-cell immunoglobulin transcription enhancer, which

results in the overexpression of Cyclin D1.¹⁶ This results in deregulation of the G1 phase of the cell cycle. While Cyclin D1 overexpression is a hallmark of MCL, it is also observed in a variety of other hematologic and nonhematologic malignancies, and the precise role that Cyclin D1 overexpression plays in the development of MCL is not understood. This translocation is found in more than 95% of MCL cases. Up to 50% of the breakpoints on 11q13 occur within a restricted area called the major translocation cluster, and this region is used to amplify genomic DNA by PCR as a diagnostic method. Using the PCR assay as a molecular diagnostic tool for MCL detects the rearrangement in only 35% of patients.¹⁶ New PCR methods are being investigated that examine the Cyclin D1/Cyclin D3 ratio by real-time PCR, and these have shown improved specificity for the diagnosis of MCL.²⁷ PCR has also been used for molecular follow-up studies of MCL.^{16,28}

Fluorescence in situ hybridization (FISH) can show the t(11;14) translocation with a greater sensitivity of >95%. Another benefit of FISH is that it can be performed on archival cytologic material.²⁹

Additional diagnostic approaches for MCL are under investigation. Microarray data suggests that there may be a disease-specific signature, including signatures for apoptosis, cell cycle, and cell signaling.³⁰ Transgenic animal studies have shown that CCND1 gene overexpression alone cannot induce lymphoma and that other oncogenic factors, such as c-myc, are needed.³¹ Cyclin D1 overexpression is the only one mechanism responsible for deregulating the G1 phase of the cell cycle in MCL. Other mechanisms include hypermethylation and inactivation of p16^{INK4a}, TP53 mutations, and loss of p27^{Kip1}.^{32–35} Microarray analysis has shown that MCL exhibits alterations in the expression of apoptosis-related molecules, with an overall pattern of antiapoptosis³⁶ and a low MCL apoptotic rate.³⁷ In addition, MCL cells have been shown to express low or absent levels of Fas and thus may have prolonged survival.³⁸ Additionally, the myeloid cell leukemia 1 (*Mcl-1*) gene, a member of the *BCL-2* gene family, and its protein product promotes cell survival and *Mcl-1*-positive MCL tumors have been shown to have a higher frequency of blastoid/large-cell morphology, and higher Ki67 immunolabelling.³⁹ Using RNA expression profiling, Rosenwald et al. have identified a set of 48 genes that stratify MCL patients into subsets that differ by more than 5 years in median survival.⁵ These recent elucidations in the biology of this disease, we hope, will in turn result in better diagnostics, prognostics, and treatments for MCL.

PROGNOSTIC FACTORS

Tumor-associated prognostic features are related to the morphologic pattern—the mantle zone variant tends to behave more indolently while the blastoid variant is

aggressive.⁴⁰ Clinical prognostic factors for MCL include poor performance status, anemia, splenomegaly, and advanced age.²³ Mutations in p53, abnormalities in the CDK inhibitors p16–p21, a high Ki67 staining index, unmutated IgV_H gene, elevated β2M, and overexpression of topo IIα are all usually associated with aggressive behavior.

TREATMENT APPROACHES

Prognosis remains poor in MCL, and patients who respond to treatment usually relapse. There is currently no standard treatment for the disease. Conventional treatment of MCL results in response rates of 20–60%. The disease invariably recurs and the median survival in this disease is approximately 3 years. Therapeutic options are continually being refined as the clinical methods of classifying MCL evolve and as the biology elucidates the histologic and cytogenetic characteristics of MCL subtypes.

CHEMOTHERAPY

Currently, the initial treatment for MCL is similar to that for other aggressive lymphomas. An anthracycline-based approach is the standard even though randomized clinical studies have not proven a survival advantage with anthracycline-containing regimens over nonanthracycline-containing regimens.^{41–43} Meusers and colleagues reported the results of a randomized study comparing CVP (cyclophosphamide, vincristine, and prednisone) to CHOP (cyclophosphamide, adriamycin, vincristine, and prednisone) chemotherapy in 63 MCL patients.⁴² No significant difference was found in response rate and overall survival (OS). A second randomized study compared two anthracycline-containing regimens with CVP.⁴¹ The response rate was better with the anthracycline regimens, but the median survival was equal in both groups. A third randomized study compared PmM (prednimustine, mitoxanthrone) with CVP.⁴³ The response rate and the event-free survival (EFS) were better with PmM, but the median overall response rate (ORR) was the same in both groups.

The most commonly used regimen is CHOP. With this the complete response (CR) rate is 20–80%, median failure-free survival (FFS) is 10–16 months, and median OS is 3 years. Several approaches have been used to intensify CHOP. In one phase II prospective study of 28 patients with aggressive MCL, complete responses following four cycles of CHOP chemotherapy were seen in only 7%. In the same study, the addition of Dexamethasone, Cytarabine, Cisplatin (DHAP) to CHOP in a sequential fashion demonstrated a complete response in 84% of the remaining patients compared to CHOP alone.⁴⁴

The MD Anderson group has used an intensive leukemic regimen, hyper-CVAD (high-dose methotrexate and cytosine arabinoside in combination with a

dose intense CHOP-like combination: hyper-fractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone), for up to 8 cycles. Several reports by the MD Anderson investigators have been published with this regimen. The number of cycles of therapy have varied between four and eight depending on whether or not autologous stem cell transplant (ASCT) was done as part of primary treatment, and several reports have also included patients for whom this regimen was used as salvage therapy. In one report of patients >65 years treated with hyper-CVAD as primary treatment,⁴⁵ the ORR was 92% (95% C.I. 73–99) with a CR rate of 68% (95% C.I. 46–85). At a median follow-up of 17 months, the median FFS for the entire group was 15 months. Hematologic toxicity was significant, but only 5% of the cycles were associated with grade 3 infection. In another study of 45 patients with advanced stage MCL (50% previously treated), subjects received four cycles of hyper-CVAD and those who achieved a CR went on to ASCT. The ORR was 93.5% (CR, 38%, and partial remission (PR), 55.5%).⁴⁶ The previously untreated patients had a 3 year OS and EFS of 92% and 72%, respectively. This was higher than CHOP or CHOP-like treated historical controls at this institution, who had a 3-year OS and EFS of 25% and 17%, respectively. A similar observation has been reported in a study comparing hyper-CVAD induction chemotherapy with CHOP or CHOP-like induction followed by ASCT, with superiority being shown in the hyper-CVAD induction group.⁴⁷ Both of these reports should be viewed with caution as they are retrospective in nature, treatment groups were not well matched, and all of the patients received ASCT after hyper-CVAD treatment. Despite the lack of randomized studies evaluating the different treatment regimens for MCL, it appears that the newer approaches (i.e., hyper-CVAD or DHAP) may result in superior ORR compared to CHOP or CHOP-like therapy. Whether the improved remission rates translate into improved survival is unclear as the median follow-up of all these studies is short (<3 years). Patients should be enrolled on clinical trials in order to evaluate these new approaches.

ROLE OF ANTIBODY THERAPY AND OTHER IMMUNOTHERAPIES

MCL is a B-cell malignancy that expresses CD20. The anti-CD20 antibody, rituximab, has been studied as a single agent in MCL with response rates of 20–40%.^{28,48–50}

In vitro and clinical observations in patients with follicular NHL suggest that the effect of rituximab might be enhanced by the synergistic effect of chemotherapy. Based on these observations, rituximab and CHOP (R-CHOP) induction therapy in patients with newly diagnosed MCL has been evaluated.⁵¹ In a phase II trial, 40 previously untreated patients with stage II through IV MCL were treated with six cycles of

R-CHOP. Forty-eight percent of patients achieved a complete response (CR)/CR unconfirmed (CRu), and 48% of patients obtained a partial response (PR), with an ORR of 96%. However, 28 of the 40 patients have already relapsed or developed progressive disease with a median PFS of 16.6 months. Twenty-five patients had PCR-detectable BCL-1/IgH or clonal IgH products in peripheral blood or bone marrow at diagnosis and nine of these had no evidence of PCR-detectable disease in peripheral blood or bone marrow after R-CHOP therapy. Despite molecular remissions, patients had similar clinical outcomes and PFS. R-CHOP has also been evaluated in a prospective randomized study by the German lymphoma study group (GLSG). Previously untreated patients with advanced disease were randomly assigned to receive conventional CHOP or R-CHOP. In early responders who achieved a CR after four cycles, no further induction was given. All other responding patients received six cycles of CHOP or R-CHOP followed by alpha-interferon maintenance therapy or a myeloablative consolidation followed by ASCT depending on the patient's age. One hundred and twenty two patients were evaluated prior to transplant, and R-CHOP was reported to result in a significantly superior CR rate compared to CHOP alone (34% vs. 7% $p = 0.00024$). Also, the addition of rituximab improved the ORR by approximately 20% in comparison to chemotherapy alone (94 % vs. 75%, $p = 0.005$). The time to treatment failure was significantly longer in the R-CHOP group, but time to progression was not significantly different.⁵²

Rituximab has also been evaluated in combination with other agents. The GLSG has also reported preliminary results of a prospective randomized trial of rituximab in combination with FCM (fludarabine, cyclophosphamide, mitoxantrone) compared to FCM alone in patients with relapsed or refractory MCL 54. A total of four courses were given. An ORR of 62% versus 43% was observed in favor of the RFCM group, with a significantly longer OS ($p < 0.005$)^{53–56}

These two randomized trials of the GLSG suggest that both in previously treated and relapsed MCL, CR rates were increased by approximately 30% and ORR by 20% with combined immunochemotherapy.

The MD Anderson group has evaluated rituximab with hyper-CVAD. Compared to prior studies with Hyper-CVAD alone, rituximab 375 mg/m² was added on day 1 of the first 6 courses and ASCT was not given to patients who achieved a CR within six courses of treatment. Seventy-seven previously untreated patients, median age 62, all with stage IV disease were treated with R-hyper-CVAD.⁵⁷ Fifty six patients received at least six cycles and were used as the denominator for response assessment. The CR rate was 90%. At a median follow-up of 14 months, the 2-year FFS and OS were 72% and 90%, respectively. In a subset analysis evaluating outcome according to age, patients <65 years treated with R-hyper-CVAD without ASCT did not have

a significantly different outcome compared to historical controls who received the same hyper-CVAD regimen with ASCT. In patients >65 years, there was a trend favoring the R-hyper-CVAD. These reports suggest that the addition of rituximab to standard induction regimens appears to result in improved response rates. Again, longer follow-up is required to assess if any impact has been made on survival.

TRANSPLANTATION

Stem cell transplantation can improve survival in other NHLs. This treatment has also been applied to MCL with mixed results.⁵⁸⁻⁶⁰ Most studies have used this approach in patients with relapsed or refractory disease.

There is emerging data suggesting that ASCT used earlier in the course of disease has a greater benefit.⁵⁸ Dreger et al. examined the impact of ASCT on the prognosis of MCL in two prospective studies with 46 patients. ASCT in these studies was not curative but, if given as intensive first line treatment, prolonged the time to progression.⁶¹ More recently, a study evaluating 28 patients who underwent B cell purged ASCT following CHOP induction showed DFS and OS of 31 months and 50 months, respectively. At 5 years, 20 of 28 patients died and only 4 had no evidence of disease.⁶² Another prospective study evaluated 21/28 patients with newly diagnosed stage III or IV MCL who achieved a CR with induction therapy and then received ASCT. The 3 year EFS and OS were 83% and 90%, respectively.⁴⁴ Another trial used dose-escalating CHOP chemotherapy for induction followed by ASCT. These patients were not required to have a CR to go on to ASCT, and only 11 of 41 patients had a CR. Twenty-four of the transplant patients achieved or maintained a CR, and the 4-year OS and FFS rates were 51% and 15%, respectively with a median FFS of 2.5 years, similar to conventional chemotherapy.^{63,64} Interestingly, 80% of the patients who achieved an initial CR prior to transplant were alive without disease at 4 years.

Retrospective studies have reached similar conclusions. A retrospective study done in Finland showed similar DFS data with ASCT to prospective trials.⁶⁵ Retrospective data supported the use of ASCT early in disease.⁶⁶ Specifically, an analysis of the European Blood and Bone Marrow Transplant registries of 195 MCL patients treated with ASCT reported on OS/PFS at 2-year and 5-year were 76%/55% and 50%/33%, respectively. Patients who were transplanted in first CR were 33% less likely to die from MCL than patients with chemosensitive disease who were transplanted later. Another study evaluating the effect of early transplant in MCL was a retrospective analysis of 69 patients at Stanford and City of Hope who underwent ASCT with or without ex vivo graft purging.⁶⁷ Patients who were in first CR at the time of transplant (39%) had an estimated 3- and 5- year OS/DFS rates of 93%/74% and 77%/50%, respectively. In comparison, the OS/DFS rates at 3- and 5- years for patients who were not in 1st

remission at the time of transplant were 64%/51% and 39%/21%. The median time to relapse in the group transplanted in first CR was 32 months compared to 10.5 months. Additionally, the relapse rate was lower: 19% versus 50%. Together, these studies clearly demonstrate the need for good induction regimens for MCL. Alternatively, the subset of MCL that is chemo-responsive may represent the only subset that benefits significantly from ASCT.

Hyper-CVAD induction treatment for MCL in combination with transplant has also been evaluated.⁴⁶ After four courses of hyper-CVAD, 45 patients were consolidated with high-dose cyclophosphamide, total-body irradiation, and autologous or allogeneic blood or marrow stem-cell transplantation (43/45 patients had Ann Arbor stage IV disease). For the 25 previously untreated patients, the OS and (EFS) rates at 3 years were 92% (95% CI, 80 to 100) and 72% (95% CI, 45 to 98) compared with 25% (95% CI, 12 to 62; $P = .005$) and 17% (95% CI, 10 to 43; $P = .007$), respectively, for the previously treated patients. When compared with a historic control group who received a CHOP-like regimen, untreated patients in the study had a 3-year EFS rate of 72% versus 28% ($P = .0001$) and a better OS rate (92% v 56%; $P = .05$).

Another recent study using hyper-CVAD induction followed by ASCT in patients with MCL⁶⁸ resulted in 5-year DFS and OS of 43% and 77%, respectively. The patients in the study had untreated MCL, with <10% MCL in the marrow at the time of ASCT and other favorable characteristics and only patients who had achieved a CR went on to transplant.

Thus, it appears that at least for patients with chemosensitive disease, ASCT as consolidation following chemotherapy induction may be associated with an improved outcome. The optimal induction regimen has not been addressed in a randomized study. A retrospective analysis by Conde et al. evaluated the induction regimens used for MCL.^{47,63} An international database of 119 patients with MCL who had received ASCT between 1988 and 2002 was evaluated. The induction regimens were primarily hyper-CVAD and CHOP-like therapy, and 50/119 patients had CR at transplant. The conditioning regimens varied and the CR rate after transplant was 87%. The estimated OS and DFS were impressive at 50% and 32%, respectively. There was a median DFS of 38 months and 50% survival rate at 10 years in this study. Comparing the induction regimens, it was found that hyper-CVAD was superior in this analysis to CHOP or CHOP-like regimens; however, the patients who received hyper-CVAD had fewer adverse prognostic features (bulky disease, advanced stage, high LDH). Despite these differences, the authors report that in the hyper-CVAD group the DFS at 4-years was 68% compared to 33% in patients treated with CHOP or CHOP-like therapy. It should be noted that none of these regimens employed rituximab along with the induction chemotherapy. Retrospective data from MD

Anderson suggests that R-hyper-CVAD was equivalent in outcome when compared to hyper-CVAD followed by ASCT. This suggests that more effective induction regimens that use immunotherapy upfront may be good alternative strategies. It is imperative to enroll patients in well designed prospective clinical trials to evaluate the role of these newer therapies.

Methods to assess molecular remission posttransplant have been evaluated and appear to be predictive of a prolonged disease-free survival.⁶⁹ Sixteen patients with MCL treated with ASCT were examined using PCR based strategies to evaluate residual tumor cells posttransplant. Molecular remission in this group was found in only 12.5%. There is a suggestion that cyclin D1/IgH-probe fusion fluorescence in situ hybridization analysis may provide additional information for evaluating the character of circulating MCL cells in peripheral blood and MRD.⁷⁰ Although this type of methodology needs to evolve fully, these types of methods may aid in the evaluation of response to different induction and high-dose therapy.

ROLE OF PURGING

MCL is particularly resistant to purging.⁷¹ The efficacy of immunological purging was assessed by using polymerase chain reaction (PCR) for minimal residual disease (MRD) on 26 MCL patients undergoing transplant. All patients had MRD detected by PCR after transplant irrespective of prior history of bone marrow involvement. This study demonstrated that reinfusion of stem cells with MRD was associated with a poor outcome. In addition, one study demonstrated that despite using anti-B-cell monoclonal antibody for ex vivo purging of the autograft, 88% of the autografts still had evidence of lymphomatous contamination.⁶² The use of in vivo purging using rituximab is promising, with evidence of clinical and molecular remissions.^{72,73} Gianni et al treated 28 patients with MCL younger than 60 years who completed at least 6 cycles of CHOP-like chemotherapy. Patients were treated with three cycles of cisplatin or doxorubicin-based debulking chemotherapy followed by high-dose sequential therapy with rituximab and ASCT. The 54-month OS and EFS rates were 89% and 79%, respectively as compared to rates for historical controls of 42% and 18%. Interestingly, clinical and molecular remission was found in 20/20 patients tested following in vivo purging, but not following debulking chemotherapy or following mobilization. Another study showed PCR negativity following transplant and in vivo purging with rituximab.⁷⁴ In this study, patients were treated with chemotherapy and subsequently received high-dose cytosine arabinoside and rituximab as in-vivo purging. Twelve patients were evaluable for molecular remission. Ten of the 12 patients achieved PCR negativity posttransplant.

Two studies have suggested that posttransplant rituximab increases the clinical and molecular response

rate of MCL patients receiving ASCT.^{75,76} In one study of advanced stage MCL, all patients who received posttransplant rituximab were alive without clinical or molecular relapse at 239 days posttransplant.⁷⁵ The treatment was well tolerated and encouraging, albeit longer follow-up is needed.

Cumulatively, these approaches employing rituximab either in vivo for purging or posttransplant suggest that molecular and clinical remission may play a role in the long term outcome. Again, none of these studies have a long enough follow-up to assess the impact on OS.

ALLOGENEIC TRANSPLANTATION

Allogeneic transplantation has only been evaluated in patients with refractory MCL, and it has been shown to induce durable remissions in some cases.⁷⁷ Twenty MCL patients underwent allogeneic transplant using a myeloablative regimen at the University of Nebraska.⁷⁸ Nine of 20 patients are alive and disease-free 1–9 years posttransplant. A trial investigating nonmyeloablative transplant in 18 patients with MCL who had failed multiple prior chemotherapies, including 28% who had failed prior ASCT, has been published. CR was achieved in 17 of 18 patients, and with a median follow-up of 26 months the estimated 3-year survival rate and current PFS was 85.5% and 82%, respectively.⁷⁷

RADIOIMMUNOTHERAPY

Radioimmunotherapy (RIT) is an attractive therapeutic option for patients with NHL, as these are radiosensitive tumors. The two clinically available radioimmunoconjugates are iodine ¹³¹I tositumomab (Bexxar) and ibritumomab tiuxetan (Zevalin) using yttrium-90. These have been used extensively in patients with indolent lymphoma, but little experience is available in MCL.

In a study from Seattle, Gopal and colleagues examined the role of ¹³¹I-radiolabeled (Tositumomab) in relapsed MCL.⁷⁹ The antibody dose was 1.7 mg/kg body weight, and the normal amount of ¹³¹I was calculated to deliver 20–25 Gy to vital normal organs. The treatment was followed 10 days later by administration of high-dose etoposide (30–60 mg/kg), cyclophosphamide (60–100 mg/kg), and infusion of cryopreserved autologous stem cells. A total of 16 patients were treated with a median number of 3 prior therapies and 7 with chemotherapy resistant disease. In 11 patients with measurable disease the CR and OS were 91% and 100%, respectively. Fifteen patients were alive at the time of evaluation and 12 had no progression of lymphoma at 6–57 months from transplant and 16–97 months from diagnosis. The ORR at 3 years from transplant was estimated at 93% and PFS at 61%. These results are encouraging and warrant further investigation.

The role of RIT in the upfront management of MCL is also being assessed. In an ongoing trial, the Eastern Cooperative Oncology Group is evaluating

radioimmunotherapy after R-CHOP induction chemotherapy. While R-CHOP may be an effective induction regimen for MCL, it is not sufficient for durable remission. In this trial, patients who respond to R-CHOP are treated with ^{90}Y trium-ibritumomab (Zevalin).

OTHER IMMUNOTHERAPIES

Interferon may offer another immunotherapeutic option in MCL. Phase II studies have demonstrated a potential for longer progression-free survival with the addition of maintenance Interferon- α .^{80,81} This warrants further investigation in randomized trials. In addition, idiotype vaccines as adjuvant to immunotherapy are under investigation.^{82,83}

NEWER AGENTS

Bortezomib is a potent and specific proteasome inhibitor that down regulates the NF- κ B pathway. Recently, two studies have reported encouraging activity with this agent in patients with relapsed/refractory MCL.^{84,85} Fifty-three percent of patients (8/15) had a response, with a median duration of 3 months. One relapsed MCL patient was retreated and achieved a second PR lasting 4+ months.⁸⁵ The mechanism of antitumor activity in MCL is not known, though the biology of MCL provides some clues. Reduced expression of P27 and loss of normal P53 function are both associated with a poor prognosis in MCL. The intracellular levels of P27 and P53 are both modulated by proteasomal degradation^{86,87} It is possible that inhibition of the proteasome by bortezomib may contribute to its activity in MCL.

Thalidomide in combination with rituximab was evaluated in relapsed/refractory MCL patients, and impressive antitumor activity has been reported.^{88,89} In one study, 16 patients with relapsed/refractory MCL were treated with rituximab at 375 mg/m² for four

weekly doses concomitantly with thalidomide. Eighty-one percent (13/16) experienced an objective response with 5 achieving a CR (31%). The median PFS was 20.4 months (95% CI, 17.3–23.6), and estimated 3-year survival was 75%.⁸⁸ There were three severe adverse events: two thromboembolic and one grade IV neutropenia. The encouraging antitumor effect warrants further investigation in MCL.

SUMMARY AND FUTURE DIRECTIONS

MCL is an aggressive lymphoma that generally presents in advanced stages and has a median survival of about 3 years. Despite response to chemotherapy, the disease typically recurs within 1 year of therapy. Improved induction therapy using intensive regimens appear to increase the time to progression. Rituximab and radio-labeled anti-CD20 monoclonal antibodies have shown encouraging results when added to chemotherapy and stem cell transplantation. Rituximab also appears to improve clinical and molecular responses in patients when used for posttransplant consolidation and in vivo purging. Nonmyeloablative transplant is being evaluated as another promising treatment option which will be useful in the older patient population. As the field evolves, defining a MCL molecular signature, which identifies alterations in gene sets which are associated with molecular, phenotypic and clinical distinctions in this disease, will impact treatment decisions.^{30,90} By using molecular profiling, we may be able to identify subsets of patients with indolent or aggressive MCL or subsets of genes that predict treatment responses.^{30,91–93}

As the optimal approach to the management of patients with MCL is still evolving, it is critical that these patients are enrolled in clinical trials to identify better treatment options.

Chapter 56

TREATMENT APPROACH TO HIGH-GRADE NON-HODGKIN'S LYMPHOMAS

John W. Sweetenham

The development of the Revised European American Lymphoma Classification and the subsequent World Health Organization (WHO) Classification of tumors of the hematopoietic and lymphoid tissues has resulted in a departure from the traditional "grading" of non-Hodgkin's lymphomas (NHLs) intrinsic to older lymphoma classifications, particularly the Working Formulation.¹ Despite this, the designation of high-grade NHL is generally considered to encompass Burkitt's lymphoma and precursor B-cell and T-cell lymphoblastic lymphoma/leukemia. Additionally, the entity of "atypical" Burkitt/Burkitt-like lymphoma, used to identify a group of aggressive B-cell NHLs with features in common with Burkitt's lymphoma (BL) and diffuse large B-cell NHL (DLBCL), is also included in this group of diseases.

PRECURSOR B- AND T-CELL LYMPHOBLASTIC LYMPHOMA

INTRODUCTION

Precursor T-cell and B-cell lymphoblastic leukemia and lymphoma are malignant diseases of lymphoblasts. Historically, the term lymphoblastic lymphoma (LBL) has been used to describe these diseases when they present with prominent nodal involvement and less clinically apparent involvement of the bone marrow or peripheral blood. LBL has been recognized as a distinct entity in most lymphoma classifications including the Working Formulation and Kiel classifications. However, since it is now clear that precursor LBL and leukemia are identical morphologically, and at the immunophenotypic and genotypic levels, they are recognized as a single entity in the WHO classification of lymphoid malignancies. Despite this, the clinical management of patients with predominantly nodal involvement has developed separately from that for lymphoblastic leukemias, and as a result, the treat-

ment approach for LBL is different from that previously adopted for acute lymphoblastic leukemia (ALL). This is further confounded by the fact that the clinical distinction between LBL and ALL has varied between centers and between publications, making the literature on this subject difficult to interpret.

FREQUENCY

LBL is a rare disease, comprising 2% of all NHLs.² Eighty-five to ninety percent of adult cases are of T-cell origin and occur most frequently in adolescent and young adult males.³⁻⁶ The median age for patients with LBL is around 20 years, with most series reporting male predominance. There has been no apparent change in the incidence of LBL in recent years.

CLINICAL FEATURES

LBL has a peak incidence in the second and third decades. Characteristic presenting features include male predominance, mediastinal involvement, occurring in 60–70% of patients, reflecting the thymic origin of the malignant cells in LBL, and pleural and pericardial effusions, sometimes with resulting cardiac tamponade. Symptoms and signs of superior vena caval obstruction may be present. Mediastinal masses are uncommon in patients with B-cell LBL. Peripheral lymph node involvement is present in 60–80% of the patients at diagnosis, most commonly in cervical, supraclavicular, and axillary regions.

LBL commonly involves the bone marrow and central nervous system (CNS). The frequency of bone marrow involvement at presentation is difficult to determine from published series in view of the variable distinction between LBL and ALL. In a recent prospective study from Europe, 21% of the adult patients with LBL had bone marrow involvement at presentation.⁷ Leukemic overspill is also common, but the frequency is obscured by inconsistent distinction between LBL and ALL.

CNS involvement is uncommon at presentation, occurring in approximately 5–10% of the patients. Typical manifestations of CNS involvement include meningeal involvement with a pleocytosis in the cerebrospinal fluid, or cranial nerve involvement, characteristically involving ophthalmic or facial nerves. Several reports suggest that CNS involvement at presentation is more common in patients with bone marrow involvement. Although CNS involvement at presentation is uncommon, it is a frequent site of relapse in the absence of adequate prophylaxis, when the incidence of relapse has been reported to be as high as 31%.⁸ Other less common sites of involvement include the liver, spleen, and subdiaphragmatic lymph nodes, as well as bone, skin, and testes.

PATHOLOGY AND PATHOGENESIS

Precursor T- and B-cell LBLs are neoplasms of lymphoblasts of T- and B-cell lineage, respectively. Morphologically, they are very similar, comprising small- to medium-sized blast cells with little cytoplasm, inconspicuous nucleoli, and moderately condensed to dispersed chromatin.⁴ Convolved nuclei are sometimes seen, but this has no clinical significance. Extensive mitotic figures are usually seen and widespread apoptosis is a common feature. The presence of apoptotic bodies being phagocytosed by macrophages produces the “starry sky” pattern typical of high-grade NHLs. Although this appearance is more characteristic of BL, it occurs relatively frequently in lymphoblastic disease, and in most cases, there are clear morphologic distinctions between the two entities. Additionally, immunohistochemical and cytogenetic features of the two diseases are distinct, so that diagnostic confusion is rare. However, the distinction of lymphoblastic disease from other NHLs subtypes can be obscured in poorly processed or fixed tissue specimens. Additionally, lymphocyte-rich thymomas have similar morphologic features, but can usually be distinguished on the basis of the epithelial distribution characteristic of thymoma.

The typical immunophenotype for T- and B-cell LBL is summarized in Table 56.1.^{9–13} Most cases of T-cell disease have clonal rearrangement of T-cell receptor genes, most commonly δ , although this finding is not specific to T-cell lineage, and may also be seen in B-cell disease. Chromosomal translocations involving T-cell receptor genes have little value diagnostically, although they provide important information regarding the pathogenesis of lymphoblastic disease (see below).

One-third of patients have chromosomal translocations involving the α and δ T-cell receptors (14q11.2), the β receptor (7q35), or the γ receptor (7p14-15).¹⁴ These translocations typically result in high levels of coexpression of T-cell receptor genes with transcription factor genes (*TAL1/SCL*, *TAL2* and *LYL1*, and *HOX11/TLX1*).^{15–17} These patterns of gene expression

Table 56.1 Immunophenotype of precursor lymphoblastic leukemia/lymphoma. Summarized from references 9–13

T cell (85–90%)	B cell (10–15%)

CD8 +/-	

also characterize different stages in thymocyte maturation which, according to recent microarray studies, may identify specific molecular subtypes of lymphoblastic disease.¹⁸ As an example, samples with gene expression profiles associated with *TAL1* or *LYL1* expression are similar to late cortical thymocytes, have relatively high expression of *bcl-2*, and demonstrate higher levels of drug resistance and a poorer prognosis.

PROGNOSTIC FACTORS

Determining prognostic factors in lymphoblastic disease has been difficult, partly because of the rarity of this disease, and the limited sample size in most published reports, and partly because of the variable criteria for distinguishing between LBL and lymphoblastic leukemia.

Retrospective studies of patients with LBL have identified adverse clinical prognostic factors for overall and disease-free survival.^{19–21} Few of these have been consistent across different series.

Coleman et al.⁸ identified favorable and unfavorable risk groups in a series of 44 patients treated at Stanford University on the basis of Ann Arbor stage IV, bone marrow or CNS involvement, and serum lactate dehydrogenase (LDH) level <300 IU/L (normal = 200 IU/L). Patients with these factors were considered poor risk, with a 5-year freedom from relapse of only 19%. Good-risk patients, who lacked these factors, had a 5-year freedom from relapse rate of 94%.

The applicability of the International Prognostic Index (IPI) for aggressive NHLs has also been investigated. A retrospective series of 62 patients from France concluded that the IPI did not have prognostic significance in adults with LBL.²² Similarly, a retrospective analysis of 26 patients with LBL was reported by the

Non-Hodgkin's Lymphoma Classification Project.²³ The number of IPI risk factors was not predictive of overall or failure-free survival.

The utility of the IPI was also investigated in a European randomized trial in adult patients,⁷ representing the only prospectively collected data set in an unselected population. This study showed a statistically significant trend for lower overall survival with an increasing number of adverse factors according to the age-adjusted IPI ($p = 0.016$). However, although there was a clearly inferior survival in patients with three adverse factors, there was little distinction between those with zero, one, or two factors, and the value of the IPI as a prognostic model remains unclear.

Data regarding immunophenotypic and genetic risk factors in precursor lymphoblastic disease have been exclusively derived from patients with lymphoblastic leukemias. In adult patients with T-cell ALL, expression of T-cell antigens including CD1, CD2, CD4, and CD5 has been associated with a favorable prognosis. In the Cancer and Leukemia Group B 8364 study, overall and disease-free survival correlated with the number of T-cell antigens expressed.²⁴

Gene expression profiles have identified subtypes of precursor T-cell lymphoblastic disease characterizing different stages in thymocyte maturation, which may identify prognostic subgroups.¹⁸ Patients with *HOX11* expression show a pattern of gene expression corresponding to the early cortical thymocyte. This group has a favorable clinical outcome. These cells are apparently developmentally arrested at a stage at which they are particularly sensitive to drug-induced apoptosis.

In contrast, those samples with gene expression profiles associated with *TAL1* or *LYL1* expression resemble late cortical and early pro-T thymocytes, respectively, and show more drug resistance and correspondingly higher levels of *bcl-2*.

For patients with B-cell disease, most studies have been reported from childhood B-cell ALL series. Translocations involving the *MLL* gene at 11q23 predict for unfavorable outcome, as does the t(9;22)(q34;q11.2). Hyperdiploid karyotype, trisomy 4, 10, and 17 are favorable risk factors.

TREATMENT

Studies conducted in the 1960s in LBL used chemotherapy regimens developed for the treatment of less clinically aggressive types of NHL.^{4,5,22,25,26} These studies reported poor outcomes. For example, Nathwani et al. reported results in 95 patients (children and adults) treated on various protocols that did not include CNS prophylaxis.⁴ Patients with leukemic involvement were included in these series. The complete response rate was 24%, and the median survival was 17 months, with less than 10% of patients alive and disease free at 5 years. Similar results were reported for other similar chemotherapy regimens.

The use of intensive chemotherapy and radiation protocols in childhood LBL resulted in substantial improvements in outcome. Long-term disease-free survival rates between 60 and 80% were reported for children treated with regimens such as LSA₂L₂. A randomized trial in childhood LBL, comparing LSA₂L₂ with COMP (cyclophosphamide, vincristine, methotrexate, prednisone) demonstrated a 2-year actuarial failure-free survival of 76% for the LSA₂L₂ arm compared with only 26% for those receiving COMP ($p = 0.0002$).²⁷

Subsequently, chemotherapy/radiotherapy regimens similar in design to LSA₂L₂, adapted from those in adult ALL, have been applied to adult patients with LBL.^{8,19,20,28-30} Most of these regimens are characterized by intensive remission induction chemotherapy, CNS prophylaxis, a phase of consolidation chemotherapy, and a prolonged maintenance phase, often lasting for 12–18 months.

Results from some of these regimens are summarized in Table 56.2. A recent study from MD Anderson Cancer Center has explored the use of hyperCVAD (fractionated cyclophosphamide, vincristine, doxorubicin, and dexamethasone, alternating with high-dose methotrexate and cytosine arabinoside) in 33 adult patients with LBL. Intrathecal CNS prophylaxis was given and mediastinal radiation was recommended (although not always given) to all patients with mediastinal presentations. They reported a 91% complete remission rate, and 3-year actuarial progression-free and overall survival rates of 66 and 70%, respectively.³¹

Since all of these series are small, differences in reported outcomes are unlikely to be significant. Results from the unselected patient series reported by the Non-Hodgkin's Lymphoma Classification Project are inferior to this, with a reported 5-year actuarial overall survival of only approximately 20%.³² This may reflect selection bias in the clinical series.

RADIATION THERAPY

In addition to the use of prophylactic cranial radiation for prevention of CNS disease, some protocols have included mediastinal radiation for patients who present with isolated or bulky mediastinal disease. The benefit of this approach is unknown. A report from MD Anderson Cancer Center described 47 patients over an 18-year period who received mediastinal radiation as a component of their initial induction therapy.³³ The use of mediastinal irradiation was associated with a lower incidence of mediastinal relapse, but had no effect on failure-free or overall survival. The 5-year overall and progression-free survival rates of 66 and 64% reported in this series are comparable to many other regimens that do not include mediastinal radiation.

STEM CELL TRANSPLANTATION AS CONSOLIDATION THERAPY IN FIRST REMISSION

Several groups have investigated the role of high-dose therapy with autologous or allogeneic stem cell

Table 56.2 Results of intensive combination chemotherapy regimens in adults with lymphoblastic lymphoma

Reference	Regimen	Number of patients	Response rate	Failure-free survival/ relapse-free survival	Overall survival
Coleman ⁸	ALL-type protocols, intensified CNS prophylaxis in the second	44	100% (95% CR, 5% PR)	3-year FFS = 56%	3 years = 56%
Slater ¹⁹	Various ALL protocols	51	80% CR for non leukemic; 77% CR for leukemic	N/A	5-year actuarial OS = 45%
Bernasconi ²⁰	Various ALL protocols	31	77%	3-year RFS = 45%	3-year = 59%
Morel ²¹	CHOP plus various ALL protocols	80	82% CR	46% at 30 months	51% at 30 months
Levine ²⁸	Modified LSA ₂ L ₂	15	73% CR 27% PR	5-year actuarial FFS = 35%	5-year actuarial OS = 40%
Weinstein ²⁹	APO	21	95% CR	3-year actuarial FFS = 58%	5-year actuarial OS = 69%
Hoelzer ³⁰	Two ALL-type protocols, including CNS and mediastinal irradiation	45	93% CR	7-year actuarial DFS = 62%	7-year actuarial OS = 51%

transplantation in first remission, in an attempt to reduce the relatively high rate of relapse after induction therapy.^{23,34–36}

Reported results of this approach, summarized in Table 56.3, have appeared superior to those achieved with conventional dose consolidation and maintenance chemotherapy. Long-term disease-free survival in most of these series has been between 60 and 80%, but most of these studies have conducted survival analyses from the date of stem cell transplantation, and have therefore selected for patients who respond to initial induction therapy, and who are likely to represent a more favorable group. Very few of these studies have included a true intent to treat analysis. One such study

has been reported by Jost et al. in which all patients were followed from the date of diagnosis. The 3-year actuarial overall and event-free survival rates were 48 and 31%, respectively.³⁵ These results are comparable to those reported for conventional dose first-line therapy.

A small randomized trial has compared the use of high-dose therapy and autologous stem cell transplantation with conventional dose consolidation and maintenance therapy as postremission therapy in adult patients with LBL.⁷ This study included 119 adult patients who were treated with intensive induction therapy, 111 of whom were assessable for response. The overall response rate was comparable to other series, at 82%. However, of 98 patients eligible

Table 56.3 Results of first remission stem cell transplantation in adults with lymphoblastic lymphoma

Reference	Induction therapy/High-dose regimen/stem cell source	Number of patients	Failure-free survival/ relapse-free survival	Overall survival
Bouabdallah ²³	Various ALL-type induction regimens/ High-dose cyclophosphamide and TBI/ allogeneic and autologous BMT	62 (30 received bone marrow transplant in first CR)	5 year EFS = 58%	5 year OS = 60%

for randomization, only 65 were actually randomized. The 3-year actuarial relapse-free survival rate was 24% for patients receiving conventional consolidation and maintenance therapy, compared with 55% for those receiving high-dose therapy and autologous stem cell transplantation ($p = 0.065$). The corresponding values for overall survival were 45 and 56% ($p = 0.71$). The fact that there was a nonsignificant trend for improved relapse-free survival in the transplant arm, but no difference in overall survival, may be due to the fact that some patients who relapsed after conventional dose consolidation therapy were “rescued” by high-dose therapy in second remission.

The role of allogeneic transplantation in first relapse is also unclear. Limited prospectively collected data are available. These were reported in the context of the European randomized trial mentioned above. In this study 12 patients with HLA-identical sibling donors were treated with allogeneic transplantation in first remission. The 3-year actuarial overall survival of 58% for this group is comparable to results in patients receiving autologous transplants. A recent study from the International Bone Marrow Transplant Registry compared outcomes for autologous and allogeneic stem cell transplantation in adult patients with LBL.³⁷ This study included a subset of patients undergoing transplantation in first remission, although this subset was not analyzed separately. Patients undergoing allogeneic transplantation in this series had a lower relapse rate following transplant, but this was offset by a much higher rate of nonrelapse mortality, resulting in equivalent overall survival in both groups. At present there are, therefore, no data to suggest that allogeneic transplantation is the optimal approach.

STEM CELL TRANSPLANTATION FOR RELAPSED OR REFRACTORY DISEASE

The use of conventional dose chemotherapy regimens as salvage therapy produces response rates of less than 10% and median overall of only around 9 months.^{8,19-21} Some studies have investigated the role of autologous stem cell transplantation in this situation.

In a retrospective study from Europe, 41 patients underwent high-dose therapy and autologous stem cell transplantation in second complete remission.³⁶ The 3-year actuarial progression-free survival and overall survival for this group were 30 and 31%, respectively. The sensitivity of the disease to conventional dose therapy given prior to the transplant was predictive of outcome. The 5-year actuarial overall survival for those with chemosensitive relapse was 31% compared with 18% for those with chemorefractory disease.

Since patients in chemosensitive relapse have a superior outcome compared to those with chemorefractory relapse, all relapsing patients should receive conventional dose salvage therapy in an attempt to induce a second remission prior to high-dose therapy. However, even in those patients with refractory

disease, the reported long-term disease-free survival of 18% is superior to that achieved with conventional dose salvage, and these patients should also be offered high-dose therapy.

In view of the relatively young age of adult patients with LBL, it is anticipated that their regimen-related mortality after allogeneic transplantation is likely to be relatively low. If a graft-versus-lymphoma effect exists in this disease, then the low relapse rate observed in patients who survive allogeneic transplantation might result in improved overall survival compared with autologous transplantation. A retrospective, case-controlled analysis from the European Group for Blood and Marrow Transplantation (EBMT) comparing autologous with allogeneic stem cell transplantation reported a lower relapse rate for patients receiving allogeneic compared with autologous stem cell transplantation (2% vs 48%, respectively, $p = 0.035$).³⁸ However, progression-free survival for both groups was equivalent because of the higher procedure-related mortality in the allogeneic group. Although one other series has reported a superior outcome for patients receiving HLA-matched allogeneic transplants, this was also a small retrospective series.²³ Patients proceeding to allogeneic transplant are likely to be favorable in terms of age, performance status, and time in remission prior to transplant—all factors that might bias for improved survival.

The study mentioned above, from the International Bone Marrow Transplant Registry, compared outcomes for autologous and allogeneic stem cell transplantation in adult patients with LBL. No difference in survival was observed.³⁷

BURKITT'S LYMPHOMA

BL is a rare tumor of mature B cells, thought to be of germinal center origin. Clinically, it is a highly aggressive disease, with frequent extranodal presentation, which may present as an acute leukemia. It is composed of monomorphic medium-sized B cells with numerous mitotic figures and basophilic cytoplasm. Single translocations involving the *c-myc* oncogene are always present in this disease, and may help to distinguish it from other aggressive B-cell lymphomas. Variant cases of BL, designated as atypical BL, Burkitt-like lymphoma, and BL with plasmacytoid differentiation are also recognized.

FREQUENCY

Three distinct clinical variants of BL are recognized, each of which has a distinct morphology and biologic behavior.

Endemic Burkitt's lymphoma

The original description of BL was based on this subtype of the disease, which occurs in equatorial Africa,

where it is the most common childhood tumor.³⁹ It shows male predominance and a peak incidence at 4–7 years. The areas of peak incidence appear to coincide with the distribution of endemic malaria.⁴⁰

Sporadic Burkitt's lymphoma

This variant is seen throughout the world, and has a peak incidence in children and young adults, with a median age of about 30 years. It comprises between 1 and 2% of all NHLs in the United States of America and Western Europe.⁴¹

Burkitt's lymphoma in association with immunodeficiency

This variant is primarily seen in patients with acquired immunodeficiency syndrome (AIDS), and may also occur in other immune compromised patients, including those who receive immunosuppressive therapy following solid organ or stem cell transplantation.⁴²

CLINICAL FEATURES

The clinical characteristics of BL differ between endemic and sporadic cases, although there is some overlap between these two entities. Frequent extranodal sites of involvement are seen in all cases. The classical presentation of endemic BL, with a jaw tumor, is seen in 50% to 70% of endemic cases, but less than 10% of sporadic BL.^{39,43,44}

The majority of cases (around 90%) of sporadic BL present with abdominal masses, frequently involving the ileocecal region.⁴⁵ Common presenting symptoms therefore include abdominal pain and distension, change in bowel habit, nausea and vomiting, and occasionally, gastrointestinal bleeding or perforation. Abdominal obstruction secondary to intussusception may also occur. Retroperitoneal disease is common, and may result in extradural extension and spinal cord compression. Other frequent sites of involvement in sporadic BL include bone marrow (20%), pleural effusions (20%), and CNS disease (15%). Breast involvement, although uncommon, is associated with onset of the disease at puberty, or during pregnancy and lactation, and is typically bilateral, and often very bulky.^{46,47}

CNS disease most commonly presents either with cranial nerve palsies or with cerebrospinal fluid pleocytosis.⁴⁸ Numbness of the lip and chin, associated with compression of the inferior alveolar nerve is relatively frequent in patients with bone marrow disease, presumably because this nerve passes through the mandible. Although this is not, in itself, indicative of CNS disease, it is a well-documented risk factor for involvement of the CNS.⁴⁹

PATHOLOGY AND PATHOGENESIS

Classical Burkitt's lymphoma

This pattern is seen in almost all cases of endemic BL, most cases of sporadic BL, and many cases of

immunodeficiency-associated disease. Affected tissues are diffusely infiltrated by monomorphic, medium-sized cells. A distinct “starry sky” pattern can be seen as a result of the presence of benign macrophages ingesting nuclear debris resulting from the apoptotic death of the lymphoma cells. A very high proliferation rate is characteristic of BL. “Squaring off” of the cytoplasm is a common feature, especially using mercury-based fixatives such as B5.¹

Variant BL with plasmacytoid differentiation

This variant is most commonly seen in BL associated with HIV infection. Pleomorphism in nuclear shape and size is more common than in classical BL. Nuclei are often slightly eccentric, and nucleoli are frequently single and central, giving the appearance of plasmacytoid immunoblasts.^{1,50} This results in a morphology that has some features of diffuse large B-cell lymphoma.

Atypical Burkitt's and Burkitt-like lymphoma

Atypical BL is characterized by a very high proliferation fraction (close to 100% Ki-67 or MIB-1 positive) in association with evidence of the presence of *c-myc* translocation.^{1,51} It differs from classical BL morphologically in that there is greater nuclear pleomorphism and nucleoli are more prominent, but present in lower numbers. The atypical morphologic features are probably related more to tissue processing artifact than to true biologic differences, and all other features of this entity are identical to classical BL, with the typical immunophenotype, including presence of CD10, absence of *bcl-2*, and cytogenetic or molecular evidence of a *myc* translocation as a single genetic abnormality.

Cases designated as *Burkitt-like* lymphoma are biologically distinct from classical BL, and have some features more consistent with diffuse large B-cell lymphoma.^{1,52} As such they represent “gray zone” cases. Although these cases usually show a diffuse pattern of lymph node infiltration, cases with a follicular pattern are sometimes seen. High mitotic rates and a starry sky pattern are common, but large centroblasts are nearly always present. These cases usually have a lower proliferation rate by MIB-1 or Ki-67, and may either lack *c-myc* translocations or show *c-myc* and *bcl-2* rearrangements in the same cells.

The typical immunophenotype for BL is summarized in Table 56.4. Tumor cells in classical and atypical BL are mature B cells that express CD19, CD20, CD22, and Cd79a, along with surface IgM, commonly with light chain restriction. Their germinal center origin is confirmed by frequent expression of CD10 and *bcl-6*.

All cases of BL have a translocation of *myc* at band q24 from chromosome 8 either to the Ig heavy chain region on chromosome 14 [t(8;14)] or to the light chain loci on chromosome 22q11 [t(8;22)] or chromosome 2q11 [t(2;8)].¹ For those cases with t(8;14) translocations,

Table 56.4 Immunophenotype and genetic/molecular features of Burkitt's lymphoma and variants

	Classical Burkitt's lymphoma	Atypical Burkitt's lymphoma	Burkitt-like lymphoma
CD10	++	++	+/-
Bcl-2	-	-	++/-
Bcl-6	++	++	+/-
Cytogenetics	t(8;14) or t(2;8) or t(8;22)	t(8;14) or t(2;8) or t(8;22)	Variable. Myc translocation may be present and may coexist with Bcl-2 translocation
Molecular features	Myc rearrangement	Myc rearrangement	Bcl-2 +/-, myc =/-

the breakpoint varies between sporadic and endemic cases. In endemic cases, the breakpoint is at the heavy chain joining region, characteristic of a relatively early B cell. In sporadic cases, the translocation affects the Ig switch region, which characterizes a later stage of B-cell development.⁵³ The *myc* gene becomes constitutively expressed with the result that the cells progress through the cell cycle. This is thought to be the critical event in lymphomagenesis in this disease, although *myc* activation also activates various target genes that are involved in the regulation of apoptosis.

The role of Epstein-Barr virus

The Epstein-Barr virus (EBV) is known to be an important factor in the development of endemic BL, where it is present in the majority of tumor cells. It is thought that the development of the lymphoma in this case is preceded by a long period of polyclonal B-cell activation secondary to multiple infective events, including the presence of EBV as well as malaria. Subsequent abnormal T-cell regulation of EBV infected cells may then lead to the development of lymphoma.^{44,54}

In contrast to endemic disease, the incidence of EBV in sporadic BL is less, at about 30% in immunocompetent patients, and about 25–40% in those who are immunosuppressed.^{42,55} Although EBV is implicated in the etiology of BL, its exact role remains unclear.

TREATMENT

The treatment of BL is largely based upon the use of dose-intensive, multiagent chemotherapy regimens, which incorporate high-dose systemic methotrexate and cytosine arabinoside for control of potential CNS as well as systemic disease. Most of the regimens developed in the last 5–10 years have initially been used in pediatric populations, and subsequently adapted for treatment of adults. Overall, modern regimens have been highly effective, with long-term remissions reported in over 90% of the patients, even with advanced and apparently poor risk disease. Risk stratification has gained increasing importance in terms of determining therapy of appropriate intensity.

Several models for risk stratification have been developed in recent years. These are summarized in Table 56.5. For adults with BL, the risk factors described for patients entered into the NCI-89-C-41 protocol have been most widely applied.⁵⁸ In the original description of this regimen in adults, patients with high-risk disease received alternating cycles of cyclophosphamide, vincristine, doxorubicin, methotrexate (CODOX-M) and ifosfamide, etoposide, cytosine, arabinoside (IVAC) therapy (see below) whereas those with low-risk disease received a less intensive treatment protocol including CODOX-M chemotherapy only. In a subsequent European trial of a modified version of this protocol, similar risk stratification was used, in which low-risk patients were defined as having a normal LDH level, WHO performance status of 0 or 1, Ann Arbor stage I or II, and no residual tumor masses >10 cm in diameter.⁵⁹ All other patients were regarded as high risk. The most widely used regimens for BL have initially been introduced in pediatric populations, and subsequently adapted for adults, usually with comparable results. Details of reports of some of these regimens are summarized in Table 56.6. Most of these regimens are highly myelosuppressive, with high rates of neutropenia and infectious complications, and require support with hematopoietic growth factors. Common aspects of these regimens include intensive induction therapy with multiple chemotherapy agents, relatively short treatment duration, absence of any proven benefit from prolonged or maintenance therapy, and the use of CNS prophylaxis and therapy. In view of the high proliferation rate of these tumors, the importance of rapid initiation of cycles of chemotherapy as early as possible after hematopoietic recovery has been realized, and the use of nonmyelosuppressive drugs at the time of neutrophil nadir to maintain dose intensity is also a principle of several regimens.

The use of radiation therapy, even as a method of CNS treatment or prophylaxis, has been largely abandoned in the absence of data from randomized trials demonstrating its benefit compared with high-dose systemic methotrexate or cytarabine, coupled with

Table 56.5 Prognostic risk factors for adult Burkitt's lymphoma

Berlin–Frankfurt–Munich (BFM) group ⁵⁶		LMB group ⁵⁷		National Cancer Institute ⁵⁸	
Risk group	Features	Risk group	Features	Risk group	Features
1	Complete surgical resection	A	Complete surgical resection stage I or abdominal stage II	Low risk	Stage I or II and LDH <150% of normal
2	Incomplete surgical resection: Stage I and II Stage III with LDH <500 IU/L	B	All patients not in groups A or C	High risk	All other patients
3	Incomplete surgical resection: Stage III with LDH 500–999 IU/L Stage V or B-cell leukemia with LDH <1000 IU/L; CNS negative	C	Central nervous system involvement or bone marrow involvement with ≥25% blasts		
4	Incomplete surgical resection: Stage III and LDH >999 IU/L Stage IV or B-cell leukemia and LDH > 999 IU/L ±CNS				

LDH, lactate dehydrogenase; CNS, central nervous system.

intrathecal therapy or prophylaxis. Despite this, some groups continue to use radiation therapy, although at reduced doses, as a component of CNS prophylaxis or treatment.⁶³ No agreed standard of care exists for the initial treatment of BL. Most regimens in common use have features as described above.

Results of these regimens have improved progressively over the last 20 years. Pediatric patients with limited-stage disease, generally defined as stage I or II, completely resected abdominal disease, have long-term disease-free survival rates of 90–100% when treated with combination chemotherapy regimens described above.

In adult patients, some single center studies have reported similar results. In the study from the National

Cancer Institute, using the NCI 89-C-41 protocol in an adult population, all patients with limited-stage disease, treated with three cycles of the CODOX-M regimen, achieved long-term disease-free survival, although patient numbers in this series were small.⁵⁸ In a subsequent multicenter study of a modified NCI 89-C-41 protocol in Europe, including an older, less selected patient population, the 2-year actuarial event-free survival was 83%.⁵⁹

Results from most other groups using comparable chemotherapy have been similar. No single combination has emerged as being superior and any intensive multiagent regimen with the characteristics described above, such as those included in Table 56.6, can be considered acceptable.

Table 56.6 Results of intensive combination chemotherapy regimens in adults with Burkitt's lymphoma

First author & reference	Regimen	Number of patients	Response rate	Failure-free survival/ relapse-free survival	Overall survival

Thomas et al ⁶²	Hyper-CVAD	26	81%	N/A	49% at 3 years

CR, complete remission.

STEM CELL TRANSPLANTATION AS CONSOLIDATION THERAPY IN FIRST REMISSION

There have been only a limited number of studies addressing the role of high-dose therapy and autologous or allogeneic stem cell transplantation in first remission in this disease. This is mainly a result of the effectiveness of intensive induction chemotherapy regimens with high survival rates as documented above. In view of these excellent results, there is little rationale for the use of early stem cell transplantation.

The largest reported series of patients with Burkitt's or Burkitt-like NHL undergoing autologous stem cell transplantation was reported by the EBMT.⁶⁴ This retrospective, registry-based study included 70 patients receiving high-dose therapy in first complete remission after induction chemotherapy. Various induction chemotherapy regimens had been used. The actuarial 3-year progression-free and overall survival rates were 72 and 73%, respectively.

In an intention to treat analysis by Jost et al., patients with LBL and BL received a brief duration induction chemotherapy regimen followed by high-dose therapy and autologous stem cell transplantation for responding patients.³⁵ The estimated 3-year event-free and overall survival were 31 and 48%, respectively, indicating the inadequacy of the initial induction therapy in this group. There is no evidence at present to suggest an improvement in survival with first remission transplantation for patients in remission after intensive induction chemotherapy regimens.

STEM CELL TRANSPLANTATION FOR RELAPSED OR REFRACTORY DISEASE

The outcome for patients with relapsed or primary refractory Burkitt's and Burkitt-like lymphoma is poor, with reported median survival duration of only 6 months after conventional dose second-line chemotherapy regimens. Very few series have specifically addressed the role of high-dose therapy in this context. The study from the EBMT included 32 patients with relapsed and refractory disease. For those with chemosensitive relapses, long-term progression-free survival of 37% was reported, suggesting that transplant strategies may benefit this group. By contrast, patients with resistant relapses or primary refractory disease progressed rapidly, with most having relapse within 6 months of autologous transplantation.⁶⁴

Very few reports have specifically addressed the role of allogeneic transplantation for Burkitt's and Burkitt-like lymphoma. There are anecdotal reports suggesting a possible graft-versus-lymphoma effect on this disease, but few comparative data with autologous stem cell transplantation. A matched analysis from the EBMT included 71 patients with BL receiving allogeneic transplants from a variety of donors, who were matched with 416 patients receiving autologous transplants.³⁸ No differences in either relapse rates or overall survival were reported according to stem cell source. At present, there is no evidence to suggest that allogeneic transplantation is associated with superior outcome, and its use should probably be reserved for patients with bone marrow or peripheral blood involvement or those treated on trial protocols.

Chapter 57

TREATMENT APPROACH TO MARGINAL ZONE AND MALT LYMPHOMAS

Emanuele Zucca

The term *marginal zone lymphoma* (MZL) is believed to be derived from B cells normally present in the marginal zone and was proposed in the Revised European–American Lymphoma (REAL) classification¹ to take account of three apparently related lymphoma subtypes, namely the extranodal “low-grade B-cell lymphoma of mucosa-associated lymphoid tissue (MALT)” usually named MALT lymphoma, the nodal “monocytoid B-cell lymphoma,” and the “primary splenic MZL with or without villous lymphocytes”. At that time, the available cytogenetic data seemed to suggest that all three of these lymphomas share similar cytogenetic alterations, but several important cytogenetic and molecular genetic observations have later revealed the distinctiveness of these lymphoid neoplasms, and each is now considered a separate subtype in the World Health Organization (WHO) classification.^{2–4}

While splenic and nodal MZL are very rare disorders, each comprising less than 1% of lymphomas,⁵ the extranodal MZL of MALT type is not uncommon. In a survey of more than 1400 non-Hodgkin’s lymphomas from nine institutions in the United States of America, Canada, the United Kingdom, Switzerland, France, Germany, South Africa, and Hong Kong, this entity represented approximately 8% of the total number of cases, including both the most common gastrointestinal (GI) and the less usual non-GI localizations.⁵

EXTRANODAL MARGINAL ZONE LYMPHOMA OF MALT

DISEASE FEATURES

Pathology

Primary gastric MALT lymphoma is the most common and best studied MALT lymphoma but the histologic features of extranodal B-cell MZL (MALT lymphomas) are similar regardless of the site of origin.^{2,6,7} The most striking feature of MALT lymphoma is the presence of

a variable number of lymphoepithelial lesions defined by evident invasion and partial destruction of mucosal glands by the tumor cells. The morphology of MALT lymphoma cells is heterogeneous. Marginal zone cells are the predominant component and are small-to-medium-size cells with irregularly shaped nuclei (centrocytelike cells). Other cell types comprise monocytoid cells and small B lymphocytes. A degree of plasma cell differentiation is often present. Any of these cytologic aspects can predominate, or they can coexist within the same case. The B cells of MALT lymphoma show the immunophenotype of the normal marginal zone B cells present in spleen, Peyer’s patches, and in lymph nodes. Therefore, the tumor B cells express surface immunoglobulins and pan-B antigens (CD19, CD20, and CD79a), and the marginal-zone-associated antigens CD35 and CD21 but lack of CD5, CD10, CD23, and cyclin D1 expression. A number of nonneoplastic, reactive T cells are often present. Scattered transformed large blast cells are also usually found. Their prognostic significance is not fully understood, but only when solid or sheetlike proliferations of large cells are present should the lymphoma be considered to have transformed. The resulting tumor cannot reliably be distinguished from other diffuse large B-cell lymphomas. Therefore, the current recommendation is that such cases be defined as diffuse large B-cell lymphoma, avoiding the term “high-grade” MALT lymphomas.²

Certain histologic features appear to indicate that the MALT lymphoma B cells might be or have been involved in an immune response: the presence of tumor lymphocytes in the germinal centers of nonneoplastic follicles (follicular colonization), the presence of scattered transformed blasts, the often prominent plasma cell differentiation, and the often rich T-cell nonneoplastic component. MALT lymphoma usually arises in mucosal sites where lymphocytes are not normally present and where a MALT is acquired in response to either chronic infectious conditions or

autoimmune processes: *Helicobacter pylori* gastritis, Hashimoto's thyroiditis, and Sjögren syndrome.⁸ Sequence analysis of the immunoglobulin genes expressed by the MALT lymphoma B cells shows a pattern of somatic hypermutation and intraclonal variation, suggesting that the tumor cell has undergone antigen selection in germinal centers and that they continue to be at least partially driven by direct antigen stimulation.⁹⁻¹²

Epidemiology and etiology

A significant association has been reported in epidemiologic studies between *H. pylori* infection and gastric lymphomas with either low-grade or high-grade histology.¹³ In vitro experiments have demonstrated that the neoplastic cells of gastric MALT lymphoma proliferate in a strain-specific response to *H. pylori* and that this response is dependent on T-cell activation by the microorganism.¹⁴ The presence of the B-cell clone that will become predominant in the transformation to MALT lymphoma has been demonstrated in the chronic *H. pylori* gastritis that preceded the lymphoma.¹⁵ More than 20 studies have reported regressions of gastric MALT lymphoma in more than half of the treated patients after antibiotic eradication of *H. pylori*.¹⁶ The association of *H. pylori* with gastric MALT lymphoma has led to the hypothesis that the microorganism may provide the antigenic stimulus for sustaining the growth of the lymphoma in the stomach. However, the tumor-derived immunoglobulin usually does not recognize *H. pylori* but does recognize various autoantigens.¹⁷

Besides *H. pylori*, other infectious agents have been associated to particular extranodal marginal zone B cell lymphomas. *Borrelia burgdorferi* may be implicated in the pathogenesis of at least a subset of cutaneous marginal zone B cell lymphomas. The microorganism can be found in skin lymphomas, and a complete remission can be achieved with adequate antibiotic therapy alone.¹⁸⁻²⁰

Ferreri et al.²¹ demonstrated the presence of *Chlamydia psittaci* in about 80% of ocular adnexa MZL and showed that antibiotics therapy aimed to the *C. psittaci* can be followed by histologic regression of these MZL.

Campylobacter jejuni has been associated with the immunoproliferative small intestine disease (IPSID, also known as alpha-chain disease) that is now considered an extranodal MZL, more frequent in Middle East, especially in the Mediterranean area.²²

Since the 1970s, it was already known that early stage IPSID may regress after antibiotic therapies eliminating unknown organism(s),²³ but only in 2004 has this lymphoma been linked to a specific pathogen.²²

All these data, together with the pattern of somatic hypermutation and ongoing mutations of the immunoglobulin genes, strongly associate the origin of extranodal MZLs, with a background of chronic anti-

genic stimulation associated with infectious conditions and/or autoimmune conditions. It can be postulated that interaction of host T cell and antigen-presenting cells with bacterial antigens or with cross-reactive autoantigens leads to a cascade of complex events, which finally results in autonomous clonal B-cell expansion and proliferation.

However, extranodal MZLs are relatively rare, while *H. pylori* infection is extremely common, being present in the stomach of one half of the world population.²⁴ Therefore, both bacterial and host factors have to interact to cause lymphoma. Polymorphisms affecting genes involved in inflammatory responses and antioxidative capacity may be part of the genetic background for the MALT lymphomagenesis in individual *H. pylori* infected persons.²⁵ The persistent antigenic stimulation may render the clone more susceptible to genetic alterations that can result in neoplastic transformation and tumor progression. Free radicals are likely to play a role in the development of B-cell genomic damage in the chronic gastritis, and their presence is increased in the presence of the CagA-positive strains of *H. pylori*.²⁶

Genetic abnormalities

The most common aberration is the t(11;18)(q21;q21), which results in a fusion of the apoptosis inhibitor gene *API2* with the *MALT1* gene.²⁷⁻²⁹ The t(11;18) is present in 30-50% of extranodal MZL of MALT type, but not in nodal MZL lymphoma and splenic MZL.³⁰ It is usually the sole cytogenetic alteration. The frequency of the t(11;18) in MALT lymphoma is site related: more frequent in the GI tract and in the lung, less common in conjunctiva and orbit, and absent or almost absent in salivary glands, thyroid, liver, and skin.^{26,31}

The t(1;14)(p22;q32) is much more rare, and it deregulates the expression of the survival-related gene *BCL10*, highly expressed in the nucleus of the neoplastic B cells of MALT lymphomas carrying this translocation.^{32,33} Interestingly, nuclear expression of *BCL10* is also present in the t(11;18)-positive MALT lymphomas, indicating that nuclear localization of *BCL10* can occur as the consequence of two apparently independent cytogenetic events.^{26,30,34} In MALT lymphomas without these translocations, as well as in nonneoplastic germinal center and marginal zone B cells, *BCL10* is expressed only in the cytoplasm.³⁵

The t(14;18)(q32;q21) translocation, cytogenetically identical to the one involving *BCL12* in follicular lymphoma but involves *MALT1* (which is localized about 5 Mb centromeric of *BCL12* on 18q21), has been described in approximately 20% of MALT lymphomas.^{31,36,37} This translocation appears to be more common in lymphomas of ocular adnexa, liver, and skin than in GI tract and lung. In contrast to t(11;18), it is often associated with additional genetic abnormalities, such as trisomies of chromosome 3 and 12.

The three seemingly disparate translocations that target *BCL10* and *MALT1* appear to affect the same

signaling pathway, resulting in the constitutive activation of nuclear factor kappa B (NF- κ B), a transcription factor with a central role in immunity, inflammation, and apoptosis.^{38,39} This activation of the NF- κ B pathway seems critical to lymphoma antigen-independent growth and progression.⁴⁰ Other cytogenetic abnormalities have also been reported but their pathogenetic role is unclear.⁶

Clinical features

The presenting symptoms of MALT lymphomas are nonspecific and mainly related to their anatomic location. Few patients present with elevated lactate dehydrogenase (LDH) or β 2-microglobulin levels.^{41,42} Constitutional B symptoms are exceedingly uncommon.⁴¹

MALT lymphoma usually remains localized for a prolonged period within the tissue of origin, but involvement of multiple mucosal sites is not uncommon, being reported in up to one-third of cases. It has been postulated that this dissemination may be due to specific expression of special homing receptors or adhesion molecules on the surface of most MALT lymphoma cells and normal B cells of MALT.^{43–45} Bone marrow involvement is reported in up to 20% of cases.⁶ Within the stomach, low-grade MALT lymphoma is often multifocal and this may explain the report of relapses in the gastric stump after surgical excision. When regional lymph nodes are involved, MALT lymphoma cells tend to localize in the marginal zone without disturbing the lymph node architecture. Gastric MALT lymphoma can often disseminate to the splenic marginal zone where it is usually undetectable by conventional histopathology. The incidental discovery of secondary small intestinal MALT lymphoma during gastrectomy for MALT lymphoma has been reported too, and concomitant GI and non-GI involvement is found in approximately 10% of cases.

DIAGNOSIS AND STAGING OF GASTRIC MALT LYMPHOMA

The stomach is the most common and best studied organ involved with MALT lymphoma and it will be helpful to discuss the clinical aspects of diagnosis, staging, and treatment of gastric MALT lymphoma separately from all other sites.

The most common presenting symptoms of gastric MALT lymphoma are dyspepsia, epigastric pain, nausea, and chronic manifestations of GI bleeding, such as anemia. The upper GI complaints often lead to an endoscopy that usually reveals nonspecific gastritis or peptic ulcer with mass lesions being unusual.⁴¹

The best staging system is still controversial.⁴⁶ We use the modification of the Blackledge staging system recommended at an international workshop.^{47,48}

The initial staging procedures should include a gastro-duodenal endoscopy with multiple biopsies from each region of the stomach, duodenum, gastroesophageal (GE)

junction, and from any abnormal-appearing site. The presence of active *H. pylori* infection must be determined by histochemistry and breath test. Endoscopic ultrasound is recommended to evaluate the presence of perigastric lymph nodes and the depth of infiltration of the gastric wall. A deep infiltration is associated with a higher risk of lymph node involvement, and a lower response rate with antibiotic therapy alone.^{49–52} Presentation with multiple MALT localizations is more frequent in patients with non-GI lymphoma, in which about one-fourth of cases have been reported to present with involvement of multiple mucosal sites or nonmucosal sites such as bone marrow.^{53,54}

Regardless of the presentation site, initial workup should include complete blood counts, basic biochemical studies (including LDH and β ₂-microglobulin), computed tomography of the chest, abdomen, and pelvis, and a bone marrow biopsy. Indeed, although the disease remains usually localized in the stomach, systemic dissemination and bone marrow involvement should be assessed at presentation, since prognosis is worse with advanced-stage disease or with unfavourable International Prognostic Index (IPI) score.⁴¹

TREATMENT OF MALT LYMPHOMA

H. pylori eradication in gastric MALT lymphoma

The regression of gastric MALT lymphoma after antibiotic eradication of *H. pylori* was first reported in 1993 by Wotherspoon and colleagues, who described the efficacy of antibiotic therapy in six patients with superficially invasive gastric MALT lymphoma.⁵⁵ Several groups thereafter confirmed the efficacy of antibiotics in inducing apparently durable lymphoma remissions in 60–100% of patients with localized *H. Pylori*-positive gastric MALT lymphoma.^{42,49,50,52,56–58} The histologic remission can usually be documented within 6 months from the *H. pylori* eradication but sometimes the period required is more prolonged and the therapeutic response may be delayed up to more than 1 year.⁴¹

It is now generally accepted that eradication of *H. pylori* with antibiotics should be employed as the sole initial treatment of localized (i.e., confined to the gastric wall) MALT lymphoma. Actually, this is at present the best studied therapeutic approach with more than 20 reported studies.^{59,60} Any of the highly effective antibiotic regimens proposed^{61,62} can be used. Several effective anti-*H. pylori* programs are available and any of them can be used.^{61–63} It is expected that following 10–14 days of antibiotic treatment, *H. pylori* will be eradicated in 85–90% of the patients.⁶³ Our regimen of choice is a 10-day triple therapy with a proton-pump inhibitor (e.g., omeprazole 20 mg b.i.d., pantoprazole 40 mg once daily, esomeprazole 40 mg once daily, or others), amoxicillin (1 g b.i.d.), and clarithromycin (500 mg b.i.d.). Metronidazole (500 mg b.i.d.) can replace amoxicillin in penicillin-allergic individuals, but metronidazole resistance is common and can

reduce the treatment efficacy. After treatment, strict endoscopic follow-up is recommended, with multiple biopsies taken at 2–3 months to document *H. pylori* eradication and, subsequently, at least twice per year for 2 years to monitor the histologic regression of the lymphoma. In cases of unsuccessful *H. pylori* eradication, a second-line anti-*Helicobacter* therapy should be attempted with alternative triple- or quadruple-therapy regimens of proton-pump inhibitors plus antibiotics. However, it is still unknown whether *H. pylori* eradication will definitely cure the lymphoma; therefore, long-term follow-up of antibiotic-treated patients is mandatory. Some cases of documented tumor recurrence following *H. pylori* reinfection have been reported, suggesting that residual dormant tumor cells can be present despite clinical and histologic remission. Relapses have also been documented without *H. pylori* reinfection, indicating the emergence of B-cell lymphoma clones that are no longer antigen dependent.^{56,58}

Several studies of postantibiotic molecular follow-up demonstrated a long-term persistence of monoclonal B cells after histologic regression of the lymphoma in about half of the cases, suggesting that *H. pylori* eradication does not eradicate the lymphoma clone.^{58,64} Therefore, histologic evaluation of post-treatment gastric biopsies remains to be a fundamental follow-up procedure. Unfortunately, the interpretation of residual lymphoid infiltrate can be very difficult, and there are no uniform criteria for the definition of histologic remission. Wotherspoon in 1993 proposed a simple score to express the degree of confidence in the diagnosis of MALT lymphoma on small gastric biopsies.⁵⁵ This scoring system has been used to evaluate the response to therapy in some trials, but many investigators found it difficult to apply in this setting and other criteria have been proposed.⁵⁶ The lack of standardized and reproducible criteria can affect the comparison of the results from different clinical trials. A novel histologic grading system has been proposed by Copie-Bergman and colleagues.⁶⁵ This system classifies the histologic features in posttreatment gastric biopsies as “complete histologic remission,” “probable minimal residual disease,” “responding residual disease,” and “no change.” It may become a useful tool but its reproducibility still needs to be confirmed on larger series.

The efficacy of antibiotic therapy is reduced in locally advanced disease, and as mentioned before, endoscopic ultrasound can be useful to predict the lymphoma response to *H. pylori* eradication. The response rate is 70–90% for the mucosa-confined lymphomas, but then decreases markedly and progressively for the tumors infiltrating the submucosa, the muscularis propria, and the serosa. In cases with documented nodal involvement, a response is unlikely.^{50,52} The t(11;18) translocation is absent in gastric MALT lymphomas showing complete regression,⁶⁶ but present in 77% of

nonresponsive tumors, including 68% of those with the disease confined to the gastric wall.⁶⁷ Therefore, this translocation can be a valuable molecular marker to predict the therapeutic response of gastric MALT lymphoma to *H. pylori* eradication^{30,67,68} and in addition to routine histology and immunohistochemistry, fluorescence in situ hybridization analysis for detection of t(11;18) may be useful for identifying disease that is unlikely to respond to antibiotic therapy.

Management of *H. Pylori*-negative or antibiotic-resistant patients

No definite guidelines exist for the management of the subset of *H. pylori*-negative cases or for the patients who fail antibiotic therapy. A choice can be made among conventional oncologic modalities but there are no published randomized studies to help with the decision. In two retrospective series of patients with gastric low-grade MALT lymphoma, no statistically significant difference was apparent in survival between patients who received different initial treatments, including antibiotics against *H. pylori*, chemotherapy, surgery with or without additional chemotherapy, or radiation therapy.^{42,69}

Excellent disease control using radiation therapy alone has been reported by several institutions supporting the approach that modest-dose involved-field radiotherapy (30 Gy given in 4 weeks radiation to the stomach and perigastric nodes) is the treatment of choice for patients with stage I–II MALT lymphoma of the stomach without evidence of *H. pylori* infection or with persistent lymphoma after antibiotics.^{70,71} Surgery has been widely and successfully used in the past, but the precise role for surgical resection should now be redefined in view of the promising results of a more conservative approach.⁴¹

Patients with systemic disease should be considered for systemic chemotherapy and/or immunotherapy with anti-CD-20 monoclonal antibodies. Only a few compounds and regimens have been tested specifically in MALT lymphomas. Oral alkylating agents (either cyclophosphamide or chlorambucil, with median treatment duration of 1 year) can result in a high rate of disease control.^{72,73} More recent phase II studies demonstrated some antitumor activity of the purine analogs fludarabine⁷⁴ and cladribine (2-CdA),⁷⁵ possibly associated with an increased risk of secondary myelodysplastic syndrome,⁷⁶ and of a combination regimen of chlorambucil/mitoxantrone/prednisone.⁷⁷ The activity of the anti-CD20 monoclonal antibody rituximab has also been shown in a phase II study to have a response rate of about 70%,⁷⁸ and it may represent an additional option for the treatment of systemic disease. Rituximab is active in gastric MALT lymphomas resistant or refractory to antibiotics, or not associated with *H. pylori* infection. Different from the setting of antibiotic therapy, the t(11;18)(q21;q21) translocation seems not to be a predictive marker of response to rituximab.⁷⁹

Management of non-gastric localizations

The stomach is the most common and best studied site of involvement, but MALT lymphomas have also been described in various non-GI sites, such as salivary gland, thyroid, skin, conjunctiva, orbit, larynx, lung, breast, kidney, liver, prostate, and even in the intracranial dura.^{53,54,80} One-fourth of non-GI MALT lymphomas have been reported to present with involvement of multiple mucosal sites or nonmucosal sites such as bone marrow.^{53,54} Nevertheless, despite presenting so often with stage IV disease, they usually have a quite indolent course regardless of treatment type (5-year survival of 90%). The rate of histologic transformation seems much lower than that in follicular lymphomas. Patients at high risk according to the IPI, and those with lymph node involvement at presentation, but not those with involvement of multiple MALT sites, have a worse outcome. Localization may have prognostic relevance. In a radiotherapy study from Toronto,⁷⁰ gastric and thyroid MALT lymphomas had better outcome, whereas distant failures were common for other sites, however, despite relapse, the disease most often maintained an indolent course.

In a multicentric retrospective survey of 180 non-gastric cases observed over a long period of time, patients were treated according to the current policy of each institution at the time of diagnosis, and the presence of organ-specific problems presumably had a role in the choice of treatment. This study showed no evidence of a clear advantage for any type of therapy.⁵³

In general, the considerations regarding the treatment of *H. pylori*-negative cases can be applied. Radiation therapy is the best studied approach⁸¹ and is the treatment of choice for localized lesions. The optimal management of disseminated MALT lymphomas is less clearly defined. The treatment choice should be “patient tailored,” taking into account the site, the stage, and the clinical characteristics of the individual patient. The anti-CD20 antibody rituximab has shown clinical activity,⁷⁸ and the efficacy of its combination with chemotherapy is being explored in a randomized study of the International Extranodal Study Group. The finding that *C. psittaci* is associated with MALT lymphoma of the ocular adnexa may provide the rationale for the antibiotic treatment of localized lesions and preliminary encouraging results have been reported, but this approach remains investigational and will need to be confirmed by larger clinical studies.

SPLENIC MARGINAL ZONE LYMPHOMA

DISEASE FEATURES

Pathology

The disease is characterized by a lymphoid infiltrate in the splenic white pulp that grows in a nodular pattern replacing preexisting follicles.^{4,82} A variable degree of red pulp infiltration is also often present. Small lymphocytes

are predominant in central areas, while medium-size cells resembling splenic marginal zone lymphocytes are present in the periphery. Plasmacytic differentiation as well as, rarely, clusters of plasma cells can be present.

The neoplastic cells show typical positivity for surface (and sometimes cytoplasmic) immunoglobulins and pan-B antigens (CD19, CD20, and CD22); they usually coexpress CD11c, and lack CD5, CD10, and CD23 expression.

Up to two-thirds of the patients with splenic MZL present the characteristic circulating villous lymphocytes, with short cytoplasmic projections. When these are more than 20% of the lymphocyte count, the term “splenic lymphoma with villous lymphocytes” is commonly used.⁸³

Bone marrow is usually involved, even in cases with no circulating neoplastic cells. The pattern of infiltration is typically nonparatrabeular, intrasinusoidal only. However, this pattern of bone marrow involvement can be found also in other small-cell lymphomas.^{84–86}

When biopsied, the liver is usually involved with a nodular infiltration of portal tracts, and hilar splenic lymph node involvement is common. According to the WHO classification, the peripheral lymph node involvement is typically absent.⁸⁷ Transformation to a diffuse large B-cell lymphoma occurs in about 15% of the cases.⁸⁸

Genetic abnormalities

Sequence analysis of the immunoglobulin genes expressed by the splenic marginal zone B cells shows that approximately half of the cases bear unmutated and half have mutated immunoglobulin heavy-chain genes,^{89,90} suggesting the possibility that this lymphoma subtype derives from different B-cell subsets than those normally present in the marginal zone. Cases with unmutated IgH genes may have a poorer prognosis and are more commonly associated with the presence of chromosome 7q loss,⁸⁹ but it has to be underscored that the 7q deletions are relatively common in hematologic malignancies and not specific for splenic MZL. Gain of chromosome 3 appears to be another common abnormality.^{91,92} The t(9;14)(p13;q32) translocation which juxtaposes the IgH locus to the *PAX5* gene^{93,94} has also been reported; however, its frequency is controversial.⁹⁵ Using cDNA microarray, Thieblemont et al. have compared the gene expression profile of splenic MZL, mantle cell lymphoma, and small lymphocytic lymphoma.⁹⁶ The gene coding for the serine threonine kinase AKT1 was the most representative among the gene clusters specific for splenic MZL; its possible role in the pathogenesis of splenic MZL needs to be further clarified.

Association with infectious agents Despite relevant geographic variations, hepatitis C virus (HCV) seems to be involved in splenic MZL and nodal MZL

lymphomagenesis.^{97–101} Of great interest, some patients with splenic lymphoma with villous lymphocytes and HCV infection achieved a lymphoma remission after treatment with interferon alfa with or without concomitant ribavirin.^{101,102} This suggests a strict relationship between HCV and splenic MZL, indicating the necessity to search for HCV infection in patients affected by this lymphoma subtype. Analogous to the *H. Pylori* infection in the gastric MZL, it appears that HCV may be responsible for an antigen-driven stimulation of the lymphoma clone. Prospective studies are warranted to confirm this interesting finding.

An association with malaria and with Epstein–Barr virus infection, both acting as strong polyclonal B-cell activators, has been shown in tropical Africa.^{103–105} Tropical splenic lymphoma appears as a form of splenic MZL, characterized by a high percentage of circulating villous lymphocytes, unmutated immunoglobulin genes, and a predilection for middle-age women.

Clinical features

Most patients are over 50 with a similar incidence in males and females.⁸⁷ The disease usually presents with massive splenogamy, which produces abdominal discomfort and pain. Diagnosis is often made at splenectomy performed to establish the cause of unexplained spleen enlargement. B symptoms are present in 25–60% of cases; anemia, thrombocytopenia, or leukocytosis are reported in approximately 25% of cases. Autoimmune hemolytic anemia is not uncommon, being found in up to 15% of patients. Splenic hilar lymph nodes appear to be involved in about 25% of cases, but peripheral lymph node involvement is typically absent. Approximately 30% of cases have liver involvement.^{106–110} Nearly all patients have bone marrow involvement, often accompanied by involvement of peripheral blood (defined as the presence of absolute lymphocytosis of more than 5%).¹⁰⁹ Because of the high frequency of bone marrow or liver involvement, about 95% of cases are classified as Ann Arbor stage IV. Serum paraproteinemia is observed in about 10–25% of cases,^{107–109} most frequently of IgM type posing the problem of the differential diagnosis with lymphoplasmacytic lymphoma/Waldenstrom macroglobulinemia.^{82,111}

In advanced stages of either splenic, nodal, or extranodal MZL, a precise diagnosis can be very difficult in cases presenting with concomitant splenic, extranodal, and nodal involvement.^{108,112}

TREATMENT OF SPLENIC MARGINAL ZONE LYMPHOMA

The clinical course is usually indolent with 5-year overall survival ranging from 65 to 80%, and most cases can be safely managed with an initial wait-and-see policy.^{107,109,110} When treatment is needed, this is usually because of large symptomatic splenomegaly or cytopenias. Splenectomy appears to be the treatment of choice;

it allows a reduction/disappearance of circulating tumor lymphocytes, and recovery of the lymphoma-associated cytopenia.^{106,107,110,112,113} The benefit of splenectomy often persists for several years, and time to next treatment can be longer than 5 years in cases where lymphocytosis persists and or progresses after splenectomy.¹¹² Adjuvant chemotherapy after splenectomy may result in higher rate of complete responses; however, there is no evidence of a survival benefit.¹¹²

Chemotherapy alone may be considered for patients who require treatment but have a contraindication to splenectomy, and also for the patient with clinical progression after spleen removal. Alkylating agents and fludarabine have been reported to be active and can be used as single agents or in combination. The anti-B-cell monoclonal antibody, rituximab, alone or in combination with chemotherapy, is capable—according to a few case reports—to induce good responses in cases refractory to standard chemotherapy.^{112,114,115} Treatment of HCV infection with interferon alpha alone or in combination with ribavirin may be helpful for the patients with splenic lymphoma with villous lymphocyte and HCV infection.^{102,116}

NODAL MARGINAL ZONE LYMPHOMA

DISEASE FEATURES

Pathology

In contrast with mucosa-based extranodal MALT lymphoma, nodal MZL is typically lymph node based. The tumor cell morphology is heterogeneous and resembles the lymph node involvement of extranodal and splenic MZL. The marginal zone and interfollicular areas are infiltrated by marginal zone B cells, monocytoid B cells, or small B lymphocytes. Plasma cell differentiation can be present, as well as some large cells.^{3,117–120}

Genetic abnormalities

No specific genomic alteration is known to occur in nodal MZL. The most common alterations, such as gain of 3q, are also present in extranodal and splenic MZL.

Analysis of the IgH genes suggest a prevalence of cases with mutated IgH genes, but, similarly to splenic MZL, unmutated cases do exist.^{121–123} These data are in accordance with the different normal B-cell populations resident within the marginal zone, which comprise both naïve and postgerminal center B cells.¹²⁴

As noted, both nodal and splenic MZL have been associated with HCV infection.^{97,98,100,101,125–127}

Clinical features

The clinical data are sparse and have been largely drawn from pathologic series rather than clinical centers.^{128,129} Nodal MZL is a disease of older people, with median age at presentation in the sixth decade, and affects both sexes, with an unusual (albeit slight)

female predominance. The most common presenting feature is a localized adenopathy, most often in the neck.

TREATMENT OF NODAL MARGINAL ZONE LYMPHOMA

There is at present no consensus about the best treatment, individual cases being managed differently according to site and stage. Indeed, there are very few studies comparing nodal MZL with the other low-grade B-cell lymphomas. Treatment options may include single-agent chlorambucil or fludarabine, or combination chemotherapy regimens (such as the cyclophos-

phamide, vincristine, and prednisone or cyclophosphamide, hydroxydaunomycin (doxorubicin), Oncovin (vincristine), and prednisone). Rituximab may also have some efficacy,¹³⁰ and anti-HCV treatment may induce lymphoma regression in some HCV-infected patients.¹¹⁶ Autologous transplantation has been used in younger patients with adverse prognostic factors and high number of large cells subtypes.¹⁰⁸ However, no prospective studies have been conducted so far, and treatment decision should be based on the histologic and clinical features of the individual patient.^{117,127}

Chapter 58

TREATMENT APPROACH TO PRIMARY CENTRAL NERVOUS SYSTEM LYMPHOMAS

Tamara N. Shenkier and Joseph M. Connors

DEFINITION

Primary central nervous system lymphoma (PCNSL) is a non-Hodgkin's lymphoma (NHL) confined to the craniospinal axis without evidence of systemic spread. It should be distinguished from nodal or extranodal NHL that has disseminated to the CNS, which is a different clinical entity. In this chapter, we will discuss the epidemiology, pathology, clinical presentation, diagnosis, and treatment of PCNSL in immunocompetent patients. PCNSL that develops in the context of acquired immunosuppression will be discussed in Chapters 66 and 67.

EPIDEMIOLOGY

In the past, PCNSL has been reported to represent about 1–2% of all NHL and 5% of all brain tumors.¹ However, these numbers do not reflect the rising incidence of this condition in the past three decades. Much of this rise has been due to the AIDS epidemic, but a two- to threefold rise has also been seen in the immunocompetent population.² Some population-based studies suggest this increase is a result of improved detection due to the widespread availability of computed tomographic (CT) scans and magnetic resonance imaging (MRI) and due to better diagnostic techniques, such as stereotactic biopsy. However, a recent Surveillance, Epidemiology and End Results (SEER) analysis refuted this hypothesis.³ It is reported that the age-adjusted incidence increased from 0.15 to 0.48 per 100,000 person-years from 1973 to 1997. This increase was seen in all age groups and both genders and outpaced the increased incidence of systemic NHL for this period sixfold. Furthermore, if this increase were due to ascertainment bias, there would have been an increased rate of glioma over time, which was not seen. Although the rate of increase of PCNSL has lev-

eled off in the last decade, it appears that the true incidence is increasing.

PATHOLOGY

The vast majority of PCNSL in immunocompetent patients are Epstein Barr virus (EBV) negative diffuse large B-cell lymphomas (DLBCL). Other histologies, such as T-cell and small lymphocytic lymphoma, are rare.^{2,4,5} Unlike other NHLs, it appears that the histological classification of PCNSL does not have prognostic or clinical importance.⁶ PCNSL usually grows in an angiocentric pattern with sheets of cells that infiltrate adjacent brain parenchyma. Perivascular reactive T-cells are seen in 30% of cases. The CNS is normally devoid of lymphoid tissue; therefore, the site of the cell of origin from which PCNSL develops is likely extraneural. This cell possesses a specific tropism for the nervous system. Both molecular genetic and immunophenotypic studies have suggested that the cell of origin is from the germinal center as BCL6 proto-oncogene mutations or BCL6 protein expression have been reported in the majority of cases.^{7,8} Further evidence for this theory is the high proportion of somatic mutations in the clonally rearranged immunoglobulin heavy chains (VH genes) from PCNSL specimens.⁹ More recent studies have demonstrated a unique immunophenotype and gene expression signature which is distinct from nodal diffuse large B cell lymphoma and which may have both prognostic and potential therapeutic implications.^{10,11}

CLINICAL CHARACTERISTICS

PRESENTATION

Most patients present with an acute or subacute manner with one of several clinical scenarios: symptoms of raised intracranial pressure (such as headache, nausea, vomiting, drowsiness, or visual abnormalities);

Figure 58.1 An example of the MRI features of PCNSL. Pre- and postgadolinium T1 MRI images showing an isodense lesion in the region of the left basal ganglia and thalamus. There is a mass effect with compression of the left lateral ventricle and moderate surrounding edema. The lesion enhances homogeneously postcontrast

progressive focal neurological deficits or, if the frontal lobes are involved or there is diffuse parenchymal infiltration, cognitive and behavioral abnormalities.¹² Unlike other primary brain tumors, seizures are uncommon, because PCNSL usually affects subcortical structures.

Central structures apart from the brain parenchyma are often affected. The eye itself is a direct extension of the brain, and 10–20% of patients with PCNSL have ocular involvement at diagnosis.^{13,14} Ocular lymphomas can involve the vitreous, retina, choroid, or optic nerve itself, and cause blurred vision, floaters, or maybe clinically silent. The process may begin unilaterally, but eventually bilateral involvement develops. The majority of patients, who present with ocular lymphoma alone, will eventually develop cerebral involvement. Concomitant involvement of the leptomeninges can be seen in 15% of patients, but is rarely the sole site of disease.

Several large retrospective studies have described the clinical characteristics of patients with PCNSL.^{5,15,16} The median age at diagnosis is about 60 years, with a wide range of 12–85 years. There is a slight male predominance, and two-third of patients present with a poor performance status. One-third of patients have elevated serum lactate dehydrogenase (LDH). One-third of patients have involvement of deep structures, including the cerebellum, basal ganglia, corpus callosum, and brain stem. Brain lesions are multifocal in 30–40% of patients, and even when the tumor is seemingly localized by MRI, microscopic disease involves radiologically normal brain tissue at

autopsy.¹⁷ Therefore, PCNSL should be considered disseminated within the CNS at diagnosis.

DIAGNOSIS

There is no single radiologic pattern of PCNSL that is pathognomonic, but several distinctive neuroimaging features can strongly suggest the diagnosis. CT scans show iso or hyperdense lesions that homogeneously enhance in 90% of cases.¹⁸ The neuroimaging technique of choice is MRI, which demonstrates an intense signal on nonenhanced T1 imaging and dense, diffuse enhancement in 90% of cases after administration of gadolinium contrast (Figure 58.1). The lesions usually have indistinct borders and less associated cerebral edema than primary gliomas or metastatic tumors.¹ They may be multiple in 30–35% of cases, are frequently periventricular in location and usually involve corpus callosum, thalamus, or basal ganglia. Experience with positron emission tomography (PET) in immunocompetent patients with PCNSL is progressively growing, but does not appear to distinguish PCNSL from other malignant brain tumors.¹⁹ The use of PET in predicting response to therapy has not yet been addressed in PCNSL.

The best method to diagnose PCNSL is stereotactic biopsy of an enhancing mass lesion. Subtotal resection is not necessary therapeutically and is usual only performed when the diagnosis of lymphoma is in doubt. In some cases, the diagnosis is established by examination of a vitrectomy specimen from the eye or cytopathology or flow cytometry of cerebrospinal fluid (CSF), obviating the need for a brain biopsy. One

distinctive feature of PCNSL is that corticosteroids given to relieve high intracranial pressure can have a potent acute antitumor effect that removes all CT or MRI signs of the lesions, sometimes prior to histologic diagnosis.¹⁸ However, without further treatment patients whose tumors have regressed will inevitably relapse. Therefore, whenever possible, steroids should be withheld until a diagnostic biopsy has been obtained.

STAGING AND PROGNOSIS

Once the diagnosis is established, usually by stereotactic biopsy of a cerebral lesion, further staging is required. All patients should have a contrast-enhanced brain MRI scan, chest radiography, testing for human immunodeficiency virus (HIV 1 and 2), routine hematology, and routine chemistry including serum LDH, protein electrophoresis, creatinine, and liver enzymes. As intraocular involvement and leptomeningeal infiltration are detected in a significant minority of cases, tests to ascertain the presence or absence of disease in these sites are warranted. Indirect ophthalmoscopy and slit-lamp examination should be employed for the evaluation of intraocular disease, and lumbar puncture is recommended in patients in whom the test can be done safely (i.e. those with no evidence of severe raised intracranial pressure). The CSF should be evaluated for protein, cytopathology and sent for flow cytometry. Any patient who presents with seemingly isolated intraocular or leptomeningeal disease should have a contrast-enhanced brain MRI to rule out concomitant intracerebral lesions.

There is controversy regarding how extensively patients with PCNSL should be evaluated for evidence of systemic lymphoma. Some advocate that staging of patients with PCNSL should be similar to that of systemic NHL. However, tests outside the CNS usually yield negative results; the disease is confined to the CNS in more than 95% of patients.²⁰ Although the inclusion of patients who have not had complete staging workup in prospective clinical trials has been reported to have led to unreliable conclusions, the omission of bone marrow examination and CT scanning of the chest, abdomen, and pelvis has not led to any change in overall outcome or pattern of relapse in a 13-year retrospective population-based study in British Columbia.^{21–23} Recently standardized guidelines for the baseline evaluation and response assessment of PCNSL have been published. In the context of clinical trials, adherence to these standards is critical to ensure comparability between studies.²⁴

Prospective studies have consistently shown that age less than 60 years and superior performance status are related to better OS.^{25,26} In a recent study, three additional factors also carried adverse prognostic significance: elevated serum LDH, elevated CSF protein concentration, and involvement of deep structures of the brain (such as brainstem, basal ganglia, cerebellum, and corpus callosum).²⁷ The overall 2-year survival for patients with 0–1, 2–3, and 4–5 factors were

approximately 80, 50, and 20%, respectively. This five factor model has not yet been validated in a separate independent cohort of patients and is not yet in wide clinical use.

PRIMARY TREATMENT

The diffuse nature of PCNSL and the existence of the blood–brain barrier (BBB) have accounted for the lack of success of treatment approaches, including those used for primary brain tumors (e.g. surgical resection and irradiation) and systemic lymphoma (e.g. CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) based chemotherapy). The best treatment modality for PCNSL has not yet been identified.

CORTICOSTEROIDS

Corticosteroids, which are part of the treatment of systemic NHL, have a role in the treatment of PCNSL, by reducing tumor-associated edema and causing lysis of malignant lymphocytes. Although initial responses may be as high as 40%, complete and durable responses are rare.²⁸ Neither the specific type nor the optimal dose of corticosteroids has been established. Occasionally, the clinical and radiographic features are highly suggestive of PCNSL, and the tumor has regressed following corticosteroids, making tissue confirmation impossible. The initial response to corticosteroids appears to predict for outcome.²⁹ Those patients with an excellent clinical and radiographic response following corticosteroids alone have a better long-term outcome than nonresponders.

SURGERY

Surgery is required to confirm the histologic diagnosis, but has no therapeutic role. The median survival of patients treated with supportive care alone is 1–3 months, compared to 4–5 months for those who undergo surgical resection.³⁰ Furthermore, because PCNSL is often multifocal and deep within the brain, resection is technically difficult. Extensive surgery should be reserved for the occasional patient who requires urgent intervention because of acute neurologic deterioration due to cerebral herniation.

WHOLE BRAIN IRRADIATION

Whole-brain irradiation (WBXRT) at doses of 40–50 Gy delivered with conventional fractions was the standard of care for years. Despite initial high response rates (60–70%), local relapse is common, and the median survival of treated patients is only 12–18 months.^{31,32} The reason for local relapse after excellent response remains unclear, especially since irradiation produces local control in 80–90% of cases of localized DLCL.³³ To assess the impact of increasing the dose of irradiation, the Radiation Therapy Oncology Group (RTOG) conducted a phase II prospective study of

PCNSL patients treated with 40 Gy WBXRT plus a 20 Gy boost to the involved area.³⁴ Despite this approach, most relapses still occurred in the brain, and the local control rate was only 39%. Seventy-nine percent of these recurrences were in the region that received 60 Gy. The median survival was 12 months.

Not only is WBXRT of 40–50 Gy only modestly effective, but it leads to unacceptable neurotoxicity in a significant proportion of patients, especially when combined with chemotherapy. Because of this problem, investigators have studied modifications of the dose or volume of irradiation. The RTOG recently reported a study using a methotrexate-based regimen in combination with 45 Gy WBXRT. The protocol was modified during the trial to deliver 36 Gy in a hyperfractionated schedule to those patients who achieved a complete response to chemotherapy.³⁵ There was no difference in local relapse or survival between those who received the lower and higher doses of irradiation, and the rate of neurotoxicity was the same. In contrast, when the dose of WBXRT was reduced from 45 to 30.6 Gy in two consecutive series of patients who achieved a complete response to chemotherapy, the 3-year OS was compromised for patients younger than 60 years (92% vs. 60% $p = 0.04$).³⁶ Another study assessed the outcome for patients treated with focal irradiation instead of WBXRT.³⁷ Patients treated with margins less than 4 cm had higher out-field recurrences compared to those treated with >4 cm margins (83% vs. 22% $p = 0.008$).

In summary, these data demonstrate that a boost to the tumor bed does not improve local control, but partial irradiation compromises it. In order to achieve the optimal benefit from irradiation, WBXRT should be administered. However, the optimal dose and fractionation of irradiation when combined with effective chemotherapy is not yet defined. The threshold at which local control is maintained and neurotoxicity is minimized remains to be determined.

CHEMOTHERAPY IN COMBINATION WITH WBXRT

Chemotherapy in combination with WBXRT, or combined modality therapy, has been used to treat PCNSL for over two decades. Initially, chemotherapy regimens used to treat systemic NHL were employed. Systemic administration of CHOP or CHOD (with dexamethasone), either before or after WBXRT, has been studied in two phase II and one randomized phase III trial.^{26,38,39} In the phase II, trials the reported median survivals of 10 and 13 months were no better than historical controls using WBXRT alone, and were associated with high toxicity and a 15% mortality. The randomized trial of WBXRT followed by CHOP or no further treatment showed no difference in failure-free or OS between the two arms, although the study was terminated early due to poor accrual. These data demonstrate that there is no role for CHOP-type therapy in the treatment of PCNSL.

The BBB is a unique obstacle to the successful treatment of brain tumors because high-molecular-weight or polar compounds cannot cross an intact BBB. Although there is partial disruption of the BBB in PCNSL, early successful treatment with corticosteroids effectively reconstitutes the barrier.⁴⁰ Successful inroads to treating PCNSL include selection of drugs with physicochemical properties, such as lipid solubility and low molecular weight, which can permeate an intact BBB. One such drug is methotrexate (MTX), an antimetabolite that can penetrate the intact BBB when given intravenously at doses over 1 g/m².⁴¹ High-dose MTX refers to systemically administered MTX, infused over 4–6 h, at doses higher than 1 g/m² and usually over 3.5 g/m², followed by folinic acid rescue. It plays a modest role in the treatment of systemic lymphoma, but has become the most important single agent in the treatment of PCNSL. The optimal schedule, dose, and regimen have not been established, but many mature phase II trials of combined modality therapy with MTX-based regimens have been published. These data are summarized in Table 58.1 and report higher median survivals than those seen with WBXRT alone. As is the case with phase II trials in general, single institutions report better outcomes than multi-institutional trials. The reasons for these differences may be treatment-related, such as less familiarity with the chemotherapy protocol, but may also include referral bias, in that only a select number of patients are fit enough to travel to a specific center for experimental treatment.

Most of these trials used intrathecal and systemic chemotherapy to prevent leptomeningeal relapse or treat occult disease. Since intravenously infused, rapidly administered MTX in doses above 3 g/m² can achieve cytotoxic CSF levels, it is unclear whether the addition of intrathecal chemotherapy is necessary. Furthermore complications arise from the placement of an Ommaya reservoir. A recent case-controlled retrospective study concluded that patients who received 3.5 g/m² of MTX did not have improved disease control or survival with the additional administration of intrathecal chemotherapy.⁴² However, this conclusion did not apply to patients with overt positive CSF cytology.

Several large retrospective series have examined outcomes according to treatment.^{5,15} They provide long-term follow-up on a heterogeneously treated group of patients. One study of 466 patients in which only 6%, who had been treated with MTX-containing combined modality regimens. Those patients who received at least two cycles of chemotherapy had a median survival of 22 months, compared to 17 months for those treated with WBXRT alone. This difference was not significant. In the series from the International Extranodal Lymphoma Study Group (IELSG), about half of the patients were treated with high-dose MTX-containing regimens prior to WBXRT.

Table 58.1 Results of combined modality treatment for PCNSL using MTX-based regimens

Chemotherapy (Systemic)		IT chemo	Institution	Median Age (yr)	N	WBXRT dose Gy (boost)	Median PFS (months)	Median OS (months)	5y%	Comments	Reference
Pre XRT	Post XRT										
MTX 1g/m ² × 2	3 g/m ² ara-C × 2	Yes	Single	58	31	40 (14)	40	42	22	5 yr CSS 60% (if < 50y)	70, 82
MTX 3.5g/m ² × 5 + vincristine procarbazine	3 g/m ² ara-C × 2	Yes	Single	65	52	45	Not reached	60	50	Median OS 33mo (if ≥ 60y) Not reached (if ≤ 60y)	46
MTX 3.5g/m ²		No	Single		25	30 (variable)	32	33			83
C5R including MTX 3g/m ² × 2 ara-C 500 mg/m ² + CHOP type		Yes	Single	51	25	20 (30)			56	Median FU 24 months	43
MTX 2.5g/m ² × 5 + vincristine procarbazine		Yes	Multi	57	102	a) 45 b) 36	24	36	32	Median OS 22 mo (if > 60y) 50 mo (if < 60 yr)	35
MTX 1 g/m ² × 2		Only in 3 pts with + CSF	Multi	58	46	45 (5.4)	40	33			49
MTX 3 g/m ² × 2 + Teniposide carmustine		yes	Multi	51	52	40		46	58 (3 yr%)	10% toxic deaths	44

XRT = irradiation; MTX = methotrexate; FU = follow-up; WBXRT = whole brain irradiation; PFS = progression-free survival; OS = overall survival; ara-C = cytarabine; IT = intrathecal; CSS = cause specific survival.

The overall 2-year survival was 37%, but rose to 60% for those patients who received MTX as part of their primary therapy. In addition, a multivariate analysis suggested that for those patients treated with MTX, the addition of high-dose cytarabine also contributed to a survival benefit. However, due to the heterogeneous treatment approach and multicenter nature of the study, one cannot determine the optimal chemotherapy approach for this disease based on these data. The observation of a better prognosis with cytarabine should be interpreted with caution as it may not be attributable to treatment itself but to other known or unknown prognostic factors affecting the selection of the treatment. We studied the outcomes for 122 patients with PCNSL treated with three consecutive therapeutic approaches over 13 years in British Columbia. The median OS was 17 months. When analyzed by intention-to-treat, outcomes had not changed over time. However, those patients who received MTX, regardless of age and performance status, had a median OS of 31 months.²³

The results of phase II studies and the retrospective series will not be corroborated by a phase III randomized trial, because expert opinion has determined that, based on the available data, MTX-based chemotherapy should be administered along with WBXRT. The median survival of patients treated with this approach ranges from 33 to 60 months, compared to 12–18 months for those given WBXRT alone. Although a selection bias cannot be excluded, it likely does not account for all of the benefit attributed to MTX. However, there are many outstanding issues regarding the use of MTX in combined modality treatment including the optimal dose of MTX, duration of treatment, and best chemotherapy regimen. Studies have used doses ranging from 1 to 8 g/m². Our data and the IELSG series showed no difference in outcome according to dose. Most studies and ongoing protocols use 3–4 g/m². Although one retrospective study suggested that cytarabine contributed independently to outcome,⁵ there has been no randomized comparison of different chemotherapy regimens. In general, the more intensive multiagent protocols, such as CSR⁴³ and MBVP,⁴⁴ have reported higher acute treatment-related morbidity and mortality compared to simpler protocols.

NEUROTOXICITY

Although the acute toxicity from simple MTX-based combined modality treatment is acceptable, delayed neurotoxicity resulting from the combined effects of MTX and WBXRT is a serious problem that limits the overall efficacy of these regimens. The condition is termed “leukoencephalopathy,” and is characterized by diffuse white matter abnormalities, cortical atrophy, and ventricular dilatation.⁴⁵ Clinically, patients present with a progressive and irreversible neurological syndrome of cognitive impairment, ataxia, and

incontinence, which develops a median of 9–16 months following treatment. The incidence of neurotoxicity seems to be related to several variables one of which is the use of WBXRT. One study reported that surviving patients older than 60 years who received WBXRT following MTX-based chemotherapy had a 83% risk of leukoencephalopathy, compared to 17% in those who were not irradiated.⁴⁶ Only 6% of patients under age 60 years who were irradiated developed this complication. However a trial from Germany in which complete responders to induction chemotherapy were randomized to WBXRT or not reported equivalent rates of neurotoxicity in older and younger participants (19% and 21%, respectively). Moreover, the rates did not differ between those who received WBXRT and those who did not.⁴⁷ Other studies have reported a 22–26% incidence of this problem.^{48,49} Subtler forms of this condition are not as well documented, but one study reported that only 20% of patients aged 40–60 years at diagnosis, who were alive and disease free at 4 years, were capable of working.⁴⁸ Finally, it is unclear whether there is an independent contribution of intrathecally administered chemotherapy to the development of leukoencephalopathy. In one trial of combined modality treatment, there was no significant difference in the rate of neurotoxicity between those who received intrathecal chemotherapy and those who did not.⁴²

In an effort to reduce leukoencephalopathy, current treatment strategies are focusing on using chemotherapy alone and deferring WBXRT for responders, especially in older patients. Since cognitive impairment often is present at diagnosis in PCNSL, this approach will not entirely prevent chronic neurological symptoms. However this complication has been reported less commonly in those patients treated with chemotherapy alone.^{47,50–52}

CHEMOTHERAPY ALONE

Chemotherapy approaches have included using MTX as a single agent, combining MTX with other drugs that penetrate the BBB, and administering high-dose chemotherapy and stem cell rescue in patients who respond to induction MTX-based regimens. These studies are outlined in Table 58.2 and demonstrate a wide range of OS. The striking difference compared to combined modality treatment appears to be the minimal neurotoxicity.

While the majority of studies have focused on using combinations of chemotherapy agents that penetrate the BBB, other investigators developed administration strategies that improve drug delivery to the brain. With the patient under general anesthesia, the femoral artery is catheterized and an osmotic agent, mannitol, can be used to temporarily disrupt the BBB. This is followed by the intravenous and intraarterial infusion of chemotherapy, and is repeated monthly for up to 12 cycles in responding patients.⁵⁹ One

Table 58.2 Results of selected trials of MTX based chemotherapy alone in the treatment of PCNSL

Chemotherapy (Systemic)		IT chemo	Institution	Median Age (yr)	N	Median PFS (mo)	Median OS (mo)	Comments	Neurotoxicity	Reference

CR = complete response; OS = overall survival; IT = intrathecal; PD = progressive disease; PFS = progression-free survival; MTX = methotrexate; BEAM + ASCT = carmustine, etoposide, cytarabine, melphalan + autologous stem cell transplant.

center treated 74 patients this way over 15 years and reported a median OS of 40 months and a 5-year OS of 42%. Ten patients experienced significant acute morbidity and mortality, but no cases of neurocognitive impairment were seen in surviving patients. There have been no randomized trials comparing conventionally administered chemotherapy to that delivered with BBB disruption. In view of this as well as the procedural complexities and acute toxicity associated with this approach, this technique has not been widely adopted.

Ongoing clinical trials are focused on adding additional agents to MTX such as thiotepa, ifosfamide, or rituximab.^{57,60,61} Rituximab is a chimeric anti CD20 monoclonal antibody that improves the survival of patients with systemic diffuse large B cell lymphoma when administered with CHOP.⁶² Because of its physicochemical characteristics, it does not penetrate an intact BBB. Despite this, several studies are currently exploring its use in the treatment of PCNSL.⁶¹ In addition to trying to enhance efficacy, current trials are also attempting to reduce the toxicity of combined modality treatment by either reducing the dose of WBXRT or deferring it entirely for patients who achieve a complete response to systemic therapy.^{63,64}

SPECIAL THERAPEUTIC CIRCUMSTANCES

INTRAOCULAR LYMPHOMA

When intraocular lymphoma (IOL) is present at diagnosis, there is usually concomitant cerebral involvement. If WBXRT is being used in the primary treatment, the eyes should also be included in the irradiation field. The long term side-effects of orbital irradiation include the development of cataracts, retinal detachment, and optic nerve atrophy. High-dose intravenous MTX alone can achieve therapeutic concentrations in the vitreous humour.⁶⁵ One study reported a complete response in four of five patients with IOL treated with this approach.⁶⁶ This suggests that orbital XRT can be deferred in patients with stable visual findings who receive MTX. One approach is to assess for persistent disease after four cycles of chemotherapy. If IOL is still detected, then orbital irradiation can be administered.

It is rare for patients to present with IOL alone. Ninety percent of these patients will eventually relapse in the brain, and any treatment approach should keep this in mind. Chemotherapy alone, with orbital and/or WBXRT reserved for persistent or progressive disease, is an attractive option that minimizes toxicity.

LEPTOMENINGEAL LYMPHOMA

Leptomeningeal involvement is seen in about 15% of patients diagnosed with PCNSL. The presentation is

commonly clinically silent and only detectable by cytological examination of the CSF. Less frequently, there can be overt cranial nerve or nerve root symptoms that are easily visible as gadolinium enhancement of the leptomeninges on MRI examination. Leptomeningeal disease is usually present with intracerebral involvement, but in 1–2% of cases it is the sole site of PCNSL.

The treatment depends on the extent of the disease. If bulky disease is present and symptomatic, localized irradiation to the spinal cord or skull base should be employed but chemotherapy, delivered either intrathecally or intravenously, is required to take care of disease disseminated throughout the CSF. Systemic chemotherapy with 8 g/m² of MTX does penetrate the CSF and achieves prolonged cytotoxic CSF concentrations at least comparable to those from intrathecal administration.⁶⁷ Intrathecal administration of MTX or cytarabine usually requires insertion of a ventricular reservoir because the drugs are given twice a week, due to the short half life in the CSF. A sustained release form of liposomal cytarabine, administered every 2 weeks, has been compared to conventional cytarabine for the treatment of lymphomatous meningitis.⁶⁸ Those patients who received the sustained release formulation had a higher response rate (71 vs 15%) and greater improvement in performance status than those who were treated with conventional cytarabine.

If leptomeningeal involvement is clinically silent and detected only by cytological examination of the CSF, it is unclear whether or not intrathecal chemotherapy needs to be given when chemotherapy regimens that include high-dose intravenous MTX are employed as primary treatment.^{42,66} One approach is to follow such patients carefully and withhold intrathecal treatment if the patient is improving and the CSF cytology clears after four cycles of MTX.

SPINAL LYMPHOMA

True intramedullary spinal cord lymphoma, in contrast to epidural disease, is very rare. Intracerebral, intraocular, and leptomeningeal disease should be ruled out with the staging investigations described in the section above. If the lymphoma is confined to the spine, combined modality treatment with MTX-containing chemotherapy and localized irradiation is recommended.

TREATMENT FOR RELAPSED OR REFRACTORY DISEASE

The majority of patients with PCNSL relapse following primary treatment, and a significant minority have progressive disease during primary treatment. One retrospective study of 173 patients concluded that patients whose overall condition is suitable to receive

salvage therapy have significantly prolonged survival compared to those who are given no further treatment (14 vs 2 months).⁶⁹ Although this improved survival may be largely due to patient, rather than treatment-related factors, fit patients should be offered salvage treatment. However, there are no standard recommendations for second-line therapy as most studies are small case series of heterogeneously treated patients. The choice of treatment depends on the patient's prior treatment, the site of relapse (brain, ocular, leptomeningeal, spinal, systemic, or a combination), and the disease-free interval.

Patients who relapse in the brain following WBXRT (either alone or as part of combined modality treatment) should be offered chemotherapy. MTX can be administered to those who did not receive it during first line therapy, although neurotoxicity remains a concern with this sequence of therapy. Several chemotherapy options have been reported to be useful for those who progress or relapse soon after MTX-based combined modality treatment. These include high-dose cytarabine (3g/m²),⁷⁰ PCV (procarbazine, lomustine, and vincristine),⁷¹ thiotepa, temozolamide,⁷² and topotecan.^{73,74} High-dose chemotherapy with thiotepa, busulfan, and cyclophosphamide followed by autologous peripheral blood stem cell (PBSC) infusion can result in 64% survival at 3 years, but was too toxic for patients over 60 years of age. Of the 22 patients who were treated with this approach, 14 had received CYVE (cytarabine and etoposide) to ascertain chemosensitivity prior to high-dose treatment.⁷⁵ There are ongoing studies using rituximab intravenously for relapsed disease.^{76,77}

WBXRT can be used at progression or relapse if it was not part of the initial therapy. One study reported an overall response of 76 % and a median survival of 6.8 months with this strategy while another reported a

median survival of 11 months.^{78,79} However WBXRT may not be essential as some patients with a long disease-free interval after receiving MTX alone as their primary treatment can be effectively retreated with the same chemotherapy regimen. In one study, 9 of 11 patients achieved a second complete response after reinduction.⁸⁰

Patients who have an isolated intraocular relapse following treatment with chemotherapy alone should be treated with ocular XRT. Since these patients are also at high risk of relapse in the brain, WBXRT can be considered, but it may be deferred until intracerebral progression is demonstrated. The report of high-dose chemotherapy and PBSC rescue described above included eleven patients with intraocular involvement, four of whom had isolated ocular disease and demonstrated its feasibility in this group. For patients whose eyes have been previously irradiated, intravitreal MTX is also an option.⁸¹

Patients who relapse in the leptomeninges can be managed with spinal cord irradiation, intrathecal or systemic chemotherapy as described in the Leptomeningeal Lymphoma section above.

SUMMARY

There are still several unresolved issues regarding the optimal management of PCNSL. The need for WBXRT, especially in patients over 60 years old, remains controversial and the best compromise between disease control and delayed neurotoxicity has not been identified. PCNSL is a chemosensitive disease but the optimal systemic regimen has yet to be defined. Other controversial issues include the role of intrathecal chemotherapy for primary treatment and the optimal salvage treatment for refractory and relapsed disease.

Chapter 59

TREATMENT APPROACH TO CUTANEOUS LYMPHOMAS

Christiane Querfeld, Timothy M. Kuzel, Joan Guitart, and Steven T. Rosen

Cutaneous lymphomas comprise both T- and B-cell subtypes and represent a heterogeneous group of non-Hodgkin's lymphomas. There are no standard guidelines for the treatment of these entities. However, precise diagnosis and identification of prognostic features is critical in determining therapy.¹ Select subtypes can be cured, while prolongation of life and effective palliation can be achieved in the majority of patients.

TREATMENT OF PRIMARY CUTANEOUS B-CELL LYMPHOMA

The classification of primary cutaneous B-cell lymphoma (PCBCL) remains controversial with separate and distinct terminology promoted by the Working Formulation, the Revised European–American Lymphoma (REAL) classification, the World Health Organization (WHO) and the European Organization for Research and Treatment of Cancer (EORTC).^{2–4} Most long-term follow-up data are based on studies according to the EORTC (Table 59.1). The varied classification schemes make it difficult to interpret the literature concerning treatment.

PCBCLs are characterized by a favorable prognosis with a tendency to remain localized to a limited area of the skin and a low risk of extracutaneous spread. Compared to cutaneous T-cell lymphoma (CTCL), experience with treatment of PCBCL is more limited and focuses on follicle center cell lymphoma (FCCL). The optimum treatment for marginal zone lymphoma (MZL)/immunocytoma (IC), large B-cell lymphoma of the leg (LBCL of the leg), and the provisional entities remains controversial. Traditional treatment approaches, including surgical excision, local radiation, and/or chemotherapy, are most commonly used, but relapses occur frequently. Antibiotics may be used as a first-line treatment of *Borrelia burgdorferi*-associated primary cutaneous B-cell lymphoma.^{5,6} Biologic therapies, such as interferon alpha and rituximab, a chimeric monoclonal antibody directed against

CD20 cell surface marker, have been incorporated into treatment strategies.^{7,8} In select patients with relapsing and refractory disease, autologous or allogeneic transplantation is appropriate.

RADIATION THERAPY

PCBCL are highly radiosensitive, and radiation therapy is often the preferred therapy for solitary or localized grouped lesions. There are few retrospective studies available on radiotherapy of PCBCL, and they include small numbers of patients. Prospective trials have not been reported. Reported complete remission rates range from 92 to 100%, with 5-year survival rates ranging from 67 to 100%.^{9–12} However, cutaneous recurrences are common, and were observed in 16–67% of patients.

In a recent retrospective study, 34 patients with PCBCL treated with radiotherapy were identified and classified according to EORTC and WHO criteria.⁹ Twenty-six patients were treated with electron beam radiation, six patients with orthovoltage radiation, and one patient each with photon beam radiation and combination of photon and electron beam radiation. The authors note that a 2- to 3-cm margin added to the radiation site is generally used at their institution, although exact data were not available. All patients achieved a complete response (CR) to initial treatment. Five-year relapse-free survival ranged from 62 to 73% for follicle center cell (FCC) by EORTC/diffuse large B-cell lymphoma (DLBCL) by WHO, FCC by EORTC/follicular lymphoma (Fol) by WHO, and MZL by EORTC and WHO, with a 5-year overall survival of 100%. Patients with LBCL of the leg by EORTC/leg DLBCL by WHO showed worse results, with a 5-year relapse-free survival of 33% and a 5-year overall survival of 67%. However, only three patients were classified as leg DLBCL. The less favorable prognosis of the anatomic site leg seems to be consistent with previously published data and EORTC classification.^{2,13} Eight of 13 relapses were confined to the skin and 5 developed extracutaneous spread. The

Table 59.1 The WHO-EORTC classification for primary cutaneous lymphomas and associated frequency and 5-year survival^a

WHO-EORTC	Frequency (%)	5-year survival (%)
Cutaneous T-cell and NK-cell lymphoma		
<i>Indolent</i>		
Mycosis fungoides	44	88
■ Follicular MF	4	80

^aData from Willemze R, Jaffe ES, Burg G, et al.: WHO-EORTC classification for cutaneous lymphomas. *Blood* 105:3768–3785, 2005.

median radiation dose was 40 Gy, and ranged from 20 to 48 Gy. Patients receiving doses less than 36 Gy showed an increased risk of recurrence.

Eich et al. retrospectively examined 35 patients with PCBCL, mostly with FCCL.¹⁰ Four patients were identified with LBCL of the leg. They treated 32 patients with electron beam radiation (5–12 MeV), 2 with photon beam radiation (5 MV), and 1 with a combination thereof (5 MeV, 6 MV). Thirty-four patients achieved a CR after initial treatment. However, cutaneous relapses occurred in 31% of

patients, mostly at nonirradiated sites. Five-year relapse-free survival of all patients was 50%, with a 5-year overall survival of 75%. Median dose to target was 45 Gy, and ranged from 27 to 54 Gy with a median fractionated dose of 1.8 Gy. Reported radiation margins ranged from 2 on the head to 5 cm on the trunk and extremities. Treatment was generally well tolerated with documented grade I reactions in 30 patients (86%) according to EORTC criteria¹⁴ and teleangiectasia in 3 patients after a median of 3 years.

Kirova et al. reported 25 patients treated with initial radiation, with similar results.¹¹ All patients were treated with electron beam therapy delivered with electrons of 8-MeV energy and total doses ranging from 30 to 40 Gy. Depending on the extent of skin disease, either extended field or localized field irradiation was used. A healthy skin margin of at least 2.5 cm was included in the radiation field. The CR rate was 92%, with a 5-year overall survival of 75%. The 5-year disease-free survival was 75%. Relapses occurred between 2 months and 13 years in 16% of the patients, primarily in unirradiated sites. Side effects were usually grade I reactions at presentation, with occurrence of skin cancer in one patient after 10 years.

Rijlaarsdam et al. reported 55 patients with FCCL. Forty patients received radiation therapy.¹² Thirty-one were treated with electron beam, eight with photon beam equipment, and one with orthovolt radiation. Doses ranged from 30 to 40 Gy with 2-cm safety margins. All patients achieved CR. The reported relapse rate was 20% (8 patients). Four patients had leg involvement. A better estimated 5-year survival rate of 89% for all patients was reported, which might be related to the indolent nature of FCCL. Three patients with tumors on the legs died of disease.

SURGERY

Except for anecdotal case reports of successful treatment of PCBCL with surgical excision, no studies have proven its efficacy. Local recurrences are frequently observed in more than 50% of patients; therefore, combinations of surgery, radiotherapy, or chemotherapy are frequently used.^{15,16} Surgical excision can be considered for small, localized lesions; however, the advantage over radiotherapy is unknown.

CHEMOTHERAPY

Systemic chemotherapy has been used in the treatment of PCBCL, especially for patients with multifocal or extensive lesions or with LBCL of the leg, as they are to be considered at higher risk of developing systemic involvement.² Several studies have shown the high efficacy of multiagent chemotherapy, with CR rates in up to 89% of the cases.¹⁷ The cyclophosphamide, doxorubicin, vincristine, and prednisone

(CHOP) regimen has been found to be superior to cyclophosphamide, vincristine, and prednisone (COP) by some investigators.^{14,17}

Rijaarsdam et al. reported a small, nonrandomized trial that included only 15 patients with FCCL treated with initial polychemotherapy.¹⁴ Eleven patients received six cycles of CHOP and four patients received COP. CR occurred in 14 of 15 patients, with an estimated 5-year survival rate of 93%. All 4 patients treated with COP relapsed, whereas only 2 of 11 patients treated with CHOP relapsed. A study by Santucci et al. of 65 patients with PCBCL included 6 patients treated with COP or COP with bleomycin (COP-B). CR occurred in all six patients; however, four of them relapsed within 2–14 months.¹⁸

A follow-up study of 81 patients, in which 46 with PCBCL were treated with CHOP or COP, showed a CR rate of 89% and a 5-year survival of 97%, with a relapse-free survival of 70%. However, the relapse rate was 33%, and 55% in patients with LCBCL of the leg.¹⁷

Recently, Sarris et al. evaluated the outcome after doxorubicin-based polychemotherapy versus radiotherapy for patients with cutaneous DLBCL diagnosed according to the Working Formulation.¹⁹ Ten patients received radiation and 33 received doxorubicin-based chemotherapy followed by radiation in 25 cases. The latter included eight patients with FCCL. The CR rate was 90% for radiation, 88% for doxorubicin-based chemotherapy, and 100% for combined modality. The 12-year progression-free survival of 71% was significantly higher in patients treated with chemotherapy/combined modality therapy compared with radiotherapy alone, in which it was 0%. Twelve-year overall survival was 77% in patients treated with chemotherapy/combined modality therapy versus 25% in patients treated with radiotherapy. In this series, the majority of patients had lesions on the head, neck, and trunk.

In contrast, Bekkenk et al. (as previously noted) found in a limited number of patients with multifocal FCCL or MZ/IC no difference in outcome and prognosis after treatment with either radiation or chemotherapy.²⁰ Polychemotherapy consisted of six cycles of either CHOP or COP therapy in nine patients with FCCL. Five patients received electron beam radiation, with a target dose of 40 Gy. All patients achieved a CR, with a median relapse-free survival of 36 months. Eight patients were diagnosed with MZ/IC. Two of them received CHOP or COP, respectively; one patient was treated with Chlorambucil, three with radiation or surgical excision, and two patients with topical steroids. Only the patient treated with CHOP achieved a CR. Cutaneous relapses occurred in two patients with FCCL treated with chemotherapy and in all patients with MZ/IC. One patient with FCCL developed extracutaneous disease.

PERIPHERAL STEM CELL TRANSPLANTATION

The prognostic value of stem-cell transplantation in larger series of patients with primary CBCL has not been evaluated. Responses to high-dose therapy (HDT) followed by autologous stem cell transplantation (ASCT) have been reported to be effective in CBCL.²¹ A series of 14 patients with cutaneous lymphomas treated with HDT/ASCT included three patients with disseminated and relapsed FCCL/DLBL. Eight patients, seven with CTCL, relapsed. Six of these patients relapsed within 4 months. No relapse occurred in patients with FCCL/DLBL, with a disease-free follow-up time of 15 months, 36 months, and 5 years, respectively.

RECOMMENDED TREATMENT APPROACH FOR PRIMARY CUTANEOUS B-CELL LYMPHOMA

The clinical course and prognosis of CBCL is excellent and significantly differs from systemic lymphomas. Our approach to treatment strategies depends on the number and localization of lesions and the patient's age and health condition. The toxicity of treatment should not outweigh the cosmetic and functional disability of the disease. We prefer initial observation for patients with unifocal or multifocal lesions. If cosmetic consequences are a concern, we use local therapies such as radiation, intralesional steroid injection, and surgery or rituximab. We reserve systemic doxorubicin-based chemotherapy with or without rituximab for recurrent multilesional or disseminated cutaneous or extracutaneous tumors or LBCL of the leg.

TREATMENT OF PRIMARY CUTANEOUS T-CELL LYMPHOMA

No treatment cures patients with the indolent forms of CTCLs, such as mycosis fungoides (MF)/ Sézary syndrome (SS) and lymphomatoid papulosis (LyP). Prognosis and survival of patients with CTCL remains dependent upon overall clinical staging and response to therapy. Over the last decade, various effective treatment modalities and novel treatment approaches have been developed for patients with MF/SS, which are based on an increased understanding of the pathobiology of the disease. However, experience with patients with other rare CTCL is limited, and the selection of treatment strategies remains more difficult.

TREATMENT OF EARLY STAGE MYCOSIS FUNGOIDES

Treatment of MF/SS includes topical and systemic therapies that can be administered alone or in combination. In early stage IA to IIA MF, the disease is mostly limited to the upper dermis, with prominent epidermotropism that can be treated successfully with topical modalities. Multiagent chemotherapy regimens,

used early in the course, demonstrated no survival benefit.²² Various topical treatment options exist for early stages.

TOPICAL STEROIDS

Although widely used, limited data are available regarding the use of topical steroids in early stage MF. In an investigational trial, 79 patients were treated daily with topical class I-III steroids.²³ Thirty-two (63%) stage T1 patients and seven (25%) stage T2 patients achieved complete clearing. Thirteen patients (40%) with stage T1 and two patients (29%) with stage T2 relapsed; however, the median observation time was only 9 months. Reported side effects were minor skin irritation in 2 patients, reversible skin atrophy in 1 patient, and reversible depression of serum cortisol levels in 10 patients.

TOPICAL CHEMOTHERAPY

Topical nitrogen mustard has been used for management of MF since 1959.²⁴ Many investigators have demonstrated the efficacy of topical nitrogen mustard in patch and/or plaque disease of MF.²⁵ A recent update of 203 patients with MF (clinical stage I-III) treated with topical nitrogen mustard demonstrated CR rates of 76–80% for patients with stage IA and 35–68% for those with stage IB disease.²⁶ Fewer than 10% of patients developed progression of disease. Most common side effects were irritant contact dermatitis. No secondary malignancies related to therapy were reported. Topical Carmustine (BCNU) showed similar results, with an 86% CR rate; however, patients may develop progressing teleangiectasias from treatment.²⁷ Mild leukopenia occurred in 3.7% of the patients.

TOPICAL RETINOIDS

Topical retinoid application may be an effective approach in early stage MF. They exert their effects through two basic types of nuclear receptors: the retinoic acid (RAR) and retinoid (RXR) receptor family. No comparison of different retinoids has been evaluated. In a dose-escalating phase I/II trial of the RXR-specific retinoid bexarotene, 0.1–1.0%, the CR rate was 21%, with an overall response rate of 63%.²⁸ Side effects were restricted to the application site and consisted of mild to moderate irritation, with erythema in 73% of the cases. Bexarotene 1% gel was approved by the Food and Drug Administration (FDA) as a therapy for stages IA through IIA MF.

PHOTOTHERAPY/PHOTOCHEMOTHERAPY

Ultraviolet (UV) light of different wavelengths has been used for many years. UVA (320–400 nm) and UVB (290–320 nm) are most common. Treatment combination with UVA and photosensitizing compounds (psoralens) is termed PUVA. PUVA has been used since 1976 in the treatment of various dermatological diseases

including CTCL, and is one of our preferred treatment options in early stage MF.²⁹ It is extremely effective at clearing patch and plaque disease; however, the impact of maintenance therapy remains uncertain. Several studies confirm high remission rates in early stages of MF, with reported complete remissions in up to 71.4% of patients.^{29–32} Long-term remissions have been reported for PUVA. We evaluated follow-up data of 66 patients with early stage disease who achieved CR after PUVA monotherapy, and showed that 50% of the patients maintained CR with a median of 84 months, and 50% of the patients relapsed with a median disease-free interval of 39 months. Median follow-up time was 94 months.³² Reported short-term side effects were most commonly nausea and erythema. About 30% of patients developed skin malignancies, such as squamous or basal cell carcinoma.

The efficacy of UVB is more limited to patch stage, while PUVA is also effective in clearing plaques. The effects of UVB phototherapy were retrospectively evaluated in 37 patients with MF limited to patch/plaque disease.³³ Seventy-one percent achieved a CR, with a median duration of 22 months. Eighty-three percent of patients with disease limited to patches achieved remission, whereas none of the patients with plaque disease achieved remission. Narrowband (NB)-UVB is considered to be less carcinogenic and may be an alternative treatment option in early stage MF. In three small retrospective analyses, patients with clinical stage IA/IB and parapsoriasis and treated with NB-UVB showed CR rates between 54.2 and 83%.^{34–36} However, remission times were short and a maintenance schedule has been difficult to establish. Long-wave ultraviolet A (UVA1) has likewise shown efficacy in single case reports.³⁷

TOTAL SKIN ELECTRON BEAM THERAPY

Recently published data of the therapeutic efficacy of total skin electron beam therapy (TSEB) from centers with extensive experience showed 40–98% complete remission rates among patients with stage IA and MF IB, with approximately 50% of patients with clinical stage IA and 25% of patients with clinical stage IB remaining in long-term remission.³⁸ TSEB treatment in early stages remains controversial because of its potential toxicity. Side effects can be significant, and consist of erythema, edema, scaling, ulceration, and irreversible loss of skin adnexa. TSEB may be repeated for palliative effects, although at reduced doses. Adjuvant therapy including PUVA, photopheresis, and INF- α may improve the duration of response.

RECOMMENDED TREATMENT APPROACH FOR EARLY STAGE MYCOSIS FUNGOIDES

Nonrandomized clinical trials have not suggested that any one skin-directed therapy is preferable. Treatment choice should be made with the patient's preference and practitioner's skill in mind. Our philosophy regarding

the management of patients is to maximize benefits while minimizing side effects. Therefore, we advocate the use of topical monotherapy. If patients fail to respond, we switch to a different topical therapy. Our first-line treatment for early stage patients is PUVA or NB-UVB therapy. However, in cases of refractory early stages we consider combination therapy such as PUVA or NB-UVB with low-dose systemic bexarotene or INF- α .

TREATMENT OF ADVANCED STAGE MYCOSIS FUNGOIDES/SÉZARY SYNDROME

Patients may ultimately progress into more aggressive and advanced disease with either cutaneous or extracutaneous tumor manifestations. Treatment goals in advanced stages should be to reduce tumor burden, to relieve symptoms, to decrease the risk of transformation into aggressive lymphoma, and to preserve quality of life. Standard methods include mono- or polychemotherapy, extracorporeal photopheresis, interferons, retinoids, monoclonal antibodies, recombinant toxins, combination therapy, and high-dose chemotherapy with allogeneic stem cell transplant.

SYSTEMIC CHEMOTHERAPY

Systemic chemotherapy should be restricted to patients with advanced stage disease or with multiple relapsed and refractory plaques and tumors. Established treatment options include single-agent or multiagent chemotherapy such as steroids, methotrexate, chlorambucil, vincristine, doxorubicin, cyclophosphamide, etoposide, and alkylators. Combination chemotherapy with CHOP or CHOP-like therapies has been shown to achieve higher response rates of approximately 70–80%.³⁹ Eighty-one patients (46 primary CBCL and 35 CTCL) were treated with COP or CHOP regimens. The overall response rate was 40% in CTCL patients, with a CR in 23% of patients. The median response duration was 5.7 months and median survival was 19 months. A phase II trial with the etoposide, vincristine, doxorubicin, cyclophosphamide, and oral prednisone (EPOCH) regimen in 15 patients with refractory CTCL resulted in an overall response rate of 80%.⁴⁰ Twenty-seven percent of patients achieved a CR, and 53% of patients achieved a partial response (PR) with a median duration of 8 months and an overall survival of 13.5 months. Grade 3 or 4 hematologic toxicity occurred in eight patients (61%).

Among single-agent chemotherapies, liposomal doxorubicin, pentostatin, and gemcitabine have been effective. An investigational trial with a limited number of patients demonstrated efficacy of pegylated liposomal doxorubicin monotherapy, with an overall response rate of 80% and a CR in 6 of 10 patients (60%).⁴¹ Recent published multicenter data of pegylated doxorubicin in 34 patients with recurrent or recalcitrant CTCL revealed a response rate of 88.2%.⁴² Twenty-seven patients (79.4%) achieved a CR with a

median duration of 12 months, ranging from 9.5 to 44 months. Adverse effects were seen in 14 patients and were generally mild compared with other chemotherapy regimen. Only six patients experienced grade 3 or 4 toxicity.

Studies of purine analogs, such as pentostatin (2-deoxycoformycin), fludarabine, and 2-chlorodeoxyadenosine (2-CdA), have demonstrated significant initial response rates of up to 100%. However, most responses were short lived and were accompanied by harmful side effects related to prolonged immunosuppression.^{43–45} Pentostatin has been evaluated in 28 heavily pretreated patients with MF/SS who were treated on a dose-escalating phase II trial, with doses ranging from 3.75 to 5.0 mg/m²; a CR was achieved in 25% of patients.⁴⁶ Most patients developed granulocytopenia with significant lowering of CD4 counts, nausea, and neutropenic fever. Kuzel et al. investigated 2-CdA in 21 patients with relapsed/refractory MF/SS.⁴⁷ Three patients (14%) attained a CR, with a median duration of 4.5 months and a range of 2.5–16 months. Gemcitabine, a novel pyrimidine antimetabolite, was investigated at two centers in a phase II trial at a dosage of 1.2 g/m² in 44 patients with clinical stage IIB–IV MF/SS.⁴⁸ Twelve percent of patients achieved a CR, and 26% of patients achieved a PR, with a median duration of 15 months and 10 months, respectively.

Temozolomide, a new oral alkylating agent, is being evaluated in a phase II trial of patients with relapsed MF and SS. Patients with MF/SS have been shown to have low levels of DNA repair enzyme O⁶ alkylguanine DNA alkyltransferase (AGT) and may be particularly sensitive to this alkylator.⁴⁹ Preliminary data have been reported with a more than 50% decrease in tumor burden in 5 of 22 patients with MS/SS (26%), lasting for a median duration of 4 months.⁵⁰ Twelve of 16 patients tested did not express AGT. Patients with AGT expression did not respond to treatment.

BIOLOGIC RESPONSE MODIFIERS

The ratio of T-helper cell type 1 (T_h1) and type 2 (T_h2) has been hypothesized to be critical for disease progression. In advanced stages there is a dominant T_h2 cytokine profile leading to an impaired host antitumor response.⁵¹ Treatments such as biologic response modifiers target the reconstitution of immune function for disease control. Currently, immune-modifying treatment options such as bexarotene, immunomodulatory cytokines such as interferon-alpha (INF- α), and interleukin 2 and 12 (IL-2, IL-12), and extracorporeal photopheresis (ECP) are used to treat MF/SS.

INTERFERON-ALPHA

INF- α was first reported in 1984 by Bunn et al. for the treatment of advanced and heavily pretreated MF/SS, with an overall response rate of 45%.⁵² Papa et al. showed response rates between 70% for advanced

stage III–IV and 80% for early stage patch/plaque disease.⁵³ Olsen et al. showed, in an investigational trial of 3 versus 36 MU daily of INF α -2a in 22 patients with clinical stage I–IV MF/SS, an overall response rate of 38% in low-dose-treated patients compared to 79% in high-dose-treated patients.⁵⁴ Side effects were dose related and were most commonly flu-like symptoms. The development of neutralizing antibodies has been associated with INF- α therapy, with variable impact on response rates.⁵⁵ They appear to be higher in patients treated with INF α -2a compared to INF α -2b. The combination therapy IFN- α and PUVA resulted in high response rates in more than 90% of patients and showed superiority to other combinations.^{56,57}

RETINOIDS

The therapeutic efficacy of some retinoids, such as isotretinoin, etretinate, and acitretin in CTCL, has been confirmed in several small, monotherapy studies.^{58–61} Response rates range from 44 to 67%, with CR rates from 21 to 35%. They seem to be equally effective, with median response duration around 8 months. Common effects consisted of skin and mucous membrane dryness. Oral bexarotene is a USFDA approved synthetic retinoid for refractory CTCL that selectively binds to RXR. In two multicenter phase II–III clinical trials it has been tested in early and advanced stages of CTCL patients.^{62,63} Reported response rates in early stages were between 45 and 54%. An overall response rate was observed in 94 patients with advanced disease, with only 4% complete responders, and with a median duration of 10 months. At the recommended dose of 300 mg/m² daily, it is associated with significant side effects, such as hyperlipidemia, hypothyroidism, and cytopenias. Retrospective comparison data suggest that there may be little difference in efficacy between bexarotene (RXR-specific retinoid) and agents such as all-*trans* retinoic acid (RAR-specific retinoid), but clear differences in toxicity exist.⁶⁴

EXTRACORPOREAL PHOTOCHEMOTHERAPY

ECP is a leukapheresis-based method in which 8-MOP treated blood mononuclear cells are exposed to UVA and returned to the patient. It is performed on two consecutive days every month. Although the mechanism of action is not completely understood, induction of apoptosis with subsequent release of tumor antigens leading to a systemic antitumor response against the malignant T-cell clone is suspected.^{65,66} In 1987 Edelson et al. published the first report on the efficacy of ECP in a cohort of 41 refractory CTCL patients. Thirty-seven patients (73%) achieved a response, with a CR in 24% of patients.⁶⁷ In the same year the FDA approved ECP for advanced and refractory CTCL. There have been several confirmatory studies reported on ECP monotherapy, with overall response rates between 50 and 73% for patients with MF/SS.^{67–70} Ideal candidates for ECP are patients with

SS with a short duration of disease without previous intense therapies, low tumor burden, modest numbers of circulating atypical cells, near normal counts of circulating CD8⁺ T lymphocytes, and exaggerated CD4 to CD8 ratio.^{68–70} The results in patients with marked immunosuppression or tumor lesions were disappointing, but provided the rationale for combining treatments. Synergistic effects have been reported with INF- α , retinoids, and TSEB.^{70–73} A retrospective study of 47 patients with advanced stage III–IV disease treated with ECP or with ECP combination therapy with INF- α , retinoids, or sargramostim reported an overall response rate of 79%.⁷¹ The overall response rate in patients who received combination therapy was 84%, with a CR in 26% of patients. The median survival for the patients undergoing combination therapy was 74 months. The effect of ECP as adjuvant therapy was evaluated in patients with advanced stage T3 and T4 disease who achieved a CR after TSEB treatment. Significantly better overall survival at 3 years was reported with adjuvant doxorubicin/cyclophosphamide (75%) or with adjuvant ECP (100%) compared to those with TSEB therapy (50%) alone.⁷³

TARGETED MODALITIES

Denileukin diftitox (Ontak)

Denileukin diftitox (IL-2 receptor specific fusion protein combined with diphtheria toxin) targets selectively the IL-2 receptor on malignant and activated T cells. In phase I/II and III trials it showed favorable 30⁷⁴ to 37%⁷⁵ response rates in CTCL patients. These trials were limited to patients with CD25 expression (alpha chain of IL-2R) in more than 20% of malignant T cells. The quality of life in responding patients was significantly improved.⁷⁶ However, adverse effects including acute transfusion-related events such as fever, rash, chills, myalgias, and vascular leak syndrome (VLS) have been reported. VLS occurred in 27% of the patients, which may be diminished by premedication with steroids.⁷⁷

Alemtuzumab (Campath-1H)

Alemtuzumab is a humanized monoclonal antibody directed against the lymphocyte surface antigen CD52, which is abundantly expressed on normal and most malignant T lymphocytes.⁷⁸ Alemtuzumab is currently the focus of many clinical trials in hematologic malignancies and has been used in the treatment of lymphomas and lymphoid leukemias. A published phase II trial of alemtuzumab in 22 patients with advanced MF/SS demonstrated a clinical response in 55% of the cases, with 32% complete remissions, including some SS patients clearing effectively circulating Sézary cells.⁷⁹ Median response duration was 12 months, and ranged from 5 to 32 months. The compound is associated with significant hematologic toxicity and infectious complications consisting of reactivation of cytomegalovirus, herpes zoster, miliary tuberculosis, and pulmonary aspergillosis.

PERIPHERAL STEM CELL TRANSPLANT

Autologous and allogeneic stem cell transplantation (SCT) is a well-established treatment option for various hematologic diseases, though there is limited experience in CTCL. A few retrospective studies have reported on autologous SCT leading to complete remissions in the majority of patients treated; however, most patients relapse rapidly.^{80,81} The duration of remission does not seem to be related to stage of the disease or absence of a detectable T-cell clone in the harvest.⁸² However, it is now suggested that a greater T-cell depletion of the harvest may be associated with a greater risk of rapid relapse, perhaps by compromising the immune antitumor response.^{82,83}

Allogeneic transplants are known to achieve more durable complete remissions, most likely due to an immunologic graft-versus-lymphoma effect. Response durations as long as 6 years posttransplant have been reported, suggesting that it may be a curative option.⁸⁴ It does, however, carry a higher risk of treatment-related mortality, including life-threatening infections and graft-versus-host disease (GVHD). Molina et al. followed six patients with advanced and refractory MF/SS who received donor-related allogeneic SCT (four patients) and donor-unrelated SCT (two patients).⁸⁵ All patients achieved a CR, with mild GVHD. Five patients remained disease free from 3 to 65 months posttransplant, and one patient died of GVHD 16 months posttransplant. Guitart et al. reported on allogeneic SCT therapy in patients with advanced stages of MF/SS who had not responded to standard treatment options.⁸⁶ A sustained CR was achieved in two patients with disease-free duration time of 15 months and 4½ years, respectively, posttransplant. There was no evidence of GVHD. One patient with advanced and refractory stage IVA and large cell transformation on histology relapsed after 9 months with limited cutaneous recurrence and remained alive more than 6 years posttransplant.

TREATMENT OF CD30⁺ LYMPHOPROLIFERATIVE DISORDERS

CD30⁺ cutaneous lymphoproliferative disorders include LyP presenting with chronic, recurrent, and self-healing skin eruptions and CD30⁺ LTCL.⁸⁷ Their common phenotypic hallmark is the CD30⁺ T lymphocyte that morphologically resembles Reed–Sternberg cells. Reported treatment modalities are doxycycline, PUVA, NB-UVB, methotrexate, INF- α , topical steroid and bexarotene formulations, and radiation.^{88–91} However, none of these treatments alter the natural course of disease; therefore, the short-term benefits should be weighed against the potential harmful side effects. Observation in patients with few lesions is recommended, whereas in patients with more disseminated disease low-dose methotrexate or UV light treatment might be effective in clearing disease.⁹²

Primary cutaneous CD30⁺ LTCL presenting with solitary or localized cutaneous nodules appear to have a favorable prognosis, as confirmed in several studies.⁹³ Spot radiation for solitary or localized lesions is the preferred treatment, with systemic chemotherapy reserved for cases with large tumor burden and/or extracutaneous involvement.^{94,95} Therapy regimens include doxorubicin-based (doxorubicin with CHOP or CHOP-like) chemotherapy, INF- α , or oral bexarotene.

TREATMENT OF SMALL- AND MEDIUM-SIZED PLEOMORPHIC T-CELL LYMPHOMA AND CD30⁻ LARGE T-CELL LYMPHOMA

Patients with CD30⁻ LTCL or small/medium-sized PTCL usually present with solitary, localized, or generalized plaques, nodules, or tumors without spontaneous regression.⁹⁶ Both entities do not express CD30 with absence of a T_h2 cytokine profile in CD30⁻ LTCL.⁹⁷ In CD30⁻ LTCL, large cells comprise over 30% of the dermal infiltrate and might resemble classical MF undergoing large cell transformation. Multiagent systemic chemotherapy is recommended in most cases, with radiotherapy limited to localized disease, although abbreviated responses are often seen with a high relapse rate. This was supported by Bekkenk et al., who reported on 82 patients with CD30⁻ peripheral T-cell lymphoma.⁹⁶ Forty-six patients were diagnosed with a primary cutaneous CD30⁻ LTCL. Most patients with solitary or localized skin lesions were treated with radiation, whereas patients presenting with multifocal skin lesions or with extracutaneous involvement were treated with doxorubicin-based chemotherapy. A complete remission was achieved in 12 (63%) of 19 patients treated with radiotherapy and in 5 (27%) of 18 patients treated with doxorubicin-based chemotherapy. Complete remissions were generally short lived, with a median duration of 6 months for radiotherapy-treated patients and 10 months for patients treated with doxorubicin-based chemotherapy. Twelve of 19 patients (63%) with small/medium-sized PTCL reached a complete remission, including 10 (83%) of 12 treated with radiotherapy and 2 (40%) of 5 patients treated with doxorubicin-based chemotherapy. The median response duration for the complete responders was 58 months. Patients with small- or medium-sized PTCL had a significantly better prognosis, with a 5-year overall survival rate of 45% compared to 12% in patients with primary cutaneous CD30⁻ LTCL.

CONCLUSION

Primary cutaneous lymphomas encompass a spectrum of clinical and histologic variants, characterized by skin-homing lymphocytes. Awareness of their unique clinical behavior provides a stage-dependent treatment approach and minimizes unnecessary interventions. Systemic progression in CBCL is uncommon

and 5-year survival rates are excellent, although relapses occur frequently. Treatment considerations for CBCL mostly rely on retrospective studies and are based on clinical presentation and morphologic evaluation. Histologic characterization of B-cell lymphomas in extranodular locations, such as the skin, can be problematic (i.e., small vs large cleaved cells), and does not appear to have the same predictive power compared to their nodal counterparts. Current clinical trials focus mainly on patients with MF/SS, as these patients represent the majority of cutaneous lymphomas. Skin-directed therapies are reserved for early stages.⁹⁸ Immune-modifying therapies have emerged for the treatment of advanced and/or refractory stages. They have the potential to reconstitute immune function while augmenting host antitumor response.

Combined immunomodulatory regimens may result in sustained remission of disease. Our gold standard for advanced stages is the combined use of PUVA and INF- α at a dose of up to 9 MU thrice weekly or as tolerated. Systemic single-agent or multiagent chemotherapies should be reserved for more advanced and refractory disease. Clinical trials are ongoing to refine protocols for combination therapy to improve efficacy and minimize toxicity. Advances in molecular biology technology may allow selective targeting of both B- and T-cell-mediated effects. Investigational agents, such as histone-deacetylase inhibitors, and the novel T-cell costimulatory agents, such as deoxynucleotide CpG7909 (cytosine-phosphorothiolated guanine-containing oligonucleotides) and lenalidomide, are being evaluated in phase I/II trials.

Chapter 60

MATURE T-CELL NON-HODGKIN'S LYMPHOMA: DIAGNOSIS AND THERAPY

Nam H. Dang and Fredrick Hagemester

T-cell lymphoid malignancies are a heterogeneous group of relatively rare diseases that are defined as distinct entities by a constellation of laboratory and clinical characteristics, including morphologic features, immunophenotypes, genetic abnormalities, clinical manifestations, and responses to treatment. The mature T- and natural killer (NK)-neoplasms as defined by the World Health Association (WHO) classification account for approximately 10% of all lymphoid malignancies.¹ However, the incidences of certain subtypes vary considerably by race and geography, with non-AIDS-related T-cell malignancies occurring much more frequently in the Far East than in North America. For example, in the Non-Hodgkin's Lymphoma Classification Project,² 9.4% of all cases of non-Hodgkin's lymphoma (NHL) (129 of 1378) were classified as peripheral T-cell lymphomas (PTCL), 33 (2.4%) of which were anaplastic large-cell lymphomas (ALCL). The frequencies of the remaining subtypes of PTCL (96 of 1378, 7%) ranged from 1.5% (Vancouver) to 18.3% (Hong Kong). Although the reason for this observed difference in frequencies is not clear for most subtypes, such variability is related in some situations to an association between a specific virus and the T-cell malignancy, such as the linkage between Epstein-Barr virus (EBV) and with NK/T-cell lymphoma and human T-cell lymphotropic virus 1 (HTLV-1) with adult T-cell leukemia/lymphoma (ATLL).

CLASSIFICATION AND CLINICOPATHOLOGICAL FEATURES

In the past, classification of T-cell lymphoid malignancies has been controversial, with no internationally accepted schema. The previously accepted morphology-based Working Formulation relied on morphology alone, and did not consider T-cell malignancies as separate and distinct entities. Rather, T-cell lymphomas that

occurred infrequently and generally had a poor prognosis were included in different pathologic subtypes (diffuse-mixed, large cell, and lymphoblastic) and were treated like their B-cell counterparts.³ Subsequently, the Revised European-American classification of lymphoid neoplasms (REAL)⁴ has subdivided all lymphomas into B-cell and T-cell lymphomas to avoid the confusion created by the Working Formulation. The REAL classification further subdivides T-cell lymphoid malignancies into two major groups based on the T-cell maturation stage: precursor T-cell neoplasms and peripheral T-cell neoplasms. Furthermore, the peripheral T- and NK-cell neoplasms are subdivided into additional categories, with some provisional subtypes. Thus, the REAL classification was a major advance in the characterization of lymphoid malignancies, because it recognized that the site of disease presentation is a significant aspect of disease biology, with extranodal T-cell lymphomas being inherently different from nodal subtypes. Following the publication of the REAL classification in 1994, new findings regarding some categories of lymphoma clarified the status of entities that were listed as provisional in the REAL classification, particularly among the T-cell lymphomas. The currently used WHO classification is based on the principles established by the REAL classification and incorporates minor additional modifications.^{1,5} Besides the precursor T-cell neoplasms, this classification includes 14 subgroups among the mature T- and NK-cell malignancies. Since the site of disease presentation represents a key aspect of disease biology and clinical course, an attempt is made to give it a more prominent role in subgroup characterization, leading to the classification of disease subtypes as being primarily leukemic, nodal, extranodal, or cutaneous (Table 60.1).

PREDOMINANTLY LEUKEMIC GROUP

There are four subtypes in the predominantly leukemic group. Comprising up to 20% of all prolymphocytic leukemia and 1% of chronic lymphocytic

Table 60.1 Mature T- and NK-cell neoplasms in the proposed WHO classification system

Predominantly leukemic malignant neoplasms
T-cell prolymphocytic leukemia
T-cell large granular lymphocytic leukemia
NK-cell leukemia
Sézary syndrome
Predominantly nodal malignant neoplasms
Peripheral T-cell lymphoma, unspecified
Angioimmunoblastic T-cell lymphoma
Adult T-cell leukemia/lymphoma
Anaplastic large-cell lymphoma
Predominantly extranodal malignant neoplasms
Nasal NK/T-cell lymphoma
Enteropathy-type intestinal T-cell lymphoma
Subcutaneous panniculitislike T-cell lymphoma
Hepatosplenic gamma/delta T-cell lymphoma
Predominantly cutaneous malignant neoplasms
Mycosis fungoides
CD30 ⁺ lymphoproliferative disease (primary cutaneous anaplastic large-cell lymphoma)

NK, natural killer; WHO, World Health Organization. Adapted from Jaffe et al.⁵

leukemia (CLL) cases, T-cell prolymphocytic leukemia (T-PLL) and CLL present clinically as overt leukemia but are often associated with involvement of lymph nodes, liver, spleen, bone marrow, skin, and mucosal surfaces. It is an aggressive disease with the median survival of patients being less than 1 year, and is rarely curable with available therapy. Cytologically, the leukemic cells are small-to-medium sized with irregular nuclei, prominent nucleoli, and abundant, non-granular cytoplasm. Immunophenotypic analysis reveals that most tumor cells express CD4, along with CD2, CD3, CD5, CD7, and the alpha/beta T-cell receptor (TCR). Molecular studies have demonstrated rearrangement of the *TCRβ* and *TCRγ* genes, with the *TCRδ* gene usually deleted and the *Ig* heavy- and light-chain genes usually in the germline configuration. A characteristic chromosomal abnormality occurring in approximately two-thirds of T-PLL/CLL patients is inv 14 (q11;q32), with trisomy 8 also having been reported.^{4,6–10}

Large granular lymphocytic leukemia (LGLL) is divided into two subtypes, T- and NK-cell leukemias. Patients with LGLL tend to be older than 50 years of age and often have multiple episodes of recurrent infections occurring over years, as well as fatigue or bleeding. Furthermore, autoimmune diseases such as rheumatoid arthritis are often associated with LGLL, particularly T-LGLL. Physical examination may reveal mild hepatosplenomegaly and lymphadenopathy, while laboratory studies often show lymphocytosis, neutropenia, anemia, and/or thrombocytopenia. The T-cell subtype usually has more adverse features, such as anemia and splenomegaly. While the clinical course

is usually indolent, some cases are quite aggressive. In particular, cases associated with EBV infection may exhibit an aggressive behavior. The circulating lymphoid cells are small with cytoplasmic granules, and may resemble B-CLL. The malignant cells of T-LGLL are often CD2⁺, CD3⁺, alpha/beta TCR⁺, CD8⁺, CD16⁺, CD25⁻, CD56⁻, and CD57⁺. However, the NK-cell tumors are CD2⁺, CD3⁻, alpha/beta TCR⁻, CD8⁺, CD16⁺, CD25⁻, CD56⁺, and CD57⁺. T-LGLL cells have rearrangements of the *TCRγ*, *TCRα*, and *TCRβ* genes, while NK-cell tumors do not have *TCR* gene rearrangements. In both types, the *Ig* genes are often in the germline configuration.^{4,11–14} Recently, expression of the ectopeptidase CD26/dipeptidyl peptidase IV has been associated with an aggressive clinical behavior in T-LGLL.¹⁵

Sézary syndrome (SS) is the leukemic variant of mycosis fungoides (MF), although it can occasionally arise de novo. Patients usually present with multiple cutaneous plaques or nodules, generalized erythroderma, lymphadenopathy, and circulating tumor cells (Sézary cells) in the peripheral blood. SS has an aggressive clinical course, with an expected survival being typically less than 2 years, particularly in the presence of extracutaneous disease. The malignancy is composed of small cells with cerebriform nuclei, and they usually express CD2, CD3, alpha/beta TCR, CD4, and CD5, with variable expression of CD25 and with one-third of cases being CD7⁺.^{4,16} Furthermore, CD26 is typically absent on the tumor cell surface, a fact that can be utilized to detect presence of tumor cells in the peripheral blood.¹⁷

PREDOMINANTLY NODAL GROUP

Peripheral T-cell lymphoma, unspecified (PTCL), is the most common of all the T-cell neoplasms. However, this subtype is less well defined than the other T-cell malignancies and has protean manifestations. While comprising less than 15% of all lymphomas in most European and US studies, it is more common in Japan and other Asian countries. Most patients with PTCL are adults who have generalized lymphadenopathy and involvement of other extranodal sites, including bone marrow, skin, liver, spleen, lung, and Waldeyer's ring, with accompanying pruritis, eosinophilia, and hemophagocytic syndrome. PTCLs are generally aggressive neoplasms and require combination chemotherapy, although current treatments usually result in relatively short duration of response and poor overall survival. The neoplastic lymphoid cells vary in size, ranging from atypical small cells to medium-sized or large tumor cells with irregular nuclei and abundant clear cytoplasm. These tumor cells display a mature T-cell phenotype, expressing such pan-T-cell antigens as CD2, CD3, CD5, CD7, CD4 or CD8, and alpha/beta TCR, while B-cell surface antigens are generally lacking. Molecular studies show rearrangements of the *TCRβ* and *TCRγ* genes in most instances, while the *Ig* genes are usually in germline configuration.^{4,18–27}

Angioimmunoblastic T-cell lymphoma is a relatively rare disorder with distinctive clinical behavior and generally poor outcome. This entity is part of a spectrum of clinical conditions ranging from angioimmunoblastic lymphadenopathy with dysproteinemia (AILD) to malignant lymphoma. Patients with AILD are at risk of developing malignant lymphomas that may be of either T-cell or B-cell lineage, while clonal populations of T cells may also be seen in AILD cases without overt histologic evidence of malignant lymphoma. Furthermore, investigators have reported cases of *de novo* lymphomas that have histologic features similar to those of lymphomas arising from an AILD background. Patients with angioimmunoblastic T-cell lymphoma often exhibit systemic disease with generalized lymphadenopathy, fever, weight loss, malaise, and skin rash. They tend to be older males with nodal and extranodal disease and numerous adverse risk factors. Laboratory studies reveal anemia (often positive for direct Coombs' test), eosinophilia, and polyclonal hypergammaglobulinemia. Although occasional remissions or protracted remissions have been reported (usually in the setting of AILD and not angioimmunoblastic T-cell lymphoma), the disease is considered aggressive, with infectious complications and progression to high-grade lymphomas. Morphologically, this disease is characterized by the presence of a mixture of small lymphocytes and large, atypical lymphoid cells with abundant and clear cytoplasm. Other characteristics include obliteration of the lymph node architecture, burned out germinal centers, and arborizing proliferation of small blood vessels. Tumor cells tend to be mature CD4⁺ T cells expressing T-cell-associated antigens, with TCR gene rearrangement seen in most cases of angioimmunoblastic T-cell lymphoma. Nonrandom and clonal chromosomal abnormalities, particularly those involving chromosomes 3 or 5, have been detected, and EBV infection is often associated with the disease.^{2,4,28-38}

ATLL is a clinicopathological entity closely associated with infection by the human T-cell leukemia/lymphoma retrovirus HTLV-1, which is transmitted either by infected cells via semen, blood products, needles, breast milk, or by transplacental migration, with an incubation period ranging from 20 to 30 years. HTLV-1 is endemic in the Caribbean basin, southeastern United States, and southwestern Japan. HTLV-1 infection is demonstrated by the presence of serum antibodies or by molecular detection of the virus through the polymerase chain reaction (PCR) technique or Southern blot hybridization. Occurring mainly in adults, ATLL presents with one of four clinical subtypes. Acute ATLL represents the most common subtype: patients generally have widespread adenopathy, hepatosplenomegaly, skin lesions, peripheral blood and cerebrospinal fluid involvement, lytic bone lesions, and hypercalcemia that may develop in the absence of bone lesions. Patients with this disorder

have a median survival duration of less than 1 year. Lymphomatous ATLL is the second most common disease subtype, with a slightly better prognosis than that reported for the acute form. Patients usually present with lymphadenopathy and involvement of visceral organs without hepatosplenomegaly or hypercalcemia. Chronic ATLL is associated with an absolute lymphocytosis and cytologically abnormal circulating cells, skin lesions, visceral involvement, and lymphadenopathy, with survival rates of more than 2 years. Finally, patients with smoldering ATLL have chronic disease for years with skin lesions, and minimal disease involvement in the peripheral blood and visceral organs. Morphologically, the circulating cells are of medium size, with basophilic cytoplasm and irregular, multilobulated nuclei. ATLL cells have a mature T-cell phenotype, expressing alpha/beta TCR, CD4, and other pan-T-cell antigens. Of note is that the tumor cells usually express high levels of CD25 on the cell surface, which may be a target for therapeutic interventions. Molecular studies show TCR gene rearrangements, and the Ig genes are often in germline configuration.^{4,39-42}

Primary nodal anaplastic large T/null-cell lymphoma (ALCL) presents as a systemic disease affecting children and adults involving lymph nodes and extranodal sites, including the skin. Considered aggressive lymphomas, these tumors require treatment with combination chemotherapy, with response and survival rates that are similar to those for diffuse aggressive large B-cell lymphomas. Although patients with these lymphomas are potentially curable, late relapses have been observed. The neoplastic cells are large blastic cells with pleomorphic nuclei, prominent nucleoli, and abundant cytoplasm. The malignant cells are often cohesive and are preferentially found within lymph node sinuses. Tumor cells classically express the activation antigen CD30, while many cases also express such activation markers as CD25, CD26, CD38, as well as the proliferation antigens CD71 and Ki-67. The systemic form of ALCL also expresses epithelial membrane antigen. The T-cell variant expresses pan-T-cell antigens such as CD2, CD3, CD5, CD7, and CD4, and lacks B-cell antigens. On the other hand, null-cell ALCL lacks immunophenotypic and molecular evidence of B- or T-cell lineage. While T-cell ALCL usually exhibits TCR gene rearrangement, there is a high rate of lineage promiscuity, since immunoglobulin genes are also found to be rearranged in T-cell ALCL, while B-cell tumors often have TCR gene arrangement. A key feature on a subset of systemic ALCL is the occurrence of chromosomal translocations involving chromosome 5q35, usually as t(2;5)(p23;q35). This chromosomal translocation juxtaposes the anaplastic lymphoma kinase (ALK) gene on chromosome 2p23 with the nucleophosmin (NPM) nucleolar phosphoprotein gene on 5q35, and is often found with the systemic form of T-cell ALCL, although it is not limited to this

subset. Besides the classic t(2;5), other translocations may also activate the *ALK* gene and participate in the pathogenesis of ALCL.^{4,43-57}

PREDOMINANTLY EXTRANODAL GROUP

Extranodal NK/T-cell lymphoma or angiocentric lymphoma is a unique clinicopathological entity associated with EBV infection that usually presents with destructive nasal or midline facial tumor. Affecting both children and adults, it is a rare disease in the United States and Europe, and is more common in Asia. Other organ involvement is common; sites include the nasal cavity, upper respiratory tract, lung, skin, kidney, and central nervous system, with lymph node involvement being relatively rare. The clinical course may be indolent or aggressive, and is at least partly dependent on the number of large lymphoid cells present. It is also commonly associated with a hemophagocytic syndrome thought to be induced by cytokine production by tumor cells leading to activation of benign histiocytes, resulting in fever, hepatosplenomegaly, pancytopenia, and hemolysis. Although the disease is often localized at presentation, chemotherapy is generally administered in conjunction with radiotherapy. However, the relapse rate is high, and overall prognosis is generally poor. In one report, although patients with angiocentric lymphoma tended to be younger than patients with other T-cell lymphomas and had favorable prognostic features, they failed to go into remission with anthracycline-based combination chemotherapy.²³ Others have reported that angiocentric nasal lymphoma typically occurs in young females (median age 49 years) at extranodal sites, but with few adverse risk factors and with limited-stage disease.² The disease is characterized morphologically by an angiocentric and angioinvasive infiltrate composing of a mixture of atypical lymphoid cells admixed with normal lymphocytes, plasma cells, and histiocytes. These tumors tend to accumulate greater numbers of large atypical lymphoid cells, and with fewer inflammatory cells over time, potentially indicating an increasingly worse clinical behavior. There is a propensity for invasion and destruction of blood vessels with prominent ischemic necrosis of tumor and normal tissues. Immunophenotypically, the tumor cells express pan-T-cell antigens CD2 and CD7, while CD3 is often absent. While they may be CD4⁺ or CD8⁺, angiocentric lymphoma cells often express the NK-cell-associated antigen CD56. Immunoglobulins and B-cell antigens are negative. Molecular studies show that *TCR* and *Ig* genes are usually germ line, while EBV genomes are usually detected by Southern blot, PCR, and in situ hybridization techniques.^{4,58-66}

A subset (10–25%) of primary intestinal lymphomas has a T-cell phenotype, also known as enteropathy-type intestinal T-cell lymphoma. This disease tends to occur in adults with a history of gluten-sensitive enteropathy or celiac disease, although it can occasionally be found

in patients without a history of enteropathy. Patients usually present with weight loss, abdominal pain, and jejunal involvement, and are typically diagnosed at the time of emergency surgery for small bowel perforation. The clinical course is often aggressive with associated poor survival rates, and death usually occurs from intestinal perforation due to chemotherapy-refractory malignant ulcers. Postmortem examination often reveals multiple jejunal ulcers that are associated with perforation, and a distinct mass may be absent. Histologic studies show that the uninvolved intestine may have blunting of villi, as is commonly seen in celiac disease. Tumors are found diffusely and contain a mixture of small, medium, and large lymphoid cells. Immunophenotypically, tumor cells are CD3⁺, CD4⁻/CD8⁻ or CD4⁻/CD8⁺, CD7⁺, CD30⁺, CD103⁺, and are negative for B-cell antigens. Molecular studies show *TCR* gene rearrangement, with *Ig* genes being germline.^{4,67-70}

Subcutaneous panniculitislike T-cell lymphoma usually presents with single or multiple subcutaneous nodules, affecting most often the extremities and trunk. The clinical course may be indolent with spontaneously waxing and waning skin lesions or may be very aggressive. Most patients are adults and usually exhibit fever, pancytopenia, and hepatosplenomegaly at diagnosis. A significant number of patients present initially with a hemophagocytic syndrome causing systemic symptoms, while others may develop a hemophagocytic syndrome during the course of their illness, with usually a fatal outcome. Bone marrow studies may be instrumental in establishing the diagnosis of disease-associated hemophagocytic syndrome. Histologically, the tumors involve the subcutaneous tissue, with infiltration of the neoplastic cells in the adipose tissue leading to coagulative necrosis. Tumor cells consist of a mixture of small and large cells, and accrual of large cells can occur over time. Immunophenotypically, the tumor cells have a mature T-cell immunophenotype, expressing CD8 and other pan-T-cell antigens. *TCR* genes are rearranged, while *Ig* genes are the germline configuration.^{4,71,72}

Hepatosplenic gamma/delta T-cell lymphoma is a rare disease found in young adults, often males, who present with marked hepatosplenomegaly and bone marrow involvement, with no or minimal lymphadenopathy, and infrequently, skin lesions. The disease is usually refractory to current treatment, with its clinical course being quite aggressive and with a high rate of disease relapse and death. These tumors are composed of medium-size lymphoid cells with irregular nuclear contours, condensed chromatin, and small nucleoli. There is sinusoidal infiltration in the liver, while the red pulp of the spleen is involved, and the white pulp is spared. The tumor cells usually express CD2, CD3, CD7, and the *TCR* gamma/delta chains, while CD5 is absent. *TCR* genes are also typically rearranged.^{4,73,74}

PROGNOSTIC FACTORS

INTERNATIONAL PROGNOSTIC INDEX

Several investigators have described the clinical aggressiveness of various subgroups of T-cell lymphomas and have correlated disease behavior with various factors at presentation. In the Non-Hodgkin's Lymphoma Classification Project analysis, there was a wide spectrum of clinical behavior for different T-cell lymphoma subsets (Table 60.2). Patients with anaplastic large T-cell lymphomas have the best 5-year survival rate (77%), while those with other T-cell subsets such as PTCL have much worse outcomes (25% 5-year survival).⁷⁵ In a recent analysis of the 96 non-ALCL PTCL cases diagnosed within the Non Hodgkin's Lymphoma Classification Project, the frequency of PTCL varied from 1.5 to 18.3% according to country of origin. Seventy percent of the patients in this study had received combination chemotherapy which contained doxorubicin, resulting in 5-year failure-free and overall survival rates of 20 and 26%, respectively. Performance status and International Prognostic Index (IPI) scores at presentation strongly correlated with 5-year overall and failure-free survival results. However, other components of the IPI, such as age, clinical stage, serum lactate dehydrogenase (LDH), and the presence of extranodal involvement, were not statistically correlated with disease outcome. There were no statistically significant differences for the overall and failure-free survival rates among various major T-cell subtypes. Of note is the fact that within the PTCL, "not-otherwise-

specified" category (PTCL, NOS), the number of transformed blast counts per 10 high-power fields was statistically significant for both overall and failure-free survival.² Although the IPI project did not allow analysis of the influence of immunophenotype on overall survival results, investigators have used the IPI to predict outcome for T-cell lymphomas. For example, Rüdiger et al.² demonstrated that IPI scores (0–2 features vs 3–5 features) separated T-cell lymphomas into groups with significantly different overall survival and failure-free survival rates. Gisselbrecht et al.²² reported that 45% of patients with T-cell lymphomas had three or more adverse prognostic factors when stratified by their IPI score compared with only 37% of those with B-cell lymphomas. Furthermore, these investigators could still separate patients with T-cell lymphomas into groups with significantly different survival rates, using the IPI system. Results for each IPI group were also significantly worse for those with T-cell tumors compared to those for patients with B-cell lymphomas who had the same IPI scores, respectively, particularly for those with IPI scores of 2 or more. Melnyk et al.²³ found that response and survival rates for patients with T-cell lymphomas were better for those with low rather than high IPI scores. In addition, Lopez-Guillermo et al.⁷⁶ reported that patients with PTCL and low plus low/intermediate IPI scores had significantly better survival rates than those with high plus intermediate/high-risk scores. In the study of Ansell et al.,⁷⁷ the IPI strongly predicted survival results when all patients were included in the analysis, and when patients were separated into cohorts of 60 years and younger and older than 60 years, the age-adjusted IPI also significantly predicted outcome. While hepatic and bone marrow involvement were also significant prognostic factors by univariate analysis, only the IPI remained significant by multivariate analysis. IPI scores also predicted overall survival rates for patients with T-cell lymphomas in the study reported by Reiser et al.,⁷⁸ as did elevated LDH, B-symptoms, and extranodal involvement; however, the presence of bulky disease (>7.5 cm), advanced-stage III/IV disease and bone marrow involvement did not. Armitage and Weisenburger⁷⁹ separated patients with PTCL into groups according to IPI, and found differences in survival rates for those with IPI scores of 0 and 1 as compared to those with IPI scores of 2 or greater, although these differences were not statistically significant. IPI scores also did not predict outcomes for patients with anaplastic large T-cell lymphomas.⁷⁹

T-CELL PHENOTYPE

The T-cell phenotype is an important adverse prognostic factor all by itself. Except for CD30⁺ anaplastic large T-cell lymphomas, patients with T-cell lymphomas have significantly lower response rates and shorter disease-free and overall survival results than do those with B-cell lymphomas.^{22,23,80} Gisselbrecht et al.²²

Table 60.2 REAL classification of lymphoma entities according to clinical aggressiveness

Subgroup	5-Year overall survival rate (%)
Anaplastic large T/null cell	77
Marginal zone, MALT	74
Follicular	72
Lymphoplasmacytic	59
Marginal zone, nodal	57
Small lymphocytic	51
Primary mediastinal large B cell	50
Burkitt-like	47
Diffuse large B cell	46
Burkitt's	44

Lymphoblastic, T cell	26
Peripheral T cell	25

MALT, mucosa-associated lymphoid tissue; REAL, Revised European–American Classification of Lymphoid Neoplasms. Adapted from The Non-Hodgkin's Lymphoma Classification Project.⁷⁵

showed that patients with non-ALCL T-cell tumors have more disseminated disease, B symptoms, bone marrow involvement, hepatosplenomegaly, and skin involvement than do those with B-cell lymphomas with comparable histologic grades. Furthermore, patients with T-cell lymphomas are more likely to be anemic, and have hypereosinophilia, hypergammaglobulinemia, and increased β_2 -microglobulin levels. On the other hand, T-ALCL patients are more likely to have localized disease with more favorable IPI scores, with better remission and overall survival rates, than those with non-ALCL T-cell or B-cell lymphomas. Complete remission (CR) rates were 63% for B-NHL, 54% for T-NHL (72% for ALCL and 49% for non-ALCL T-NHL). Five-year survival rates were 52% for B-NHL, and 41% for T-NHL (64% for ALCL and 35% for non-ALCL T-NHL). Five-year event-free survival rates were 42% for B-NHL and 33% for T-NHL. Five adverse factors significantly influenced survival outcome by multivariate analysis: age greater than 60 years, disseminated stage, elevated LDH, performance status, and non-ALCL T-cell lymphoma histology. Coiffier et al.⁸⁰ compared patients with PTCL and B-cell diffuse large-cell lymphoma, and found that PTCL patients were more likely to have an aggressive presentation with advanced-stage and B symptoms. While there was no difference in response rates between the two groups, patients with T-cell lymphomas had higher relapse rates (43% vs 29%), shorter freedom-from-relapse results (median: 34 months vs outcome not reached), and shorter overall survival rates (median: 42 months vs 50 months). Multivariate analysis demonstrated that the T-cell phenotype was an independent adverse prognostic factor. Comparing patients with ALCL and non-ALCL PTCL, Lopez-Guillermo et al.⁷⁶ showed that ALCL histology was an important variable predicting favorable results, with CR rates of 69% for those with ALCL and 45% for those with other PTCL; median survival results were 65 months for ALCL and 20 months for other PTCL; and 4-year survival probabilities were 62% for ALCL and 32% for other PTCL. In another series containing 560 cases of aggressive lymphomas (68 patients with T-cell and 492 with B-cell lymphomas) at MD Anderson Cancer Center, the T-cell phenotype was an independent adverse prognostic factor, with T-cell tumors having worse outcomes than B-cell lymphomas of comparable IPI or MD Anderson Prognostic Tumor Score Index. Patients with T-cell lymphomas were more likely to have advanced disease, B symptoms, and other poor prognostic features compared to those with B-cell lymphomas, including elevated LDH or β_2 -microglobulin levels. However, age and extranodal disease distributions were not significantly different between these two groups. Compared to their B-cell counterparts, T-cell lymphomas had lower CR rates (65% for T-cell and 76% for B-cell lymphomas), shorter 5-year failure-free survival (38% for T-cell and 56% for B-cell lymphomas), and lower over-

all survival (38% for T-cell and 63% for B-cell lymphomas). Consistent with other studies, patients with ALCL had higher response and survival rates. There was a significantly greater number of deaths in patients with non-ALCL tumors more than 3 years after treatment, many of which were due to late relapses.²³

TREATMENT MODALITIES

CONVENTIONAL CHEMOTHERAPY

Treatment of the non-ALCL T-cell lymphomas with conventional chemotherapy designed for B-cell lymphomas has had only limited success. Common anthracycline-containing regimens result in low response rates and short durations of remission, and the vast majority of patients develop resistant disease. For example, Armitage et al. evaluated 134 cases of PTCL diagnosed at three centers from 1973 to 1986: 80 patients had been treated with intensive regimens such as CHOP [cyclophosphamide, hydroxydaunorubicin (doxorubicin), Oncovin (vincristine), and prednisone] with or without bleomycin, CAP-BOP (cyclophosphamide, doxorubicin, procarbazine, bleomycin, vincristine, and prednisone), COMLA (cyclophosphamide, vincristine, methotrexate, and cytosine arabinoside), and MACOP-B (methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin).²¹ While the median survival was 17 months and the 4-year survival was 28% for all 134 patients, for the 80 patients who received intensive combination chemotherapy, 50% achieved a CR, with the 4-year durability of remission being 41% and the overall survival of this intensively treated group being 45%. However, the 4-year disease-free survival for those with stage IV disease, comprising 50% of the patients, was only 10%. Ansell et al.⁷⁷ evaluated 78 patients seen at the Mayo Clinic with T-cell lymphomas from 1985 to 1995; most received doxorubicin-containing regimens, including CHOP, ProMACE-CytaBOM (methotrexate, prednisone, doxorubicin, cyclophosphamide, etoposide, cytarabine, bleomycin, and vincristine), and m-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone). The median overall survival duration for the 78 patients on study was 22 months (range 1–105 + months). The median survival for high-risk IPI patients was 6 months, compared to 15 months for high-intermediate IPI patients, and 24 months for low-intermediate IPI patients, and the median survival for the low-risk group was not reached; the differences in survival rates were statistically significant. There were no significant differences in response rates among the T-cell subtypes, and univariate analysis showed no statistically significant survival differences among various T-cell subgroups. Rüdiger et al. studied 96 cases of non-ALCL PTCL evaluated in the Non-Hodgkin's Lymphoma Classification Project, 70% of whom had received

doxorubicin-containing regimens. The 5-year overall survival was 26%, and the failure-free survival was 20%.² Physicians from French and Belgian centers evaluated 288 PTCL patients (60 cases of T-ALCL and 228 cases of non-ALCL PTCL) treated with anthracycline-containing regimens, including m-BACOD (methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, and dexamethasone), ACVB (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisone), and NCVB (mitoxantrone, cyclophosphamide, vindesine, bleomycin, and prednisone), followed by consolidation and maintenance therapies or autologous transplantation in many cases. The CR rates were 54% for all patients, 72% for those with ALCL, and 49% for those with non-ALCL T-cell lymphomas, and 5-year survival rates were 41, 64, and 35%, respectively. Five factors adversely and significantly influenced survival by multivariate analysis: age greater than 60 years, advanced stage, elevated LDH, performance status, and non-ALCL T-cell lymphoma.²² Lopez-Guillermo et al.⁷⁶ evaluated 174 T-cell lymphomas from Spanish institutions; 30 were ALCL and the rest consisted of PTCL unspecified, angioimmunoblastic T-cell, angiocentric, intestinal T-cell, and hepatosplenic gamma/delta T-cell lymphomas. Most patients received CHOP-like therapy. CR rates were 69% for ALCL cases and 45% for other PTCL subtypes, with a median survival of 65 months for ALCL and 20 months for other PTCL, and 4-year survival probabilities of 62 and 32%, respectively. From MD Anderson Cancer Center, Melnyk et al. evaluated 68 T-cell lymphoma patients treated from 1984 to 1995 with anthracycline-containing regimens such as CHOP–bleomycin alternating with DHAP (dexamethasone, cisplatin, and cytarabine), CHOP–bleomycin alternating with CMED (cyclophosphamide, etoposide, methotrexate, and dexamethasone), CHOP–bleomycin alternating with OPEN (vincristine, etoposide, mitoxantrone, and prednisone), or alternating triple therapy consisting of ASHAP (cytarabine, doxorubicin, cisplatin, and methylprednisolone), MBACOS (doxorubicin, cyclophosphamide, vincristine, bleomycin, methylprednisolone, and methotrexate), and MINE (mesna, ifosfamide, mitoxantrone, and etoposide).²³ Similar to reports of others, the CR rate was 65%, the 5-year failure-free survival rate was 38%, and overall survival result was 38%, and those with ALCL had better results. Interestingly, a significant number of deaths in patients with non-ALCL T-cell lymphomas occurred 3 years after treatment, many of whom died due to late relapses.

Other investigators also have reported that T-ALCL has a better prognosis than non-ALCL cases. Compared to the non-T-ALCL PTCL, the 33 T/null (indeterminant)-ALCL patients in the Non-Hodgkin's Lymphoma Classification Project were significantly younger, less likely to have advanced-stage disease or bone marrow involvement, more likely to have favorable IPI score, and importantly, had greater survival results. The estimated 5-year overall survival for all T/null-ALCL

patients in this series was 75% and the failure-free survival was 56%, and most (81%) of these patients had been treated for curative intent with doxorubicin-containing regimens. Patients with ALK+ and ALK– disease had no significant differences in clinical features or survival.⁸¹ However, in a study reported by the British Columbia Cancer Agency and the University of Nebraska Medical Center, which evaluated 57 patients with systemic T/null ALCL treated with doxorubicin-containing multiagent chemotherapy protocols for curative intent, the 5-year overall survival rate was 57% (56% for 32 cases of T-ALCL and 83% for 25 cases of null-ALCL).⁸² ALK protein expression was an independent predictor of survival, as there was a statistically significant survival difference between the ALK+ (31 cases) and ALK– (26 cases) groups. For the ALK+ cases, the 5-year overall survival was 93% and the 5-year failure-free survival was 88%, while the 5-year overall survival was 37% and the 5-year failure-free survival was 37% for the ALK– cases. Finally, in a retrospective study involving patients with systemic T/null ALCL from multiple European institutions, the majority of whom received doxorubicin-containing regimens, showed that the ALK+ subgroup had an overall survival of 71% compared to only 15% for the ALK– subset. Ten-year disease-free survival rates were 82% for the ALK+ group and 28% for the ALK– subset.⁸³

Studies evaluating treatment for other specific T-cell lymphoma subtypes that are non-ALCL generally have reported disappointing responses, duration of response and survival rates. T-prolymphocytic leukemia (T-PLL) is relatively resistant to conventional chemotherapy, as demonstrated by a study involving 78 patients with T-PLL.⁷ Thirty-two patients had received alkylating agents and nine (28%) experienced transient partial remissions (PRs). Five of 15 patients (33%) had responded to CHOP, with 1 CR lasting 3 months. However, of the 31 patients treated with pentostatin, 15 experienced responses (3 CRs, lasting 8, 10, and 12 months, and 12 PRs), of which 8 responses were in 15 patients treated with pentostatin as first-line therapy. Chott et al. reported results for 27 patients with intestinal T-cell lymphoma; only 7 of 14 treated with multiagent chemotherapy completed therapy. Twenty of these 27 patients have died, and 17 died within 6 months from diagnosis. The overall median survival was 4 months, and patients with stage I had better survival rates than other patients.⁶⁷ In another study with 45 patients with hepatosplenic gamma/delta T-cell lymphoma, most of whom were treated with alkylating agents, CHOP or CHOP-like therapies, second- or third-generation regimens for high-grade lymphomas, and autologous or allogeneic stem cell or peripheral stem cell transplantation, CRs were obtained in five and relapses were common and early in the treatment course. Thirty-six patients were dead at the time of this study, with a median survival of only 8 months (range 0–42 months).⁸⁴ However,

Matutes et al. reported results for 15 patients with ATLL who received alpha-interferon and zidovudine (AZT), 11 of whom had previously received anthracycline-containing chemotherapy regimens. Seven patients had progressive disease, and eight were in remission at the time of study completion. When starting alpha-interferon and AZT, four patients had progressive disease, eight were in partial/complete remission, and three untreated patients had active disease. PRs lasting 2+ to 44+ months (median duration 10 months) occurred in 10 (67%) patients, four (26%) had no responses, and one was not evaluable. Eight patients died 3–41 months from diagnosis. Median survival for all 15 patients was 18 months; survival for nonresponders ranged from 4 to 20 months (median 6 months), and the 6 patients with PR were alive 8–82 months from diagnosis, with 55% of all patients alive at 4 years. This study therefore suggested that this combination may improve the outcome of ATLL and help maintain responses, and should be studied in other populations.⁸⁵

Standard treatments for nasal NK/T-cell lymphoma are unsatisfactory. In a retrospective analysis of Chinese patients with primary NHL of the nose and nasopharynx, many of whom received CHOP, CEOP (cyclophosphamide, epirubicin, vincristine, and prednisone) or ProMACE-CytaBOM, with or without radiation, patients with NK/T-cell lymphoma had very poor results.⁸⁶ Compared to patients with T-cell (24 patients, 21.3%) or B-cell (38 patients, 33.6%) phenotypes, those with NK/T-cell lymphoma (51 patients, 45.1%) had the highest male-to-female ratio, more frequent involvement of the nasal cavity alone, a higher risk of skin dissemination, more frequent development of hemophagocytic syndrome, and worse prognosis. The CR rate for NK/T-cell disease was 56%, compared to 69.6 and 76.3% for T-cell and B-cell phenotypes, respectively. The 5-year actuarial disease-free survival rates were 25.1% for NK/T-cell disease, 41.9% for T-cell phenotype, and 40.9% for B-cell phenotype. The 5-year actuarial overall survival was 31.1% for NK/T-cell phenotype, 57.7% for T-cell phenotype, and 35% for B-cell phenotype. The median overall survival was 12.5 months for NK/T-cell phenotype, 93.4 months for T-cell phenotype, and 17 months for B-cell phenotype. In another study, investigators treated patients with localized nasal NK/T-cell lymphoma with four cycles of CHOP and involved-field radiation therapy, obtaining a response of 58% and an estimated overall 3-year survival of 59%. In fact, only 35% of patients completed the planned sequential chemoradiotherapy due to disease progression during chemotherapy. These results led to the authors' conclusion that better treatments were needed for localized nasal NK/T-cell lymphoma.⁸⁷

HIGH-DOSE CHEMOTHERAPY/STEM CELL TRANSPLANT

Several groups have examined the impact of high-dose chemotherapy on T-cell lymphomas. Investigators at

MD Anderson Cancer Center performed a retrospective analysis of 36 patients with relapsed or refractory PTCL who received high-dose chemotherapy and autologous (29 patients) or allogeneic (7 patients) hematopoietic transplantation.⁸⁸ The 3-year overall survival rate was 36%, and progression-free survival (PFS) rate was 28%. The 3-year probabilities of survival for the autologous and allogeneic groups were 39 and 29%, respectively, while the PFS rates at 3 years were 32 and 14%, respectively. The pretransplant serum LDH level was the most important prognostic factor for both overall survival and PFS results. Furthermore, patients with an IPI score of ≤ 1 had better overall survival, but not PFS rates, than those with greater IPI scores. At a median follow-up of 43 months, 13 patients (36%) were still alive with no evidence of disease. These data were comparable to published studies of high-dose chemotherapy for relapsed or refractory B-cell lymphomas, and suggested that stem cell transplant should be considered for selected patients with T-cell lymphomas. In a study reported by Vose et al., 41 patients with relapsed intermediate- or high-grade lymphomas (17 cases of T-cell and 24 cases of B-cell lymphomas) underwent high-dose therapy and autologous transplantation for salvage therapy. Comparable results were obtained for B- and T-cell lymphomas.⁸⁹ The T-cell patients had a slightly higher CR rate that was not statistically significant (59% compared to 42%), with the durations of response being similar (50% at 30 months, with no late relapses). The 2-year overall survival rates for both groups were also similar, being 35% for T-cell lymphomas and 30% for B-cell lymphomas, as were the 2-year disease-free survival rates (28% for the T-cell group and 17% for the B-cell patients). Predictors of poor outcome for both groups of patients were poor performance status, bulky tumor, and high LDH levels. A study involving 40 patients with relapsed T-cell lymphomas from Norway and Sweden also examined the role of high-dose therapy with autologous stem cell transplantation.⁹⁰ All patients had chemosensitive disease and had received anthracycline-containing regimens, mainly CHOP, VACOP-B (etoposide, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin), or MACOP-B (methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, and bleomycin), prior to transplantation. At the time of stem cell transplant, 17 patients were in first PR or CR, and 23 were in second or third PR or CR. Conditioning regimens included BEAM (carmustine, etoposide, cytarabine, and melphalan) in 15 patients, BEAC (carmustine, etoposide, cytarabine, and cyclophosphamide) in 14, BEAC without etoposide and total body irradiation (TBI) in 1, cyclophosphamide and TBI in 8, and melphalan and mitoxantrone in 2. There were three (7.5%) treatment-related deaths; however, 32 patients (80%) achieved or maintained a CR after stem cell transplant, with relapses occurring in 16 patients, all within 2 years following transplantation.

Table 60.3 Results of phase II trials with pentostatin in T-cell lymphoma

Adapted from Verstovsek et al.¹⁰⁶

The 3-year overall, event-free, and relapse-free survival rates were 58, 48, and 56%, respectively. As expected, patients with ALCL had better outcomes than did other histologies (79 and 44%, respectively). Furthermore, these data appeared similar to those reported for stem cell transplant for relapsed high-grade B-cell lymphomas.⁹¹ Others have studied allogeneic HLA-matched sibling transplantation with combined marrow and CD34⁺-enriched peripheral blood stem cell transplantation after cytoreductive chemotherapy and TBI for refractory cutaneous T-cell lymphoma (CTCL), suggesting that this approach may be potentially beneficial for selected patients.⁹²

PURINE ANALOGS

The purine analogs pentostatin (deoxycoformycin), fludarabine, and cladribine (2-chlorodeoxyadenosine/2-CdA) are a group of structurally similar drugs that are active agents in the therapy of T-cell lymphomas.

T-cells have high levels of adenosine deaminase (ADA), a key enzyme involved in purine metabolism, and as ADA inhibitors, these drugs produce DNA damage and impairment of DNA repair. As single agents, the purine analogs are relatively well tolerated, with myelosuppression being usually mild, although it tends to be more severe with cladribine than with pentostatin. Of note is the fact that these agents produce lymphopenia and immunosuppression, occasionally resulting in the development of opportunistic infections.

Several studies have demonstrated that pentostatin has activity against T-cell lymphoma (Table 60.3). Investigators at the Royal Marsden Hospital in London demonstrated that pentostatin has activity in post-thymic mature T-cell malignancies. Mercieca et al.⁹⁸ obtained an overall response rate of 32% for 145 patients treated with pentostatin for a variety of mature T-cell tumors, most of whom had disease considered relapsed or refractory to anthracycline-containing

regimens or alkylating agents. The median overall duration of response was 6 months, ranging from 3 to 66 months. For the 55 patients with T-PLL, 5 achieved a CR and 20 achieved a PR, lasting from 3 to 16 months (median 6 months), for an overall response rate of 45%. For the 16 patients with SS, 3 experienced a CR and 7 had PRs, ranging from 3 to 66 months (median 9 months), for an overall response rate of 62%. However, 13 patients with other types of CTCL, including 5 with MF, did not respond to pentostatin. Nonetheless, of the four patients with circulating Sézary cells without skin involvement, two (50%) had PRs in terms of improvement in peripheral lymphocytosis and bone marrow function. Two of the five patients with LGLL leukemia also achieved a CR, one lasting 18 months and the other lasting 12 months. However, other subsets of T-cell disease in this study had lower response rates to pentostatin. Two of the 25 patients with ATLL achieved a CR, one lasting 33 months and the other died of an opportunistic infection while still in CR 5 months after stopping drug treatment; another achieved a PR lasting 5 months, with an overall response rate of 12%. Meanwhile, 27 patients with PTCL were treated, with 5 PRs and no CR, for an overall response rate of 19%. The duration of response was from 3 to 28 months, with a median response duration of 9 months. There was no statistically significant difference in the response rates of previously untreated patients compared to those for patients previously treated with one or more regimens (35% vs 29%, respectively), with histologic subtype being the single most important factor influencing results.

Other investigators have studied pentostatin for patients with relapsed CTCL or PTCL with prominent cutaneous manifestations.¹⁰⁴ Of the 24 patients evaluable for response, six (25%) patients had CR and 11 (46%) patients had PR. Ten of 14 (71%) patients with SS, four of six (66%) with tumor stage MF, and three of three with PTCL responded. Although the median response duration of the patients with tumor-stage MF was only 2 months (range 1–2 months) and 3.5 months for SS patients, there were two SS patients with prolonged responses lasting greater than 1 year. One of the three PTCL patients had an ongoing CR at 20 months. The most common side effect observed in these patients who had received a median of three prior therapies (range 1–12) was significant lowering of CD4 counts, and several subsequently developed herpes zoster infection.

Recently, investigators at MD Anderson Cancer Center treated 14 patients with relapsed noncutaneous T-cell lymphomas with pentostatin, and reported details regarding its lymphopenic effects.¹⁰⁷ One patient (7%) had a CR and six (43%) had PRs, with the median PFS result for responders being 6 months (range 2–15 months). A significant reduction in circulating CD26⁺ T lymphocytes was observed in treated patients, potentially associated with immunosuppression. In one patient with PR, the decrease in the levels

of CD26⁺ T lymphocytes was associated with genital herpes reactivation, while resolution of this opportunistic infection was associated with a recovery in CD26⁺ T-cell levels, once pentostatin was discontinued. Since CD4⁺CD26⁺ T lymphocytes are memory helper T cells, the selective loss of CD26⁺ T cells in lymphoma patients treated with pentostatin has important clinical implications, and may partly explain the relatively high incidence of opportunistic infections observed in patients receiving this agent.

The other purine analogs, cladribine and fludarabine, also have activity in T-cell lymphomas, although relatively limited data are available. One study involving 25 patients with relapsed or refractory cutaneous T-cell lymphoproliferative disorders (24 MF or SS and 1 Ki-1 + ALCL) showed that 2-CdA treatment resulted in a 24% response rate, with 3 patients (12%) having a CR with a median duration of 4.5 months (range 2.5–16 months) and three patients having a PR with a median duration of 2 months (range 2–4 months). The most significant toxicities were myelosuppression and infection, with opportunistic infections occurring in a significant percentage of patients.^{108,109} Another study also demonstrated 2-CdA activity in T-cell lymphomas, as 22 patients with such varied diagnoses as T-LGLL, T-PLL, T-CLL, SS, MF, and PTCL who were treated with 2-CdA had a response rate of 41%. Four responders (18%) had CRs (1 T-PLL, 1 MF, and 2 T-LGLL) while five patients (23%) had PRs (2 T-CLL, 1 SS, and 2 PTCL). All patients with PR and one CR patient developed relapses at a median of 7 months (range 5–26 months), while three patients with CR remain in remission at 30+, 36+, and 54+ months. The median overall survival was 12 months, and the main toxicities were fever and infection.¹¹⁰ To date, there is only limited published data to suggest that fludarabine has single-agent activity in certain subsets of T-cell lymphoma, particularly MF.^{111,112}

Several investigators have studied purine-analog-containing combination therapies for T-cell tumors. In a phase II study of 41 patients with advanced MF/SS, the combination of pentostatin and intermittent high-dose recombinant interferon alfa-2a resulted in CR in two and PR in 15 patients, for an overall response rate of 41%. The PFS duration for responders was 13.1 months, and common toxicities for this combination included opportunistic infection and interferon-related constitutional symptoms.¹¹³ The combination of fludarabine and interferon alfa-2a was also tested in another phase II trial of 35 patients with advanced MF/SS, with 4 CRs and 14 PRs for an overall response rate of 51%.¹¹⁴ The median PFS duration for responders was 5.9 months, with three of the CRs still in remission after 18–35 months. Significant toxicities included constitutional symptoms, neutropenia, and infections. Another study with 12 patients with advanced refractory primary CTCL demonstrated that treatment with the combination of fludarabine and cyclophosphamide resulted in 1 CR and 4 PRs for an overall response rate

of 42%. The mean duration of response was 10 months, with bone marrow toxicity being the common and significant side effect.¹¹⁵ Finally, the combination of fludarabine, mitoxantrone, and dexamethasone has produced 1 CR that has lasted 15 months after treatment cessation in a patient with aggressive subcutaneous panniculitislake T-cell lymphoma.¹¹⁶

GEMCITABINE

Gemcitabine is a novel pyrimidine antimetabolite with clinical activity and a low-toxicity profile in solid tumors and selected T-cell hematologic malignancies. A phase II study involving 44 previously treated patients with either MF ($n = 30$) or PTCL with exclusive skin involvement ($n = 14$) treated with gemcitabine reported 5 (11.5%) CRs and 26 (59%) PRs, for an overall response rate of 70.5%.¹¹⁷ Responses varied by histology: three of 30 (10%) MF patients attained a CR and 18 of 30 (60%) had PRs, while two of 14 (14.5%) PTCL patients had CRs and eight of 14 (57%) achieved PRs. The median duration of CR was 15 months (range 6–22 months) and of PR was 10 months (range 2–15 months). Treatment was generally well tolerated, and hematologic toxicities were mild. Gemcitabine was also found to be effective and well-tolerated therapy for relapsed or refractory T-cell malignancies in another study involving 10 patients with various histologies.¹¹⁸ There were 2 CRs and 4 PRs, for an overall response rate of 60%, with a median duration of response of 13.5 months.

A pivotal, multicenter phase III trial was then performed to evaluate the activity of denileukin diftitox in patients with CD25⁺ CTCL.¹¹⁹ Patients were randomized to receive denileukin diftitox given at a dose of either 9 $\mu\text{g}/\text{kg}/\text{day}$ for 5 days every 3 weeks or 18 $\mu\text{g}/\text{kg}/\text{day}$ for 5 days every 3 weeks, with no steroid premedication. Thirteen of 36 patients receiving the higher dose had an objective response, as compared to eight of 35 patients in the lower dose cohort. Overall, 20% of patients had PRs while 10% had CRs, with the mean duration of response being 6.9 months. There were CRs in both groups, with the 3 CRs in the lower dose group having early stage (IB) disease, while the 3 CRs in the higher dose group had stage IIB or higher disease, suggesting a role for the higher dose in patients with advanced-stage disease (Table 60.4). An increase in the titer of antidenileukin diftitox antibodies was seen in most patients, which did not have a significant effect on antitumor efficacy. Regarding tumor CD25 status, 58% of all skin samples of CTCL patients met the inclusion criteria of having greater than 20% CD25 positivity on tumor cell surface. However, in multiple instances, the results from multiple biopsies taken from the same patient showed a wide range of CD25 expression. Side effects included acute hypersensitivity-type events related to drug administration, associated with dyspnea, back pain, hypotension, chest tightness, pruritus, and flushing. Transient elevation of liver enzymes was also seen, as well as rashes and

Table 60.4 Denileukin diftitox in cutaneous T-cell lymphoma—results from pivotal phase III trial¹¹⁹

flulike symptoms. A vascular leak syndrome, associated with hypotension, edema, and hypoalbuminemia, was also noted in approximately 25% of patients. Most side effects were transient and tended to occur early in treatment. Steroid premedication was not used in the pivotal trial to avoid ambiguity in interpreting efficacy; however, in a subsequent study with 15 CTCL patients, which allowed for the use of intravenous steroids, there was a higher response rate (60%) with denileukin diftitox with a substantial decrease in adverse effects.¹²¹ The improvement in patient's tolerability associated with concurrent steroid administration may have led to greater patient compliance and treatment completion, potentially resulting in better response rate; in the pivotal phase III trial, many patients discontinued therapy prior to completing four cycles due to toxicity and were deemed nonresponders. Therefore, steroid premedication may ultimately lead to greater patient compliance and higher response rates with this drug. Besides its efficacy in CTCL, denileukin diftitox also has activity in other T-cell lymphomas and deserves further study in these diseases.^{122,123}

CAMPATH-1H/ANTI-CD52 ANTIBODY

CD52 is a nonmodulating glycosylphosphatidylinositol-linked protein that is expressed, in abundance, on normal and malignant B and T lymphocytes, monocytes, macrophages, and eosinophils, but not on hematopoietic progenitor cells.^{124,125} Given the high expression of CD52 on the surface of malignant cells, specific antibody targeting this antigen may serve as appropriate novel therapy for these CD52-expressing tumors. Campath-1H is a genetically engineered human IgG1 anti-CD52 monoclonal antibody, consisting of the hypervariable regions of the parental rat antibody inserted into the framework domains of normal human immunoglobulin *IgG1* genes. As a humanized antibody, Campath-1H may work through a number of mechanisms, including complement-mediated lysis, antibody-dependent cell cytotoxicity, and apoptosis. Different cell types express different levels of CD52 on their surface, which may explain in part the observed variation in their sensitivity to Campath-1H-mediated lysis.¹²⁶ Campath-1H treatment is generally well tolerated, with the most significant toxicity being prolonged lymphopenia associated with opportunistic infections, especially in heavily pretreated patients.

Prior to the development of Campath-1H, a predecessor antibody, the rat antibody Campath-1G caused clearance of malignant cells from the blood and bone marrow in various lymphoid malignancies, suggesting potential clinical applications for anti-CD52 antibody therapy.¹²⁷ In a subsequent phase II study involving 39 patients with T-PLL, all but two patients of whom had received prior therapy with a variety of agents, investigators obtained an overall response rate of 76%, with 60% CR and 16% PR.¹²⁸ The median disease-free interval was 7 months (range 4–45 months). Clearance of

tumor cells from the blood and bone marrow was generally rapid but did not cause tumor lysis syndrome. Disease resolution from skin, spleen, and lymph nodes also occurred in approximately half of the affected patients, although those with bulky lymph node masses, serous effusions, or hepatic or central nervous system involvement had more resistant disease. There was a statistically significant difference in survival for patients achieving a CR (median 16 months) as compared to partial responders (median 9 months) or nonresponders (median 4 months). Meanwhile, 12 patients were retreated with Campath-1H following relapse, with five (42%) achieving a second CR and one achieving PR, with responses lasting 5–6 months. Seven patients received high-dose therapy with autologous stem cell support, and stem cells harvested from these patients were free of T-PLL cells as documented by flow cytometry and PCR studies. Three of these patients remained alive in CR at 5, 7, and 15 months following autograft. Four additional patients underwent allogeneic stem cell transplants, with three being alive in CR up to 24 months following allograft. As expected, major toxicities were prolonged lymphopenia and opportunistic infections. In a retrospective analysis of compassionate use of the drug for relapsed or refractory T-PLL, 76 patients treated with Campath-1H had an overall response rate of 51% including a 39.5% CR rate, with the median duration of CR being 8.7 months (range 0.13+ to 44.4 months) and median time to progression for all patients being 4.5 months (range 0.1–45.4 months).¹²⁹ These figures are very favorable in this population whose response rate to first-line chemotherapy was only 32%, with a 6% CR rate and a median time to progression of only 2.3 months (range 0.2–28.1 months). Specific organ CRs varied: 39% in the bone marrow, 33% in the spleen, 32% in lymph nodes, 30% in the liver, and 43% in the skin. Campath-1H also had activity in patients with advanced CTCL. A phase II multicenter study was done in Europe, which enrolled previously treated patients with low-grade NHLs, including CTCL.¹³⁰ Out of the eight patients with MF, there were four responders (50%), including 2 CRs. This response rate was higher than the 14% response rate (six of 42 patients had PR) seen with the B-cell lymphoma patients under study. Among the four responding MF patients, the median time to progression was 10 months (range 2–14 months). Consistent with previous findings, the most pronounced antitumor effect was seen in blood, bone marrow, and skin, while there was low response with bulky lymph nodes and splenomegaly.

CONCLUSION

T-cell lymphoid malignancies represent a heterogeneous group of relatively rare diseases that are defined as distinct entities by a constellation of laboratory and

clinical features, including morphologic features, immunophenotype, genetic features, clinical manifestation, and clinical course. Recent classification attempts have considered mature T-cell malignancies as separate entities, with site of disease presentation being an important part of disease behavior. Excluding rare exceptions such as ALCL, our knowledge regarding disease pathophysiology, prognostic factors, and disease-specific molecular features is still incomplete, due to their relative rarity and heterogeneity. Also, except for ALCL and certain CTCL, T-cell tumors often have systemic involvement, are generally aggressive, and are relatively refractory to currently available treatments. Therefore, there is an urgent need to identify novel molecular targets on T-cell malignancies for future therapy, which may also serve as potential prognostic markers for selected disease subsets. For most T-cell lymphoid malignancies, available treatment modalities have included conventional combination chemotherapy, often with anthracycline-containing regimens, resulting in rather disappointing results in terms of response rate, response duration, and overall

survival. Other agents with published activities include the purine analogs and gemcitabine, and these drugs need further study. Recent efforts have focused on the use of targeted therapy, especially the fusion protein denileukin diftitox and the monoclonal Campath-1H/anti-CD52 antibody, which have definite activity in various subsets of T-cell tumors. Other investigational agents including monoclonal antibodies targeting cell surface antigens are under development in various clinical trials at the present time. However, in view of the unsatisfactory outcomes seen in most cases of T-cell lymphoid malignancies, novel therapies should be explored in large, prospective randomized trials involving multiple institutions, and patients with these malignancies should be enrolled on these trials as the first choice of therapy. Potential combinations involving established chemotherapy regimens with emerging targeted therapies that exhibit novel mechanisms of action and nonoverlapping toxicities should also be considered for the treatment of T-cell lymphoid malignancies to improve clinical outcomes.

Chapter 61

TREATMENT APPROACH TO HIV-RELATED LYMPHOMAS

Mark Bower

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) following infection with human immunodeficiency virus (HIV) was brought to the world's attention in 1981, with the first case reports of *Pneumocystis carinii* pneumonia (PCP) in homosexual men in Los Angeles. These reports were quickly followed by descriptions of Kaposi's sarcoma (KS) in similar patient groups. There followed a cornucopia of opportunistic infections and isolated reports of high-grade B-cell non-Hodgkin's lymphomas (NHL), both primary cerebral lymphomas and systemic NHL. By 1985, high-grade B-cell NHL was included along with KS as an AIDS-defining illness by the Centers for Disease Control (CDC), following the publication of a series of 90 homosexual men with NHL.¹ A number of other cancers occur at an increased frequency in people with HIV infection, including Hodgkin's lymphoma, anal cancer, lung cancer, and testicular seminoma^{2,3}; however, these malignancies have not been included in the definition of AIDS. In addition, an increased incidence of multicentric Castleman's disease (MCD) has been found in people with HIV, following the recognition of an association between MCD and AIDS-associated KS.^{4,5} Studies by the World Health Organization have shown that by December 2003, over 20 million people had died of AIDS and 42 million people were living with the virus. The number of people newly infected with HIV is approximately 6 million per year.⁶

Dramatic improvements in the antiviral therapy of HIV infection occurred in the second half of the 1990s which have altered the natural history of HIV infection in those economies where these medicines are widely available. The introduction of highly active antiretroviral therapy (HAART) has led to a fall in the incidence of both opportunistic infection and AIDS-associated malignancies. The development of effective antiretroviral therapies commenced with the introduction of nucleoside reverse transcriptase inhibitors

starting with zidovudine in 1987. In the last 8 years, three new classes of antiretroviral agents have been introduced: protease inhibitors (PIs) (saquinavir, indinavir, ritonavir, nelfinavir, and lopinavir), non-nucleoside reverse transcriptase inhibitors (nevirapine, delavirdine, and efavirenz), and fusion inhibitors (enfuvirtide). The introduction of the first two classes in the late 1990s led to the use of combination HAART. HAART has had an enormous impact on the treatment of HIV in terms of overall survival, incidence of opportunistic infections, and quality of life. In randomized studies, HAART led to a dramatic decline in the mortality and morbidity of HIV.⁷ However, only 1 million of the estimated 42 million people infected with HIV worldwide are receiving HAART, as the majority of affected people live in developing countries. In addition, even in the established market economies with access to medical treatment, many individuals remain undiagnosed and consequently do not receive HAART.

AIDS-RELATED SYSTEMIC LYMPHOMA

EPIDEMIOLOGY OF AIDS-RELATED LYMPHOMA IN ERA OF HAART

NHLs are associated with both congenital and iatrogenic immunosuppression, and so it was perhaps not surprising that an increased incidence was demonstrated early in the AIDS epidemic. Registry linkage studies in the pre-HAART era found that the incidence of NHL in HIV-positive individuals was 60–200 times higher than in the matched HIV-negative population^{8,9} and the relative risk was even greater for primary cerebral lymphomas. Following the introduction of HAART, the incidence of both KS and primary cerebral lymphoma has fallen significantly in both registry linkage and cohort studies.^{10–12} In contrast the effects on systemic NHL are less clear although some cohort studies suggest a modest nonsignificant decline in the incidence,^{13–15} including in the hemophilia population.¹⁶

An international meta-analysis of 20 cohort studies compared the incidence of systemic NHL between 1992–1996 and 1997–1999. This meta-analysis confirmed an overall reduction in the incidence of both primary cerebral lymphoma (rate ratio = 0.42) and systemic immunoblastic lymphoma (rate ratio = 0.57) but not Burkitt's lymphoma (rate ratio = 1.18).¹⁷

PREDICTORS OF AIDS-RELATED LYMPHOMA

Genetic, infectious, and immunologic factors influence the development of AIDS-related lymphoma. For example, germline chemokine and chemokine receptor gene variants have been found to influence the chance of developing these tumors.^{18,19} Acyclovir has mild activity against Epstein–Barr in vivo, and one case–control study has shown that administration of high-dose acyclovir (≥ 800 mg/day) for ≥ 1 year was associated with a significant reduction in the incidence of NHL.²⁰

An analysis of a cohort of over 8000 HIV-positive patients has identified three factors in multivariate analysis that are significantly associated with the development of NHL: age, nadir CD4 cell count, and no prior HAART.²¹ As the CD4 count falls, the development of lymphoma becomes more likely, and this may explain the declining incidence of NHL since the introduction of HAART, as it is thought that the immune restoration that accompanies HAART protects against the development of AIDS-related lymphoma. Nonetheless, the risk of lymphoma persists even among patients who are on HAART and have no detectable HIV viremia.²²

CLINICAL PRESENTATION OF AIDS-RELATED LYMPHOMA

The majority of patients with systemic AIDS-related lymphomas present with advanced stage disease and B symptoms. Extranodal disease, bone marrow involvement, and leptomeningeal disease are all common features. Hepatic involvement occurs in up to 25% patients, while one in five patients has bone marrow involvement by NHL. In addition, HIV infection itself is associated with trilineage abnormalities of hematopoiesis^{23,24} and the poor hematologic reserves add to the myelotoxicity of cytotoxic chemotherapy. Central nervous system (CNS) involvement by systemic AIDS-associated NHL is frequent; leptomeningeal disease is present at diagnosis in 3–10% and is significantly associated with both Burkitt's lymphoma and paraspinal or paranasal involvement.^{25–28}

In the published series from our institution (Chelsea & Westminster Hospital, London) that compared the clinical characteristics of 99 AIDS-related lymphomas presenting prior to 1996 and 55 that presented between 1996 and 1999, there were no differences in the stage at presentation, presence of B symptoms, bone marrow infiltration, or performance status between the

two groups. However, the patients who developed lymphoma in the HAART era were less likely to have had a prior AIDS diagnosis, were older, and had higher CD4 cell counts at the time of lymphoma diagnosis.²⁹ Thus, although there has been a change in the immunologic parameters of lymphoma patients, this would seem to reflect changes in the population at risk rather than any alteration of the biology of the lymphomas. A further analysis of patients who presented with lymphoma in the era of HAART compared those who were receiving HAART at the time of lymphoma diagnosis ($n = 17$) with those who were not ($n = 34$). Again there were no significant differences between the stages or disease sites at presentation but the CD4 cell counts at lymphoma diagnosis were higher in those on HAART.

TREATMENT OF AIDS-RELATED LYMPHOMA IN THE ERA OF HAART

During the 1980s, conventional chemotherapy schedules were used at full dosages for patients with better prognostic factors. However, marked toxicity and an increased incidence of opportunistic infections lead to modifications of the standard lymphoma regimens, such as the modified methotrexate, bleomycin, doxorubicin, cyclophosphamide, vincristine, dexamethasone (mBACOD) schedule used by the AIDS clinical trials group (ACTG).³⁰ The subsequent development of hematopoietic growth factors allowed more myelotoxic schedules to be studied. Full-dose mBACOD with granulocyte-macrophage colony-stimulating factor (GM-CSF) support was compared with low-dose mBACOD in ACTG-142, a randomized trial. The median survival in the low-dose arm was 7.7 months and was 6.8 months in the standard-dose arm. There was no difference in either response or survival duration; however, an increased incidence of neutropenic sepsis was recorded in the full-dose arm (Table 61.1). Of note, more patients had active lymphoma at the time of death in the low-dose arm of the study, suggesting that the enhanced anti-tumor activity of the standard schedule was being offset by the greater toxic deaths.²⁷ A number of phase II trials were conducted in this era with complete remission (CR) rates of 14–68% but the median survival in unselected patients never exceeded 1 year (Table 61.2).

The only other randomized controlled trial of treatment for AIDS-related systemic NHL was also conducted predominantly in the pre-HAART era. The European Intergroup Study devised a risk stratified trial in which patients were allocated into one of three prognostic groups on the basis of CD4 count $< 100 \times 10^6/L$, a prior AIDS-defining diagnosis, and an eastern co-operative oncology group (ECOG) performance status score > 1 . In the good prognosis group, 188 patients were randomized between ACVB/LNH84 (doxorubicin, cyclophosphamide, vindesine, bleomycin, and prednisolone) and CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisolone) regimens. Complete

response rates were 65% and 56%, respectively, and there was no difference in overall survival, suggesting that as with other studies in high-grade lymphoma, nonmyeloablative dose intensification offers little benefits as first-line treatment. One hundred and thirty-nine patients with intermediate-risk disease (one adverse factor) were randomized to receive either full-dose CHOP or half-dose CHOP. Patients treated with full-dose CHOP had a significantly higher complete response rate (59% compared to 35%), although this did not translate into an improved overall survival. It should be remembered that the majority of patients were enrolled onto this study prior to the widespread use of HAART and that only around a quarter of the patients were receiving HAART at entry. The poor-risk group was randomized between half-dose CHOP and vincristine and prednisolone, but recruitment to this arm is incomplete.³¹

A number of groups have recently described an improvement in the overall survival for these patients compared to historical controls since the introduction of HAART. In two studies, the outcome of treatment with CHOP chemotherapy has been compared in the pre- and post-HAART eras, and improved CR rates and overall survivals have been demonstrated⁴⁶ (Table 61.3). However, in many series, there has been no change in the lymphoma response rates and the

improvements in survival duration may be related to reduced deaths from opportunistic infections among patients who achieve durable tumor remissions⁴⁸⁻⁵¹ (Tables 61.3 and 61.4).

Infusional chemotherapy for high-grade lymphoma was pioneered at the Albert Einstein Cancer Center in New York, using the combination of cyclophosphamide, doxorubicin, and etoposide (CDE) administered as a 96-h continuous infusion for up to six courses at 4-weekly intervals, together with granulocyte colony-stimulating factor (G-CSF).⁵⁹ Early reports of a selected group of 25 patients with AIDS-related lymphomas who were treated with CDE and didanosine reported an impressive median survival of 18.4 months, and this schedule was widely heralded as a breakthrough in the management of AIDS related lymphoma (ARL).⁶⁰ The same schedule was then combined with saquinavir, with similar results, although there was more mucositis with the PI.⁶¹ A large multicenter phase II trial of infusional CDE has been conducted by the Eastern Cooperative Oncology Group, and the results have been far less impressive as is so often the case following encouraging initial single-center studies⁶² (Table 61.5).

At the National Cancer Institute, EPOCH (etoposide, prednisolone, vincristine, cyclophosphamide, and doxorubicin) has been developed which omits all

HAART for the duration of the chemotherapy. Initial reports have been encouraging with a complete response rate of 79%. However, there was a dramatic fall in CD4 cell count during chemotherapy, and even on restarting the HAART at the end of chemotherapy this took 12 months to recover to baseline levels⁶⁴ (Table 61.5). This phase II study has been expanded to 39 selected patients⁶³ and is currently under investigation in a multicenter study under the auspices of the AIDS malignancy consortium. As there are no comparative studies, it is difficult to recommend an optimal gold standard therapy, and there are advocates of conventional CHOP as well as supporters of infusional therapies.

The use of infusional chemotherapy requires G-CSF support, and this is also frequently necessary with CHOP in this patient group in view of the high frequency of myelodysplasia. Although it was considered a possibility that GM-CSFs could stimulate HIV replication, there is no evidence that the use of these agents results in a rise in HIV viremia or progression of HIV disease.

The high rate of leptomeningeal disease at presentation, which may be asymptomatic,³⁰ led to the widespread use of staging lumbar punctures and the use of prophylactic intrathecal chemotherapy for patients considered to be at high risk of relapse in the cerebrospinal fluid (CSF). The prophylactic administration of intrathecal chemotherapy to patients with these risk factors but without meningeal disease at presentation prevented meningeal relapse in 81%.²⁵

Chemotherapy results in a decline in CD4 cell counts in both immunocompetent and immunocompromised patients,^{65,66} and prophylaxis to prevent opportunistic infections, particularly in this patient group, requires careful attention. It is well established in the management of HIV infection that prophylaxis should commence against PCP when the CD4 cell count falls below 200/mm³ and against *Mycobacterium avium* complex (MAC) when it falls below 50/mm³ (Ref. 67).

The prolonged T-cell depletion recorded following EPOCH⁶⁴ was previously demonstrated for patients receiving chemotherapy in the pre-HAART era.⁶⁸ The concomitant use of chemotherapy and HAART has been widely practiced, and a study in patients with ARL has demonstrated that when used together the CD4 cell count declines by 50% during chemotherapy but recovers rapidly within 1 month of completing

chemotherapy. The CD8 and natural killer (CD16 and CD56) cell counts follow a similar profile, while the B-cell (CD19) count recovers more slowly but is restored to prechemotherapy levels by 3 months. There was no change in the HIV mRNA viral load during chemotherapy.⁶⁹ In view of the decline in CD4 cell count by 50%, PCP prophylaxis should commence at CD4 cell counts of 400/mm³ and MAC at CD4 counts of 100/mm³.

The improved survival described since the introduction of HAART and the preservation of immune function suggest that the combination of chemotherapy with HAART is an important step forward in the management of AIDS-related lymphomas.^{46,47,58,69} However, there are both toxicity and pharmacokinetic drawbacks to the concomitant administration of chemotherapy and HAART. As mentioned in the first series describing the use of saquinavir with CDE, there was an increased incidence of mucositis⁶¹ and more anemia in another series including patients receiving concomitant PIs.⁴⁷ The PI class of antiretrovirals may modify the metabolism of cytotoxic drugs via inhibition of the CYP3A4 enzyme, and indeed pharmacokinetic studies have demonstrated a modest delay in the clearance of cyclophosphamide in patients receiving indinavir, compared to historical controls, although no increase in hematologic toxicity was observed.⁵⁸ We have recently compared CDE-chemotherapy-induced toxicity among patients receiving concomitant PI or PI-sparing HAART regimens (chiefly non-nucleoside reverse transcriptase inhibitor [NNRTI] based). The concomitant administration of PIs was associated with a significantly higher rate of grade III–IV infections and grade III–IV neutropenia, although there was no difference in survival between the groups.⁷⁰

OUTCOMES IN THE ERA OF HAART

The CR rates for regimens using the combination of chemotherapy and HAART are 48–92% and the published 2-year overall survivals are 48–60%.^{46,47,53,58,71} These response rates and survival duration statistics are starting to approach those seen in the general population with advanced-stage high-grade lymphoma. Indeed, while the prognostic factors for survival in the pre-HAART era were predominantly immunologic (prior AIDS-defining illness and CD4 cell count),^{34,72} a more recent analysis of prognostic factors in AIDS-related lymphoma closely resembles that for the general population, with the International Prognostic

Index being an equally valuable guide in both circumstances.^{73,74}

FUTURE DEVELOPMENTS FOR AIDS-RELATED LYMPHOMAS

The improvements in the treatment of HIV infection have led to a more aggressive management strategy for AIDS-related lymphomas, and this has resulted in better outcomes. Further refinements mirror those seen in immunocompetent patients with high-grade lymphoma, including the addition of anti-CD20 antibodies to first-line therapy and the use of high-dose chemotherapy with autologous stem cell transplantation at first relapse.

As almost all AIDS-related NHL express CD20, several groups have explored the role of rituximab, humanized monoclonal antibody to CD20, either alone or as an adjunct to chemotherapy in the management of AIDS-related NHL.^{55,75} CD20 antigen is a hydrophobic transmembrane protein that is located on pre-B and mature B lymphocytes. It is also expressed in greater than 90% B-cell NHLs including systemic AIDS-related NHLs, but it is not expressed on hematopoietic stem cells, pro-B cells, normal plasma cells, or other normal tissues. Rituximab efficiently lyses AIDS-related NHL cells in vitro via complement-dependent cytotoxicity and antibody-dependent cellular cytotoxicity.⁷⁶ Early trials are encouraging,⁷⁷ although profound and prolonged B-cell lymphopenia has been observed following rituximab.⁷⁸ Indeed, rituximab has been administered with CDE in a phase II pilot trial with concomitant HAART, and the 2-year overall survival was 80%⁵⁵ and achieved a complete response rate of 80% when used in combination with CHOP.⁵⁶ However, in a randomized phase III study of CHOP with or without rituximab that enrolled 142 patients, preliminary results have been disappointing with no difference in response rate or duration between the trial arms. Moreover, there was a higher incidence of neutropenic sepsis and death among those receiving rituximab.⁷⁹ Patients have also undergone successful autologous stem cell transplantation for AIDS-related lymphomas despite predictions that adequate harvesting would prove difficult due to myelodysplasia.⁸⁰⁻⁸⁵

PRIMARY CEREBRAL LYMPHOMA

Primary CNS lymphoma (PCL) is defined as an NHL that is confined to the craniospinal axis without systemic involvement. This diagnosis is rare in immunocompetent patients but occurs more frequently in patients with both congenital and acquired immunodeficiency. AIDS-related PCL occurs equally frequently across all ages and transmission risk groups, and the tumors are high-grade B-cell diffuse large cell or immunoblastic NHLs. The presence of Epstein-Barr

virus (EBV) is a universal feature of HIV-associated PCL but EBV is not found in other PCLs.^{86,87} EBV may be detected by immunocytochemical staining of biopsy tissue or by polymerase chain reaction (PCR) amplification of CSF using EBV-specific oligonucleotide primers.

EPIDEMIOLOGY OF HIV-ASSOCIATED PRIMARY CEREBRAL LYMPHOMA

Registry linkage studies confirmed a markedly increased relative risk of PCL among patients with AIDS, with an incidence as high as 2–6% in one early report.⁸⁸ This high incidence of PCL was confirmed by both cohort and linkage studies. Patients who develop PCL generally have advanced immunosuppression and for the most part have had a prior AIDS-defining illness. Shortly after the introduction of HAART, a decline in the incidence of PCL was recognized by many clinicians, and a meta-analysis of cohort studies that compare the pre- and post-HAART eras confirmed a significant decline (relative risk 0.42; 99% confidence interval 0.24–0.75).¹⁷ Indeed this fall is more dramatic than that seen for systemic AIDS-related lymphomas and PCL is associated with more severe immunosuppression than systemic AIDS-related lymphoma.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

The commonest causes of cerebral mass lesions in HIV-seropositive patients are toxoplasmosis and primary cerebral lymphoma and the differential diagnosis often proves difficult. Both diagnoses occur in patients with advanced immunodeficiency (CD4 cell counts $<50 \times 10^6/L$) and present with headaches and focal neurologic deficits. Clinical features that favor PCL include a more gradual onset over 2–8 weeks and the absence of a fever. CT and MRI scanning usually reveal solitary or multiple ring enhancing lesions with prominent mass effect and edema. Again, these features occur in both diagnoses, although PCL lesions are usually periventricular while toxoplasmosis more often affects the basal ganglia. Thus, the combination of clinical findings and standard radiologic investigations rarely provide a definitive diagnosis. Moreover, toxoplasma serology (IgG) is falsely negative in 10–15% of patients with cerebral toxoplasmosis. More than 85% patients with cerebral toxoplasmosis will respond clinically and radiologically to 2 weeks of anti-toxoplasma therapy, and this has become the cornerstone of the diagnostic algorithm for cerebral masses in severely immunodeficient patients.

In these patients, it has been a standard practice to commence empirical anti-toxoplasmosis treatment for 2 weeks duration, and resort to a brain biopsy if there is no clinical or radiologic improvement. This strategy avoids the routine use of brain biopsy in these patients who frequently have a very poor performance status

and prognosis. Although this algorithm avoids early surgical intervention, it is relatively ineffective in diagnosing PCL early, and may compromise the outcome of therapy in these patients. In addition, there is a disinclination to treat patients with radiotherapy or chemotherapy empirically based exclusively on the failure of anti-toxoplasmosis treatment without a definitive histologic diagnosis.

The discovery that all HIV-associated PCLs are associated with EBV infection has led to the development of a PCR method that can detect EBV DNA in the CSF. This has become established as a diagnostic test with a high sensitivity (83–100%) and specificity (>90%).^{89–91} In addition, radionuclide imaging by ²⁰¹thallium single photon emission computed tomography (²⁰¹Th-SPECT) or ¹⁸F-fluorodeoxyglucose positron emission tomography (FDG-PET) is able to differentiate between PCL and cerebral toxoplasmosis. PCLs are thallium avid and demonstrate increased uptake on PET scanning; however, although both techniques have high specificity for PCL, neither are highly sensitive and thus cannot be used alone but, in combination with PCR, are emerging as a diagnostic alternative to brain biopsy. The application of PCR and ²⁰¹Th-SPECT in the diagnosis of contrast-enhancing brain lesions in 27 patients was shown to result in a positive and a negative predictive value of 100% and 88%, respectively, which supports their combined value as an alternative to brain biopsy.⁹¹ Further studies are now required to compare effectiveness of PCR with ²⁰¹Th-SPECT or FDG-PET.

TREATMENT OF HIV-ASSOCIATED PRIMARY CEREBRAL LYMPHOMA

The standard treatment modality is whole brain irradiation, but the median survival time is just 2.5 months or less. Although patients who were treated with radiotherapy or chemotherapy lived longer than those who received best supportive care only, no randomized studies have been conducted and it remains uncertain whether therapy improves survival.⁹² There is an increasing enthusiasm for the treatment of PCL in immunocompetent patients with both radiotherapy and chemotherapy, and recent results have been encouraging. The use of chemotherapy for PCL is limited by the poor penetration of cytotoxics into brain parenchyma due to the blood–brain barrier and the toxicity, especially myelosuppression, of these agents in patients with advanced immunosuppression and poor performance status. Combination chemotherapy prolongs survival in immunocompetent patients with PCL but at the cost of severe myelotoxicity. Single-agent chemotherapy with intravenous high-dose methotrexate and folinic acid rescue was studied in AIDS patients with PCL in the context of a prospective uncontrolled study that included 15 patients. The results showed a complete response in 47% of patients, a median survival of 19 months, a low relapse rate of

approximately 14%, and no evidence of neurologic impairment nor treatment-limiting myelotoxicity.⁹³ A controlled trial of intravenous methotrexate versus whole brain irradiation is needed to confirm these encouraging results. Now that antiretroviral therapies are improving survival, it may be necessary to reassess currently available diagnostic and treatment modalities aiming to cure HIV-associated PCL.

HIV-ASSOCIATED HODGKIN'S LYMPHOMA

As with other AIDS-related malignancies, oncogenic viruses are thought to play a central role in the pathogenesis of HD. Single-cell PCR amplification methods can identify EBV in the Reed–Sternberg cells in approximately 10–70% HD, and in patients with HIV-associated HD, EBV is found in the Reed–Sternberg cells in nearly all cases.⁹⁴ There are also differences in the histopathology of HD between the immunocompetent population and the people with HIV. Two histopathological subtypes occur at a higher frequency in people with HIV: these are mixed cellularity (approximately 40%) and lymphocyte depleted (approximately 20%).^{95,96} In the HIV-negative population, these subtypes occur at 24% and 3–6%, respectively, and are associated with a worse prognosis compared to the more common nodular sclerosing and lymphocyte-predominant subtypes. Mixed cellularity subtype is more common in developing countries and in the elderly,^{96,97} and immune dysfunction and epidemiologic differences of EBV are thought to be responsible for this; however, their prognosis is still better than the HIV-seropositive population.

EPIDEMIOLOGY OF HIV-ASSOCIATED HODGKIN'S LYMPHOMA

Although HD occurs quite frequently in patients with HIV, both illnesses affect similar age groups, and there was debate as to whether the incidence is increased in people with HIV. Cohort studies from San Francisco⁹⁸ and New York⁹⁹ early in the HIV epidemic failed to identify an increased risk, and to this day HD is not an AIDS-defining diagnosis. However, subsequent subgroup analysis of the New York data suggested that there was an increased incidence of HD among intravenous drug users (IVDU) with HIV. Moreover, the Italian Cooperative group for AIDS-related tumors described 35 patients with HIV and HD and almost all of these patients were IVDU.¹⁰⁰

More recent cohort studies, including the San Francisco City Clinic cohort¹⁰¹ and multicenter AIDS cohort study (MACS),¹⁰² report a relative risk of 19 compared to the age-adjusted general population. The most comprehensive data to date come from large linkage studies across the United States and Puerto Rico, which gave a relative risk of 7.6.¹⁰³ This figure has been repeated in other large linkage studies and is

significantly lower than that for NHL in patients with HIV. The difference between the early small cohorts and these later large cohorts is probably due to the small number of HD cases seen rather than due to a real change in incidence over time. Since the introduction of HAART, the incidence of some AIDS-related malignancies such as KS and primary cerebral lymphoma has fallen while of others such as systemic NHL appears to be unchanged. There are as yet no reports that describe the effect of HAART usage on the incidence of HD.

CLINICAL PRESENTATION OF HIV-ASSOCIATED HODGKIN'S LYMPHOMA

HIV-seropositive patients with HD generally present with more advanced-stage disease than do seronegative patients. In the seven reported series, 70–85% of seropositive patients present with Ann Arbor stage III or IV, while less than half of the immunocompetent patients with HD will have stage III/IV disease at presentation.^{95,96,104–108} Moreover, B symptoms occur in 70–100% of HIV-seropositive patients with HD, although it may be impossible to distinguish the relative contributions of HIV and HD to these symptoms. Extranodal HD also occurs more commonly (up to 70%) than in the HIV-negative population. The bone marrow is the most commonly involved extranodal site affecting 50% of patients; other extranodal sites include skin, liver, and occasionally the CNS. Furthermore, there is a lower incidence of mediastinal involvement in the HIV-seropositive population (13%) compared to the general population with HD (70%).⁹⁵ The mixed cellularity histologic subtype, which is more common in HIV-positive patients, does not affect the mediastinum as commonly as the other types; nevertheless, the histologic differences do not account for all the difference observed in mediastinal disease.

The median CD4 cell count at diagnosis of HD is between 128 and 306/ μ L in the published series all of which pre-date the HAART era. This is higher than the median CD4 cell count reported in the pre-HAART era for high-grade NHL. At presentation of HD, 50–90% of patients had been previously diagnosed with HIV, while 4–46% (median 11%) had a prior AIDS-defining diagnosis. Thus HD tends to present at an earlier stage of immunosuppression than NHL, and it is intriguing that HD is not a feature of iatrogenic immunosuppression in allograft transplant recipients, although post-transplant NHL is a well-recognized entity.

TREATMENT OF HIV-ASSOCIATED HODGKIN'S LYMPHOMA

Since most patients will present with relatively preserved immune function and no prior AIDS-defining illness, clinicians have generally adopted a similar approach to the first-line therapy in HIV-seropositive patients as for the general population. Most patients

have advanced disease at presentation and are therefore candidates for combination chemotherapy. In the general population, HD is associated with a complex immunologic deficit. At the time of HD diagnosis, the CD4 cell count and function is often normal but becomes depressed during the progression of the disease, resulting in an increased incidence of opportunistic infections compared to other malignancies. It is hardly surprising that when the immunosuppressive effect of HIV is added to this, opportunistic infections become a major source of morbidity during chemotherapy.

The published series of HD in patients with HIV include a total of 359 patients. In all the series, there is a similar predominance of advanced-stage disease and mixed cellularity histology. The chemotherapy schedules that have been used, although not consistent in any series, have been mainly MOPP (mustine, vincristine, procarbazine, and prednisolone), ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine), or an alternating hybrid of the two (MOPP/ABVD). In these unrandomized, uncontrolled series, no regimen has been shown to produce higher response rates or longer response durations or survival. The CR rates ranged between 44% and 79% with a median of 58%, while the median survival was 11 months with a range between 10 and 18 months. The largest study consisted of 114 patients,¹⁰⁵ the median age was 29 years, 79% were IVDU, and the median CD4 count was 275/ μ L. The combination of MOPP and ABVD showed some benefit over MOPP alone (CR rate 68% vs 38%); however, this has not been reported in other series. These response rates and overall survivals are considerably worse than the results published for HD in the general population, where response rates exceed 80% and the median survival exceeds 10 years.

A major portion of poor survival in HIV-seropositive patients with HD is due to infectious complications. In the published series, 45–75% of patients developed opportunistic infections during chemotherapy. In one study, 71% of patients became neutropenic during treatment.¹⁰⁹ Concurrent G-CSF has been used in two studies, but this has no demonstrated benefit on toxicity or mortality.^{96,108} After 1 year, 55% of patients had developed an AIDS-defining diagnosis (usually an opportunistic infection), and 3 years after HD had been diagnosed 71% of patients had AIDS compared to only 24% of a matched seropositive population.⁹⁵ It has been proposed that chemotherapy may be responsible for the progression of immunosuppression; however, this may be a less important factor following the introduction of HAART. Indeed the incidence of opportunistic infection during chemotherapy for HD was only 13% among patients concomitantly receiving zidovudine monotherapy. It remains to be seen whether HAART will further reduce the infectious complications and progressive immunosuppression during and following chemotherapy for HD.

The prognostic factors for overall survival in patients with HIV and HD identified in the pre-HAART era relate chiefly to immunosuppression rather than HD. Poor prognostic factors at presentation included a low CD4 count (0% 18-month survival if less than 300/ μ L), prior AIDS-defining diagnosis, anemia, and a poor performance status.⁹⁵ These variables are similar to those for NHL in the same era; however, more recent data for NHL from the late 1990s have shown that the prognostic factors for HIV-associated NHL closely resemble those for NHL in the general population. It remains uncertain whether HAART will reduce the incidence or improve the outcome of HIV-associated HD. Certainly in the HAART era there is greater enthusiasm for an aggressive approach including progenitor stem cell transplantation for these patients.

HIV-ASSOCIATED MULTICENTRIC CASTLEMAN'S DISEASE

Benjamin Castleman first described multicentric Castleman's disease (MCD) as a case record of the Massachusetts General Hospital, familiar to all the readers of the *New England Journal of Medicine*, in 1954.¹¹⁰ Interest in MCD has grown in recent years with the AIDS epidemic, since there has been an increased incidence of MCD in HIV-positive patients. This followed the recognition of an association between MCD and AIDS-associated KS, again following initial publication of case reports.^{4,5} Castleman's disease is divided into localized disease and MCD which is characterized by polylymphadenopathy and multiorgan involvement. The localized form is treated with surgery but the management of MCD is less clear and has a more aggressive course. Histologically, it is divided into the hyalinized vascular form and plasma variant, the former being more common in localized disease and the latter more common in MCD. MCD is associated with Kaposi's sarcoma herpesvirus (KSHV) infection, which is also known as human herpesvirus 8 (HHV-8). The virus encodes a homolog of interleukin 6 (IL-6), a proinflammatory cytokine, which is thought to mediate some of the clinical features of MCD. The diagnosis is established by biopsy and treatment is often based on case reports in the literature, as there are no randomized trials. Surgery has less of a role but splenectomy may be useful as a debulking procedure to alleviate hematologic sequelae. Systemic treatments have included chemotherapy as well as anti-herpesvirus treatment to reduce the KSHV viral load, and HAART to reduce HIV viral burden. Lately, treatment with monoclonal antibodies against both IL-6 and CD20 has been studied. The introduction of HAART has altered the natural history of HIV infection; however, its impact on MCD is difficult to ascertain.

The plasma cell variant of MCD occurs most frequently in people with HIV infection. The histologic appearances are of an intense plasmacytosis in the interfollicular areas of the nodes, with a prominent increase in capillaries and postcapillary venules, which may be hyalinized. The concentrically arranged mantle zone may produce a characteristic 'onion peel' appearance. KSHV has been demonstrated in nearly all MCD samples from HIV-positive patients and in half MCD patients without HIV infection.¹¹¹ KSHV is also present in the malignant cells of plasmablastic lymphomas that occur more frequently in patients with MCD.^{112,113}

CLINICAL FEATURES OF HIV-ASSOCIATED CASTLEMAN'S DISEASE

In general, MCD presents in the fourth or fifth decade of life but occurs earlier in people who are HIV positive. Patients often present with generalized malaise, night sweats, rigors, fever, anorexia, and weight loss. On examination, they have multiple lymphadenopathy, hepatosplenomegaly, ascites, edema, and effusions both pulmonary and pericardial. Laboratory investigations may reveal thrombocytopenia, anemia, hypoalbuminemia, and hypergammaglobulinemia. The systemic symptoms are attributed to IL-6 and can be severe enough to cause pancytopenia, organ failure, particularly respiratory and renal, as well as shock, requiring admission into intensive care units. HIV-infected patients with MCD have a greater preponderance for pulmonary complications. MCD is more likely to lead to neuropathic complications than does locally confined Castleman's disease. Patients can develop polyneuropathies, leptomeningeal and CNS infiltration, as well as myasthenia gravis.¹¹⁴ The polyneuropathy is a chronic inflammatory demyelinating neuropathy and may be present as part of the rare POEMS syndrome (Crow-Fukase disease). POEMS syndrome consists of polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes. Patients are diagnosed with POEMS syndrome if they have two of these clinical features as well as plasma cell dyscrasia. Not only is MCD itself potentially fatal due to organ failure, but it is also associated with a 15-fold increased incidence of NHL. The majority of these lymphomas are plasmablastic and are thought to arise from expansion of plasmablastic microlymphomas seen in MCD lesions.^{112,113}

TREATMENT OF HIV-ASSOCIATED CASTLEMAN'S DISEASE

There are no definitive gold standard treatments for MCD. No randomized trials have been conducted on account of the infrequency of the diagnosis, and often only case reports have appeared in the literature. Although surgery is the mainstay of treatment for localized Castleman's disease, with complete removal of the mediastinal lesions being curative, it

has a limited role in MCD. Splenectomy, in addition to establishing the histologic diagnosis, may have a therapeutic benefit as a debulking procedure, as some of the hematologic sequelae such as thrombocytopenia and anemia may in part be due to splenomegaly. Following splenectomy, there is often resolution of the constitutive symptoms but this may be short lived, and some form of maintenance therapy is needed to prevent relapse.¹¹⁵

For immunocompetent patients, the chemotherapy regimens for MCD are based on lymphoma schedules such as CHOP. However, in the pre-HAART era, these schedules were associated with marked toxicity in HIV-positive patients, and as a consequence, other schedules were developed. In the largest published study from Paris of 20 patients, there was a partial response in 9/9 patients with single agent vinblastine; however, only 4 patients remained stable with maintenance therapy (4–6 mg/2 weeks). Four patients received upfront ABV (adriamycin, bleomycin, and vincristine), three achieving a partial remission. Intermittent treatment with cyclophosphamide

achieved a partial response in a further three patients.¹¹⁵ Although there is little evidence on which to base treatment strategies, in many centers combination chemotherapy is used initially to induce remission in aggressive forms of MCD. This may be followed by gentler, single-agent chemotherapy regimens, such as vinblastine or etoposide, to maintain the response.

Studies have now been undertaken to see if the addition of HAART in the treatment of MCD has any effect on morbidity and mortality. The effect of HAART has been described in seven patients with MCD and HIV infection.¹¹⁶ Six patients responded to chemotherapy, and immune reconstitution was described in five patients. However, patients continued to require long-term chemotherapy to prevent further episodes of MCD. The mean survival was 48 months, which was longer than that described in the pre-HAART era patients when most patients succumbed to opportunistic infections related to HIV. In addition, there were no cases of plasmablastic lymphoma as a complication of MCD.

Chapter 62

POSTTRANSPLANT LYMPHOPROLIFERATIVE DISORDERS

Terrance Comeau and Thomas Shea

INTRODUCTION

The term posttransplant lymphoproliferative disorder (PTLD) is used to describe a heterogeneous group of lymphoproliferative diseases that occur in hematopoietic stem cell transplant (HSCT) and solid organ transplant (SOT) recipients. These lymphoid disorders were first documented in the 1960s and were initially called “reticulum cell sarcomas.”¹ Interestingly, a subgroup of these diseases was labeled “pseudolymphomas” as these retained the ability to undergo spontaneous regression.² We now have a greater understanding of PTLD, a disease that most often involves B cells and usually is associated with reactivation of latent Epstein–Barr virus (EBV) infections in the setting of decreased T-cell function. The incidence of this disorder is generally reported to range from 0.8 to 20%, but is felt to be underreported due to its varied clinical presentation.^{3,4} These lymphomas are seen in different settings, and, some situations are much more likely to predispose to their occurrence than others. It is imperative that transplant physicians remain cognizant of this entity, as effective therapies are now available that can lower the mortality rate from the 50–80% range seen in the early 1990s^{5–8} to cure rates approaching 100% if patients are diagnosed when the tumor burden is low.^{9–10}

PATHOPHYSIOLOGY

EBV, also known as human herpesvirus 4 (HHV4), is the prototype of the gamma subfamily of potentially oncogenic herpesviruses.¹¹ EBV was discovered over 35 years ago by electron microscopy of cells cultured from Burkitt’s lymphoma tissue by Epstein, Achong, and Barr¹²; it is ubiquitous and is known to infect over 90% of people and to persist in the body for life.¹³

Primary EBV infections occurring in early childhood are often asymptomatic. In contrast, primary

infections occurring in adolescence and young adulthood often lead to the self-limiting lymphoproliferative disease called infectious mononucleosis (IM), characterized by the triad of fever, lymphadenopathy, and pharyngitis.

EBV, which usually infects humans by entering the oropharynx in saliva, replicates in epithelial cells by coupling of the viral gp 350 glycoprotein with the CD21 receptor on B cells. This leads to host cell infection and subsequent infiltration of oropharyngeal tissue. EBV-infected B cells express a pattern of EBV latent genes known as “latency III” genes. Hence, these cells express multiple viral proteins including the six nuclear proteins known as EBV nuclear antigens (EBNAs) 1, 2, 3a, 3b, 3c, and LP; integral membrane proteins known as latent membrane proteins (LMP) 1, 2a, and 2b; and two untranslated RNAs known as EBERS 1 and 2 (EBV-encoded small RNAs). EBNA1 binds to viral DNA and is responsible for the maintenance of EBV episomes in replicating B cells.¹⁴ EBNA2 up-regulate cellular proteins that contribute to the growth and transformation of B cells. LMP1 also functions as a constitutively activated member of the tumor necrosis factor receptor superfamily that activates a number of signaling pathways in a ligand-independent manner. LMP1 can substitute for CD40 *in vivo* and leads to the activation of the transcription factor NF- κ B (nuclear factor kappa B), which in turn results in cytokine production and B-cell proliferation. Finally, LMP2a alters B-cell receptor (BCR) signaling by mimicking the rescue signal normally delivered by this receptor, thereby enabling nontransformed B cells to survive without appropriate BCR signaling.

Normally, B cells transformed by EBV or containing replicating virus are highly immunogenic and induce an intense cytotoxic T lymphocyte (CTL) and natural killer cell response. These activated T cells, appearing in the peripheral blood as atypical lymphocytes, help control the proliferation of infected B cells. Fortunately, most EBV-infected B cells are eliminated,

but some are able to persist because they down-regulate immunogenic EBV proteins, thus allowing the cells to avoid immune recognition. Eventually, the EBV genome forms an episome that remains latent in resting memory B cells. These EBV-infected cells now express only the “latency 0” gene pattern, which consists of LMP2a, the EBERS, and possibly EBNA1.^{13,15} Hence, in the immunocompetent host, an equilibrium is established in which rare EBV-infected cells lacking expression of immunogenic proteins coexist with EBV-specific CTLs. EBV undergoes lytic replication in numerous B cells in the oropharynx of healthy carriers. When people become immunosuppressed after HSCT or SOT, critical T-cell control of B-cell growth is no longer present, leading to unchecked proliferation of EBV-infected cells, which may in turn result in B-cell hyperplasia or frank malignancy.¹⁵

The origin of EBV-infected cells in PTLD varies depending on the transplant population being studied. In SOT patients, the PTLD cells are usually of recipient origin. However, most PTLD cells in the HSCT setting are donor derived. It should be noted that primary EBV infection may also result in PTLD; this is usually seen in children.

INCIDENCE AND RISK FACTORS

The incidence of PTLD varies depending on the type of transplant, recipient age, and type of immunosuppression used (Tables 62.1 and 62.2). The incidence of PTLD is 4 times higher in pediatric than in adult transplant recipients.¹⁶ In SOT recipients, the incidence of PTLD varies with the type of allograft: 19% of intestinal transplants, 2–10% of heart transplants, 5–9% of heart–lung transplants, 2–8% of liver transplants, and 1–10% of renal transplants.¹⁶ Additional risk factors for PTLD in SOT patients include high levels of immunosuppression (particularly with antithymocyte globulin), EBV seronegative recipient of a seropositive donor, development of primary EBV infection after transplant, and presence of cytomegalovirus (CMV) disease. For example, PTLDs are the most common tumors in children after organ transplant and represent over 50% of all posttransplant tumors; this is in contrast to adults where such tumors comprise only

Table 62.2 Relative risk of PTLD in HSCT by method of T-cell depletion¹⁹

Method of T-cell depletion (TCD)	Relative risk
No TCD	1
CAMPATH-1 monoclonal antibody	2
Elutriation/density gradient centrifugation	2.6
Lectins	4.1
Anti-T-cell monoclonal antibody	12.3
Sheep red blood cell rosetting	15.6

15% of posttransplant malignancies.¹⁷ In addition, children undergoing small intestine transplants may have an EBV-PTLD incidence as high as 32%.¹⁸

For patients undergoing HSCT, several risk factors have been identified to predict for the risk of PTLD in different settings. Curtis et al. evaluated over 18,000 patients who underwent allogeneic HSCT at 235 centers worldwide. The cumulative incidence of PTLD was 1% at 10 years. The incidence was found to vary markedly with time after transplant, with high rates occurring during the first 5 months, followed by a steep decline in incidence between 6 and 12 months post-transplant.¹⁹ The high incidence of PTLD during the first 5 months after transplant is consistent with studies that show the temporal pattern of immune reconstitution in HSCT recipients. For example, Lucas et al. noted that levels of anti-EBV CTL precursors appear to return to normal by 6 months posttransplant in most patients.²⁰ In their multivariate analysis, Curtis et al. found that the risk of early (<1 year posttransplant) PTLD was strongly associated with unrelated or ≥ 2 human leukocyte antigen (HLA)-mismatched related donors, T-cell depletion methods that selectively target T cells or T + NK cells or E-rosetting, use of antithymocyte globulin for prophylaxis or treatment of acute graft-versus-host disease (GVHD), and use of the anti-CD3 monoclonal antibody 64.1 (given for therapy of acute GVHD). The cumulative incidence of PTLD for patients with 0, 1, 2, or 3–4 major risk factors were 0.5, 1.7, 8, and 22.3%, respectively. They also noted a weaker association with the occurrence of acute GVHD grades II–IV and with conditioning regimens that included total body irradiation (TBI). The risk appeared to vary by dose of fractionated TBI, with a 3.5- to

Table 62.1 Risk factors for PTLD

Solid organ transplant	Hematopoietic SCT
Allograft type (e.g., intestinal)	Type of transplant
High levels of immunosuppression (e.g., Antithymocyte globulin)	High levels of immunosuppression (e.g., Antithymocyte globulin)
EBV seronegative recipient of seropositive donor	Donor type: unrelated or ≥ 2 HLA-mismatched related donor
Presence of CMV disease	T-cell depletion

EBV, Epstein–Barr virus; HLA, human leukocyte antigen; CMV,

4.3-fold increased risk seen for doses ≥ 13 Gy. The only risk factors identified for late-onset (>1 -year posttransplant) PTLD were extensive chronic GVHD and TBI dose.¹⁹ There is a suggestion that conditioning regimens containing fludarabine also may be associated with an increased risk of PTLD.²¹

Significant differences were detected among T-cell depletion techniques used. As noted above, a high risk of PTLD was observed among recipients of grafts that were T-cell depleted using monoclonal antibodies or sheep red blood cell E-rosetting techniques that selectively targeted T (or T + NK) cells. However, lower rates of PTLD were associated with methods that removed both T and B cells, such as CAMPATH-1 monoclonal antibodies, elutriation, and lectins.¹⁹ This was also confirmed in a study by Hale and Waldmann in which 2401 recipients received grafts that were T-cell-depleted with CAMPATH-1M or 1G; the cumulative risk of PTLD was only 1.1%. They hypothesized that the depletion of B cells may reduce the viral load or virus target tissue in the interval before full recovery of T-cell function.²² Patients receiving CD34 selected allografts do not appear to be at an increase risk of PTLD as the B-lymphocyte contamination of the isolated CD34⁺ cells is low.²³

Rare cases of PTLD have been reported in recipients of autologous HSCTs.^{15,24} Powell et al.²⁵ reported an unexpectedly high incidence of EBV-PTLD in patients undergoing CD34⁺ selected autologous peripheral blood stem cell transplant for neuroblastoma: 5 of 156 patients (3.5%). This is in contrast to a report by Gross et al. who reported no cases of EBV-PTLD in their review of 853 autologous stem cell transplants.⁴

Finally, EBV-negative PTLDs appear to be morphologically and clinically distinct from EBV-positive PTLDs in that they tend to have a later onset, a higher prevalence of monomorphic lymphomas, and a greater proportion derived from T cells.^{19,26–28} Although EBV-negative PTLDs have distinct features and are felt to be associated with a poor prognosis, some do respond to decreased immunosuppression, similar to EBV-positive cases.^{27,28}

CLINICAL FEATURES

The presentation of PTLDs may range from an asymptomatic state to a rapidly progressive, fulminate course with a fatal outcome.⁸ Hence, it is important to maintain vigilance in high-risk patients. Symptoms are varied and may be related to the EBV viral infection, B symptoms from overt lymphoma, organ dysfunction, and/or mass effect. Early symptoms may be nonspecific and may include malaise, fever, and weight loss. In children with primary EBV posttransplant, IM is the most common presentation: fever, tonsillar and adenoid hypertrophy, cervical lymphadenopathy, and hepatomegal with abnormal liver enzymes. Patients with central nervous system (CNS) involvement may

present with seizures. Gastrointestinal (GI) involvement may manifest with abdominal pain, diarrhea, GI bleeding or perforation. It is important to remember that dysfunction in the organ transplanted may be an indication of involvement by PTLD. Reams et al. reported that 70% of their lung and heart–lung recipients who developed PTLD presented with thoracic organ involvement.²⁹ Hence, any transplant patient who experiences adenopathy, mass lesions, unexplained fever or pain, weight loss, or dysfunction of the transplanted organ should be investigated for PTLD.

EVALUATION

Serologic testing has traditionally been used to investigate EBV-related disorders. However, such testing may be unreliable in the transplant population as a result of altered antibody production by host immunosuppression and passive transfer of antibody from blood products given in the peritransplant period. One of the most useful techniques to evaluate for EBV-PTLD is polymerase chain reaction (PCR) testing of peripheral blood, which may detect disease before the onset of clinical symptoms.³⁰ High EBV viral loads in high-risk patients often predict for the development of EBV-PTLD. Aalto et al. evaluated serum samples from 12 HSCT recipients who had died from PTLD using quantitative PCR (qPCR) for EBV-DNA.³¹ They found that all of the PTLD patients became EBV-DNA positive with progressively rising copy numbers, and that EBV-DNA was first detectable 23 days before death, which was earlier than the onset of symptoms (which occurred 15 days before death). In their patient population, they noted that qPCR for EBV-DNA in serum was highly sensitive (100%) and specific (96%). However, Wagner et al. found that the detection of two or more levels of EBV-DNA above 4000 copies/mcg had a sensitivity of 100% for the prediction of early PTLD but a specificity of only 50%.³² Carpentier et al. evaluated the utility of EBV early-antigen (EA) serologic testing in conjunction with peripheral blood EBV-DNA viral load testing as a marker for risk of PTLD. They found that at the EBV-DNA threshold at which PTLD occurs, the positive predictive value based on the absence of high-titer EA antibody was increased to 75%; that is, patients with high EBV-DNA load but without significant EA antibody titers had a 75% risk of developing PTLD.³³ Such testing would not be useful in patients with EBV-negative PTLD or those EBV-positive patients who do not shed large amounts of EBV into the peripheral blood.³⁴

Detailed radiologic investigations including CT scans of the chest, abdomen, and pelvis are necessary to evaluate the extent of disease. Patients with GI complaints may require endoscopy with biopsy. Thoracentesis may be necessary to evaluate pleural effusions, and paracentesis to evaluate ascites. Patients with CNS signs or symptoms or abnormal head CT

Figure 62.1 *PTLD: reactive plasmacytic hyperplasia-type polyclonal*

scans or MRI scans may warrant a lumbar puncture with CSF evaluation. Castellano-Sanchez et al. reported the features of 12 patients with primary CNS PTLD; by neuroimaging, most patients showed multiple (3–9) intra-axial, contrast-enhancing lesions. CNS PTLDs were noted to be uniformly high-grade lymphomas and were associated with extremely short survival periods.³⁵

Tissue biopsy confirms the diagnosis of PTLD. Excisional biopsy provides adequate tissue for evaluation of cell type, clonality, virologic studies, and architectural background (Figures 62.1 to 62.8). Cytology alone has a limited role in the diagnosis of PTLD as it does not permit subclassification. Immunophenotyping by flow cytometry or immunohistochemistry should be performed to determine the cell type (B vs T) and cell marker status, which may direct therapy (e.g., CD20 expression). While the majority of these are B-cell tumors and are associated with EBV, approximately 9% of all PTLD and as many as 27% of EBV-negative tumors may be of T-cell origin.^{26–28} PTLD can be confused with organ transplant rejection

Figure 62.3 *PTLD: polymorphic monoclonal*

unless the cells are identified as B cells by B-cell markers such as CD19, CD20, CD21, or CD22. Also, PTLD may coexist with acute rejection. When the allograft itself is affected, histologic features such as plasmacytoid infiltrates, immunoblastic cells, nodular infiltrates, and serpiginous necrosis, especially in the absence of neutrophils, is suggestive of PTLD. Tumor clonality may be determined by evaluating for immunoglobulin or T-cell receptor gene rearrangements. Evaluation for viral markers should also be performed with in situ hybridization for Epstein-Barr early RNA (EBER) or immunostaining for EBV LMP.^{3,16}

A formal classification system of PTLD was established by two international consensus groups (ASTS/ASTP EBV-PTLD Task Force and the Mayo Clinic organized International Consensus Development Meeting on EBV-Induced PTLD) and published in 1999.³ They suggested that the term PTLD should be used to encompass the large spectrum of EBV lymphoproliferative processes seen after organ or stem cell transplantation.

Figure 62.2 *PTLD: polymorphic polyclonal type*

Figure 62.4 *PTLD: monomorphic*

Figure 62.5 PTLD Burkitt's type (touch prep)

Figure 62.7 PTLD: plasmacytoma-like (monoclonal kappa)

In addition, they recommended that posttransplant IM and plasma cell hyperplasia continue to be included under the heading of PTLD, but that they be clearly segregated as reactive hyperplasias. They also recommended that the term PTLD, when not further qualified, be used to refer to neoplastic forms of PTLD that are termed "polymorphic PTLD" (including polymorphic lymphoma and polymorphic B-cell hyperplasia, which can be a monoclonal lesion), or "lymphomatous" PTLD (including so-called monomorphic PTLD). Harris et al. described polymorphic PTLDs as destructive lesions that produce architectural effacement of lymph nodes but that, unlike most lymphomas, show a full range of B-cell maturation from immunoblasts to plasma cells with small- and medium-sized lymphocytes and numerous cells resembling centrocytes/cleaved follicular center cells.³⁶ In contrast, monomorphic PTLDs often have sufficient architectural and cytological atypia to be categorized

as high-grade lymphomas. Monomorphic PTLDs are characterized by infiltrates causing nodal architectural effacement with confluent sheets of transformed cells; all or most cells are large, transformed, blastic cells with prominent nucleoli and basophilic cytoplasm.³⁶ Most monomorphic PTLDs fall into the category of diffuse large cell lymphomas. The consensus groups also stated that neoplastic forms of EBV-positive PTLD should ideally have (1) disruption of underlying architecture by a lymphoproliferative process, (2) presence of monoclonal or oligoclonal cell populations as revealed by cellular and/or viral markers, and (3) evidence of EBV infection in many of the cells. The demonstration of a lymphoid tumor containing unequivocal evidence of any two of these features was felt to be sufficient to establish the diagnosis of neoplastic PTLD. A working diagnosis could be made in the presence of (1) or (2) alone in the proper clinical setting. In practical terms, this eliminates all inflammatory lesions in which EBV might be demonstrated, with the exceptions of plasma cell hyperplasia and IM.

Figure 62.6 PTLD: Burkitt's type (EBV ISH)

Figure 62.8 PTLD: myeloma type

Table 62.3 Harris formulation*Early/Benign PTLD*

Plasmacytic or atypical lymphoid hyperplasia
 Infectious mononucleosis-like syndrome

- Nodal disease with preservation
- <3 months posttransplantation
- Polyclonal

Polymorphic PTLD

- Nodal disease with effacement of lymph node architecture or extranodal disease
- Full range of B-cell maturation
- Monoclonal
- Normal cytogenetics
- No oncogene mutations

Monomorphic PTLD (Non-Hodgkin's B- or T-Cell lymphoma)

- Nodal disease with effacement of lymph node architecture or invasive extranodal disease
- Monomorphic sheets of transformed B cells
- Monoclonal
- Some with abnormal cytogenetics or mutations in ras or p53

PTLD-Other

T-cell-rich, large B-cell (Hodgkin's-like) lymphoma

- Nodal disease
- Background of small T-cells with superimposed Reed–Sternberg-like cells
- Monoclonal

Plasmacytoma-like lesions

- Nodal disease with effacement of lymph node architecture by mature plasma cells with monoclonal immunoglobulin
- Monoclonal

Multiple myeloma

Criteria For Evaluation of Clonality (Specify B or T Cell)

C0 Polyclonal
 C1 Monoclonal-not further categorized

- C1a Monoclonal component estimated at <50% of cells
- C1b Monoclonal component estimated at ≥50% of cells
- C1c Multiclonal or oligoclonal pattern

CX not evaluated

Criteria For Evaluation of EBV within PTLD (detection by EBER2 or LMP1 expression)

E0 EBV negative
 E1 EBV Present-not further categorized

- E1a Nonclonal viral pattern
- E1b Clonal viral pattern

EX not evaluated

Finally, they recommended that the classification system formulated by Harris et al.³⁶ be used (Table 62.3) with supplemental information (clonality, EBV status) appended to the histological diagnosis of PTLD. The World Health Organization (WHO) also defined several categories of PTLD (Table 62.4).

Although no specific staging system for PTLD exists, the consensus group recommended that the Ann Arbor Staging Classification with Cotswold modifications be used.

Table 62.4 World Health Organization categories of PTLD

WHO Categories of Posttransplant lymphoproliferative disorders

Early lesions

- Reactive plasmacytic hyperplasia
- Infectious mononucleosis-like

PTLD polymorphic

- Polyclonal (rare)
- Monoclonal

PTLD monomorphic (classify according to lymphoma classification)

B-cell lymphomas

- Diffuse large B-cell lymphoma (immunoblastic, centroblastic, anaplastic)

- Burkitt/Burkitt-like lymphoma

- Plasma cell myeloma

T-cell lymphomas

- Peripheral T-cell lymphoma, not otherwise categorized

- Other types (Hepatosplenic, gamma-delta, T/NK)

Other types (rare)

- Hodgkin's disease–like lesions (associated with methotrexate therapy)

- Plasmacytoma-like lesions

MANAGEMENT

The prevention and treatment of EBV-PTLD may include numerous modalities (Table 62.5), the choice of which may be dictated by certain prognostic features (Table 62.6). The survival rates of patients who develop PTLD vary widely depending on the type of transplant (SOT vs HSCT), category of PTLD (early polyclonal vs monoclonal monomorphic), and the therapy employed.¹⁵

REDUCTION OF IMMUNOSUPPRESSION, SURGERY, RADIATION THERAPY

Decreasing immunosuppressive therapy is often the first step taken in the management of PTLD in the SOT setting and has proven to be efficacious in small case series reports, with response rates ranging from 23 to 89%. Tsai et al. reported one of the largest series on the outcome of 42 adult organ transplant recipients who developed PTLD and were treated with reduction in immunosuppression with or without surgical resection of all known disease: 73.8% achieved a complete remission. Of those patients who were treated with reduction in immunosuppression alone, 63% responded, with a median time to documented response of 3.6 weeks. They noted that an elevated LDH ratio, organ dysfunction, and multiorgan involvement by PTLD predicted for lack of response to reduction in immunosuppression. In patients with none of these risk factors, 89% responded to reduction in immunosuppression, while 60% with 1 risk factor responded and 0% with 2–3 risk factors responded. However, such a maneuver is associated with the risk

Table 62.5 Management of PTLD

Monitor EBV-DNA viral load by PCR in cell-free plasma once every 1–2 weeks in high-risk transplant patients.
When EBV reactivation occurs, screen patients for signs and symptoms of early PTLD.
Obtain histologic confirmation of PTLD and perform staging studies to document extent of disease. This includes serum LDH, CT/PET scans, and bilateral bone marrow aspirate and biopsy.
Reduce immunosuppressive therapy as tolerated by SOT or HSCT recipient.
Consider surgery or radiation therapy for localized disease.
Patients who fail to respond to reduction in immunosuppression should be considered for therapy with rituximab if CD20 expression documented.
Patients who fail to respond to rituximab or who are not candidates for such therapy should be considered for cytotoxic chemotherapy. Patients with stage IV disease and those with an elevated LDH may be considered for initial combination therapy with both chemotherapy and rituximab.
If available, HSCT patients can be considered for adoptive immunotherapy with donor T-cells.

SOT: Solid organ transplant; EBV: Epstein–Barr virus; PTLD: post-transplant lymphoproliferative disorder; LDH: Lactate dehydrogenase; HSCT: Hematopoietic stem cell transplant.

of allograft rejection, which can be fatal in setting of heart, liver, or lung transplantation. In this study, almost all cases of acute rejection could be treated by increasing immunosuppression without compromising the initial effect of immunosuppression on reduction of the PTLD. Tsai et al. noted that the high response rate and low rejection rate in this study suggests that one can often find a level of immunosuppression sufficient for PTLD resolution while simultaneously protecting the allograft in many patients.³⁷ Liver, pancreas, and kidney transplant patients are often treated with complete cessation of all immunosuppression, except for a maintenance dose of steroids to prevent an adrenal crisis, as acute rejection can be quickly identified noninvasively by following liver enzymes and serum creatinine. Severe rejection can then be aborted with reinstatement of immunosuppre-

Table 62.6 Poor prognostic features

Multivisceral disease (4 or more sites)
CNS involvement
HSCT vs SOT

LDH: lactate dehydrogenase; HSCT: Hematopoietic stem cell transplant; SOT: solid organ transplant.

sion and rescue of the graft. In contrast, for heart and lung transplant recipients, immunosuppression is reduced but not stopped completely. For example, drugs such as azathioprine and mycophenolate mofetil are discontinued, while drugs such as steroids, cyclosporine, or tacrolimus are maintained at a reduced dose. Patients not responding with a CR (Complete Remission) or PR (Partial Remission) by 4 weeks should be evaluated for additional therapies. Radiation therapy applied to localized PTLD may also be curative.

Unfortunately, HSCT recipients rarely benefit from a decrease in immunosuppressive therapy as endogenous immune recovery posttransplant may take several weeks to months.

ANTI-B-CELL THERAPY

There are numerous reports that support the effectiveness of anti-B-cell therapy for the treatment of PTLD in both SOT and HSCT patients.^{38,39} Benkerrou et al.⁴⁰ reported the outcome of 58 patients after SOT or HSCT with EBV-PTLD who were treated with anti-CD21 plus anti-CD24 antibodies: 61% of patients achieved a CR, with a 1-year overall survival of 46% (compared with 29% in historical controls). Several recent reports have demonstrated a benefit from the use of rituximab, a humanized monoclonal IgG1 kappa antibody against the CD20 antigen found on the surface of malignant and normal B cells, but not on other normal tissues. It has been found to mediate complement-dependent cell lysis and antibody-dependent cellular cytotoxicity.⁴¹ Milpied et al. reported the outcome of 32 transplant recipients with PTLD who were treated with rituximab: response (CR + PR) was seen in 65% of SOT and 83% of HSCT recipients, with 73% surviving at 1 year.⁴² Ganne et al. reported the outcome of eight cases of PTLD occurring after SOT. Complete remission was achieved in seven patients, and seven patients maintained functioning grafts.⁴³ Rituximab is often used as first-line therapy in patients with PTLD occurring after HSCT and as second-line therapy after failure of reduction in immunosuppression in SOT recipients.

Rituximab has also been used in the preemptive setting for the prevention of PTLD in high-risk patients. van Esser et al.⁴⁴ evaluated EBV reactivation by PCR viral load testing in patients undergoing allogeneic HSCT. They found that patients undergoing a T-cell depleted allogeneic HSCT were at high risk for PTLD if the plasma EBV viral load exceeded 1000 genome equivalents/milliliter (gEq/mL). Although the negative predictive value of viral load testing was 100%, the positive predictive value was only 39%, indicating that many patients were still able to mount an effective immune response and clear the viral reactivation. They suggested that monitoring the reconstitution of EBV-specific T lymphocytes may add to the predictive value of the viral load by PCR; such assays are now available and include the enumeration of EBV-specific

Figure 62.9 Pulmonary nodule

T cells by tetramer binding or by the induction of intracellular interferon -gamma (IFN- γ) in T cells after specific stimulation.⁴⁴ In order to evaluate the prevention of EBV-PTLD by preemptive use of rituximab, van Esser et al.⁹ evaluated 49 recipients of a TCD allogeneic HSCT by performing EBV viral load by PCR. Preemptive therapy with a single infusion of rituximab was given to 15 patients with an EBV viral load of 1000 gEq/mL or more. A total of 14 patients demonstrated a complete response, as defined by prevention of EBV-PTLD and complete clearance of EBV-DNA from the plasma, which was achieved after a median of 8 days.

Figure 62.10 Neck adenopathy

They compared this outcome with their historical cohort with the same high-risk features and showed a reduction of PTLD incidence from 49 to 18% and reduction in PTLD mortality from 26 to 0%.⁹ However, not all B-cell PTLD express CD20. Kaleem et al. found that 16% of the PTLD cases they evaluated by flow cytometry showed almost complete lack of CD20 expression and several other cases showed partial and dim expression on CD20.⁴⁵

Finally, analysis of patients with PTLD in remission after chemotherapy or withdrawal of immunosuppression has confirmed a relationship between disease activity and EBV viral load by PCR. However, Yang et al. suggest that this correlation may not exist in patients treated with rituximab. They note that EBV-infected lymphocytes in the peripheral blood differ in their sensitivity to rituximab from tumor cells of PTLD; that is, EBV-infected cells in the peripheral blood rapidly decline with therapy, whereas the response of tumor cells is variable. They caution that monitoring viral load in peripheral blood may not predict clinical response in patients with PTLD treated with rituximab.⁴⁶

RAPAMYCIN

Rapamycin is a macrolide antifungal antibiotic isolated from *Streptomyces hygroscopicus* that has potent immunosuppressive properties. It blocks cell cycle progression from phase G1 to S and inhibits some signal transduction pathways. Besides its inhibitory effects on normal cells of the immune system, rapamycin also inhibits proliferation of transformed cell lines, such as B cells transformed by EBV.

Garcia et al. recently reported two cases of PTLD after renal transplantation that were successfully treated with rituximab in association with rapamycin. This is a potentially useful combination as it allows for the maintenance of some degree of the immunosuppression necessary to preserve graft function while exerting anti-PTLD effects.⁴¹

CHEMOTHERAPY

Chemotherapy is usually considered for use when the preceding treatment options have failed, as it may be associated with significant morbidity and mortality. Unfortunately, HSCT patients, who are more resistant to reduction in immunosuppression, are frequently in need of early chemotherapy. Patients with high LDH and multiorgan involvement are another group most likely to require such therapy. Perhaps the early identification of such risk factors may permit more rapid initiation of effective chemotherapy regimens. Anthracycline containing regimens such as CHOP and ProMACE-CytaBOM have been used in the past and may provide long-term relapse-free survival.¹⁵ However, recent investigations in children and adults with PTLD after SOT have demonstrated a high response rate with less toxicity and mortality with low-dose combination chemotherapy. For example, Gross et al.⁴⁷ showed that

low-dose cyclophosphamide/prednisone induces a high response rate (>90%) with minimal toxicity. However, the 2-year event-free survival was only 58%. To improve the long-term outcome, Orjuela et al. recently reported the results of a pilot study in which six patients with PTLD following SOT were treated with 2–6 courses of CPR (cyclophosphamide, prednisone, and rituxin) and reported an overall response rate of 100% (85% CR, 15% PR). All patients in CR survived with functioning allografts.⁴⁸ Oertel et al. reported their experience with salvage chemotherapy (carboplatin/etoposide with G-CSF support) in patients with refractory or relapsed PTLD after SOT: five of nine patients achieved a complete remission.⁴⁹

ADOPTIVE IMMUNOTHERAPY

Khatri et al. demonstrated the striking temporal relationship between the endogenous expansion of a TCR V β -restricted, CD3⁺CD8⁺ population of MHC class I-restricted CTL and the regression of a monoclonal PTLD in a HSCT recipient. Unfortunately, the delay in recovery of such immune surveillance against transformed EBV-positive B cells results in the development of potentially fatal PTLD. T-cell immunotherapy has been reported to be efficacious in the management of PTLD in this setting.³⁹ O'Reilly et al. reported on 18 HSCT patients with EBV-PTLD who were treated with nonspecific donor lymphocyte infusions (DLI): 16 of 18 patients experienced eradication of PTLD. However, only 10 survived in sustained CR and 3 patients died of GVHD, a major side effect of DLI.⁵⁰ Attempts have been made to improve the efficacy and reduce the risk of GVHD by administering EBV-specific CTLs.⁵¹ Rooney et al. detailed the outcome of 39 recipients of matched unrelated donor/partially mismatched related donor transplants who received prophylactic EBV-specific CTLs (EBVs-CTL). None of the treated HSCT recipients developed PTLD, whereas 7 of 61 controls not receiving such therapy developed PTLD.⁵²

In the SOT setting, adoptive immunotherapy has also been evaluated on a limited basis. Nalesnick et al. reported the experience of seven SOT recipients with PTLD; peripheral blood mononuclear cells harvested from the patients were cultured with interleukin-2 (IL-2). The infusion of these lymphokine-activated killer cells into the four patients with EBV-positive tumors resulted in sustained involution of their tumors. Unfortunately, two patients suffered organ rejection.⁵³ Haque et al. reported their experience with three SOT patients whose EBV-specific cells lines were cultured from autologous T cells collected prior to transplant; the prophylactic infusion of these cells after transplant resulted in the suppression of circulating EBV-DNA levels to below pretransplant levels. Interestingly, the EBV-specific CTLs were measurable in the patients' blood for 3 months posttransplant.⁵⁴ Finally, a phase 1/2 trial with eight SOT patients who

had progressive PTLD unresponsive to conventional treatment were given infusions of partly HLA-matched allogeneic EBV-specific CTLs from a frozen bank of CTLs derived from healthy blood donors. Three of the five patients who completed treatment achieved a complete remission, and the EBV load in their peripheral blood fell to undetectable levels in all patients who responded to treatment; no GVHD developed and graft function improved in three cases.⁵⁵ It was noted that tumor responses were mainly seen in those with early, localized, polyclonal disease.

EBVs-CTL therapy may not find widespread use for several reasons: it requires 2–3 weeks to generate such cells, the technology for larger scale expansion of EBV-CTLs is expensive, such technology is not available in every transplant center, and this approach is not effective in patients who develop EBV deletion mutants.¹¹

ARGININE BUTYRATE

Arginine butyrate and other histone deacetylase inhibitors induce the activity of certain genes. Exposure of EBV-positive tumor cells to butyrate results in robust induction of herpesvirus in immediate-early and early (lytic) genes, including thymidine kinase (TK), and a modest induction of lytic replication. There is now extensive experience in the administration of arginine butyrate over extended periods of time to adults and children with sickle cell anemia or β -thalassemia to therapeutically reactivate fetal globin expression. In vitro studies demonstrated that induction of EBV-TK activity was possible in EBV-immortalized B cells and that these previously ganciclovir-resistant cells were then rendered susceptible to antiviral nucleoside analogs. Faller et al. have used arginine butyrate to induce the latent viral TK gene expression and enzyme induction in tumor cells and then treated the patients with ganciclovir: 5 of 10 previously refractory patients experienced a complete clinical response and an additional 2 patients achieved a partial response.⁵⁶

ANTI-INTERLEUKIN 6 THERAPY

IL-6 is a cytokine that is known to promote the growth and differentiation of B cells. A phase 1–2 study was reported by Haddad et al. in which 12 SOT recipients with PTLD refractory to reduction of immunosuppression were treated with anti-IL-6: 5 of 12 patients achieved CR and 3 patients achieved a PR.^{57,58}

ANTIVIRAL THERAPY

Many studies have incorporated antiviral nucleoside analog drugs such as acyclovir and ganciclovir. The nucleosides require conversion to the monophosphate form by the viral enzyme TK. Additional phosphorylations are then performed by cellular kinases. Acyclovir or ganciclovir triphosphates are then preferentially incorporated into DNA by viral DNA polymerase,

where they then act as obligate chain terminators. However, TK and viral DNA polymerase are enzymes that are only expressed during lytic infection, while EBV-PTLD is thought to result from latently infected proliferating B cells. Hence, no effect of these drugs would be expected with respect to the prevention or treatment of PTLD. Nevertheless, acyclovir is often instituted when EBV-PTLD is diagnosed, but there is scant information documenting the effectiveness of either acyclovir, ganciclovir, or newer antiviral agents such as cidofovir.¹¹ Despite a paucity of data supporting the merits of using antiviral therapy in this setting, the European Best Practice Expert Group on Renal Transplantation suggests that in the case of EBV-positive B-cell lymphomas, antiviral treatment with acyclovir, valacyclovir, or ganciclovir may be initiated for at least 1 month or according to the blood level of EBV replication when available.⁵⁹

INTERFERON ALPHA THERAPY

There are numerous case reports in the literature demonstrating the effectiveness of IFN- α in the management of EBV-PTLD after HSCT and SOT. Davis et al. reported the outcome of 14 patients with EBV-PTLD who were treated with IFN- α 3 million U/m² daily for at least 3 weeks and continued for 6–9 months in

responders: 8 of 14 patients achieved a CR.⁶⁰ Patients treated with IFN- α in various studies have received additional therapies, and this makes it unclear whether IFN- α is truly an effective therapy for PTLD.¹¹ The toxicity and lower response rates associated with IFN- α also makes it less appealing than more recent options such as rituximab.

SUMMARY

In conclusion, over the last decade our understanding of the pathophysiology of PTLD has enabled us to detect the disorder at a subclinical stage that permits the institution of therapies capable of improving outcome. Indeed, the high mortality reported in the 1980s and early 1990s appears to have been supplanted by much improved long-term survival rates. These improved outcomes have been based primarily on the use of antibodies such as the anti-CD20 agent rituximab for early-stage patients and combined with chemotherapy for patients with more advanced disease. Ongoing advances in our understanding of immunobiology and development of newer immunosuppressive agents may one day allow patients undergoing SOT or HSCT to avoid such a complication.

Chapter 63

TREATMENT APPROACH TO ADULT T-CELL LYMPHOMA/LEUKEMIA

Karen W.L. Yee and Francis J. Giles

INTRODUCTION

Human T-cell leukemia virus type 1 (HTLV-1), a double-stranded RNA retrovirus, has been demonstrated to be the causative agent in the development of adult T-cell leukemia/lymphoma (ATL/L). HTLV-1 infection is endemic in the southwestern part of Japan and the Caribbean basin, with geographic clusters reported in Africa, Central and South America, the Middle East, and the southeastern United States.¹

The majority of individuals infected with HTLV-1 are asymptomatic carriers; however, a proportion will develop either ATL/L or a chronic inflammatory syndrome [e.g., HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP), polymyositis, arthropathy, infective dermatitis, and uveitis].²⁻⁷ The lifetime risk of an HTLV-1 carrier developing either ATL or HAM/TSP is 1–5% and 1–2%, respectively.⁸⁻¹¹ ATL occurs only after a long latency period, ranging from 10 to 30 years, with the accumulation of additional oncogenic events.¹²⁻¹⁴

Four criteria need to be fulfilled in order to make the diagnosis of ATL: (1) histologically and/or cytologically proven T-cell lymphoid malignancies (i.e., usually expression of CD2, CD3, CD4, and CD5 with absent CD7 and CD8), (2) abnormal T lymphocytes consistently present in the peripheral blood, except in the lymphoma type (i.e., flower cells and/or small and mature T lymphocytes with incised or lobulated nucleus), (3) seropositivity for HTLV-1 (by indirect immunofluorescence, enzyme-linked immunosorbent assay, passive hemagglutination, or Western blot), and (4) clonal integration of proviral DNA into the cellular DNA of neoplastic T cells [by Southern blot analysis, polymerase chain reaction (PCR), or inverse PCR].¹⁵⁻¹⁹

ATL is classified into four clinical subtypes (i.e., acute, lymphoma, chronic, or smouldering) with different prognoses and outcomes (Table 63.1). Because of the heterogeneous outcomes, even within a subtype, it

may be prudent to stratify all patients into high- and low-risk groups at the time of diagnosis on the basis of the following poor prognostic features: hypercalcemia, elevated levels of serum lactate dehydrogenase, poor performance status, age over 40 years, and multiple sites of disease.¹⁶ Patients with low-, standard high-, and extremely high risk disease had median survival times of 37, 8, and 2.4 months, respectively.¹⁶ Other features that have been associated with a poor outcome and/or progression from smouldering or chronic ATL to acute ATL include poor performance status, increased serum creatinine, high white blood cell count, microsatellite instability, high expression of the proliferation marker Ki-67, unusual immunophenotype, integration of a defective HTLV-1 provirus, deletions of *p15* and/or *p16* genes, and high serum thymidine kinase, serum soluble interleukin 2 receptor (IL-2R), serum β_2 -microglobulin, or serum parathyroid hormone-related protein levels.^{16,20-30} However, none of these risk factors have been prospectively validated.

CONVENTIONAL TREATMENT MODALITIES

CHEMOTHERAPY

Chronic and smouldering ATL

Approximately 90 patients with chronic or smouldering ATL have been treated with chemotherapy.^{1,24,31-34} Overall survival (OS) does not appear to be significantly improved with chemotherapy compared to historical controls (10.9–16 months vs 24.3 months, respectively),^{1,32,33} with only one retrospective study showing a median survival of 37.9 months for 51 patients treated with a variety of chemotherapy regimens.²⁴

Acute and lymphomatous ATL

Patients with acute and lymphoma subtypes of ATL have been treated with a variety of chemotherapeutic regimens, initially those used for non-Hodgkin's lymphoma, with complete response (CR) rates of 19–36%

Table 63.1 Clinical subtypes of adult T-cell leukemia¹⁵

Features	Subtypes			
	Smouldering (n = 45)	Chronic (n = 152)	Lymphoma (n = 156)	Acute ^a (n = 465)

^b With T lymphocytes $>3.5 \times 10^9/L$ (including abnormal T lymphocytes).

^c If abnormal T lymphocytes in PB $<5\%$, patients should have biopsy-proven malignant lesion(s).

^d Biopsy-proven; +/- no specific qualification.

Modified from Shimoyama et al. 1991.

and median survivals of 4.7–10 months.^{16,35–37} Attempts to improve the response rates and OS led to the incorporation of multiple non-cross-resistant agents, extended duration of therapy, and incorporation of intrathecal chemotherapy (in an attempt to prevent meningeal recurrence), yielding CR rates of 17–44% (Table 63.2).^{1,24,31–33,38–44} Responses were not durable and significantly lower for patients with ATL compared with B-cell non-Hodgkin's lymphoma or peripheral T-cell lymphoma.^{38,39,42} Reported response durations were less than 8 months,^{32,44} and median OS was only 5.5–13 months.

These studies^{32,38,39,42,44} demonstrate the limitations of treating patients with ATL with conventional agents. The lack of good-quality responses (i.e., CRs) achieved with chemotherapy is a consequence of several factors: intrinsic resistance of ATL cells secondary to P-glycoprotein overexpression, mutations of the tumor suppressor gene *p53*, expression of the free-radical scavenger, ATL-derived factor, and abnormalities of topoisomerase II activities.^{45–50}

STEM CELL TRANSPLANTATION

Autologous stem cell transplantation

Acute and lymphomatous ATL

At least 13 patients with ATL (nine acute and four lymphoma) have received an autologous stem cell

transplantation (ASCT).^{51–59} Median age was 49 years (range 33–65 years); 61.5% of patients had refractory disease, partial responses (PRs), or were in early relapse at the time of transplant. All patients achieved or maintained either a CR (92.3%) or a PR (7.7%) post-ASCT. Although disappearance of the monoclonal band by Southern blot analysis and by inverse PCR after ASCT can be demonstrated in a few cases, the durability of remission is unclear.^{51,52} Clinical outcomes have been complicated by early recurrence and fatal infections, with OS of 0.47–12+ months and only 8% of patients surviving >12 months post-ASCT. CD34⁺ selection does not improve results; Southern blot analysis of the peripheral blood stem cells (PBSCs) revealed contamination with HTLV-1-infected cells⁵⁷ and have been documented relapses despite.^{52,53,57,59} ASCT does not have a role in the treatment of patients with ATL, outside of an investigational trial.

Allogeneic stem cell transplantation

Myeloablative stem cell transplantation

The disappearance of the proviral monoclonal band by Southern blot analysis and PCR after allogeneic stem cell transplant has been demonstrated; however, serial analysis was not performed to determine durability of remission.^{60–64} At this time, it is unclear

^a Median age not reported; ^b for ATL patients treated with both VEPA and VEPA-M; ^c etoposide, interferon alpha, interferon gamma, cyclophosphamide, vincristine, prednisolone, or other single agent; ^d for all 854 patients (including 137 untreated patients); ^e includes 51 chronic and 11 smouldering subtypes; ^f for acute vs lymphoma subtype; ^g except for one acute ATL patient who received single-agent cyclophosphamide, one lymphoma subtype supportive care only, and one chronic ATL topical therapy for skin disease (two patients also received PBSCT); ^h includes one chronic subtype; ⁱ includes patients with acute (*n* = 51), lymphoma (*n* = 22), and progressive chronic (*n* = 14) ATL; ^j mean; ^k includes 14 chronic subtypes; ^l includes 10 chronic subtypes.

whether undetectable minimal residual disease is associated with improved relapse-free survival and OS.

Chronic and smouldering ATL

The use of myeloablative matched-related donor (MRD) allogeneic stem cell transplantation has been

reported in only four patients with chronic ATL (Table 63.3).^{60,67,71} Median age was 40.5 years (range 33–55 years); three patients had a PR and one relapsed disease at the time of transplant. Seventy-five percent of donors were HTLV-1 seronegative. All patients achieved either a CR (75%) or a PR (25%) after transplantation.

^a After stem cell transplant.

Median OS was 16.5 months (range 7.7–32.7+ months) with 50% of patients dying from graft-versus-host disease (GvHD). At the current time, the role of allogeneic transplantation in this setting remains to be defined.

Acute and lymphomatous ATL

Results of myeloablative allogeneic transplantation have been described in 28 patients with acute ($n = 23$) and lymphomatous ($n = 5$) ATL (Table 63.3).^{61–71} Median age was 44.5 years (range 15–51 years); 28.6% of patients had relapsed, refractory, or progressive disease at the time of transplant, and 21.4% had a PR. Sixty-four percent of donors were HTLV-1 seronegative. Only three patients received a matched unrelated donor (MUD) transplant, two a T-cell-depleted transplant, and one a two-antigen mismatch related transplant. All patients achieved a CR after transplantation. Median OS was 14 months (range 1.6–80+ months). Survival data, based on (i) donor HTLV-1 status, (ii) ATL subtype, and (iii) recipient status at the time of transplant, have been evaluated in patients who received an MRD, unmanipulated, allotransplant. Median OS for recipients of donor HTLV-1-seropositive stem cells was 9.7 months (range 4.5–80+ months) compared to 8.6 months (range 4.1–34.4+ months) for donor HTLV-1-seronegative stem cells; for acute subtypes, 8.4 months (range 4.1–80+ months) compared to 9.3 months (range 9.3–23.3+ months) for lymphomatous subtypes; and for patients transplanted in CR, 13 months (range 10.1–34.4+ months) compared to 9.3 months (range 9.3–80+ months) and 4.5 months (range 4.1–24+ months) for patients

transplanted in PR and with progressive, relapsed, or refractory disease, respectively

Nonmyeloablative stem cell transplantation

The importance of the host immune responses in eradicating ATL cells and controlling disease onset or recurrence is underscored by a graft-versus-leukemia effect postallogeneic transplantation,^{60,61} recurrence of disease after T-cell-depleted allogeneic stem cell transplants,^{64,66} and reports of ATL occurring postsolid organ transplantation.⁷² Reconstituted cellular immunity, as manifested by induction of cytotoxic T lymphocytes against HTLV-1-infected cells, in ATL patients after nonmyeloablative allogeneic stem cell transplantation from HTLV-1-negative HLA-identical siblings may contribute to graft-versus-leukemia effects.⁷³ These data, together with the high treatment-related mortality associated with standard allogeneic transplantation, have provided the impetus for studies, using low-intensity conditioning regimens.

Acute and lymphomatous ATL

Results of nonmyeloablative stem cell transplantation have been reported for eight patients with ATL (five acute and three lymphoma) (Table 63.4).^{70,71,74,75} Median age was 55 years (range 52–59 years); 50% of patients had either refractory or progressive disease at the time of transplantation, and 25% had a PR. A fludarabine-based regimen was used in all but two cases.^{70,74} Five out of six patients achieved a CR after transplant; however, median survival was only 2.3 months (range 0.8–9+ months). The two patients who had achieved a CR at the time of transplant were still alive at 8+ and 9+

Table 63.4 Nonmyeloablative allogeneic stem cell transplant for treatment of ATL

^a After stem cell transplant.

months^{70,74}; one of whom demonstrated undetectable proviral load in the peripheral blood mononuclear cells by PCR analysis.⁷⁴

Evaluation of transplantation data is complicated by heterogeneity in patient selection, choice of conditioning regimen, source of stem cells, degree of antigen mismatch, and HTLV-1 status of donors. For both myeloablative and nonmyeloablative allogeneic stem cell transplantations, the optimal conditioning regimen, source of stem cells (bone marrow vs peripheral blood), and type of GvHD prophylaxis are unclear. The use of HTLV-1-seropositive, but disease-free, donors is also uncertain. HTLV-1-seropositive donors may improve transplantation results by providing viral-specific immunocompetent cells and preventing clonal expression of infected lymphocytes posttransplantation. However, there is a theoretical concern that recipients of stem cells from HTLV-1-seropositive donors, with oligoclonal integration in donor germline by Southern analysis,⁶² will be at risk of developing or relapsing with ATL after allogeneic stem cell transplantation.

OTHER TREATMENT MODALITIES

RETROVIRAL AND IMMUNOMODULATORY AGENTS

Retroviral monotherapy

Maintenance of viral DNA load can occur through either host genome replication or viral replication through the HTLV-1 reverse transcriptase.¹⁹ HTLV-1 replication can be inhibited by a variety of nucleoside reverse transcriptase inhibitors, including zidovudine, zalcitabine, tenofovir, and possibly, lamivudine.^{76,77} Zidovudine (AZT) is a thymidine analog, which after phosphorylation is incorporated into proviral DNA causing chain termination. It is unclear whether zidovudine monotherapy has significant activity.⁷⁸

Interferons

Single-agent interferon alpha has been evaluated in a small series of patients with acute, lymphomatous, and chronic ATL, with OR rates of 25–33% and CR rates of 0–25%.^{79,80} There have been anecdotal reports using interferon beta and gamma to treat patients with ATL with modest activity.⁸¹ Twelve patients have been treated with interferon alpha in combination with bestrabucil, a conjugate of chlorambucil and β -estradiol, and prednisolone.⁸² Nine of the patients (75%) obtained a PR with a median response duration of 9 weeks.

Retrovirals and interferon

The mechanism of action of combination zidovudine and interferon alpha remains unclear. The therapeutic effects may be mediated by inhibition of HTLV-1 replication rather than a direct cytotoxic effect on leukemic cells.⁸³

Chronic or smouldering ATL

Only three patients with smouldering ($n = 1$) or chronic ($n = 2$) ATL have been treated with combination zidovudine and interferon alpha, with none achieving a CR.^{84–86}

Acute and lymphomatous ATL

AZT and interferon alpha have been used to treat over 80 patients with acute or lymphomatous ATL (Table 63.5).^{84–91} The majority of patients had acute ATL and had received prior therapy. Overall response rates ranged from 14 to 89% with CR rates of 0–53%. Higher responses may be achieved in previously untreated patients.⁹¹ Median OS remained dismal and was usually <12 months. However, it appears to be significantly increased in responders.^{87,90,91}

These therapeutic outcomes have not exceeded those with recent chemotherapeutic regimens, but can be administered to patients with poor performance status⁸⁷ and may be associated with less toxicity, the major toxicities being hematologic.

NUCLEOSIDE ANALOGS

There are currently three analogs of deoxyadenosine, i.e., fludarabine, cladribine, and pentostatin, in clinical use for the treatment of lymphoproliferative disorders. In patients with ATL, most experience has been obtained with pentostatin and the least with fludarabine.⁹³

Single-agent cladribine (2-chlorodeoxyadenosine) has limited activity in patients with relapsed or refractory acute or lymphomatous ATL (OR 7%; CR 0%).^{94,95} At least four studies have assessed the effectiveness of pentostatin (deoxycoformycin) monotherapy in patients with ATL.^{96–99} The majority of patients had either acute or lymphomatous subtypes, and had received prior therapy. Overall response rates were 15–20% with CR rates \leq 10%. The majority of studies did not report OS.^{96,97,99}

Given these encouraging results, a multicenter phase II trial evaluated the efficacy of pentostatin in combination with doxorubicin, vincristine, etoposide, and prednisolone in 60 patients with previously untreated ATL (34 acute, 21 lymphoma, and 5 chronic).¹⁰⁰ Median age was 56 years (range 31–69 years). Fifty-nine patients were evaluable for response. Overall response was 52.5% (CR 28.8%; PR 23.7%). However, therapy was discontinued in 62.7% of patients—52.5% during induction therapy because of progressive disease and 10.2% because of toxicity. Only 17% completed the entire 10 cycles of therapy. Both median follow-up and median OS were 7.4 months. Therefore, pentostatin-containing regimens have limited activity in patients with ATL.

ARSENIC TRIOXIDE

Treatment of HTLV-1-transformed cells and primary ATL samples with arsenic trioxide can inhibit cell

Table 63.5 Retroviral and/or immunomodulatory agents for treatment of acute and lymphoma ATL

Patient characteristics				Response				Reference
N (evaluable)	Median age (range, years)	Acute subtype (%)	Prior therapy (%)	Median F/U (months)	Response rate (%)	Median disease control (months)	Median OS (months)	
<i>Interferon alpha and zidovudine</i>

18 (12)	47.5 (22–68)	61	83.3	NR	OR 25 CR 8; PR 17	Response duration 2.4	6	86
19 (17) ^e	45 (27–75)	79	31.6	36+	OR 76 CR 53; PR 23	EFS 7	11	91
<i>Interferon alpha and arsenic trioxide</i>								
7	46 (28–56)	57	86	1.5	OR 57 CR 14; PR 43	PFS 1.5	1.5	92

EFS, event-free survival; F/U, follow-up; PFS, progression-free survival; IFN, interferon; AZT, zidovudine.

^aIncludes one smouldering subtype; ^bincludes two chronic subtypes; ^call six nonresponders did not survive for >1 month; ^dat the time of study, 8 of 15 patients were in CR or PR; therefore, 10 of 15 patients achieved or maintained a response on AZT and IFN (but no further details provided); ^e3 of these patients had been previously reported (Refs. 84 and 85).

proliferation and induce apoptosis.^{101–103} A synergistic effect is achieved when arsenic is combined with interferon alpha, leading to G₁ cell cycle arrest, inhibition of cell proliferation, and induction of apoptosis.¹⁰¹

A phase II study assessed the efficacy of combination therapy with arsenic trioxide and interferon alpha in seven patients with relapsed or refractory ATL (four acute and three lymphoma).⁹² Median age was 46 years (range 28–56 years). None of the patients completed the planned treatment because of toxicity ($n = 3$) or disease progression ($n = 4$). Median treatment duration of arsenic trioxide was 22 days (range 17–28 days) and 21 days (range 4–28 days) for interferon alpha. Overall response was 57% (CR 14%; PR 43%). Progression-free survival was 1.5 months (range <1–32+ months) with a median OS of 1.5 months (range 1–32+ months).

Experience with retinoids as a single agent or in combination with interferon alpha and zidovudine in patients with ATL has been limited. Less than 15 ATL patients have been treated,^{104–109} with only 1 patient with concomitant acute promyelocytic leukemia and smoldering ATL achieving a CR.¹⁰⁴ It is unclear whether improved efficacy may be obtained on combining retinoids with chemotherapy or novel targeted therapies.

TOPOISOMERASE INHIBITORS

Conventional topoisomerase II inhibitors, such as the epipodophyllotoxins (e.g., etoposide) and the anthracyclines (e.g., doxorubicin), have been administered to patients with ATL, usually as part of a multiagent chemotherapy regimen (see above) (Table 63.2).¹¹⁰

Irinotecan hydrochloride

Irinotecan hydrochloride (CPT-11), a camptothecin derivative, is a prodrug that is converted to the active compound SN-38, which in turn inhibits topoisomerase I. CPT-11 was evaluated in a phase II study involving 13 patients (3 acute and 10 lymphoma) with relapsed or refractory ATL.¹¹¹ Median age was 63 years (range 44–78 years). The OR rate was 38.5% (CR 7.7%; PR 30.8%) with a median response duration of 31 days. All responders had lymphoma subtype. Grade 3 or 4 toxicities included leukopenia (66.7%), thrombocytopenia (41.7%), anemia (33.3%), and diarrhea (46.2%). One treatment-related death occurred.

Sobuzoxane

Sobuzoxane (MST-16), a topoisomerase II inhibitor, is an orally administered bis(2,6-dioxopiperazine) analog prodrug that is converted to the active metabolite ICRF-154.¹¹² MST-16 has been administered to 24 patients with ATL (13 acute, 8 lymphoma, and 2 chronic) in a dose-escalating phase I/II study.¹¹³ Median age was 55 years (range 41–76 years). Twenty-five percent of patients had been previously treated. Of the 23 evaluable patients, OR rate was 43.5% (CR

8.7%; PR 34.8%); all responses occurred in previously untreated patients. Responses were observed mostly in patients who received MST-16 at doses of 1200–1600 mg/day. Median duration of responses was 282 days and 41 days for patients who achieved a CR and PR, respectively. Common grade 3 or 4 toxicities included reversible leukopenia (80%) and anemia (26.1%).

Based on the findings of the phase I/II study, MST-16 has been evaluated at a dose of 1600 mg/day.¹¹⁴ Preliminary results in six patients with ATL (subtype not specified) have been presented.¹¹⁴ Median age was 47 years (range 41–76 years). Only one patient had received prior therapy. Overall response rate was 66.7% (CR 33.3%; PR 33.3%) with a median response duration of 5 months. The major toxicity was myelosuppression.

MONOCLONAL ANTIBODIES

Anti-Tac antibodies

Unmodified anti-Tac monoclonal antibodies

Nineteen patients with ATL (11 acute, 4 lymphoma, and 4 chronic) were treated with an unmodified murine anti-Tac monoclonal antibody.¹¹⁵ Nine patients were previously untreated. Therapy was relatively well tolerated. Three of six responding patients developed human antimurine antibodies (HAMA) against the anti-Tac antibody. An OR rate of 32% (CR 11%; PR 21%) was achieved with response durations of 9 weeks to over 3 years. Responses were seen in patients with lymphoma ($n = 2$), chronic ($n = 3$), and acute ($n = 1$) subtypes; only two were previously treated and four had soluble IL-2R levels of less than 10,000 U/mL. To overcome limitations with murine antibodies, including a short circulating half-life in humans, increased immunogenicity with repeated dosing, and relatively ineffective recruitment of host antibody-dependent cellular cytotoxicity, a humanized anti-Tac antibody (daclizumab) was developed.^{116,117} Anecdotal reports of remissions in patients with chronic and smoldering forms of ATL treated with daclizumab have been observed.¹¹⁸ Therefore, single-agent daclizumab is currently being evaluated in patients with ATL in a phase I/II study.

Radiolabeled anti-Tac monoclonal antibodies

Yttrium-90 radiolabeled murine anti-Tac antibody has been administered to 18 patients with ATL (11 acute, 2 lymphoma, and 5 chronic) in a phase I/II study.¹¹⁹ Eight patients were previously untreated. Five of nine responding patients developed HAMA against the anti-Tac antibody. Grade 3 or 4 toxicities consisted of myelosuppression (67%), transient hepatotoxicity (17%), and renal toxicity (6%). An OR rate of 56% (CR 12%; PR 44%) was achieved with response durations of 1 month to over 33 months. Responses were seen in patients with chronic ($n = 3$) and acute ($n = 6$) subtypes; only three were previously treated and five had soluble IL-2R levels of less than 10,000 U/ml.

SUPPORTIVE CARE

Patients with ATL often present with infectious complications (i.e., bacterial, fungal, protozoal, and/or viral) at diagnosis (Table 63.1).¹⁵ Infectious complications at diagnosis were observed less frequently in the lymphoma subtype than all other subtypes ($P < 0.01$), suggesting that this subset of patients may be less immunosuppressed.¹⁵ Several mechanisms have been reported to account for this immunodeficient state, including impaired cytotoxic function of HTLV-1-infected CD8⁺ lymphocytes, modulation of helper T-lymphocyte responses with predominantly a T_H1 cytokine response, and suppressed production of T lymphocytes in the thymus in HTLV-1-infected individuals.^{120–122}

Prevention of opportunistic infections is, therefore, crucial to improving survival in ATL. Prophylactic cotrimoxazole is effective in reducing the incidence of *Pneumocystis carinii* pneumonia in patients with ATL. Stool should be screened for *Strongyloides* at diagnosis, and patients with positive cultures treated. These patients may require prolonged prophylaxis against *Strongyloides*. Similarly, prophylaxis against fungal and viral infections should be considered.

SUMMARY

There is currently no curative or proven effective therapy for ATL. Given the poor results with conventional

therapies, every possible attempt should be made to enroll patients with chronic, acute, and lymphomatous ATL onto investigational clinical trials.

For patients who are not candidates or cannot be enrolled onto a clinical trial, the following approach may be considered. Because of the lack of proven effective therapy and relatively long survival, patients with smouldering ATL should be observed until signs of disease progression. In order to minimize treatment-related toxicities and mortality, patients with low-risk chronic ATL should not receive chemotherapy, but may benefit from therapy with AZT and interferon alpha or monoclonal IL-2R antibodies. For patients with high-risk chronic, acute, or lymphomatous ATL, chemotherapy with anthracycline-based regimen or combination of AZT and interferon alpha should be instituted in an attempt to achieve a CR or PR. Patients with chemosensitive disease and a suitable donor should proceed with an allogeneic transplant. For patients with no response, progressive disease, or relapsed disease, investigational agents against novel targets (previously described) should be considered. Since most patients relapse after chemotherapy or AZT and interferon alpha therapy, patients who achieve a CR and are not candidates for or do not wish to receive an allogeneic stem cell transplant, some form of maintenance therapy should be considered, such as AZT and interferon alpha (after chemotherapy), or monoclonal IL-2R antibodies. All patients should receive prophylaxis against *Pneumocystis carinii* pneumonia, and should be evaluated for prophylaxis against fungal, viral, and *Strongyloides* infections.

Chapter 64

AUTOLOGOUS HEMATOPOIETIC CELL TRANSPLANTATION FOR NON-HODGKIN'S LYMPHOMA

GINNA G. LAPORT AND ROBERT S. NEGRIN

Non-Hodgkin's lymphoma (NHL) is the fifth most common cancer among men and women with a projected incidence of over 54,000 new cases in the United States in 2004.¹ Many patients with NHL can be cured today with frontline combination chemotherapy and/or radiotherapy. However, for patients with suboptimal responses to initial therapy or for patients with relapsed or refractory disease, salvage therapy alone is typically inadequate to achieve long-term survival.^{2,3} Fortunately, high-dose chemotherapy (HDC) with autologous hematopoietic cell transplantation (AHCT) offers curative potential. Dose-intensive treatment has unequivocally been shown to be the treatment of choice for patients with relapsed, chemosensitive, intermediate-grade lymphomas, and recent data have shown that a certain subset of these patients benefit from AHCT while in first remission. Until recently, HDC had not consistently yielded durable responses for patients with relapsed indolent lymphoma but new data showing a survival advantage was recently reported.⁴ However, the role of AHCT and the appropriate timing in such entities as mantle cell lymphoma (MCL), the T-cell lymphomas, and high-grade lymphomas remains controversial. This chapter will discuss the application of HDC with AHCT in NHL and review emerging advances such as the role of rituximab (RTX) for in vivo purging and posttransplant maintenance therapy and the use of radioimmunotherapy (RIT) in the preparative regimen.

RATIONALE FOR HIGH-DOSE CHEMOTHERAPY

The rationale for high-dose cytotoxic chemotherapy stems from the steep dose-response curve of alkylating agents and radiotherapy (RT) and tumor cell response in human tumors.^{5,6} Doubling the dose of alkylating agents increases tumor cell kill by a log or more and

utilizing a 5- to 10-fold increase in the dose of alkylating agents overcomes the resistance of tumor cells against lower doses.⁷ HDC also aims to destroy the tumor cells in an expediently timely manner to prevent the emergence of resistant clones. The observation that increasing doses of alkylating agents conferred a decreased survival of murine lymphoma cells in vivo provided initial evidence of a dose-response curve specifically in tumor cells of lymphoid origin.⁸ In 1978, investigators from the National Cancer Institute were the first to report the use of HDC followed by autologous hematopoietic cell transplantation (AHCT) for patients with relapsed lymphoma.⁹ These encouraging results were the initial clinical evidence that has led to the widespread application of this aggressive treatment modality.

INTERMEDIATE/AGGRESSIVE LYMPHOMA

AHCT is curative in a subset of patients with relapsed intermediate-grade lymphoma and is considered a standard therapy for patients with chemosensitive disease at first relapse. In 1987, Philip et al. reported the prognostic significance of chemosensitivity to salvage therapy prior to autologous stem cell transplantation in patients with recurrent or refractory NHL.¹⁰ This multi-institutional study accrued 100 patients with either primary refractory, sensitive relapse or resistant relapse. The actuarial 3-year disease-free survival (DFS) was 0% in the primary refractory group, 14% in the resistant relapse group, and 36% in the sensitive relapse group. Subsequently, the PARMA study in 1995 was the pivotal randomized phase III trial that unequivocally demonstrated the benefit of dose-intensive chemotherapy over conventional salvage treatment.¹¹ A total of 215 patients with intermediate-grade ($n = 163$) and high-grade ($n = 52$) NHL in first or second relapse initially received DHAP (dexamethasone, cytarabine, cisplatin) as salvage therapy.

The 109 patients who responded were randomized to autologous stem cell transplantation versus additional courses of DHAP. After 5 years of follow-up, the final analysis clearly favored the autologous stem cell transplantation arm in terms of event-free survival (46% vs 12%, $p = 0.0001$) and overall survival (53% vs 32%, $p = 0.038$). The 90 patients who did not respond to salvage therapy and who were not randomized experienced a dismal 5-year overall survival (OS) of only 11%.

Subsequent updates from the PARMA trial have retrospectively examined certain patient characteristics to identify factors of predictive value. Time to relapse (relapse within 12 months vs later than 12 months) and elevated lactate dehydrogenase (LDH) levels at relapse were features with negative prognostic value, whereas time to relapse was also a powerful prognostic factor for both OS and progression-free survival (PFS).¹² Interestingly, T-cell immunophenotype and large tumor size, frequently considered adverse prognostic factors, were not found to negatively influence outcome. The International Prognostic Index (IPI) was also used retrospectively as a prognostic model at the time of relapse and was highly predictive of both response and OS in the PARMA trial.¹³ Blay et al. reported that the IPI at relapse highly correlated with OS for patients in the DHAP arm but not for patients in the transplant arm. For the DHAP-treated patients, the 5-year OS was 48% for patients with an IPI of 0 compared to 0% for patients with an IPI of 3. For patients who underwent BMT, the 5-year OS showed little variance ranging from 47 to 51% among all IPI risk groups. However, for patients with an IPI > 0 , a survival advantage was seen in favor of the BMT arm when compared to the DHAP arm. Thus, patients in the low-risk group fared well regardless of the therapy administered with a median survival of 56 months after relapse in both arms.

The group from Memorial Sloan Kettering Cancer Center also evaluated the prognostic significance of the secondary age adjusted IPI in 150 patients with relapsed or primary refractory diffuse large cell lymphoma (DLCL) who received ICE (ifosfamide, carboplatin, etoposide) as second-line chemotherapy.¹⁴ The PFS and OS were 70 and 74% for low-risk patients (0 factors) compared to 16 and 18%, $p < 0.001$, respectively, for high-risk patients at the time of relapse. Specifically, for patients with ICE-chemosensitive disease, the OS rates were 83 and 26% for the low-risk and high-risk groups, respectively ($p < 0.001$), demonstrating that high-risk patients fare poorly regardless of chemosensitivity. Thus, the secondary age-adjusted IPI appeared to hold more prognostic value compared to chemosensitivity as this clinical index may actually be more reflective of disease biology.

Gugliemi et al. examined risk factors retrospectively in 474 patients with DLCL at relapse who received various salvage regimens including chemotherapy,

surgery, and/or RT with only 20% of patients proceeding to AHCT.¹⁵ Relapse within 12 months from diagnosis, elevated serum LDH, advanced stage, and poor performance status represented independent prognostic factors for PFS and OS for patients with chemosensitive disease and for those who proceeded to AHCT. Similar to the PARMA findings, this analysis also demonstrated that the T-cell phenotype was not a negative prognostic factor. Caballero et al. reported the results of 452 patients, who received HDC, from the GEL-TAMO Cooperative Group.¹⁶ Approximately half of the patients had active disease with 32% being in first complete remission (CR) and 19% in second CR. The three variables that significantly influenced DFS and OS were number of prior regimens to reach first CR, disease status at transplant (first CR vs \geq second CR), and total body irradiation (TBI) in the conditioning regimen. Patients who received chemotherapy only experienced significantly longer PFS and OS although a higher percentage of patients in the TBI group had progressive disease prior to AHCT. As seen in the Memorial Sloan Kettering analysis, the age-adjusted IPI at transplantation was also predictive of OS. Not surprisingly, response to transplant predicted OS with patients who achieved a CR posttransplant experiencing a 64% OS compared to 17% and 4% for partial remission (PR) and nonresponding patients, respectively.

HIGH-DOSE CHEMOTHERAPY IN FIRST OR PARTIAL REMISSION

The application of AHCT to patients with NHL as frontline therapy has been explored by several investigators based primarily on the success of this treatment modality in the chemosensitive relapse setting (see Table 64.1). Encouraging results have been reported in some but not all studies most likely due to the fact that the published trials are heterogeneous with respect to patient selection, timing of transplantation, choice of induction and conditioning regimens, length of induction phase, remission status requirements, and nonuniform histologic subtypes.

The LNH87-2 trial by the GELA (Groupe d'Etude des Lymphomes de Adulte) group was a phase III trial that enrolled 916 patients with intermediate- and high-grade lymphoma in first CR with one or more unfavorable prognostic factors who received induction treatment using the LHN84 protocol.²⁴ Only those patients who achieved a CR (61%, $n = 541$) were randomized to receive sequential chemotherapy or proceed to autologous stem cell transplantation. Initial analysis revealed no difference in DFS and OS between the two consolidative treatment arms. However, a subset analysis of the higher risk population who had two or three risk factors favored the autologous stem cell

Table 64.1 Randomized trials of autologous hematopoietic cell transplantation for newly diagnosed aggressive NHL

transplantation arm for both DFS and OS at 8 years (55% vs 39%, $p = 0.02$ and 64% vs 49%, $p = 0.04$, respectively).²² The LNH93-3 study, which accrued between 1993 and 1995, was a follow-up randomized trial that was eligible only to patients in the high-intermediate- or high-risk age-adjusted IPI prognostic categories.²⁵ With the intention of improving upon the 61% CR rate seen in the earlier trial, a novel abbreviated, intense firstline regimen that incorporated HDC at day + 60 was administered. A total of 370 patients were randomized either to receive full standard induction course or a short induction phase with a debulking course followed by two cycles of standard therapy before receiving AHCT. Patients in the transplant arm experienced both inferior OS and EFS with the early closing to accrual in 1996 due to the poor results. A final update published in 2002 reported the continued inferiority in terms of EFS and OS in the transplant arm with a 5-year median follow-up.¹⁹ The shortened induction phase in the HDC arm was thought to contribute to the negative outcome. A recent retrospective analysis from the GELA group pooled the data of 330 patients from the LNH-87 and LNH-93 trials to estimate the prognostic effect of clinical and biologic variables. Only the patients who obtained a CR prior to transplantation were included. T-cell phenotype, more than one extranodal site, or bone marrow (BM) involvement were adverse prognostic factors for both DFS and OS. The age-adjusted IPI was of no prognostic value.²⁶

Other studies utilizing abbreviated standard induction therapy also showed no benefit of HDC over standard therapy. The German High Grade Non-Hodgkin's Lymphoma Study Group randomized 312 patients all younger than 60 years and with elevated serum LDH levels who obtained at least a PR to standard therapy.²⁰ Both arms received consolidative involved field radiation therapy (IFRT). With a median follow-up of 46 months, there was no difference in EFS or OS between the conventional and transplant groups (EFS: 49% vs 59%, $p = 0.22$; OS: 63% vs 62%, $p = 0.68$) even among the high-intermediate- and high-risk subgroups. A phase III European Organization for Research and Treatment of Cancer trial of 194 patients with responsive disease yielded similar results.²¹ With a median follow-up of 53 months, an intent to treat analysis also showed no benefit in terms of disease progression between the two treatment arms, and a subset analysis of the IPI risk groups also failed to yield an advantage for the experimental group.

As with the LNH93-3 trial, Martelli et al. also sought to assess the role of early intensification with HDC and AHCT as frontline therapy but restricted accrual to patients with intermediate-high- or high-risk patients according to the age adjusted IPI.¹⁸ Seventy-five patients received the standard MACOP-B (methotrexate, doxorubicin, cyclophosphamide, vincristine, prednisone, bleomycin) regimen for 12

weeks or MACOP-B for 8 weeks prior to autologous HCT. An intent to treat analysis demonstrated no difference in 5-year PFS and OS. These results may be somewhat confounded by the fact that 44% of the patients in the conventional chemotherapy arm received AHCT postrelapse and 40% of the patients in the transplant arm actually did not receive a transplant for reasons including progression and patient refusal.

The recently published French GOELAMS (Groupe Ouest-Est des Leucemies et des Autres Maladies du Sang) study is the first large randomized trial that included all age-adjusted IPI risk groups except the high-risk group since it was known that the use of standard CHOP (cyclophosphamide, doxorubicin, vincristine, prednisone) in this group tended to yield poor outcomes.¹⁷ A total of 197 patients were randomized to full course CHOP or CEEP (cyclophosphamide, epirubicin, vindesine, prednisone) for two cycles followed by an intensification regimen with high-dose methotrexate and cytarabine before proceeding to transplant. With a median follow-up of 4 years, the estimated 5-year EFS clearly favored the transplant arm over the chemotherapy arm (55% vs 37%, $p = 0.037$) but did not translate into an OS advantage except among the patients in the high-intermediate group. The patients in this particular subgroup experienced both an improved EFS (56% vs 28%, $p = 0.003$) and OS (74% vs 44%, $p = 0.001$) favoring the transplant arm (see Figures 64.1 and 64.2).

Before the IPI was widely utilized, two Italian groups conducted randomized trials enrolling patients with high risk-features such as bulky or advanced-stage disease.^{23,27} There were favorable trends with regards to freedom from progression or DFS but no advantages were seen in OS. For patients who are considered slow responders to up-front chemotherapy, AHCT does not appear to benefit this group. Two randomized trials from the Netherlands and Italy failed to show a survival advantage with early AHCT.^{28,29}

Based on the array of published evidence regarding AHCT for first-line therapy in aggressive NHL, it appears that patients in the high-intermediate- or high-risk age-adjusted IPI categories experience better outcomes with AHCT upfront but only when this strategy is applied after a full course of induction therapy for maximal cytoreduction. RTX was not available at the commencement of these trials so the impact of the combination of RTX with CHOP on transplant outcome has not been assessed. Thus, the potential impact of incorporating RTX in both the control and transplant arms is an area of ongoing investigation. Many of the above studies were also plagued by high dropout rates in the transplant arms and the use of transplant for salvage in the control arm, which also confounded outcome data.

Figure 64.1 Event-free survival among patients with a high-intermediate risk according to the age-adjusted International Prognostic Index. (CHOP denotes cyclophosphamide, doxorubicin, vincristine, prednisone.) (Copyright 2004, Massachusetts Medical Society, from Milpied et al.²⁵ All rights reserved)

MANTLE CELL LYMPHOMA

MCL represents 5–10% of all lymphoma cases and is characterized by the t(11;14) translocation resulting in rearrangement of the *bcl-1* locus and cyclin D1 protein overexpression.^{30–32} Patients with MCL typically present with advanced-stage disease and carry a median overall survival of only 3 years despite high initial response rates.³¹ Thus, the absence of curative therapy has led to the increased application of HDC with AHCT as part of frontline therapy and as early salvage treatment for relapsed disease (see Table 64.2). Although numerous published studies have demonstrated high initial rates of CR, plateaus in the survival curves are yet to be convincingly demonstrated, especially for patients transplanted beyond first CR. The MD Anderson Cancer Center Group administered intensive induction therapy with the hyperCVAD (cyclophosphamide, doxorubicin, vincristine, prednisone, cytarabine, methotrexate) regimen followed by AHCT to 25 patients as frontline therapy and to 20

previously treated patients.⁴⁰ The 3-year EFS and OS rates were 72% and 92%, respectively, for the newly diagnosed patients compared to only 17 and 25% for the previously treated patients. A historical control group that received a CHOP-like regimen without AHCT had a median 3-year EFS of only 28%. The prognostic significance of remission status was also confirmed in a large retrospective analysis of 195 patients from the European Bone Marrow Transplant Group (EBMT) and Autologous Bone Marrow Transplant Registry (ABMTR).³⁴ The 5-year PFS and OS rates for all patients were 33 and 50%, respectively. Patients who were transplanted beyond first CR were nearly 3 times more likely to succumb to relapse than patients transplanted in first remission. The combined Stanford/City of Hope experience also demonstrated better outcomes for first CR patients as the median time to relapse was 32 months compared to 11 months for patients transplanted beyond first CR.³⁷ However, late relapses were seen in both groups of patients. This trial also found that the number of prior chemotherapy regimens and

PFS/EFS: progression-free survival/event-free survival; OS: overall survival; CHOP: cyclophosphamide, doxorubicin, vincristine, prednisone; CBV: cyclophosphamide, carmustine, etoposide; EBMT: European Bone Marrow Transplant Group; CR1: first complete remission; BEAM: carmustine, etoposide, cytarabine, melphalan; BEAC: carmustine, etoposide, cytarabine, cyclophosphamide; TBI: total body irradiation, VP: etoposide; CY: cyclophosphamide; ara-C: cytarabine; Mel: melphalan; CRC: cancer research center.

the use of TBI in the preparative regimen did not improve survival which was in contrast to a French study that reported significantly improved DFS for patients who received TBI-based conditioning regimens.⁴¹ Investigators from the University of Nebraska reported a 2-year EFS of 35% and OS of 65% in 40 MCL patients who were transplanted in either first CR, sensitive relapse or were induction failures.⁴² In a multivariate analysis, patients who received three or more prior regimens had a dismal 2-year EFS of 0% compared with 45% for patients who received less than three prior therapies which was in contrast to the Stanford/City of Hope findings regarding impact of prior therapies.

The Nordic Lymphoma Group also tested an augmented CHOP induction regimen followed by AHCT as primary therapy.³⁶ Only patients who responded after three cycles of CHOP proceeded to transplantation. In an intent to treat analysis, the 4-year failure-free survival (FFS) and OS rates were 15% and 51%, respectively. Chemosensitivity was a favorable prognostic factor as patients transplanted in CR experienced a statistically significant improved FFS and OS compared to PR patients. Interestingly, tumor cell contamination was measured in the autografts and no correlation was seen between the number of tumor cells reinfused and outcome.

In a similar fashion, a French group also incorporated AHCT after CHOP chemotherapy but only for slow responders.³⁸ Patients who achieved less than a CR received DHAP for intensification before proceeding to AHCT. The 3-year EFS and OS rates were 83% and 90%, respectively, with a median follow-up of 4 years. The EFS incidence was particularly notable since

patients with mantle zone histology, a known favorable prognostic factor, were excluded and a majority of patients had an increased *beta-2* microglobulin level, a reported poor prognostic factor.⁴³

Because of the continuous patterns of relapse seen in all of the above mentioned studies, alternative strategies have been explored including the use of RTX during mobilization for the purposes of in vivo purging due to the concern that autologous grafts contaminated by tumor cells can potentially contribute to relapse. The role of RTX as maintenance therapy after AHCT to eradicate minimal residual disease (MRD) is also the subject of active investigation. Magni et al. treated seven patients with four doses of RTX in combination with high-dose sequential chemotherapy with autologous stem cell support and successfully obtained polymerase chain reaction (PCR)-negative leukapheresis products.⁴⁴ The Milan Group recently published some of the most encouraging results to date in 28 previously untreated patients who received standard dose debulking chemotherapy followed by four cycles of sequential chemotherapy in which autologous stem cell support was provided after the last three cycles.³⁵ RTX was included in three of four cycles including the mobilization cycle. The OS and EFS rates at 54 months were 89% and 79%, respectively, with 24 of 27 evaluable patients remaining in continuous CR. These results compared much more favorably to a historical control group that had an OS of 42% and EFS of 18% and to previously published trials. This technique of combining RTX with high-dose sequential chemotherapy proved to be an effective method of in vivo purging as leukapheresis products from 20 informative patients were PCR negative.

A multicenter trial from Canada also produced similar results when RTX was incorporated during mobilization and as posttransplant maintenance therapy.³³ With an impressive 80 months of follow-up, the PFS and OS rates were 89% and 88%, respectively. The feasibility of combining radiolabeled antibody therapy with AHCT was explored by the Seattle Group.³⁹ Tositumomab (¹³¹I-labeled CD20-specific monoclonal antibody) was added to high-dose cyclophosphamide and etoposide in 16 heavily pretreated MCL patients. The CR and overall response rates were 91% and 100%, respectively, with a 3-year PFS and OS of 61% and 93%, respectively. These were unexpectedly favorable outcomes since most patients had received greater than three prior regimens or were chemorefractory at the time of transplant.

FOLLICULAR NHL

For patients with follicular NHL, several studies have shown improved DFS but one recently published study has also shown an advantage for OS (see Table 64.3). EBMT conducted a randomized trial known as the CUP Trial in which 140 patients with relapsed follicular NHL were randomized to either chemotherapy alone, AHCT with a purged autograft using monoclonal antibodies, or AHCT with an unpurged autograft.⁴ With a

median follow-up of 69 months, the patients who received AHCT, purged or unpurged, showed a significantly higher 2-year PFS and OS compared to the chemotherapy patients. There was no difference between the two AHCT arms in these endpoints. OS rates at 4 years for the chemotherapy arm, unpurged AHCT arm, and purged AHCT arm were 46%, 71%, and 77%, respectively. The 2-year PFS was 26%, 58%, and 55%, respectively. There was a significant reduction in hazard rates for both PFS and OS when a comparison was performed between the chemotherapy patients and the combined groups of autologous AHCT patients (see Figures 64.3 and 64.4).

As with conventional chemotherapy, the outcome for patients who receive AHCT is related to the number of prior chemotherapy regimens received. Three retrospective studies have shown that patients with follicular lymphoma (FL) undergoing AHCT who had received more than three prior chemotherapy regimens showed inferior survival compared to patients treated with less than three prior regimens.^{49,52,53}

In a large retrospective series of 904 patients from the International Bone Marrow Transplant Registry (IBMTR), 67% of patients underwent AHCT with an unpurged graft, 14% received a purged graft, and 19% received a myeloablative allogeneic HCT.⁵⁴ The 5-year OS rates of 55%, 62%, and 51%, respectively, were comparable between all three groups despite a markedly

lower relapse rate among the allogeneic recipients. The lower recurrence rate in the allogeneic group was offset by a higher treatment related mortality. Negative prognostic factors included advanced age, refractory disease, high LDH, BM involvement, and a poor performance status. A direct comparison between the purged and unpurged autologous recipients revealed a significantly lower risk of recurrence among the purged recipients, which contradicted the CUP trial findings that showed no impact of purging. Patients are assigned to a treatment strategy based on the availability of an HLA-matched sibling.

In a prospective manner, several groups have evaluated the efficacy of early intensive therapy in newly

diagnosed FL patients or patients in first remission. Three such trials from Stanford, Dana Farber, and the GOELAMS group utilized HDC with TBI and *ex vivo* antibody purging of the autograft.^{46,47,55} With a median follow-up of 5–6 years for all three trials, the OS approached 90% in the first two trials with the latter trial reporting an OS of 64%. The latter trial accrued older patients and patients with higher tumor burdens. An Italian multicenter group transplanted 111 patients, most being in first remission and who received unmanipulated grafts.⁵⁶ Relapse-free survival and OS were superior compared to conventional chemotherapy with the patients transplanted in second CR experiencing almost a twice as

Figure 64.4 Overall survival for patients randomized to three arms in the CUP trial.³ (CUP denotes chemotherapy, unpurged autograft, purged autograft.) (Reprinted with permission for the American Society of Clinical Oncology from Schouten et al.⁴)

high a relapse rate compared to first CR patients. Nearly 5% of the patients, however, developed a secondary malignancy, which is similar to the previously mentioned studies in this particular subset of patients. Another large Italian multicenter trial (Gruppo Italiano Trapianto Midollo Osseo) with newly diagnosed FL patients reported an impressive 4-year DFS and OS of 67% and 84% with high-dose sequential chemotherapy.⁴⁵ This trial demonstrated the importance of achieving a molecular remission as the subgroup of patients who were PCR negative for either the *bcl-2* translocation or the heavy chain (IgH) gene rearrangement after transplant had a projected DFS of 85%.

There has been mounting evidence confirming the prognostic relevance of molecular monitoring of MRD in indolent lymphoma patients who are known to express the *bcl-2*/IgH rearrangement. The attainment of PCR negativity after transplantation appears to be highly predictive of continued CR as shown in trials from Dana Farber, St Bartholomew's, University of Heidelberg, and an Italian multicenter group.^{45,50,51,57} In the Heidelberg study, the relapse rate was 4.5 times higher in patients who were PCR positive in either the BM or peripheral blood at any given time posttransplantation in comparison with PCR-negative patients.⁵⁷ The Dana Farber Group demonstrated the negative impact of persistent PCR positivity in the graft after in vitro purging as the 8-year freedom from relapse was 83% in the patients who received PCR-negative grafts compared to 19% in patients who received PCR-positive grafts.⁵¹ In contrast, the St Bartholomew's trial found no correlation between PCR status of the reinfused BM and outcome, but PCR negativity following transplantation portended a more favorable outcome.⁵⁰

Various in vitro purging methods have been utilized to decrease or eliminate residual tumor cells from the harvest product but are typically expensive, labor intensive, and can be associated with substantial cell losses. Thus, in vivo purging is a more attractive strategy and RTX has recently emerged as a promising agent for this purpose when given concurrently with chemotherapy. Three recent studies have evaluated the effectiveness of this combination and yielded stem cell harvests with no PCR-detectable disease in the graft.^{44,58,59} One such study by Magni et al. evaluated 15 patients with MCL or FL who were given two cycles of intensive chemotherapy with two doses of RTX.⁴⁴ Ninety-three percent of the patients who received RTX had PCR-negative harvests compared to only 40% of the patients who had received the identical chemotherapeutic regimen without RTX. Four other studies that incorporated RTX specifically into the mobilization regimen yielded PCR-negative harvests ranging from 60 to 100% of the products that were known to be PCR positive prior to collection.⁶⁰⁻⁶³ The effect of in vivo purging on clinical outcome is still

unclear but should become more evident as the data mature.

As a method to augment targeted radiation to lymphomatous sites while reducing toxicity to healthy organs, the Seattle Group explored the feasibility of administering high-dose RIT with the ¹³¹I-antiCD20 monoclonal antibody, tositumomab, with AHCT in previously treated FL patients.⁴⁸ A multivariable comparison was performed with FL patients who received conventional HDC with AHCT. The RIT regimen was well tolerated with the RIT patients experiencing significantly superior PFS and OS compared to the historical HDC patients (PFS: 48% vs 29% and OS: 67% vs 53%, respectively). The treatment-related mortality (TRM) risk of 3.7% compared favorably with the 11% TRM observed in the historical HDC group.

The occurrence of histologic transformation (HT) occurs in up to 70% of low-grade lymphoma patients and carries a median survival of 1 year or less after transformation with conventional chemotherapy.⁶⁴⁻⁶⁶ However, this adverse prognosis may be modified by HDC with AHCT although this is controversial. Initial reports from Nebraska and the EBMT reported poor outcomes after AHCT for this subset of patients.^{67,68} A more recent update from the EBMT found similar outcomes after AHCT for transformed patients compared to case-matched controls with low-grade disease or *de novo* high- or intermediate-grade disease.⁶⁹ Increased LDH at the time of transformation was the only adverse predictive factor for both OS and PFS. However, a TRM of 18% was seen which was similar to the 20% TRM reported from the Princess Margaret Hospital in another retrospective analysis in which TRM was closely linked to advanced age. In the Princess Margaret study, the median OS for the 35 transformed patients was a notable 58 months from the time of transformation with the best outcomes seen in patients who attained a CR prior to transplant.⁷⁰ The Stanford Group published a 4-year DFS of 49% and OS of 50% in 17 patients with HT, which was similar to the updated EBMT study.⁴⁹ Comparable outcomes after transplantation also were reported by Corradini et al. with a 10-year projected EFS of 54% for HT patients compared to 65% for patients who retained a low-grade histology.⁷¹ Together these data suggest that patients with HT may benefit from dose-intensive chemotherapy, especially patients with chemosensitive disease, and that the occurrence of HT does not necessarily portend a poor outcome.

PERIPHERAL T-CELL LYMPHOMA

The prognostic significance of the T-cell phenotype in NHL is controversial but it has generally been shown that patients with peripheral T-cell lymphoma (PTCL) have a worse outcome compared to patients with B-cell diffuse lymphoma^{72,73} when treated with conventional

chemotherapy. It has been challenging to draw definitive conclusions regarding the effect of HDC with AHCT in this patient population due to the low incidence of this subtype and the heterogeneity of the lymphomas that fall under this classification that are not always clearly delineated in published studies. Rodriguez et al. of the Spanish GEL-TAMO group (Spanish Group for Lymphoma and Autologous Transplantation) has reported the largest series to date of 115 patients with PTCL treated with AHCT.⁷⁴ The 5-year OS and DFS rates were 60% and 56%, respectively, with a median follow-up of 37 months. When the outcome of the 37 patients who were transplanted in first remission was examined separately, OS increased to 80%, which was statistically significant. The age-adjusted IPI and LDH at transplant were of relevant prognostic significance in this particular study. In contrast, the patients with refractory disease had a 0% OS which concurred with an EBMT report of 64 patients of varying remission status in which most of the 8 refractory patients experienced dismal outcomes.⁷⁵ Actuarial OS at 10 years was 70% for all patients. The Princess Margaret Group and two Scandinavian studies showed that PTCL patients of the anaplastic large cell lymphoma (ALCL) subtype tended to experience better outcomes after AHCT compared to the other histologic subtypes under PTCL.^{76–78} Jantunen et al. reported a 5-year OS of 85% for ALCL patients compared to 35% for the other PTCL histologies. Song et al. from the Princess Margaret Hospital compared 36 patients with PTCL to 97 patients with B-cell DLCL and found no difference in EFS (37% vs 42%, respectively) and OS (48% vs 53%, respectively) after AHCT. Again, more favorable outcomes among the ALCL patients compared to the other PTCL patients were observed. The ALCL patients had superior survivals relative to the PTCL-not otherwise specified subgroup but similar outcomes compared to the DLCL patients. The Memorial Sloan Kettering series excluded ALCL patients and also reported no difference in EFS or OS between PTCL patients and corresponding DLCL patients.⁷⁹ The secondary age-adjusted IPI was a strong predictor for EFS as patients in the high-intermediate- or high-risk groups fared poorly regardless of chemosensitivity. An MD Anderson series of 36 PTCL patients reported the predictive relevance of the pre-transplant IPI for OS but not for PFS with pretransplant LDH affecting both PFS and OS.⁸⁰ The GEL-TAMO group also examined the impact of AHCT in 35 patients who were primary induction failures and obtained a 5-year DFS and OS of 43% and 51%, respectively, thus indicating that HDC/AHCT can rescue initial chemotherapy failures.⁸¹ On the basis of these data, a subset of patients with PTCL may be cured with AHCT, especially those who demonstrate chemosensitive disease. The role of HDC as frontline therapy is less clear although the limited available data show encouraging results.

HIGH-GRADE LYMPHOMA/BURKITT'S LYMPHOMA

There have been few reports and no randomized studies evaluating the role of HDC/AHCT in patients with Burkitt's lymphoma (BL). Brief duration high-intensity chemotherapy protocols currently confer survival rates approaching 70% and HDC has not improved outcome as compared to frontline therapy.^{82,83} Smeland et al. reported a 65% OS for newly diagnosed BL patients treated with high-intensity chemotherapy with a comparable 71% OS seen for patients who underwent AHCT in first remission. The data from the EBMT registry concurred showing a 3-year actuarial OS of 72% for 70 adult BL patients transplanted in first CR. For patients with chemosensitive relapse and resistant disease, the OS rates were 37% and 7%, respectively.⁸⁴ The City of Hope reported similar results with a 3-year DFS and OS of 60% for 10 BL patients who received AHCT in first CR or PR.⁸⁵ Thus, patients with recurrent or refractory BL should be channeled toward an allogeneic HCT as AHCT has been generally unsuccessful in such patients.

Lymphoblastic lymphoma is a clinically aggressive disease that accounts for only 2% of the NHLs. This clinical entity is usually composed of precursor T cells, has a predilection for young males, and frequently involves the BM and/or central nervous system.⁸⁶ Because of the frequent BM involvement and its resemblance to acute lymphoblastic leukemia, allogeneic transplantation is typically recommended in most cases. However, a recent retrospective analysis from the IBMTR/ABMTR failed to find a survival advantage for 76 patients with lymphoblastic lymphoma who received an allogeneic transplant compared to 128 patients who received an autograft.⁸⁷ The 5-year OS rates were 39% vs 44%, respectively. Although the 5-year relapse rate was significantly lower in the allogeneic patients (34% vs 56%, $p = 0.004$), the 5-year TRM was higher in the allogeneic recipients (25% vs 5%). Independent of the source of stem cells, multivariate analysis revealed that BM involvement at the time of transplant and disease status beyond first remission were associated with inferior outcomes. Another retrospective analysis of 214 patients from the EBMT demonstrated superior outcomes for patients who received an autograft in first CR compared to patients transplanted in second CR or patients with resistant disease.⁸⁸ The 6-year actuarial OS rates were 63%, 31%, and 15%, respectively. The efficacy of AHCT versus conventional dose consolidation as postremission therapy was studied in a European prospective trial of 119 patients.⁸⁹ Autologous transplantation produced a trend for improved RFS but not for OS (57% and 53%, respectively) when compared to conventional dose maintenance therapy after 37 months of follow-up. Thus,

both retrospective registry data and a few other series suggest that autologous transplantation can confer long-term remissions in a select group of patients.

POSTTRANSPLANT CONSOLIDATION/ MAINTENANCE THERAPY

HDC with AHCT can cure nearly half of NHL patients with chemosensitive disease and about 30% of patients with primary refractory disease. However, relapse still accounts for the majority of deaths in this patient population with most relapses occurring in sites of previous bulk disease. IFRT as adjuvant therapy posttransplantation is a strategy that can reduce this risk. Advantages for administering IFRT posttransplantation include the ability to tailor radiation dose based on residual disease volume, which may allow use of lower radiation doses and avoid delaying HDC in patients with rapidly progressive disease. The University of Chicago group transplanted 53 patients with relapsed/refractory NHL with 6 patients receiving IFRT to sites of persistent disease after transplantation.⁹⁰ Although the sample size was small, the IFRT patients experienced significantly improved local control of persistent disease sites (100% vs 29%, $p = 0.01$) and had a lower incidence of recurrences in previously active sites. Not surprisingly, the sites at greatest risk of relapse were sites failing to achieve a CR to induction therapy regardless of subsequent response to AHCT. Vose et al. from Nebraska demonstrated that not receiving IFRT either before or after transplant was an adverse prognostic factor for OS in a series of 184 patients with NHL patients with primary refractory disease.⁹¹ The University of Rochester group provided AHCT to 136 relapsed/refractory NHL patients.⁹² Fifty-one patients received posttransplant IFRT. Of the 58 patients transplanted with bulky disease, the 30 patients who received IFRT had a 3-year EFS of 35% versus 16% ($p = 0.04$) for the 28 patients who did not receive IFRT. Bulky disease was defined as nodal or extranodal disease >2 cm in diameter or $>20\%$ of marrow involvement with lymphoma. The patients with nonbulky disease did not experience a survival advantage with IFRT as consolidation. Unfortunately, there are no comparative trials addressing the role of IFRT after transplantation but IFRT should be offered as a valuable adjunct in this setting to reduce relapse rates in sites of previous bulk disease and to confer local control in residual sites after transplantation. However, potential concerns associated with IFRT include increased incidence of pneumonitis, transient cytopenias, and an increased risk of secondary MDS/AML.^{93,94}

Numerous other strategies that have been employed to reduce the relapse risk include cytokine therapy with IL-2, antibody-based therapies, and cellular therapies involving IL-2 activated products with natural

killer cells or cytokine-induced killer cells.⁹⁵⁻⁹⁹ However, the use of the anti-CD20 monoclonal antibody, RTX, as maintenance therapy after transplantation to eliminate residual tumor cells is increasingly being explored. Given its minimal toxicity profile and non-cross-resistant mechanism with chemotherapy, RTX has currently emerged as the most appealing agent for adjuvant therapy posttransplantation for patients with indolent, aggressive, and mantle cell B-cell NHL. In a German multicenter phase II study, 20 patients with newly diagnosed FL and 10 patients with MCL received four weekly doses of RTX at a median of 2 months posttransplant.¹⁰⁰ The addition of RTX increased both the complete clinical and molecular remission rates over time. At 6 months of follow-up, the clinical CR rate of 59% increased to 88% after 24 months of follow-up. Additionally, prior to transplantation, 22% of peripheral blood or BM samples were PCR negative. These numbers increased to 53% immediately after AHCT to 72% immediately after RTX administration and then to an impressive 100% PCR negativity at 6 months posttransplantation. These results indicated that clearance of MRD can continue for several months after RTX administration. The RTX was well tolerated with a 4% incidence of transient leukopenia and lymphocytopenia although seven patients developed pneumonia. B-cell peripheral blood counts normalized approximately 12 months after RTX consolidation therapy. Buckstein et al. administered RTX maintenance therapy to 17 patients with follicular NHL who had also received RTX prior to the mobilization regimen.¹⁰¹ At a median of 1 year of follow-up, all assessable patients remained in CR and all seven patients evaluable for molecular monitoring remained *bcl-2* negative at 6 months. In this study, four of 12 patients who received alpha-interferon instead of RTX for maintenance relapsed at a median follow-up of 28 months. In other published reports, Magni et al. and Ladetto et al. demonstrated the safety and feasibility of incorporating RTX for the purposes of in vivo purging and post-HSCT maintenance therapy in patients with B-cell NHL including follicular NHL.^{44,58} A large ongoing trial in Europe conducted by the EBMT is evaluating the roles of both in vivo purging and maintenance therapy with RTX in a multicenter setting for FL patients in second or third remission. This trial involves a four-arm randomization to either in vivo purging and maintenance, purging without maintenance, maintenance without purging, or no RTX administration.

The Stanford Group administered four weekly infusions of RTX to 28 patients with NHL beginning 42 days after transplant with additional infusions given at 6 months.⁹⁷ All patients had rapid depletion of B cells with no increase in infection or significant adverse events except for an isolated transient neutropenia that occurred in 54% of the patients. At a median follow-up of 30 months, the EFS and OS rates were 83% and 88%,

respectively. These results compare very favorably when the subgroup of 21 patients with DLCL were compared to a historical control group of DLCL patients who underwent AHCT without RTX maintenance therapy (see Figure 64.5). The 2-year EFS and OS rates were 58% and 62%, respectively, in the control group. Longer follow-up and the results of an ongoing Intergroup randomized trial will reveal the true clinical benefit of RTX maintenance therapy, but initial data speak strongly for both the safety and efficacy in the adjuvant setting.

RISK OF SECONDARY MYELOYDYSPLASIA/ ACUTE MYELOGENOUS LEUKEMIA AFTER AUTOGRAFTING

Secondary malignancies are a known late complication after conventional and HDC with treatment-related myelodysplastic syndrome (t-MDS) and treatment-related acute myelogenous leukemia (t-AML) being the most predominant type of secondary malignancies observed after AHCT.¹⁰²⁻¹⁰⁴ This particular late effect in NHL patients following AHCT has been extensively described by numerous groups with the reported crude incidence varying from 3 to 12%

and the estimated actuarial risk ranging from 3 to 19% at 5–10 years.¹⁰⁵⁻¹¹¹ The median time from AHCT to diagnosis of t-MDS/t-AML is approximately 2–4 years with median survival durations following this complication being only several months. Allogeneic transplantation salvages only a minority of these patients. The most common associated cytogenetic abnormalities include aberrations of chromosome 5 and/or 7 or complex abnormalities that have a strong association with cumulative doses of alkylating agents.^{112,113} Topoisomerase II inhibitors such as etoposide and doxorubicin have been associated with 11q23/21q22 abnormalities and a shorter latency period.^{114,115}

It is not clear whether the antecedent chemotherapy and RT or the transplantation conditioning regimen has the greater impact in the development of t-MDS/t-AML. A case-control analysis from the ABMTR analyzed 2739 patients with NHL or Hodgkin's disease who had undergone AHCT and found that the type and intensity of prior chemotherapy contributed substantially to the development of this late complication.¹¹¹ The 7-year cumulative risk of developing t-MDS/t-AML was 3.9% with the relative risk being four to eight times higher for patients who had received large cumulative doses of mechlorethamine or chlorambucil, respectively. The dose of TBI was also important, as patients who received >13.2 Gray had a relative risk of 4.4, compared to patients who received <13.2 Gray. Prior chemotherapy was also implicated in a Danish series of NHL and HD patients, which found that HDC with AHCT did not increase the risk of leukemic complications above the level observed after conventional chemotherapy.¹⁰⁶ Thus, antecedent chemotherapy was the most important predictive factor. The Dana Farber Group reported a 19.8% actuarial incidence at 10 years without evidence of a plateau in 552 NHL patients who underwent AHCT with cyclophosphamide and TBI as the conditioning regimen.¹⁰⁹ Prior IFRT and lower number of cells infusion during transplantation were the only variables that differed between patients who did and did not develop MDS/AML.

Although there is a consensus that cumulative dose of prior chemotherapy is related to the development of t-MDS/t-AML, the contribution of TBI in the preparative regimen toward the development of this late complication remains controversial. The EBMT retrospectively studied 5000 patients with lymphoma who had undergone AHCT. Sixty-eight patients developed MDS with a median follow-up of 3 years.¹¹⁰ Multivariate analysis revealed TBI in the conditioning regimen, older age at transplant and low-grade histology as independent variables predictive of MDS development. The low-grade histology patients were also more likely to have received a greater total dose of alkylating agents such as chlorambucil and cyclophosphamide prior to AHCT compared

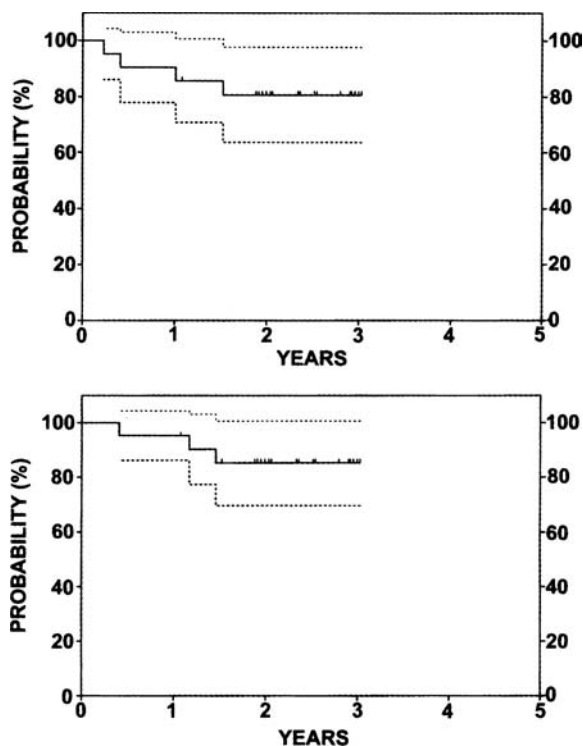

Figure 64.5 Event-free survival (top) and overall survival (bottom) for 21 patients with relapsed or refractory diffuse large B-cell lymphoma. Dotted lines represent 95% confidence interval. Tic marks represent censored data. (From Horwitz et al.⁹⁷ with permission. Copyright American Society of Hematology)

to the patients with intermediate/high-grade disease. An MD Anderson series reported that the use of TBI was independently associated with an increased risk of t-MDS/t-AML, especially when combined with high-dose cyclophosphamide and etoposide.¹⁰⁸ Prior fludarabine administration and BM involvement also increased this risk. The City of Hope Group did not find the use of TBI in the conditioning regimen to be of prognostic value but demonstrated that pretransplant RT did confer a higher risk, which concurred with the DFCI findings.¹⁰⁷ In contrast to the ABMTR analysis and the above-mentioned Danish study, pretransplant chemotherapy did not affect the risk of t-MDS/t-AML. However, for patients who received etoposide for stem cell priming, a 12.3 fold increased risk of developing t-AML with 11q23 abnormalities was seen. In summary, t-MDS and t-AML are serious consequences after AHCT. The assessment of occult cytogenetic abnormalities before hematopoietic cell mobilization or harvest should be routinely performed, especially in heavily pretreated patients who may already harbor early MDS prior to transplantation.

CONCLUSION

Autologous transplantation has emerged as an effective therapy for patients with NHL of a variety of histologies at various points in disease treatment. Randomized clinical trials have demonstrated improved outcomes as compared to standard chemotherapy in several settings including for patients with intermediate-grade B-cell DLCL with chemosensitive relapse and for patients with high risk features in first CR. Patients who do not achieve a CR with initial induction chemotherapy also can be salvaged with AHCT. Patients with relapsed low-grade lymphoma who have not been heavily pretreated also benefit from AHCT. However, the occurrence of secondary malignancies, especially t-MDS and t-AML, is a problematic late effect that adversely impacts long-term survival rates. Newer concepts such as immunotherapy with monoclonal antibodies, cell-based therapies and nonmyeloablative allogeneic transplantation are under active investigation in an effort to further improve outcomes.

Chapter 65

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR NON-HODGKIN'S LYMPHOMA

Hillard M. Lazarus

INTRODUCTION

HISTORICAL PERSPECTIVE: AUTOLOGOUS STEM CELL TRANSPLANTATION

Although many non-Hodgkin's lymphoma (NHL) histologic subtypes can be cured using combination chemotherapy, many patients experience relapse or never achieve remission after initial therapy. For several decades, high-dose chemoradiation therapy and autologous stem cell transplantation (auto SCT), using either autologous bone marrow or, subsequently, autologous peripheral blood stem cells (auto PBSC), has been demonstrated to be an effective therapy for sensitive-relapse NHL patients.¹⁻³ This modality can also be effective in refractory relapse or even primary refractory disease states.^{4,5} Some investigators have reported data supporting a recommendation for use of auto SCT in NHL patients at high risk for relapse.^{6,7} Obvious benefits of auto SCT are use of self as a donor, no need for posttransplant immunosuppression and its attendant risks, and the avoidance of graft-versus-host disease (GvHD). On the other hand, this modality usually is ineffective in the setting of significant tumor bulk, cannot be offered to patients who have been subjected to extensive previous treatment limiting mobilization of blood stem cells,⁸ and lacks graft-versus-lymphoma (GvL) effect. The major limitation of auto SCT is relapse after transplant, due, in part, to intrinsic lymphoma resistance to cytotoxic agents and the potential for reinfusion of occult tumor cells that may contribute to relapse.⁹ In vitro purging methods indirectly have been shown to provide benefit in some patients, but the results are not conclusive.^{10,11} The prognosis after relapse in auto SCT recipients is extremely poor.

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION

Hematopoietic stem cell transplantation using cells collected from an allogeneic donor (allo SCT) is an option being used with increased frequency. In the past, this approach was used less often in view of limited donor availability, and high nonrelapse mortality, in part, due to GvHD. Allo SCT has the potential for improving patient outcome, as there is no infusion of lymphoma cells (normal donor) and the donor effector cells provide the potential for a GvL effect¹² (Table 65.1).

GRAFT-VERSUS-LYMPHOMA EFFECT

Evidence for a graft-versus-malignancy or GvL effect in NHL is mixed (Table 65.2). In a review, Mollee and colleagues¹³ noted the conflicting results in a number of studies, as the GvL effect was not uniform in the

Table 65.1 Allo SCT compared to auto SCT for NHL: advantages and disadvantages

Advantages	Disadvantages
Normality of infused stem cells	Increased non-relapse mortality
Grafts-versus-lymphoma effect	Increased "allogeneic-radiated" morbidity
Avoidance of secondary AML/MDS	Age and donor restrictions
No graft contamination by lymphoma	Increased costs Lack of randomized trials

AML, acute myeloid leukemia; MDS, myelodysplastic syndrome.

Table 65.2 Evidence of graft-versus-malignancy effect in humans

- Abrupt immunosuppression withdrawal or GvHD or flare reestablishes complete remissions
- Relapse higher in syngeneic than in allogeneic graft recipients
- GvHD protective against relapse in some patient subgroups
- T-cell depletion increases relapse rates in CML patients
- Donor lymphocyte infusions can induce complete remissions
- Allo SCT relapse rates are lower than those for auto SCT

GvHD, graft-versus-host disease; CML, chronic myeloid leukemia

intermediate- and high-grade histologic subtypes. The data for follicular NHL, a slower growing neoplasm, are more convincing. Tse and colleagues¹⁴ recently reported the benefit of GvL across many studies in which low-grade NHL patients underwent allo SCT using either a myeloablative or reduced-conditioning regimen.

REASONS TO CONSIDER ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR NHL

Clinicians and investigators have offered patients allo SCT rather than auto SCT for a variety of reasons, including technical considerations such as failure to collect sufficient stem cells for transplant. Alternatively, health care professionals may recommend an allo SCT for inherent biases, such as resistance to therapy and gross marrow involvement (Table 65.3). Also, some patients who relapse after an auto SCT are offered an allograft.

MYELOABLATIVE ALLO SCT IN FAILED AUTO PBSCT

Freytes et al.¹⁵ recently published a retrospective analysis of IBMTR data collected from 1990 to 1999 on 114 lymphoma ($N = 35$ Hodgkin's disease and $N = 79$ NHL) patients who received a myeloablative allo SCT after a failed auto SCT. Sixteen patients had low-grade

Table 65.3 Reasons for clinicians and investigators to consider allo SCT rather than auto SCT

- Resistance to initial therapy
- Resistance to salvage therapy

- Bone marrow histologic (gross) involvement
- Failure to harvest auto PBSCT
- Relapse after auto SCT

NHL, 52 intermediate- and high-grade, and 8 had other types such as composite, mantle-cell, and peripheral T-cell NHL. A variety of graft sources were used (61% sibling-matched; 14% haploidentical sib; 25% unrelated). Treatment-related mortality was 22% at 1 year and 25% at 5 years. Overall survival at 3 years was 33% and decreased to 24% by 5 years after allo SCT. Similarly, progression-free survival (PFS) was 25% and 5% at 3 and 5 years, respectively. Complete remission at time of transplant and use of total body irradiation (TBI) in the preparative regimen were associated with lower rates of tumor progression and higher overall survival. These results are quite disappointing, but reflect both a poor-risk patient group, as well as an emerging approach. Specifically, van Besien and colleagues¹⁶ noted dramatic improvement in overall survival after myeloablative HLA sibling-matched allo SCT from 39% during the 1990–1993 period to 72% over 1997–1999. Readers of the literature must take into account such improvements when comparing studies, especially when not conducted during concurrent periods of time.

MYELOABLATIVE ALLO SCT AS FIRST TRANSPLANT: AGGRESSIVE NHL

Several single-arm cohort studies have used myeloablative allo SCT for relapsed or, rarely, high-risk (for relapse) aggressive as well as low-grade NHL patients. Significantly fewer aggressive NHL patients have undergone this approach, as historically most patients have been offered auto SCT as therapy. Table 65.4 shows five series of myeloablative allo SCT for NHL.^{17–21} Most patients exhibited refractory disease at time of transplant, and as a result of extensive prior therapy and anticipated complications such as GvHD, nonrelapse mortality was quite high, accounting for death in one third to one half of patients. One single-institution series reported by Stein and colleagues²⁰ noted only a 15% overall survival at 5 years after transplant, a reflection of advanced, heavily pretreated patients.

MYELOABLATIVE ALLO SCT AS FIRST TRANSPLANT: LOW-GRADE (FOLLICULAR) NHL

Table 65.5 illustrates the results of seven reports in which follicular NHL patients were given myeloablative conditioning followed by infusion of allogeneic stem cells.^{22–28} Aside from the IBMTR²² and EBMTR²³ communications of registry data, all series are quite small and follow-up is somewhat limited for the slower growing (compared to aggressive) NHL subtypes. Relapse rates are low, partially explained by the more potent GvL effect in low-grade NHL (compared to aggressive histologies) observed with allo SCT; van

Besien and coworkers²⁹ noted that diffuse large-cell NHL was among the least sensitive to the GvL effect. In fact, in two series of allo SCT in low-grade NHL by Toze and colleagues²⁶ and Forrest et al.,²⁷ no relapses

were reported; additionally, two relapses after allo SCT were reinduced into a complete remission using chemotherapy, indicating that all 16 allografts were alive in complete remission.

COMPARISONS OF ALLO SCT VERSUS AUTO SCT

A number of investigations have reported trials comparing allo SCT to auto SCT for intermediate- and high-grade as well as low-grade NHL (Tables 65.6 and 65.7). Most of these studies were retrospective comparisons, often using observational databases from groups such as the IBMTR/ABMTR and the EBMTR. The reports often do not provide intricate detail regarding specific patients outcome. In several instances, the investigators reported the data using case-matched controls, and indicated hazard ratios for measures of patient outcome. In the case of intermediate- and high-grade NHL, Bierman and associates¹⁰ recently published a combined IBMTR/EBMTR analysis involving more than 3000 NHL patients receiving stem cell transplants. A total of 2018 patients received unpurged autografts while 376 patients were given purged autografts. Further, 774 patients received T-cell replete allografts and 119 allografts that were T-cell depleted. These groups were compared to 89 syngeneic grafts. These data from this observational database analysis failed to demonstrate a GvL effect. Recipients of unpurged auto SCT, however, had a fivefold increase risk of relapse compared to the syngeneic group; further, unpurged auto SCT patients had a twofold increased relapse rate compared to purged graft recipients. In the case of low-grade NHL patients, this finding was associated with an improved overall and disease-free survival. This information provides indirect evidence that autologous tumor contamination may

contribute to NHL relapse, an advantage possessed by use of an allograft.

COMPARISONS OF ALLO SCT VERSUS AUTO SCT: INTERMEDIATE- AND HIGH-GRADE NHL

Table 65.6 shows a number of publications comparing allo SCT and auto SCT.^{7,10,24,30-34} Among the earliest reports were small series by Milpied and colleagues⁷ and Bureo and coworkers.³² Chopra et al.³⁰ communicated one of the first matched case-control studies. The way they reported their data enabled them to evaluate various NHL subtypes. For both lymphoblastic lymphoma and intermediate- and high-grade NHL, the benefit of a reduced treatment-related mortality in auto SCT was offset by a higher relapse rate, i.e., allo SCT and auto SCT results were comparable. Subsequently, Peniket and the EBMTR²⁴ retrospectively analyzed data from 1982 to 1998, in which they compared 1185 allogeneic transplants (as the first transplant) for lymphoma with 14,687 autologous procedures. Patients receiving allogeneic transplants were subdivided according to histology: low-grade NHL (231 patients); intermediate-grade NHL (147 patients); high-grade NHL (255 patients); lymphoblastic NHL (314 patients); Burkitt's lymphoma (71 patients); and Hodgkin's disease (167 patients). Actuarial overall survival at 4 years from transplantation was as follows: low-grade NHL 51.1%; intermediate-grade NHL 38.3%; high-grade NHL 41.2%;

Table 65.7 Comparative analyses detailing outcome of myeloablative transplantation for low-grade NHL

PFS, progression-free survival; EFS, event-free survival; OS, overall survival; NR, not reported.

lymphoblastic lymphoma 42.0%; Burkitt's lymphoma 37.1%; and Hodgkin's disease 24.7%. These outcomes are relatively poor because of the high procedure-related mortality associated with these procedures, particularly in patients with Hodgkin's disease (51.7% actuarial procedure-related mortality at 4 years). Multivariate analysis showed that for all lymphomas apart from Hodgkin's disease, status at transplantation significantly affected outcome. A matched analysis revealed that for all categories of lymphoma, overall survival was better for auto SCT than for allo SCT. Relapse rate was better in the allo SCT group for low-, intermediate- and high-grade, and lymphoblastic NHL. Allo SCT appeared superior to auto SCT in producing a lower relapse rate, but overall survival will not be superior until the toxicity of such procedures is reduced.

COMPARISONS OF ALLO SCT VERSUS AUTO SCT: FOLLICULAR NHL

There are few trials prospectively designed to compare allo SCT versus auto SCT for follicular NHL patients. Table 65.7 illustrates the results using myeloablative preparative regimens for allo SCT as compared to auto SCT for use in follicular NHL.^{16,35-37} Again, most series are small in size except for communications from registry analyses, such as the recent report by van Besien et al.¹⁶ Treatment-related mortalities for allo SCT are approximately 30%, nearly a log-fold higher compared to auto SCT. On the other hand, relapse rates in the allo SCT group are significantly lower, approxi-

mately 20%, with no reported relapses in the small series by Verdonck.³⁵ Such opposing effects may not offset each other and could result in improved overall survival in those receiving allo SCT, although follow-up is short.

CONCEPT OF REDUCED-CONDITIONING ALLO SCT

In recent years, reduced conditioning or nonmyeloablative conditioning has been used to avoid the toxic effect of the preparative regimen, yet allow donor cell engraftment to take place, and ultimately to result in a GvL effect.³⁸⁻⁴⁰ These highly immunosuppressive but less toxic regimens rely upon engraftment and subsequent immunologic effect to eradicate NHL. Diaconescu and colleagues⁴¹ at the Fred Hutchinson Cancer Research Center reported in preliminary fashion a retrospective comparison of reduced conditioning versus myeloablative conditioning for NHL patients undergoing HLA-identical allografts. They noted that despite the former group having a higher median age, higher comorbidity index, and greater likelihood of prior allograft, the treatment-related mortality at 100 days was 8.8% compared to 20.6% in the myeloablative group.

Table 65.8 shows five studies describing the data for NHL patients who underwent a reduced-conditioning allo SCT for relapse after an auto SCT.⁴²⁻⁴⁶ The information presented reflects either retrospective registry analyses⁴² or small single institutional studies. Mantle-cell NHL patients appeared to fare poorly in the registry

report due to a high treatment-related mortality (46%), but had a favorable outcome in the study from MD Anderson Cancer Center.⁴⁶ Despite the poor prognostic characteristics of an auto SCT failure, many patients remain alive in complete remission, although for the most part the follow-up period is brief. The single institution report from Escalón et al.⁴⁶ shows a strikingly excellent outcome of a 95% PFS at 3 years after allo SCT. That such patients can be treated using an initial auto SCT and subsequently salvaged using a reduced-conditioning allo SCT supports the contention of many investigators that poor-risk NHL should receive planned tandem auto SCT followed within months by a reduced-conditioning allo SCT. The rationale is that the auto SCT provides significant tumor cytoreduction allowing maximal antitumor benefit of the new donor effector cells given in the course of an allo SCT.

REDUCED-CONDITIONING ALLO SCT AS FIRST TRANSPLANT: FOLLICULAR NHL

Data from five small studies using reduced-intensity conditioning and allo SCT as first transplant for follicular NHL are shown in Table 65.9.^{47–50} In several reports, a variety of hematologic malignancy patients were treated in this fashion, and the data for follicular NHL have been culled out. The median follow-up for these series is short, but treatment-related mortality remains relatively low at approximately 20% at 1 year, except in the report by Robinson and colleagues.⁵⁰ In that study, the authors note inexplicably high treatment-related mortality and relapse rates. More patients need to be accrued to therapy and a longer duration of follow-up must be reported before stating that reduced-intensity

allo SCT changes the natural history of follicular NHL; however, the high PFS rate of approximately 70% is encouraging. The monoclonal antibody Campath-1, now being used with increased frequency, may contribute to improved patient outcome.⁵¹ Chakraverty et al.⁵¹ incorporated Campath-1 into the conditioning regimen for 47 matched-unrelated donor allo SCT, 29 of whom failed auto SCT. Eighty-five percent of patients attained full donor chimerism and day 100 nonrelapse mortality was 14.9%. One-year progression-free and overall survivals were 61.5 and 75.5%, respectively.

THERAPY FOR SPECIFIC NHL SUBTYPES

NHLs are a heterogeneous group of lymphoid malignancies whose clinical behavior and response to therapy exhibit considerable variation. Mantle-cell NHL, for example, resembles a low-grade NHL morphologically, behaves aggressively, yet is incurable using conventional therapies. Use of auto SCT in mantle-cell NHL in relapse provides extremely poor prospects of attaining long-term disease-free survival.⁵² Martinez et al.⁵³ and Grigg and colleagues⁵⁴ reported series in which allo SCT salvaged such patients, due in large part to the contribution of GvL when GvHD develops. Examples of other successful initiatives already have been related earlier in this review. Further support for GvL in this context is the report from Berdeja and colleagues⁵⁵ who noted poorer survival in mantle-cell NHL patients compared to other histologic types; these patients received T-cell depleted grafts that compromise the GvL effect.

Peripheral T-cell NHL represents a less common, more resistant histologic subtype, one in which the

newer anti-B-cell monoclonal antibodies such as rituximab have no effect. Corradini et al.⁵⁶ recently reported a phase II reduced-conditioning trial in 15 relapsed and 2 primary refractory peripheral T-cell NHL patients. Patients received thiopeta, fludarabine, and cyclophosphamide followed by blood stem cells obtained from sibling-matched ($N = 14$), sibling one-antigen mismatched ($N = 2$), and matched-unrelated donors ($N = 1$). Two-year nonrelapse mortality was 6% and 12 patients attained complete remission. Three-year progression-free and overall survivals were 64 and 81%, respectively.

DONOR LYMPHOCYTE INFUSIONS

Infusions of lymphocytes obtained via apheresis collections from the patient's allogeneic stem cell donor, i.e., donor lymphocyte infusions (DLIs), have been used as effectors to provide salvage therapy for some patients who have relapsed after allo SCT. The most effective disease targets for this approach have been chronic myeloid leukemia and multiple myeloma, although other hematologic malignancies may respond.⁵⁷⁻⁶¹ Several small series have reported mixed results in lymphoma patients who relapsed after allo SCT.⁶²⁻⁶⁴ In one of the larger series, Mandigers and associates⁶⁴ treated seven patients with low-grade NHL in relapse after an allo SCT and noted two partial and four durable complete responses lasting at least 43-89 months after infusion. DLIs appear to be more effective in lower grade rather than higher grade NHL and in the setting of low tumor volume. Infusions often are administered after cytotoxic therapy with or without monoclonal antibody therapy and after the patient has been tapered off all immunosuppressive therapy. It is unclear, however, if the GvL effect can be separated from GvHD effect using unmanipulated DLI. The most effective cell dose is not uniformly established, as the time to DLI after the transplant may play a role in efficacy and toxicity. This therapy is associated with a high incidence of GvHD and aplasia of bone marrow, resulting in a nearly 20% fatality incidence.^{57,60}

FUTURE CONSIDERATIONS

A number of potential directions to improve upon allo SCT are listed in Table 65.10. Clearly, maneuvers to reduce nonrelapse mortality are most desirable. Targeted antilymphoma regimens using radioimmunconjugates rather than TBI have been implemented in auto SCT and are being developed for allo SCT.^{65,66} Supportive care strategies, including better anti-infective agents, are being improved upon. GvHD remains a major contributor to treatment-related mortality, and the addition of sirolimus to the GvHD prophylaxis armamentarium may be extremely effica-

cious.⁶⁷ Other intriguing possibilities include the use of methods to enhance GvL effect, such as dendritic cell vaccines. DLI, occasionally used successfully in the setting of relapse after allo SCT in NHL, may be associated with the development of severe and fatal GvHD. Newer uses of DLI include preemptive infusion in patients at high risk for relapse (due to aggressive disease or because the allograft was T-cell depleted), or use of selective, i.e., CD8⁺ T-cell depleted, DLIs in an attempt to provide GvL effect without GvHD.⁶⁸⁻⁷⁰ As discussed above, a number of investigators are using tandem auto SCT followed by allo SCT approaches. Recently, several groups have begun using novel conditioning regimens incorporating agents such as pentostatin⁷¹ or the combination of pentostatin and extracorporeal photopheresis (ECP).⁷² Chin et al.⁷² reported in preliminary fashion their allo SCT reduced-intensity regimen combining lower dose TBI, pentostatin, and ECP in poor-risk patients. A total of 106 patients were enrolled using matched-related ($N = 76$) or matched-unrelated ($N = 30$) donor stem cell infusion. Seventy-six (72%) patients were alive without tumor 100 days after transplant. At a 15-month median follow-up, overall patient outcomes, such as chronic GvHD (47%) and relapse (23%), did not differ significantly between matched-related and matched-unrelated donors.

Some investigators have proposed improved diagnostic model approaches for low-grade and intermediate-/high-grade NHL in a manner similar to those developed for auto SCT using the International Prognostic Index.^{73,74} This strategy could become a powerful tool to compare results of different treatment regimens as well as to guide clinical management.

Other areas of investigation include more selective monitoring of residual NHL to induce either GvHD and GvL, or the need to begin additional anti-NHL

Table 65.10 Future directions

- Minimizing treatment-related complications, i.e., improved supportive care, targeted preparative regimens
- Newer GvHD prevention approaches: sirolimus
- Use of new GvL maneuvers, i.e., dendritic cell vaccines
- Advanced donor lymphocyte infusion techniques, i.e., preemptive administration or selective T-cell depletion
- Strategies to improve upon engraftment in reduced-conditioning regimens
- Linkage of specific cytoreduction regimens in resistant relapses before reduced-conditioning regimens
- Develop improved prognostic scoring before transplant as done for auto SCT
- Sequential auto SCT/allogeneic SCT
- Development of novel preparative regimens, i.e., pentostatin and extracorporeal photopheresis approaches
- Monitor tumor load after allograft for more therapy, i.e., real-time PCR assay for t [14;18]
- Expand donor pool, i.e., matched-unrelated and haploidentical donors

therapies. Chang et al.⁷⁵ evaluated tumor load using a real-time quantitative polymerase chain reaction assay for t(14;18), which they correlated with the clinical course of follicular NHL patients after stem cell transplant. None of six patients who remained in remission had samples with a tumor load >0.01% after transplant. In contrast, four of five patients (three allo SCT/two auto SCT) with relapsed/progressive disease had increasing tumor loads of >0.01% after transplant ($P < 0.02$). This technique likely will be validated with a greater number of cases. Finally, expansion of the donor stem cell pool will make allo SCT more available for more patients. Recent studies have demonstrated the feasibility of mismatched and haploidentical donors for allo SCT.⁷⁶⁻⁷⁸ Sykes and colleagues⁷⁸ reported five patients with refractory NHL undergoing stem cell transplantation from haploidentical related donors sharing at least one HLA A, B, or DR allele on the mismatched haplotype. Four patients showed mixed hematopoietic chimerism with a predominance of donor lymphoid tissue and varying degrees of myeloid chimerism. Two patients exhibited antilymphoma effect and were in GvHD-free states of complete and partial clinical remission at 460 and 103 days after stem cell transplantation. Bierman and the National Marrow Donor Program⁷⁷ recently presented preliminary data in which unrelated donor stem cells

were the source of cellular rescue for NHL patients undergoing allo SCT.

SUMMARY

Allo SCT has begun to assume an increasing role in the management of NHL. This approach provides several advantages over auto SCT, including provision of a lymphoma-free graft, reduced rates of secondary myelodysplastic syndrome and leukemia, and a potentially curative GvL effect. The latter appears to be considerably more pronounced in low-grade NHL such as follicular NHL, compared to more aggressive histologies. When applied to chemosensitive patients, the lower relapse rates and reasonable long-term outcomes make allo SCT a promising therapy to pursue. Patient populations, such as those with bone marrow involvement or very high-risk disease, can be identified as having suboptimal outcomes after auto SCT and may benefit from such an approach. While the exact role of allo SCT remains to be determined, broad recommendations can be suggested for the management of patients with NHL. New approaches to allo SCT, including the use of matched-unrelated donors and reduced-intensity conditioning regimens, may expand the applicability of this potentially curative modality.

Chapter 66

DEFINITION OF REMISSION, PROGNOSIS, AND FOLLOW-UP IN FOLLICULAR LYMPHOMA AND DIFFUSE LARGE B-CELL LYMPHOMA

John W. Sweetenham

INTRODUCTION

The emergence of new technologies impacts the care of patients with non-Hodgkin's lymphomas (NHLs). The advent of new functional imaging techniques, such as fluorodeoxyglucose positron emission tomography (FDG-PET) is being evaluated not only as a staging investigation, but also as a method for assessing response to therapy, and determining prognosis. The use of molecular techniques for the detection of residual disease after completion of therapy raises questions regarding currently used definitions of response. The prognostic significance of disease detected at the molecular level is under evaluation, as is the use of molecular studies for follow-up. The clinical prognostic factors identified by the International Prognostic Index (IPI) have provided a model for risk stratification of patients with diffuse large B-cell lymphoma (DLBCL). A similar index, the Follicular Lymphoma International prognostic Index (FLIPI), has now gained widespread use for low-grade follicular lymphoma (FL). These clinical indices have proved useful for risk stratification and for providing general prognostic information to patients with these diseases. However, there is marked variability in outcome within the risk groups identified by these prognostic models, indicating the biologic and clinical heterogeneity of these diseases. Recent gene expression profile (GEP) and tissue microarray (TMA) studies have identified patterns of gene expression and immunohistochemical features which have prognostic value independent of the IPI or FLIPI. It is likely that future prognostic models will incorporate this information.

Optimum follow up strategies for patients with NHL are unclear. The value of new (and established) imaging technologies for early detection of relapse has been systematically evaluated in only a small number of studies. The potential role of molecular techniques for early detection of subclinical relapse is also being explored.

The advent of these new techniques is therefore leading to redefinition of many of the criteria used for the assessment of prognosis, remission, and follow-up in malignant lymphomas, particularly the most common subtypes, namely DLBCL and FL.

STANDARD RESPONSE CRITERIA IN NHL

The use of clinical response endpoints in trials in NHLs has been an intrinsic component of clinical trial design for many years. This is based largely on the observation that long-term disease-free and overall survival for patients in many clinical trials has been shown to correlate closely with the degree of clinical response. This observation holds true for first line therapy and for patients who receive second line regimens including the use of high-dose therapy and autologous stem cell transplantation (ASCT). Although a close correlation between response and event free and overall survival has been confirmed in multiple studies in aggressive NHL, results in studies in FLs and other indolent lymphomas have been less clear. Many studies have shown a correlation of clinical response with event- or failure-free survival in FLs, but in view of the indolent nature of these diseases, correlations with overall survival have been inconsistent. Additionally, in aggressive NHL, the persistence of residual masses after the completion of therapy, especially at sites of

initial disease bulk, does not always indicate the presence of residual active disease. Inconsistencies in the assessment of response at sites such as the spleen and bone marrow have also added to uncertainty regarding the definition of response and comparability of results in different clinical trials.

An International Workshop to standardize response criteria for NHL was therefore developed in 1998 and published in 1999 in an attempt to provide uniform interpretation of clinical trial results across all studies.¹ This included agreed definitions of response and appropriate endpoints and follow-up schedules for use in the trial setting. The definitions provided are based primarily on clinical, radiologic, and histopathologic criteria, and they have since been modified by the inclusion of functional imaging data. A formal update of the criteria is in progress and will incorporate other data including flow cytometric analysis and molecular studies.

A summary of the response criteria is shown in Table 66.1.

The specific definitions are given next.

Complete remission (CR)

- Complete resolution of all clinically and radiologically detectable disease, all lymphoma-related symptoms, and all lymphoma-related biochemical abnormalities (such as elevated lactate dehydrogenase [LDH]).
- Lymph nodes and nodal masses must regress to normal size (defined as ≤ 1.5 cm for lymph nodes initially >1.5 cm). Lymph nodes initially measuring 1.1–1.5 cm must regress to ≤ 1 cm in greatest transverse diameter, or by more than 75% of the sum of the perpendicular diameters (SPD).
- If the spleen is enlarged on CT scan prior to therapy, it must regress in size and not be palpable by physical examination. Normal splenic size was not defined. Any macroscopic nodules noted in the spleen by any imaging modality must be resolved. Similar criteria apply to other organs such as the liver and kidneys.
- In view of conflicting data regarding the use of unilateral and bilateral bone marrow biopsies at staging, the workshop defined an adequate marrow evaluation as one with a minimum total biopsy

length of 20 mm. If the marrow is involved at diagnosis, CR requires complete clearing of the infiltrate on repeat biopsy, which must be from the same site and the same minimum length. At the time of the initial workshop publication, since the significance of flow cytometric, molecular and cytogenetic data were not clear, these have not, to date, been incorporated into the standardized criteria (see next).

CR Unconfirmed (CR_u). The patients fulfill criteria for CR, with the following exceptions:

- Residual lymph node masses more than 1.5 cm in maximum transverse diameter which have regressed by more than 75% of the SPD. Individual nodes which were previously confluent must regress by more than 75% of the SPD compared with the size of the original mass.
- Indeterminate bone marrow—defined as having increased number or size of lymphoid aggregates without cytologic or architectural atypia.

Partial remission (PR)

- In SPD of the six largest nodes or nodal masses, $\geq 50\%$ decrease. Where possible, these masses should be from disparate lymph node regions, be readily measurable and include mediastinal and retroperitoneal masses if these are present.
- No increase in the size of other lymph nodes, liver, or spleen.
- Splenic and liver nodules must regress by at least 50% in the SPD.
- Involvement of other organs is considered assessable but not measurable.
- Bone marrow assessment is regarded as irrelevant because it is assessable but not measurable.
- No new sites of disease.

Stable disease (SD)

- Less than PR, but more than progressive disease (PD) (see next)

Progressive disease

- More or equal to 50% increase from the nadir in SPD of any previously identified abnormal node

Table 66.1 Response criteria for non-Hodgkin's lymphoma according to International Workshop

Response category	Physical examination	Lymph nodes	Lymph node masses	Bone marrow
CR	Normal	Normal	Normal	Normal
CR _u	Normal Normal	Normal Normal	Normal >75% Decrease	Indeterminate Normal or indeterminate
PR	Normal Normal Decrease in liver/spleen	Normal $\geq 50\%$ decrease $\geq 50\%$ decrease	Normal $\geq 50\%$ decrease $\geq 50\%$ decrease	Positive Irrelevant Irrelevant
Relapse/progression	Enlarging liver/spleen, new sites	New or increased	New or increased	Reappearance

- Appearance of any new lesion during or at the end of therapy

Relapse

- Appearance of any new lesion or increase by $\geq 50\%$ in the size of any previously involved site
- More or equal to 50% increase in greatest diameter of any previously identified node greater than 1 cm in short axis or in the SPD of more than one node

At the time of the initial description of these criteria, response assessment was based entirely upon physical examination, and routine radiologic and pathologic criteria.

CT scanning was considered the standard imaging modality for nodal disease. The standardized criteria require assessment by CT scan no more than 2 months after completion of therapy. Bone marrow aspirate and biopsy is considered mandatory only to confirm CR if involved initially or if new abnormalities develop in the peripheral blood count or smear.

The Workshop also defined a series of acceptable end-points for clinical trials as documented on Table 66.2.

In most studies of aggressive NHL, remission status, defined according to these criteria, is strongly correlated with outcome. In general, a partial remission after combination chemotherapy is associated with a high risk of subsequent relapse and a low probability for long-term disease-free survival. In studies of low-grade FL, this is less clear. Although many single center studies have demonstrated that the achievement of a CR to a particular regimen is associated with superior disease-free survival and overall survival compared with patients achieving a PR, comparative trials of different regimens have typically shown that higher response rates frequently correlate with higher rates of disease-free survival or event-free survival, but this rarely correlates with improved overall survival. There are several potential explanations for this, including the effectiveness of subsequent treatments to “rescue” patients who relapse after a particular regimen. However, recent data for new first line regimens in the

treatment of FL suggest that these treatments may be improving overall survival in these diseases. If these observations are confirmed, the use of refined criteria for response in FL may become central to management. If the presence of residual subclinical disease in indolent lymphomas proves predictive of subsequent relapse and survival, the potential for early treatment will require investigation.

USE OF FUNCTIONAL IMAGING IN RESPONSE ASSESSMENT IN NHL

The use of functional imaging techniques in response assessment in NHL has now been evaluated in several studies. The potential advantage of functional imaging in this context is based on the well-documented limitation of CT-based assessments of response to therapy in NHL. This is because CT is unable to differentiate between viable tumor, fibrosis, or necrosis in a residual mass at the completion of therapy. Initial data from studies in which functional imaging has been used as an adjunct to staging have suggested that this modality may have a higher specificity and sensitivity in patients with aggressive compared with indolent lymphomas. Consequently, most data so far has been collected for patients with aggressive subtypes of NHL, particularly DLBCL. Although gallium scintigraphy has been used previously in this context, most recent data has described the use of FDG-PET. Most studies have investigated the use of this technique separately from conventional imaging techniques such as CT scanning, although some recent studies have assessed the potential addition of FDG-PET to conventional response assessment. In all cases, the studies have determined the predictive value of FDG-PET in terms of subsequent relapse and survival.

Spaepen et al. have reported results for 96 patients with various subtypes of aggressive NHL undergoing PET scans at the completion of various combination chemotherapy regimens.² Sixty-seven of these patients had negative PET scans at the completion of therapy, of which 80% remained in clinical CR with a median

Table 66.2 Definition of endpoints for clinical trials according to International Workshop

End point	Response category	Definition	Point of measurement
Overall survival	All patients	Death from any cause	Entry onto trial
Event-free survival	CR, CR _u , PR	Failure or death from any cause	Entry onto trial
Progression-free survival	All patients	Disease progression or death from NHL	Entry onto trial
Response duration	CR, CR _u , PR	Time to relapse or progression	First documentation of response
Disease-free survival	CR, CR _u	Time to relapse	First documentation of response
Time to next treatment	All patients	Time next treatment is required	Trial entry
Cause-specific death	All patients	Death related to NHL	Death

follow-up of just under 2 years. The remaining 20% of patients relapsed in a median of 316 days. All of the 29 patients with positive PET scans at the completion of therapy relapsed at a median of 105 days. A similar study by Mikhael reported a positive predictive value (PPV) of 100% and a negative predictive value (NPV) of 82% for PET scanning used at the completion of therapy.³ Several other studies have now been reported, with similar results, all suggesting that FDG-PET predicts tumor viability and subsequent relapse in residual masses with 80–90% PPV, after first line and, in some cases, salvage therapy, including ASCT.^{4–6}

A recent retrospective study from Juweid et al. has assessed the use of FDG-PET in combination with the International Workshop criteria (IWC) in patients with aggressive NHL in an attempt to determine whether PET scanning adds increased discrimination in outcome compared with conventional response criteria.⁷ The study included 54 patients with aggressive NHL, mostly DLBCL who underwent FDG-PET and CT scanning between 1 and 16 weeks after completion of 4–8 cycles of cyclophosphamide, doxorubicin, vincristine, prednisone (CHOP)-based chemotherapy. Responses to therapy were assessed by conventional IWC and by an additional set of criteria which included PET. Based on subsequent risk of relapse, used as a surrogate for the accuracy of each methods of response assessment, IWC plus PET provided a more accurate assessment, in particular because PET was able to identify a subset of patients in PR by IWC who were PET negative, and carried a more favorable prognosis. Further studies are underway at the moment, which will probably further define the value of PET in this situation and it is likely that the IWC will be modified in the near future to integrate data from functional imaging.

Additionally, the use of functional imaging early in the course of therapy is being assessed as a method of response assessment and prediction of subsequent outcome (see the section on prognostic factors).

It is important to emphasize that most present data regarding PET scanning for response assessment relates to aggressive NHL. Few data are available for indolent subtypes of lymphoma.

ASSESSMENT OF MOLECULAR RESPONSE AND MINIMAL RESIDUAL DISEASE

In contrast to studies of functional imaging, the use of molecular response as an endpoint has been addressed mostly in the context of FLs. Standard clinical and pathologic techniques including routine light microscopy and immunohistochemistry are capable of detecting tumor cells to the level of approximately 1 in 100 normal cells. Lower levels of disease, detected by molecular techniques, are designated as minimal residual disease (MRD). Molecular techniques can detect tumor cells to the level of 1 in

1,000,000 normal cells. Clearing of disease at the molecular level is termed molecular remission (MR). The relationship between MR and clinical outcome is unclear at present, and MR is therefore being incorporated into study endpoints in many clinical trials in FL.

Two targets for monitoring of MRD have been evaluated in FL. The t(14;18) (q32;q21) translocation is detectable in most cases of FL. It can be detected by fluorescence in situ hybridization (FISH) techniques, or by polymerase chain reaction (PCR). In the uncommon case of FL without a detectable t(14;18), the IgH gene rearrangement unique to the malignant clone, also detectable by PCR, has been used for MRD detection. Most studies exploring the role of MRD have assessed this either in peripheral blood, bone marrow, or both.

There is increasing evidence that treatment regimens which result in molecular remissions in FL are associated with prolonged clinical remissions. In a study from MD Anderson Cancer Center, 194 patients with low-grade follicular NHL and a detectable bcl-2 gene rearrangement were treated with one of three chemotherapy regimens.⁸ Most patients also received interferon α as maintenance therapy. Although a correlation was observed between molecular and clinical CR rates, one-third of patients achieving clinical CRs were not in MR at the completion of therapy and one-third of patients in PR after 3–5 months eventually achieved MR. Patients achieving MR during the first year following treatment had significantly longer failure-free survival rates than those not in MR (4 year failure-free survival = 76% vs 38%; $p < 0.001$). MR was independently predictive of outcome in multivariate analysis and was also predictive within the group of patients in clinical CR. In this study, there was a concordance rate of approximately 70% between results in the peripheral blood and bone marrow, indicating that the tissue used for evaluation of MRD is an important variable. This study demonstrated that conventional dose chemotherapy regimens produce a significant MR rate in FL, a fact which has subsequently been confirmed in many other studies, especially those in which rituximab has been used as a component of first-line therapy in combination with chemotherapy.^{9–11} This study also demonstrated that the achievement of both clinical CR and MR improved with time over the first 20 months of follow-up from completion of therapy, indicating that the timing of response assessment may influence the correlation between these parameters and outcome. Additionally, despite the strong correlation between achievement of MR and failure-free survival, most patients eventually progressed, indicating that MR does not equate with cure.

Several studies have now demonstrated a similar relationship between the attainment of MR and prolonged failure-free survival, and have also confirmed that the re-emergence of PCR detectable disease (or an increase in the level using quantitative PCR techniques) is correlated with subsequent clinical relapse.^{12–14}

The use of MR has also been investigated in the context of patients with FL undergoing high-dose therapy and ASCT. Most of these studies have demonstrated a correlation between PCR negativity in the blood and bone marrow and subsequent disease-free survival after ASCT.¹²⁻¹⁴ Freedman et al. reported experience in 153 patients undergoing high-dose therapy and ASCT for relapsed FL.¹² All of these patients were treated with cyclophosphamide and total body irradiation (TBI), and all had in vitro manipulation of the stem cell product with monoclonal antibodies prior to reinfusion. In this series, continued PCR negativity in the peripheral blood and marrow after ASCT correlated with continued clinical CR, an observation made in several other smaller post ASCT studies.

In summary, there are accumulating data which suggest that the achievement of MR in FL is a meaningful endpoint which correlates with clinical outcome. At present, molecular endpoints have not been incorporated into the IWC, although this is likely to change. In the meantime, the use of molecular endpoints in FL trials is essential to obtain further information on the predictive value of molecular response.

Despite encouraging data, there are several limitations to the use of molecular endpoints. The bcl-2 rearrangement can be detected in the blood of 5-10% of normal individuals (although using quantitative techniques, it is usually present at much lower levels than in the FL population).^{15,16} Optimal timing for the evaluation of MR is uncertain at the moment, since PCR-detectable disease can continue to diminish and eventually disappear several months after completion of therapy.^{8,17} Monoclonal antibodies such as rituximab have been shown to clear PCR-detectable disease from the blood and bone marrow more effectively than from lymph nodes, indicating that the specific therapy and the site of evaluation for MRD can both influence the molecular response.^{18,19}

PROGNOSIS AND PROGNOSTIC FACTORS

DIFFUSE LARGE B-CELL LYMPHOMA

The clinical factors identified in the IPI for aggressive NHL have gained widespread use for risk stratification in clinical trials and are used by many clinicians to provide prognostic information for patients with these diseases.²⁰ The risk groups and observed relapse-free and overall survival rates are summarized in Table 66.3. The age adjusted IPI (aa-IPI) is also frequently used, especially for studies investigating dose-intensive approaches such as first remission high-dose therapy and ASCT. A stage-adjusted IPI has also been proposed for patients with limited stage disease.²¹ The clinical utility of the IPI and aa-IPI has been confirmed in multiple studies of first-line therapy for aggressive NHL, and more recently, in studies for patients undergoing salvage therapy with ASCT.²²

Although the IPI and aa-IPI have been valuable tools for risk stratification, there is marked variability in outcome within each of the IPI risk groups, reflecting the underlying biological and pathologic heterogeneity of aggressive NHL. Even in studies where entry is restricted to patients with DLBCL, this variability is still present, indicating the need for more patient-specific, biologically based risk factors.

Molecular and immunohistochemical risk factors in DLBCL

Expression of many individual proteins detected by immunohistochemistry has been shown to have prognostic value in DLBCL. Examples of some of these are summarized in Table 66.4. The technique of GEP in which expression of thousands of genes can be investigated using cDNA or oligonucleotide probes has now been reported by several groups. The patterns of gene expression have been shown to correlate with clinical outcome and have led to the development of new prognostic models.

Table 66.3 Five year relapse free and overall survival rates according to the IPI and age-adjusted IPI

IPI			
Risk group	Number of adverse factors ^a	5 year RFS (%)	5 year OS (%)
Low	0 or 1	70	73
Low-intermediate	2	50	51
High-intermediate	3	49	43
High	4 or 5	40	26
Age adjusted IPI			
Risk group	Number of adverse factors ^b	5 year RFS (%)	5 year OS (%)
Low	0	86	83
Low-intermediate	1	66	69
High-intermediate	2	53	46
High	3	58	32

RFS, relapse-free survival; OS, overall survival.

^aAdverse risk factor for IPI are stage III or IV disease, age >60 years, elevated LDH, ECOG performance status ≥ 2 , ≥ 2 extranodal sites.

^bAdverse risk factor for age-adjusted IPI are stage III or IV disease, elevated LDH, ECOG performance status ≥ 2 .

Table 66.4 Examples of individual immunophenotypic features with reported prognostic significance in DLBCL

Immunophenotype	Impact on prognosis
bcl-2 expression	Adverse
Mutated p53	Adverse
High proliferative rate defined by Ki-67	Adverse
Cyclin D2 positive	Adverse
CD 5 expression	Adverse
MUM-1 positive	Adverse
bcl-6 expression	Favorable
HLA class II expression	Favorable
Tumor infiltrating lymphocytes	Favorable

Alizadeh et al. initially reported results using the lymphochip cDNA microarray to analyze biopsies from 44 patients with DLBCL.²³ In this study, patients with high levels of expression of genes characteristic of normal germinal center B-cells (GCB) were shown to have higher overall survival rates than those with expression profiles characteristic of activated B-cells (ABC). A study of material from 77 uniformly treated DLBCL patients reported by Shipp et al. using oligonucleotide microarrays identified a predictive model based on expression of 13 genes.²⁴ Rosenwald et al. subsequently described a 17-gene predictive model based on further studies using a cDNA microarray which identified four gene expression signatures characteristic of GCB, proliferating cells, reactive stromal and immune cells in the lymph node, and expression of major histocompatibility (MHC) class II antigens.²⁵ There was no concordance between individual genes identified in the 13- and 17-gene models previously described, possibly because the microarrays used in the studies differed and different techniques were used to develop the predictive models. The potential clinical utility of prognostic scores based on microarrays is limited by these technical differences, as well as the requirement for fresh, or optimally cryopreserved samples, and by the costs of these techniques. In an attempt to overcome some of these problems Lossos et al. have described a simplified six-gene model using quantitative RT-PCR in 66 patients with DLBCL, all treated with CHOP or related regimens.²⁶ Genes correlated with shorter survival were *BCL2*, *CCND2*, and *SCYA3*. Those associated with longer survival were *BCL6*, *LMO2*, and *FN1*.

Results from all of these studies have been shown to provide prognostic information which helps to refine the predictive value of the IPI. However, in view of the limitations of GEP studies outlined earlier, there has been recent interest in the use of TMAs which allow immunohistochemical analysis of protein expression from multiple tissue sections on single slides, and

which can be performed on routinely fixed and paraffin-embedded clinical specimens.

A recently published study of TMAs in DLBCLs has examined expression of CD10, bcl-6, MUM1, FOXP1, cyclin D2, and bcl-2 in samples from 152 patients with DLBCL, of which 142 had previously been analyzed using GEPs.²⁷ Using bcl-6, CD10, and MUM1 expression, it was possible to identify samples as GCB-like or ABC-like. As shown in Table 66.5, there was a marked difference in event-free and overall survival according to phenotype, the survivals being very similar to those described for the same series classified according to GEPs. High IPI score and non-GCB phenotype were independent adverse prognostic factors in multivariate analysis. Subsequent studies have confirmed the adverse prognostic significance of non-GCB phenotype identified by TMAs.^{28,29} These early results suggest that TMAs are likely to have more clinical utility than GEPs since the availability of frozen material will remain a limitation for genetic studies. A small number of immunohistochemical stains, rather than multiple stains used in TMAs may prove to have adequate predictive value in future studies. Prospective evaluation of GEPs, TMAs, and expression of individual proteins by immunohistochemistry should continue to be an integral part of new clinical trials in DLBCL in an attempt to produce more specific prognostic factors. This is particularly true since the addition of rituximab to combination chemotherapy for DLBCL. Several studies have demonstrated the superiority of rituximab/chemotherapy combinations compared with chemotherapy alone in the treatment of DLBCL. However, to date, all of the published data regarding TMAs and GEPs as prognostic tools is based on samples from patients treated with chemotherapy only. Recent reports have shown that the addition of rituximab to chemotherapy can modify the prognostic significance of certain factors. For example, the adverse prognostic effect of absent bcl-6 expression in DLBCL patients treated with CHOP does not apply to patients receiving CHOP-rituximab.³⁰ Two recent studies have demonstrated that the adverse prognostic significance of bcl-2 expression in DLBCL is lost in patients treated with chemotherapy/rituximab combinations.^{31,32}

At present, the IPI and aa-IPI should be regarded as the standard system for identifying risk groups in DLBCL. Ongoing studies of GEPs and TMAs based in samples from patients treated with rituximab-based

Table 66.5 Tissue microarray criteria for GCB versus non-GCB derivation of DLBCL

	CD10	Bcl6	MUM1	5 year EFS (%)	5 year OS (%)
GCB	+ (-)	+ (-)	-	63	76
Non-GCB	-	-	+	36	34

EFS, event-free survival; OS, overall survival.

combinations are in progress and are likely to refine the IPI in the future.

“Early” functional imaging in DLBCL

The use of “early” functional imaging using FDG-PET has been shown to be predictive of prognosis in DLBCL by several groups. As previously described, FDG-PET is gaining an emerging role in the assessment of disease at the completion of therapy. However, the use of this technique at completion of therapy, although having prognostic value, is otherwise of limited clinical utility since there is no evidence to suggest that changing, or intensifying therapy for patients not in CR at the completion of primary treatment improves outcome. Functional imaging performed earlier (after one or more cycles of chemotherapy) might be a more accurate predictor of outcome than that performed at completion of chemotherapy since it may identify relatively resistant clones which are slow to respond to chemotherapy. Early detection of resistant disease might allow an early change of therapy, and even if not, might give more accurate predictive information on which to base subsequent management, including follow-up. Studies from Memorial Sloan Kettering Cancer Center have investigated the use of FDG-PET after one cycle of chemotherapy in a series of patients with NHL and Hodgkin’s lymphoma and compared these results with scans performed at the completion of therapy in the same group of patients.³³ A positive FDG-PET was associated with a significantly shorter PFS at both time points. However, the PPV was higher after one cycle of therapy compared with at the completion of therapy (90% vs 83%). A similar difference was observed for the NPV (85% vs 65%) and the false negative rate (15% vs 35%) both of which also favored PET after one cycle.

A recent study from France has reported results from 90 patients with aggressive NHL treated with a variety of doxorubicin-based combination chemotherapy regimens who underwent FDG-PET after two cycles of therapy.³⁴ Forty-one percent of patients in this study received rituximab as a component of first-line therapy. Early FDG-PET was negative in 54 patients and positive in 36. At completion of induction therapy, 83% of patients with negative early FDG-PET had achieved clinical CR compared with 58% of those with positive FDG-PET. Significant differences were observed in 2 year event-free survival (82% vs 43%; $p < 0.0001$) and overall survival (90% vs 61%; $p < 0.006$) in favor of the FDG-PET negative group. Furthermore, the predictive value of early FDG-PET was seen in all IPI risk groups, indicating its independence from the IPI as a prognostic factor.

Early FDG-PET therefore represents another approach which may provide important prognostic information to refine the IPI. Potential limitations include the uncertainties regarding the criteria for designation of a “positive” or “negative” scan, the availability of functional

imaging, and the expense of this technique. It is also possible that the predictive value of early PET may be limited to certain regimens, particularly standard regimens using fixed doses of chemotherapy. Recent studies of regimens with dynamic dose adjustments according to toxicity, such as dose-adjusted EPOCH-R (etoposide, prednisone, vincristine, cyclophosphamide, doxorubicin, rituximab)³⁵ have shown poor predictive value of early FDG-PET scanning, possibly because of a relatively early adjustment of dose which eradicates relatively resistant tumor clones more quickly (W.H Wilson, MD, PhD, personal communication).

FOLLICULAR LYMPHOMA

Retrospective analyses of patients with FL have identified many clinical factors with adverse prognostic significance, including advanced age, high number of nodal sites of involvement, advanced anatomic stage, the presence of tumor bulk, and elevated LDH. The IPI described for aggressive NHL has also been applied to patients with FL, and several studies have shown it to have predictive value. The use of the IPI is limited by the fact that a relatively small number of patients have high-risk disease according to this index, limiting the patient populations for prospective studies in “poor risk” disease. Additionally, clinical factors with prognostic value in indolent lymphoma may differ substantially from those in aggressive NHL because of the biological difference between these two entities.

The FLIPI has therefore been developed and is now regarded as the standard clinical prognostic tool for patients with low grade FL.³⁶ The risk groups and 5- and 10-year survival rates associated with each of these groups are summarized in Table 66.6.

A recent European study has compared the FLIPI with the IPI and also with an Italian Prognostic Index developed for FL, in a population of 465 patients with low-grade disease.³⁷ They demonstrated that all three indices provided useful prognostic stratification. The FLIPI identified a higher proportion of patients with high-risk disease. However, the concordance between the three indices was only 54%, indicating that as with DLBCL there is substantial biological and clinical heterogeneity within each risk group and emphasizing the need for more accurate predictors of outcome.

MOLECULAR AND IMMUNOPHENOTYPIC PROGNOSTIC FACTORS IN FOLLICULAR LYMPHOMA

As with DLBCL, many molecular, cytogenetic, and immunohistochemical factors have been shown to have prognostic significance in small series of patients with FL.³⁸⁻⁴⁰ Some of these are summarized in Table 66.7. The variability in the prognostic factors identified across many of these studies reflects selection bias into the various studies, heterogeneity of treatment

Table 66.6 Five year and 10 year overall survival rates for patients with FL according to FLIPI risk group

Risk group	Number of adverse factors ^a	Distribution of patients (%)	5 year OS (%)	10 year OS (%)
Low	0–1	36	90.6	70.7
Intermediate	2	37	77.6	50.9
high	≥3	27	52.5	30.5

OS, overall survival.

^aAdverse risk factors for FLIPI are age ≥ 60 years, Ann Arbor stage III or IV, hemoglobin <12 g/dL, serum LDH > upper limit of normal, number of nodal sites > 4.

regimens, and the lack of consistency in the diagnosis and grading of FLs, which has been documented in many previous studies.

As with aggressive NHL, the use of GEP has recently been applied to the study of FLs in an attempt to refine prognostic groups identified by the FLIPI and IPI. The largest GEP study to date has been reported from the Leukemia and Lymphoma Molecular Profiling Project (LLMPP).⁴¹ In this study, cDNA microarrays were performed on 191 biopsies from patients with FL for which clinical follow-up data were available. This study identified two gene expression signatures, both with high levels of genes characteristic of immune response functions. One of these signatures was associated with favorable and the other with adverse prognosis. Many of the immune response genes identified in both signatures are typically expressed in macrophages, and further studies demonstrated that the signatures with prognostic significance were expressed in cells other than the germinal center derived malignant B-cells. This study demonstrated the potential prognostic significance of the immune response in this disease, especially since the gene

expression signatures had predictive value independent of the IPI.

Consistent with these observations, a recent study from British Columbia has examined the potential prognostic significance of lymphoma-associated macrophage (LAM) content in low-grade FL, using routine immunohistochemical staining for a macrophage marker (CD68) in routinely processed and fixed clinical specimens.⁴² Out of 99 evaluable patients with FL, all uniformly treated between 1987 and 1993, 87 were classified as having low LAM content and 12 as having high LAM. The median overall survival for each group was 16.3 years versus 5.0 years, respectively ($p = 0.0003$). In multivariate analysis, LAM and IPI retained independent predictive value. TMA studies are in progress for patients with FL at present and are likely to identify candidate immunohistochemical markers which will be used to construct refined prognostic models in the future.

In the meantime, clinical prognostic factors such as the FLIPI or IPI will remain the standard tool for clinical practice and clinical trials.

Few studies of functional imaging have been conducted in FL, and most suggest that the PPV and NPV of FDG-PET are relatively low, suggesting that this is unlikely to provide a useful prognostic tool in these diseases.

Table 66.7 Examples of morphologic, immunohistochemical, and molecular markers with prognostic significance in FL

Marker	Impact on prognosis
Histologic grade	Higher grade carries adverse prognosis
Ki-67 (proliferation marker)	Higher proliferation rate carries adverse prognosis
Diffuse areas	Adverse
Loss of p53	Adverse
Loss of p16	Adverse
Gain of c-myc	Adverse
bcl-6	Variable in different series
bcl-2	Variable—site of breakpoint in rearranged <i>bcl-2</i> gene has prognostic significance

FOLLOW-UP

Very few studies have formally addressed the optimal follow-up schedule and optimal follow-up procedures for patients with NHL. Although routine imaging techniques such as CT scanning and FDG-PET are now commonly used for the early detection of relapse, there are no published studies evaluating the utility of PET in this context, and studies of CT scanning and other imaging modalities have failed to show a high rate of early detection of relapse (although most studies were reported in the early 1990s with inferior scanning technology to that now available).⁴³

Although molecular techniques such as quantitative PCR may help detect early, subclinical relapse in some subtypes of NHL, especially FL, there is no evidence at present to suggest that early treatment

intervention in this context improves survival compared with the treatment of clinically detected relapse, although this may change with the increased use of monoclonal antibodies in this disease.

The International Workshop defined a recommended follow-up schedule and investigations for patients with NHL on clinical trials to establish consistency across different studies. Their recommendations were that patients should be evaluated a minimum of every 3 months after completion of treatment for 2 years, then every 6 months for 3 years, and then annually for at least a further 5 years. For patients with aggressive lymphoma, few recurrences occur beyond 10 years, although the group acknowledged that for low-grade FL, longer follow-up would be required, not only for the detection of relapse but also to monitor for late side effects of therapy such as secondary myelodysplastic syndrome or acute myeloid leukemia which have been reported with increasing frequency in the FL population.

Minimum testing recommended at each follow-up visit was for a history, full physical examination, complete blood count, and LDH. No recommendations

were made regarding the appropriate intervals for imaging or other investigations.

Although this schedule has some utility for clinical trial design, follow-up schedules will to some extent be determined by the aggressiveness of the disease, the presenting prognostic factors, and the estimated risk of relapse. Investigations will be determined by the original sites and extent of disease, although at least one study in aggressive NHL has shown that over 60% of relapses occur in new sites of disease, suggesting that follow-up investigations should not be specifically directed to the original sites of disease.

As further information accumulates regarding the predictive value of PCR-based techniques, or functional imaging, these are likely to be incorporated into routine follow-up schedules. However, it is important to point out that the early detection of relapse is only helpful if effective treatment strategies are available for salvage therapy. The impact of early detection of relapse on survival is likely to be determined more by the effectiveness of salvage therapy than the ability to detect low levels of subclinical disease.

Chapter 67

TREATMENT OF TRANSFORMED NON-HODGKIN'S LYMPHOMA

Philip J. Bierman

INTRODUCTION

Four patterns of histologic variation have been described for patients with non-Hodgkin's lymphoma (NHL).¹ Mixed architectural pattern refers to a single biopsy which reveals areas with both diffuse and follicular patterns. Composite lymphomas contain more than one distinct type of lymphoma (or Hodgkin's lymphoma and NHL) in the same biopsy. Discordant lymphoma refers to different types of lymphoma that occur at different locations, simultaneously. Histologic transformation (or evolution, or conversion, or progression) refers to a change in lymphoma histology that occurs during the course of a patient's disease.

Transformation is frequently unrecognized until discovered at postmortem examination. Usually, transformation refers to a change from low-grade or indolent histology to more aggressive histology, although other definitions have been used. Frequently, progression from follicular to diffuse histology is used to define transformation, and at other times transformation may be defined as an increase in the number of large cells in a biopsy.

In 1928, Maurice Richter described a patient with "chronic lymphoid leukemia" and progressive lymph node enlargement.² At autopsy, the lymph nodes, liver, and spleen were infiltrated by small lymphocytes and "endothelioid tumor cells" described as a "reticular cell sarcoma." Since then, the term Richter's syndrome has been used to describe the development of large-cell lymphoma in a patient with chronic lymphocytic leukemia (CLL). Retrospective series have demonstrated the occurrence of Richter's syndrome in 2–3% of CLL patients.^{3,4} This syndrome has been described in CLL patients who are in remission, as well as those with active disease, and is classically associated with systemic symptoms, progressive lymphadenopathy, extranodal disease, elevated serum lactate dehydrogenase (LDH), and poor prognosis.

EPIDEMIOLOGY

INCIDENCE

The true incidence of histologic transformation is difficult to determine for a wide variety of reasons.¹ As noted above, there are a number of differences in the way in which transformation is defined. It may also be difficult to distinguish patients with histologic transformation from those with unrecognized discordant pathology at diagnosis. Most authors suggest that patients with evidence of transformation within 6 months of diagnosis have discordant pathology, rather than transformation.^{5–7} There is also a lack of uniformity regarding patient follow-up in many series. Long-term follow-up of large cohorts is necessary to determine the true frequency of transformation, since transformation may be a late event. Many studies cite crude incidence rates instead of actuarial risk. In addition, the risk of transformation includes all patients in some series, while other reports restrict calculations to patients who have progressed and received biopsies. Accurate statistics on the risk of transformation are also impaired by a lack of standardized criteria for biopsy of suspected sites of relapse.¹ For example, peripheral nodes are more likely to be biopsied than less accessible nodes. Infrequent biopsies of suspected sites of relapse will underestimate the risk of transformation. A single biopsy of only one site of relapse may fail to identify transformation that has occurred in another location. In addition, autopsy findings may not be included in some series. Finally, results from older series may not be applicable to patients managed more recently because of refinements in lymphoma classification, ease of detecting relapse and performing biopsies, and possible influences of newer treatments.

A wide variety of situations have been described, in which changes in the histology of lymphoma occur over time.⁸ Examples include progression of CLL/small lymphocytic lymphoma to diffuse large B-cell lymphoma

and Hodgkin's lymphoma, progression of follicular lymphoma to diffuse large B-cell lymphoma, progression of marginal zone lymphoma to diffuse large B-cell lymphoma, and progression of mycosis fungoides to peripheral T-cell lymphoma. This chapter will focus mainly on transformation of follicular lymphomas and, to a lesser extent, on Richter's syndrome.

The frequency of NHL transformation has been examined in several series (Table 67.1). It is impossible to compare the different results due to variations in the way calculations are performed. The true rate of transformation may be overestimated, since many series perform calculations on the basis of only those patients who progress and undergo a repeat biopsy. Conversely, true rates of transformation may be underestimated, since many patients do not have repeat biopsies and few patients are examined at autopsy.

Some studies have shown a risk of transformation that plateaus after 6 or 7 years.^{16,21} Other reports have shown a continuous risk of transformation without evidence of a plateau.^{6,7,17} The median time to documentation of histologic transformation was 57 months for a group of low-grade lymphoma patients (follicular small cleaved cell, follicular mixed small cleaved cell and large cell, and small lymphocytic) managed with initial observation.¹⁷ Other investigators have reported a median time from diagnosis to transformation ranging from 26 to 66 months.^{6,15,16,19,22}

RISK FACTORS

A number of prognostic factors have been analyzed for their association with transformation. In a series examining histologic progression of follicular lymphomas, it was noted that patients who transformed were more likely to have had early stage disease at initial diagnosis and were more likely to have received local radiation as primary treatment when these patients were compared to others with unchanged histology.⁵ In another series, histologic transformation was found to be associated with involvement of extranodal sites of disease, stage IV disease, presence of systemic symptoms, and bulky abdominal disease at diagnosis, as well as failure to achieve a complete remission with initial therapy.⁶ Lack of response to initial therapy has been associated with a higher risk of transformation in other series,²¹ and it has been suggested that eradication of primary disease with initial therapy may reduce the incidence of transformation. Elevated serum β_2 -microglobulin level was associated with a higher risk of transformation in one series.²¹

Other series have failed to identify risk factors associated with transformation.^{7,16} It does not appear that an initial "watch-and-wait" strategy alters the risk of transformation.¹⁷ Similarly, the risk of transformation appears to be similar when patients with follicular large-cell lymphoma are compared to patients with

follicular small cleaved-cell and follicular mixed-cell lymphomas.²¹ Treatment with fludarabine or other nucleoside analogs was not shown to influence the progression of CLL to large-cell lymphoma in one series,³ although other groups have shown unexpectedly high rates of histologic transformation in patients with CLL and follicular lymphoma who were treated with fludarabine.²³ The Stanford group found that the risk of histologic conversion was not influenced whether patients were initially treated with involved-field radiation, total lymphoid or whole body irradiation, single-agent chemotherapy, or combination chemotherapy.¹⁶

CLINICAL FINDINGS AND OUTCOME

In most reports, transformed lymphomas have been associated with aggressive disease and poor outcomes. Systemic symptoms and relapse at new or extranodal sites are frequently noted.^{3,5-7,16,17,24,25} Other findings such as central nervous system relapse²¹ and hypercalcemia²⁶ have also been associated with histologic transformation.

The median survival was only 4 months in a French series of patients with Richter's syndrome,²⁵ and only 5 months in a series of patients with Richter's syndrome from MD Anderson Cancer Center.³ Patients who achieved remission with subsequent therapy had longer survival than those who had poorer responses ($P < 0.001$). Similar findings were noted from Stanford.¹⁶ The median survival following documentation of histologic conversion of low-grade lymphomas was 8.5 months, as compared to 6 years for patients who continued to have indolent histology when rebiopsied ($P < 0.0001$). In this series, achievement of a complete remission after histologic conversion was also associated with a better prognosis. In another French series, the median survival following transformation of follicular lymphoma was 7 months.²¹ The median survival for patients with transformation at the time of first progression was 5 months, as compared with 47 months for patients who still had follicular lymphoma at first progression ($P < 0.01$). Factors associated with improved survival following transformation were treatment with a CHOP-like (cyclophosphamide, doxorubicin, vincristine, and prednisone) regimen and normal LDH level. Another series examining outcomes in patients with nodular lymphomas noted that median survival following first repeat biopsy was 77 months for patients who retained nodular architecture, as compared to 11 months for patients with histologic progression.⁵ An autopsy series from Massachusetts General Hospital showed that median survival from diagnosis was 55 months among patients who maintained a diagnosis of nodular lymphoma, as compared with 32 months for patients who progressed to a diffuse architectural pattern.¹² A series from the National Cancer Institute showed that median survival was 32

Table 67.1 Incidence of histologic transformation of non-Hodgkin's lymphoma

References	Study population	Incidence	Remarks
9	56 of 618 lymphomas (includes Hodgkin's lymphoma) with sequential biopsies	13/56 = 28%	Incidence refers to cases undergoing "dedifferentiation"
10	94 of 210 follicular lymphomas with sequential biopsies or autopsy	28/94 = 30%	Incidence refers to cases showing transformation to diffuse architecture
11	22 of 136 "macrofollicular" lymphomas with sequential biopsies or autopsy	22/30 = 73%	Incidence refers to cases showing transformation to diffuse architecture
12	18 of 65 nodular lymphomas with autopsy	8/18 = 44%	Incidence refers to cases showing transformation to diffuse architecture
13	30 relapsed lymphomas of 64 lymphomas with "favorable" histology	9/30 = 30%	Incidence refers to cases showing transformation to a "higher grade"
14	Autopsy findings of 35 lymphomas with initial nodular architecture	22/35 = 63%	Incidence refers to cases showing transformation to diffuse architecture
15	28 of 56 nodular lymphomas with sequential biopsies	11/28 = 39%	Incidence refers to cases showing transformation to diffuse architecture
5	63 of 203 nodular lymphomas with sequential biopsies	19/63 = 30%	Incidence refers to cases showing transformation to diffuse or large-cell architecture
16	78 relapsed or refractory lymphomas of 150 with favorable histology lymphomas	23/78 = 29% Actuarial risk = 20% at 5 years and 50% at 8 years for patients with active disease	Incidence refers to case showing transformation to "unfavorable" histology
17	23 of 83 low-grade lymphomas initially managed with observation with sequential biopsy	10/23 = 43% Actuarial risk = 19% at 8 years for all 83 patients	Incidence refers to case showing transformation to intermediate-grade or high-grade histology
18	Autopsy findings of 56 lymphomas with nodular architecture	36/56 = 64%	Incidence refers to cases showing transformation to diffuse "aggressive" histology
7	34 of 75 nodular small cleaved-cell lymphomas with sequential biopsies	13/34 = 38%	Incidence refers to cases showing transformation to "transformed" (non-cleaved-cell) histology
6	51 of 127 follicular low-grade lymphomas with sequential biopsies	30/51 = 59% Actuarial risk = 30% at 5 years and 56% at 10 years for relapsed patients	Incidence refers to cases showing transformation to intermediate-grade or high-grade histology
19	496 low-grade lymphomas	34/496 = 7%	Incidence refers to cases showing transformation to a more aggressive histology
20	72 of 148 follicular lymphomas with sequential biopsies or autopsy	23/72 = 32%	Incidence refers to cases showing transformation to diffuse or large-cell architecture
21	220 follicular lymphomas	52/220 = 24% Actuarial risk = 22% at 5 years and 31% at 10 years for all patients, and 33% at 5 years and 51% at 10 years for patients who progressed	Incidence refers to cases showing transformation to a more aggressive diffuse lymphoma

Figure 67.1 Overall survival of 74 patients with follicular low-grade NHL following histologic transformation. (Reprinted from Ref. 22)

months for patients who relapsed with a nodular pattern, as compared with 17 months for those who relapsed with a diffuse pattern ($P = 0.068$).¹⁵ The median survival among patients from Vanderbilt University with indolent lymphoma was 2.5 months for those who exhibited histologic transformation, as compared with 37.5 months for those who retained their initial histologic pattern ($P < 0.001$).⁷ Median survival following histologic progression was 4 months in a series of follicular low-grade lymphomas from Denmark,⁶ and 12 months in a series from Iowa.²⁶ The median survival following histologic transformation was approximately 1 year in a series from London.²⁰ In another series of 74 patients from Stanford, the median survival was 22 months following transformation (Figure 67.1).²² Limited stage at the time of transformation ($P = 0.01$), absence of prior therapy ($P = 0.01$), and response to therapy ($P = 0.005$) were associated with longer survival after transformation. These results have been used to support the use of a “watch-and-wait” approach for the initial management of patients with low-grade follicular lymphomas. Finally, a French series examined outcomes of patients with follicular lymphomas who were treated on phase III trials.²⁷ The 5-year survival was estimated to be 15% for patients with subsequent transformation, as compared to 45% for those who retained follicular architecture ($P = .00001$).

These results demonstrate that histologic transformation is frequently associated with aggressive clinical behavior and poor survival. In some series, overall survival from the time of diagnosis was shorter in patients who subsequently demonstrated histologic progression.^{5,7} Nevertheless, transformation may be a late event in the course of disease, and survival from the time of diagnosis may not be different when patients with unchanged histology are compared to patients who have undergone transformation.^{15,16}

ETIOLOGY OF TRANSFORMATION

DEMONSTRATION OF CLONALITY

Some “transformed” lymphomas and their preceding follicular lymphomas may be clonally unrelated.^{28,29} However, evidence suggests that most transformed follicular lymphomas are derived from the same clone as the antecedent follicular lymphoma. This was shown in studies that demonstrated identical serum monoclonal proteins from a patient before and after transformation, and by studies showing cytoplasmic immunoperoxidase staining for the same protein in biopsies performed before and after transformation.³⁰ Investigators from Stanford examined paired lymphoma biopsies obtained before and after transformation from follicular to diffuse histology.³¹ They were able to demonstrate a common clonal origin on the basis of anti-idiotypic monoclonal antibody cross-reactivity, concordant immunoglobulin and *bcl-2* gene rearrangements, and sequencing of light-chain variable genes. The same group also identified identical mutations of the *bcl-6* gene in paired lymphomas that were biopsied before and after transformation.³² Analyses of immunoglobulin V_HDJ_H gene sequences³³ and *bcl-2* rearrangements at other institutions^{28,34,35} have also demonstrated that diffuse large B-cell lymphomas may be clonally related to antecedent follicular lymphomas.³³

CLL and the subsequent diffuse large B-cell lymphoma are clonally related in many situations,³⁶⁻³⁹ although the two clones may be genetically unrelated in as many as 50% of cases.^{36,40,41}

GENETIC ABNORMALITIES

Numerous molecular events have been associated with the process of transformation. Several groups have found mutations in the p53 tumor suppressor gene in transformed lymphomas.^{42,43} Occasionally, p53 mutations can be identified in patients with follicular lymphoma prior to transformation, and this finding in nontransformed follicular lymphoma may be associated with a poor prognosis.⁴² Mutations in the *bcl-6* gene have also been associated with progression from follicular lymphoma to diffuse large B-cell lymphoma. The Stanford group identified *bcl-6* translocations in 39% of follicular lymphomas that were known to have subsequently transformed, as compared with 14.1% in biopsies from patients that were not known to have transformed ($P = 0.0048$).⁴⁴ Rearrangements of *myc* have also been identified in transformed lymphomas and the presence of these rearrangements in follicular lymphomas may be associated with a poor prognosis and greater risk of transformation.³⁴ cDNA microarray analysis of transformed lymphomas has demonstrated patterns of increased expression of *c-myc* and associated targets in some specimens and decreased expression of these genes in others.⁴⁵ In addition, expression

patterns of transformed lymphomas were similar to follicular lymphomas and markedly different than *de novo* diffuse large B-cell lymphomas. Loss or inactivation of the p15 and p16 tumor suppressor genes has also been associated with aggressive tumors and the progression of follicular lymphomas.^{46,47}

Various cytogenetic abnormalities have been identified in transformed lymphomas, although the t(14;18) translocation is generally retained. Breaks involving bands 6q23-26 and 17p were associated with a significantly shorter time to transformation for follicular lymphomas ($P < 0.001$).⁴⁸

Various genetic abnormalities associated with histologic transformation of follicular lymphomas are displayed in Table 67.2. These results suggest that histologic transformation of follicular lymphomas frequently involves acquired genetic lesions, although no common pathways have been identified.⁶²

TREATMENT OF TRANSFORMED FOLLICULAR LYMPHOMAS

CONVENTIONAL THERAPY

Prospective treatment trials have not been performed for patients with transformed lymphomas. Most series are small and contain heterogeneous patient populations. Details of treatment are limited in many reports, and other series include patients treated in a variety of ways and patients treated in a manner that might be considered suboptimal today.

In a series from the National Cancer Institute, 50% of patients with progression from nodular to diffuse histology attained complete remissions with combination chemotherapy regimens.⁵ The median duration of remission was 11 months, although one patient remained alive and in remission at 83 months follow-

ing treatment. In a series from Denmark, histologic progression from follicular low-grade histology to an intermediate- or high-grade histology was associated with a response rate below 20%.⁶ In a French series, transformation was defined as progression from follicular histology to a more aggressive diffuse lymphoma.²¹ The response rate was 63% in the 30 patients who were treated with CHOP-like regimens. Some of these patients were subsequently treated with high-dose therapy followed by autologous hematopoietic stem cell transplantation. Another group of 22 patients was elderly or had a poor performance status and was mostly treated with regimens that did not contain anthracyclines. The actuarial 3-year survival was 32% for patients who received anthracycline-based therapy as compared with 5% for the others ($P = 0.003$). The 13 patients with transformed lymphomas in the Vanderbilt series were treated with radiation or a variety of chemotherapy regimens that did not always include anthracyclines.⁷ The median survival following histologic transformation was 2.5 months, and the outcome did not appear to be influenced by the choice of therapy. In another series from Iowa, there were no complete remissions among eight patients with transformed lymphomas who received anthracycline-based therapy, and only short remissions in a patient who received radiation therapy and one who received COPP (cyclophosphamide, vincristine, procarbazine, and prednisone).²⁶ In the London series of 18 patients who transformed from follicular to large-cell histology, 6 (33%) attained remissions using combination chemotherapy regimens appropriate for high-grade lymphoma.²⁰ Only two patients remained free of disease at 15 months and 5 years, respectively.

The Stanford group has reported the largest series of treatment results for transformed lymphomas.²² Transformation was defined as progression from follicular low-grade histology to diffuse intermediate- or high-grade histology. Patients were mostly treated with doxorubicin-containing combination chemotherapy ($n = 43$), radiation ($n = 12$), or other chemotherapy combinations ($n = 16$). The complete remission rates were 40, 70, and 20%, respectively, although the majority of the patients receiving radiation therapy had limited-stage disease. Attainment of complete remission was significantly more likely in patients with limited disease at transformation ($p < 0.01$). The median disease-free survival was 45 months for complete responders, with a median survival of 81 months after transformation.

The MD Anderson Cancer Center has included patients with transformed lymphoma in trials of salvage therapy for NHL. The complete response rate was 50% and the partial response rate was 17% following treatment with ESHAP (etoposide, methylprednisolone, cytarabine, and cisplatin).⁶³ Thirty percent of these patients were projected to be alive at 3 years. A 36% complete response rate was noted when patients with

transformed lymphoma were treated with ESHAP alternating with MINE (mesna, ifosfamide, mitoxantrone, and etoposide).⁶⁴

These results confirm the poor prognosis of patients with follicular lymphoma following histologic transformation. Nevertheless, some patients are able to attain a complete response following treatment with conventional combination chemotherapy, and occasional long-term remissions have been reported. Conventional chemotherapy may also be used to achieve remission prior to the use of high-dose therapy (see below). Radiation should be considered alone or in combination with conventional therapy, especially for patients with localized disease.

MONOCLONAL ANTIBODIES

The introduction of monoclonal antibodies has revolutionized the treatment of NHL. Rituximab, a chimeric anti-CD20 antibody, was the first monoclonal antibody approved for cancer treatment. Approximately 50% of patients with relapsed low-grade and follicular lymphomas will respond to treatment with this agent.⁶⁵ Rituximab also has substantial activity against aggressive lymphomas,⁶⁶ although it has not been extensively evaluated for transformed lymphomas. In a phase III trial comparing rituximab with ⁹⁰Y ibritumomab tiuxetan (see below), three of four patients with transformed lymphomas responded to rituximab, alone.⁶⁷

Rituximab has been combined with EPOCH (etoposide, prednisone, vincristine, cyclophosphamide, and doxorubicin) to treat 18 patients with transformed B-cell lymphomas in a trial from Switzerland.⁶⁸ The median event-free survival was 12.4 months.

More recently two anti-CD20 radiolabeled antibodies, ⁹⁰Y ibritumomab tiuxetan and ¹³¹I tositumomab, have been specifically approved for the treatment of transformed B-cell NHL. The overall response rate was 56% in nine patients with transformed B-cell lymphomas who were treated with ⁹⁰Y ibritumomab tiuxetan.⁶⁷ At the University of Michigan, the complete response rate was 50% and the overall response rate was 79% for patients with transformed lymphomas following treatment with ¹³¹I tositumomab.⁶⁹ The median progression-free survival was 13.9 months for responders. The outcome was similar for patients with low-grade lymphoma and significantly better than the outcome in patients with de novo aggressive lymphomas who received this treatment (Figure 67.2). The response rate was 39% for 23 patients with transformed lymphomas included in the pivotal trial of ¹³¹I tositumomab.⁷⁰ Patients had received a median of four prior chemotherapy regimens and 48% had bulky disease. The response rate was higher in patients who had transformed to follicular large-cell histology as compared to patients with diffuse histology after transformation. The multicenter trial of ¹³¹I tositumomab included 10 patients with transformed B-cell

Figure 67.2 Progression-free survival of 59 patients with relapsed or refractory NHL following treatment with ¹³¹I tositumomab. (Reprinted from Ref. 69)

lymphoma.⁷¹ The complete response rate was 50%, and the overall response rate was 60%. The median response duration was 12.1 months, and these results were similar to other patients with low-grade lymphomas.

The Seattle group used a higher dose of ¹³¹I tositumomab followed by autologous stem cell transplantation to treat patients with transformed lymphomas, although individual patient results were not reported.⁷²

TRANSPLANTATION

Several reports of autologous hematopoietic stem cell transplantation for NHL have included patients with transformed lymphomas and have shown that prolonged remissions can be attained,^{27,73-75} although these reports have not always provided specific details on patients with transformed histology.

A retrospective study from the University of Nebraska compared outcomes following autologous stem cell transplantation of 10 patients with transformed lymphomas and 8 patients with follicular lymphomas.⁷⁶ All patients with nontransformed lymphomas were alive between 246 and 1804 days following transplantation, while most of the patients with transformed lymphomas had early transplant-related deaths and only one was alive 99 days after transplant ($P = 0.002$). A retrospective analysis from France also examined outcomes of patients with follicular lymphoma following autologous stem cell transplantation.⁷⁷ Overall survival of the 16 patients transplanted after histologic transformation was similar to that of 44 patients with follicular lymphoma; however, failure-free survival was significantly worse for patients

Table 67.3 Autologous hematopoietic stem cell transplantation for transformed non-Hodgkin's lymphoma

Reference	No. of patients	Early mortality	Results	Comments
84	19	1 (5%)	Median OS 4.4 years 10 (53%) CCR	
85	27	0 (0%)	5-year OS 58% 5-year DFS 46%	6 patients had CLL/SL
86	35	7 (20%)	Median OS 33 months 5-year OS 37%	Includes patients with intermediate-grade lymphoma who relapsed with follicular lymphoma and patients with composite lymphoma
83	18	0 (0%)	4-year OS 61% 4-year EFS 38%	Includes 1 patient with CLL/SL
87	50	4 (8%)	5-year OS 51% 5-year PFS 30%	

OS, overall survival; CCR, continuous complete remission; DFS, disease-free survival; CLL/SL, chronic lymphocytic leukemia/small lymphocytic lymphoma; EFS, event-free survival; PFS, progression-free survival.

with transformed lymphomas ($P = 0.04$). A small series from the European Bone Marrow Transplant Group also noted that results of autologous stem cell transplantation were poor for patients with transformed lymphomas.⁷⁸ A retrospective analysis from Dana-Farber Cancer Institute compared outcomes of autologous stem cell transplantation in 51 patients with low-grade lymphomas and 18 patients following transformation to lymphomas with diffuse architecture.⁷⁹ The 4-year disease-free survival was 23% for patients with transformed lymphomas, as compared with 47% for patients with low-grade histology, although this difference was not statistically significant ($P = 0.2$).

Other analyses have demonstrated somewhat better results of transplantation for patients with transformed lymphomas. A series from Boston found no differences in time to treatment failure when autologous transplants in 10 patients with transformed lymphomas were compared to 68 patients with intermediate- and high-grade histology who were treated with autologous transplantation.⁸⁰ A series from Sweden compared results of autologous bone marrow and stem cell transplantation of 11 patients with follicular lymphoma and 11 with transformed lymphomas.⁸¹ No significant differences in disease-free survival were noted. The Stanford group reported that the actuarial 4-year disease-free survival and 4-year overall survival were 49 and 50%, respectively, in 17 patients with transformed lymphomas who had undergone autologous bone marrow or stem cell transplantation.⁸² These results were similar to patients with follicular low-grade lymphomas and follicular large-cell lymphomas who had been transplanted. The group from Cleveland Clinic also examined results of autologous peripheral blood stem cell transplantation for patients with lymphomas that had transformed to diffuse large-cell histology.⁸³ The actuarial 4-year overall survival and event-free survival rates were 61 and 38%,

respectively (Table 67.3). These values were 53 and 37%, respectively, in a group of transplanted patients with de novo diffuse large-cell histology ($P = \text{ns}$). An analysis from the European Bone Marrow Transplant Registry showed that actuarial 5-year overall survival and progression-free survival rates were 51 and 30%, respectively, in 50 patients who received autologous hematopoietic stem cell transplants for follicular lymphomas (Table 67.3; Figure 67.3).⁸⁷ No significant differences in overall survival or progression-free survival were identified when these values were compared to transplanted patients with low-grade ($P = 0.939$ and 0.673 , respectively) or intermediate/high-grade histology ($P = 0.438$ and $.533$, respectively).

Investigators from Seattle have piloted a novel regimen combining ¹³¹I tositumomab (see above) with high-dose etoposide and cyclophosphamide, followed

Figure 67.3 Overall survival (OS) and progression-free survival (PFS) of 50 patients with transformed follicular low-grade NHL following high-dose therapy and autologous hematopoietic stem cell transplantation. (Reprinted from Ref. 87)

by autologous stem cell transplantation.⁸⁸ Patients with transformed lymphomas have been included in this trial.

Results of autologous hematopoietic stem cell transplantation in series examining transformed lymphomas are displayed in Table 67.3. These results show that transplantation can be accomplished with low transplant-related mortality and that prolonged disease-free survival can be observed. Nevertheless, it is not clear in some series that there is a plateau in progression-free survival following transplantation, and it is unknown whether patients are cured.^{77,79,83-87} In addition, myelodysplastic syndromes, acute myelogenous leukemia, and second malignancies have been reported following autologous transplantation for transformed lymphomas.⁸⁵⁻⁸⁷ Of interest is the fact that some patients have relapsed with follicular histology following autologous stem cell transplantation.^{77,84,87}

Prognostic factors following autologous transplantation for transformed lymphomas have not been well characterized. The group from Dana-Farber Cancer Institute noted that 5-year overall survival following transplant was estimated at 80% for patients who underwent histologic transformation within 18 months of diagnosis, as compared with 31% for those with late transformation ($P = 0.04$).⁸⁵ The European analysis showed inferior progression-free survival following transplant for transformed lymphoma in patients with an elevated LDH level ($P = 0.0031$) and those with chemotherapy-resistant disease ($P = 0.0478$).⁸⁷ Age above 60 years has also been associated with inferior transplant outcome for transformed lymphoma.⁸⁶

Allogeneic transplantation

There is very little published experience with allogeneic stem cell transplantation for transformed lymphomas, although it is possible that patients might benefit from this approach, because of a graft-versus-lymphoma effect or because this approach eliminates the possibility of infusing malignant cells with the autograft. Rare patients with transformed lymphomas have been included in larger series of allogeneic transplantation for lymphoma, although it is impossible to identify results in these specific patients.^{89,90} A French cooperative group analysis of allogeneic transplants for aggressive NHL included 14 patients who had transformed low-grade lymphomas or CLL out of a total of 73 cases.⁹¹ The only patient who relapsed more than 15 months after transplant had a transformed low-grade lymphoma and relapsed with low-grade histology 7 years after transplant. A report from the University of Chicago described one patient with transformed lymphoma who was alive and well 70 months following allogeneic transplantation.⁹² A report of reduced-intensity allogeneic transplantation from MD Anderson Cancer Center described two

patients with transformed low-grade lymphomas who died of transplant-related complications.⁹³

TREATMENT OF RICHTER'S SYNDROME

Treatment results of Richter's syndrome are largely anecdotal or based on small series, and are subject to the same limitations discussed earlier. In a series from the University of Iowa, patients were primarily treated with chemotherapy regimens that did not contain anthracyclines, such as CVP (cyclophosphamide, vincristine, and prednisone).⁴ Only one patient, who was treated with radiation, attained a complete remission and survived more than 3 months. Patients with Richter's syndrome (two with Hodgkin's lymphoma) in a French series were treated with a variety of chemotherapy regimens.²⁵ The median survival was 4 months, and there was no evidence of improved outcomes with anthracycline-containing regimens. Six patients, including four with localized disease treated with additional radiation, had sustained remissions between 5 and 77 months.

Thirty-three patients with Richter's syndrome at MD Anderson Cancer Center were able to receive treatment.³ All except one were treated with systemic chemotherapy, nine received additional radiation, and one received radiation, alone. The overall response rate was 41%, and the majority of patients in this group received doxorubicin-based or fludarabine-based therapy. The overall survival was significantly better for patients who responded to therapy ($P < .001$). Four patients remained alive and in remission between 5 and 16 months. One patient relapsed with CLL more than 10 years after treatment.

The MD Anderson group has also reported results of the hyper-CVXD (cyclophosphamide, vincristine, liposomal daunorubicin, and dexamethasone) regimen in a series of 29 patients with Richter's syndrome.⁹⁴ Complete responses were obtained in 11 (38%) patients, and six had ongoing remissions between 6 and 19 months from starting therapy. The median survival was 10 months for all patients. The median survival was 19 months for those who attained a complete remission and 3 months for others ($P = 0.0008$). A regimen of fludarabine, cytarabine, cyclophosphamide, cisplatin, and granulocyte-monocyte colony-stimulating factor had little activity and significant toxicity in a cohort of patients with Richter's syndrome.⁹⁵

Diffuse large B-cell lymphomas have also arisen in patients with lymphoplasmacytic lymphoma/Waldenström macroglobulinemia. In one series of 12 such patients, 73% died within 10 months of transformation.⁹⁶ The majority were treated with aggressive anthracycline-containing regimens. Only one patient, treated with autologous stem cell transplantation, was alive and in remission.

There were five transplant-related deaths in a series of eight patients who received allogeneic bone marrow transplants for Richter's syndrome.⁹⁷ Three patients were alive and in continuous remission between 14 and 67 months after transplant. The same institution described one patient with Richter's syndrome who was alive and in remission at least 5 months following a reduced-intensity allogeneic transplant.⁹³

SUMMARY

Histologic transformation is frequently observed when patients with follicular lymphomas have disease progression. The original and transformed lymphomas are often clonally related, although they sometimes arise

from different clones. Although the literature suggests that the prognosis is poor for patients with transformed lymphomas, some patients experience long-term disease-free survival. Patients with transformed lymphomas should probably be treated with aggressive chemotherapy regimens that are used for patients with diffuse large B-cell lymphoma. Involved-field radiation therapy should also be considered for patients with localized disease. Long-term disease-free survival has also been observed following high-dose therapy and autologous hematopoietic stem cell transplantation. This approach should be considered for patients with chemotherapy-sensitive disease. There are now two radiolabeled antibodies that are specifically approved for the treatment of transformed B-cell lymphomas, and they provide another treatment option for selected patients.

Chapter 68

NEW FRONTIERS IN NON-HODGKIN'S LYMPHOMA THERAPY

Eric Winer, Sridar Pal, and Francine Foss

INTRODUCTION

A number of novel strategies have evolved for the treatment of refractory non-Hodgkin's lymphoma (NHL). Novel targeting agents that have demonstrated success in clinical trials include radiolabeled antibodies, fusion toxins, which direct cytotoxic moieties into the cell via membrane receptors, and antisense oligonucleotides, which bind to mRNA and inhibit translation of proteins in the cell. A number of agents that target specific intracellular pathways have also been developed, including bortezomib, which inhibits proteasome function, the histone deacetylase (HDAC) inhibitors, which modulate gene transcription, and gallium nitrate, which inhibits transferrin-dependent enzymatic pathways. Finally, the newer technologies have been developed to implement immunotherapeutic approaches.

MONOCLONAL ANTIBODIES

Rituximab was the first humanized monoclonal antibody to be widely used in the treatment of patients with low- and intermediate-grade B-cell NHL. Subsequently, antibodies directed against a variety of epitopes have been developed and have demonstrated clinical efficacy. Unmodified anti-CD22 antibody as well as immunotoxin and radioimmunoconjugates of this antibody have demonstrated activity in vitro and in a limited number of patients with refractory B-cell lymphoma.¹⁻³ CD30, which is expressed on a subset of T-cell lymphomas, including anaplastic large cell lymphomas and Hodgkin's disease, has been an attractive target for antibody-based therapies because its expression is limited on normal cells to activated lymphocytes and natural killer cells. SGN-30, a humanized anti-CD30 antibody, has been shown to induce growth arrest and apoptosis in Hodgkin's cell lines in vitro, and a phase II clinical trial is underway to further define its clinical efficacy.⁴ Alemtuzumab (Campath-1H) is a humanized mAb targeting CD52 and has

recently been approved in the United States for the treatment of fludarabine-refractory B-cell chronic lymphocytic leukemia. Impressive activity has also been demonstrated in T-cell prolymphocytic leukemia and mycosis fungoides.⁵ In a study of 16 patients with low- or intermediate-grade B-cell NHL who relapsed or were refractory to conventional therapy and were treated with alemtuzumab, eight (44%) achieved a clinical response, two (11%) had stable disease, and five (28%) had progressive disease. All responders had low-grade histologies.⁶ Humanized anti-CD4 antibody (HuMax) is used in clinical trials in patients with relapsed and refractory cutaneous T-cell lymphoma (CTCL) and CD4-expressing peripheral T-cell lymphomas.

FUSION TOXINS

A number of strategies have been developed to target cytotoxic proteins to tumor cells, including conjugated immunotoxins, single-chain antibody-immunotoxin conjugates, and fusion toxins. Table 68.1 summarizes in vitro and in vivo data using immunotoxins in lymphoid malignancies. The major limitation of immunotoxins, in which the toxin moiety is conjugated to a monoclonal antibody, is their ability to be internalized by the cell and translocate efficiently into the cytoplasm where they can inhibit protein synthesis. Because of their large size, conjugated immunotoxins may not be efficiently translocated into the cell and may, by nature of their epitopes, be immunogenic. Both ricin A-chain and pseudomonas exotoxin-based immunoconjugates have been developed and have demonstrated limited efficacy and significant toxicity in patients with Hodgkin's disease and NHL.⁷⁻¹¹

Denileukin diftitox is a genetically engineered fusion protein combining the enzymatically active domains of diphtheria toxin and the full-length sequence of interleukin-2 (IL-2), and targets tumor cells expressing the intermediate- and high-affinity IL-2 receptors (IL-2R).¹² Denileukin diftitox has been approved for the therapy of refractory CTCL based on

Table 68.1 Immunotoxins in lymphoma

Immunotoxin	Activity in vitro or in clinical trials	Reference
Rituximab/saporin-S6	Induced apoptosis in B-cell NHL cells in vitro, synergistic with fludarabine in vitro	Polito et al.
anti-CD19 (HD37-dgRTA) + anti-CD22 (RFB4-dgRTA)	In vitro study of combination immunotoxins demonstrated 100% survival in acute lymphocytic leukemia xenograft	Herrera et al.
anti-CD22 (RFB4-dgRTA)	Phase I study in B-cell NHL; 15 patients with refractory disease, 38% PR	Vitetta, 1991.
Ki-4.dgA anti-CD30 immunotoxin	Phase I study of 17 pts with refractory CD30 ⁺ lymphoma: 1 CR, 1 PR	Schnell et al.
anti-B4-bR	Phase II study in 16 CD19 ⁺ refractory B-cell NHL patients, no durable responses	Multani et al.
G28-5 sFv-PE40	In vitro activity in B-cell NHL, targets CD40	Francisco et al.
BL22 (RFB4(dsFv)-PE38)	In vitro efficacy, targets CD22	Barth et al.
anti-Tac(Fv)-PE38 (LMB-2)	Phase I trial in 35 patients with CD25 ⁺ lymphoma: 7 PR (1 HD, 1 CLL, 3 hairy cell, 1 CTCL, 1 ATL)	Kreitman et al.

CLL, chronic lymphocytic leukemia, CTCL, cutaneous T-cell lymphoma; NHL, non-Hodgkin's lymphoma.

an overall response rate of 30% in heavily pretreated patients.^{13,14} Toxicities include hypersensitivity related to the infusion of protein and a low-grade vascular leak syndrome seen in 23% of patients manifested by low albumin, peripheral edema, and/or hypotension. Recent studies using steroid premedication and hydration have significantly reduced the incidence and severity of these events in patients with CTCL.¹⁵

Previous studies have demonstrated IL-2R expression on a variety of B-cell non-Hodgkin's lymphomas, including both low- and intermediate-grade lymphomas.^{16,17} In a phase I study of escalating doses of denileukin diftitox ranging from 3 to 31 $\mu\text{g}/\text{kg}/\text{day} \times 5$ days for a 21-day cycle, the expression of IL-2R was determined by immunohistochemistry as an entry criteria. Of 66 B-cell NHL patients screened, 29 expressed a component of the IL-2R (p55 or CD25, or p75 or CD122).¹⁶ The overall response rate in 23 heavily pretreated NHL patients was 17%, including 2 of 9 patients with intermediate-grade NHL who had partial responses. On the basis of these data, a phase II study was initiated at MD Anderson Cancer Center to evaluate the efficacy of denileukin diftitox in relapsed/refractory B NHL.^{18,19} All low- and intermediate-grade B-cell NHL patients were eligible, and IL-2R expression was determined based on expression of CD25 on tumor cells. Denileukin diftitox was administered at 18 $\mu\text{g}/\text{kg}/\text{day}$ for 5 days every 3 weeks, for up to eight cycles. Corticosteroid premedication prior to each drug infusion was given in an attempt to reduce the incidence and severity of acute hypersensitivity. Most patients had undergone multiple prior treatments, including autologous stem cell transplants, and many

had compromised bone marrow reserve. Of 29 patients treated, there were three (CR) complete response (one follicular mixed B-cell lymphoma, one B-cell DLCL, one mantle cell lymphoma), and four (PR) partial response (one SLL, three B-cell DLCL) for an overall response rate of 24%. Another study exploring the activity of denileukin diftitox in B-cell NHL was conducted by the Eastern Cooperative Oncology Group to explore the activity in IL-2R expressing and nonexpressing low-grade B-cell NHL. Studies are underway to further explore the activity of denileukin diftitox in combination with rituximab in low- and intermediate-grade refractory B-cell NHL and B-CLL.

RADIOLABELED ANTIBODIES

Another targeting strategy for NHL has been the use of radioimmunoconjugates. Radiolabeled antibodies are capable of delivering a radiation dose to neighboring cells while minimizing doses to nonmalignant tissues. Low-dose-rate radiation continues to expose cells to radiation even after initial exposure, resulting in accumulation of cell damage leading to apoptosis in cells that may have been effectively repaired after more conventional high-dose-rate radiation.

Two radioimmunoconjugates targeting the CD20 epitope on B cells have been FDA approved for patients with B-cell NHL (Table 68.2). ¹³¹I tositumomab (Bexxar) and ⁹⁰Y-ibritumomab tiuxetan differ in the characteristics of their radioisotope. ⁹⁰Y-ibritumomab tiuxetan consists of the high-energy β emitter ⁹⁰Yttrium

Table 68.2 Radioimmunotherapy in non-Hodgkin's lymphoma

¹³¹ I tositumomab	Clinical trial and response rates	Response duration
Kaminski et al.	60 patients with LGL: 81% ORR, 20% CR	6.5 months
Zelenitz et al.	250 patients with LGL: 56% ORR, 30% CR	13.5 months
Kaminski et al.	76 patients with untreated LGL: 95% ORR, 74% CR	62% 5 year PFS6
Coleman et al.	55 patients with rituximab relapsed/refractory disease who had CR	Median not reached at 3.9 years
Y-90 Ibritumomab tiuxetan		
Witzig et al.	34 patients Phase I/II study: 82% ORR, 26% CR	12.9 months
Witzig et al.	143 patients randomized to Y-90 Ibritumomab tiuxetan vs rituximab ORR 80% for Y-90 Ibritumomab, 30% CR	11.2 months
Witzig et al.	57 patients rituximab refractory: 74% ORR, 15% CR	6.8 months

LGL: low-grade lymphoma; CR: complete response; ORR: overall response rate; PFS: progression-free survival.

and has a half-life of 28 h. Beta particles deliver high energy (2.2 MeV) within a radius of approximately 5 mm, which corresponds to 100–200 cell diameters. ¹³¹I tositumomab emits both gamma and beta particles and has a decay half-life of 8 days.^{20–22}

The pivotal trial for ¹³¹I tositumomab by Kaminski and colleagues in 2001 was a phase III nonrandomized, multicenter, single dosimetric, and therapeutic dose study in refractory/relapsed low-grade or transformed low-grade B-cell NHL.²³ The purpose of this study was to compare the efficacy of ¹³¹I tositumomab to the last qualifying chemotherapy regimen. Sixty patients, virtually all with stage III or IV disease, were enrolled. Eighty-eight percent of patients had at least two risk factors by the International Prognostic Index.²⁴ The median number of prior treatments was four, and 27% of patients had prior radiation therapy. The response rate was 65% with a median duration of 6.5 months. The highest responses were seen in patients with small tumor burden (81%), patients who had not received radiotherapy (77%), and those with nontransformed low-grade NHL (81%). The only variables significantly associated with higher rate of response in a multivariate analysis were tumor burden less than 500 g and nontransformed histology.

Adverse events included fatigue (43%), fever (30%), nausea (25%), infection (25%), chills (15%), vomiting (13%), pruritis (13%), anorexia (10%), and hypotension (10%). The hematologic nadir occurred on days 43, 46, and 34 for red cells, white cells, and platelets, and median recovery occurred at 74, 78, and 73 days, respectively. In this study, five patients developed myelodysplastic syndrome 1.2–7.5 years after treatment, but all had previously received alkylating agents.²⁵ Two patients later developed bladder cancer, but both had previously received cyclophosphamide. An elevation of Thyroid stimulating humane (TSH) was noted in five patients, but was asymptomatic in all five.

Further analysis of a combined database from five trials using ¹³¹I tositumomab reported a median response duration of 20.2 months in patients with transformed low-grade lymphoma.²⁶ The overall response rate was 56% with a median duration of response of 14.7 months. In previously untreated, advanced-stage follicular lymphoma ($n = 76$), ¹³¹I tositumomab induced a response in 95% of patients, with 74% achieving CR.²⁷ Further analysis of several studies of ¹³¹I tositumomab demonstrated “remission inversion,” a longer response to radiolabeled antibody than to the last cytotoxic therapy.²⁸ In studies of rituximab-refractory patients, the overall response rate was 68% with 30% CR.^{29,30} Retreatment with ¹³¹I tositumomab has been reported with a 56% response rate to the second dose and a median response duration of 10.7 months. In this population, the annual incidence of myelodysplastic syndrome was 4.1%.³¹ Combination studies of ¹³¹I tositumomab with other agents such as fludarabine³² are underway.

⁹⁰Y-ibritumomab tiuxetan was FDA approved in the United States at a dose of 0.4 mCi/kg, with a dose reduction to 0.3 mCi/kg in patients with low platelets (100,000–150,000/mL).²² Unlike ¹³¹I tositumomab, ⁹⁰Y-ibritumomab tiuxetan does not require individualized dosimetry. Witzig et al. reported the superiority of ⁹⁰Y-ibritumomab tiuxetan versus rituximab in 143 patients with CD20-positive relapsed or refractory low-grade, follicular, or transformed NHL who had received a median of two previous chemotherapies and half of whom were refractory to their last therapy.³³ The response rates of ⁹⁰Y-ibritumomab tiuxetan versus rituximab were 80% versus 56%, respectively ($p = 0.002$), and complete responses were seen in 30% versus 14% ($p = 0.04$), respectively. Overall response favored the follicular lymphoma subgroup with a response rate of 86%. The time to progression estimates were similar at 11.2 months in the ⁹⁰Y-ibritumomab

tiuxetan group and 10.1 months in the rituximab group.

Combined safety data from 349 patients treated on this and four other trials showed the incidence of thrombocytopenia and neutropenia to be 61% and 57%, respectively.³³ In this group of patients, 13% received granulocyte colony-stimulating factor, 8% erythropoietin, and 22% and 20%, respectively, platelet and red blood cell transfusions. ⁹⁰Y-ibritumomab tiuxetan was approved in 2002 for use in relapsed or refractory low-grade, follicular, or transformed B-cell NHL. A long-term follow-up study has reported a time to progression of 12.6 months and response duration of 11.7 months.³⁴

Other trials have further defined the use of ⁹⁰Y-ibritumomab tiuxetan in subgroups of patients. A single arm phase II study in rituximab refractory patients reported an overall response rate of 74% and complete response rate of 15%.³⁵ Patients with detectable levels of rituximab in their serum at the time of radiolabeled antibody administration had a lower response rate than those with nondetectable levels. Currently, multiple trials are evaluating the combination of ⁹⁰Y-ibritumomab tiuxetan as an in vivo purge prior to autologous stem cell transplantation. Thirty-one patients treated with ⁹⁰Y-ibritumomab tiuxetan have subsequently been successfully mobilized for stem cell transplantation with no increased toxicity.³⁶ A phase I study is evaluating sequential treatments of ⁹⁰Y-ibritumomab tiuxetan 3–6 months following initial treatment. With the use of prophylactic growth factors, retreatment with lower doses of ⁹⁰Y-ibritumomab tiuxetan in 15 patients has been safe and well tolerated.²⁰ Finally, investigators are still trying to determine the best time to give radioimmunotherapy. In a retrospective analysis, Emmanouilides et al. reported in a study of patients who received ⁹⁰Y-ibritumomab tiuxetan as second-line therapy that the response rate and duration were greater than those reported in more heavily pretreated patient populations.³⁷

ANTISENSE OLIGONUCLEOTIDE THERAPY

Antisense oligonucleotides (AS-ON) are short, single-stranded DNA molecules no longer than 25 bases which are complementary to a region of mRNA. When they attach by complementary base pairing, the messenger RNA is degraded, thus preventing downstream protein expression. In 1977, Paterson and colleagues demonstrated that gene expression could be modified by exogenous nucleic acids by use of single-stranded DNA in a cell-free system.³⁸ The following year, Zamecnik and Stephenson were able to reproduce the same results using the first synthetic oligonucleotide.³⁹ For several years, the field remained static due to concerns about reproducibility in more complex eukaryotic cells and the lack of acceptable targets. In 1983,

these concerns were eliminated when Simons et al. showed that antisense RNA was a naturally occurring process in eukaryotic cells and is used for regulating gene expression.⁴⁰ In the following decade, the human genome initiative has accelerated our understanding of the human genome and discovered multiple possible targets.

AS-ON exert their effect when these short sequences of single-stranded deoxyribonucleotides hybridize to selected mRNA sequences forming a heteroduplex of the mRNA and DNA. This complex engages the endogenous RNaseH cleaving the mRNA moiety, destroying the message, and releasing an intact AS-ON.⁴¹ The molecule is then free to hybridize to another mRNA sequence. The resulting decrease in the target mRNA pool leads to a reduction in the specific encoded protein. In addition, the heteroduplex cannot appropriately dock with the normal ribosomal machinery, thereby inhibiting translation into a functional protein.⁴²

To date, the most widely studied AS-ONs are targeted against Bcl-2. Bcl-2 is an antiapoptotic protein that inhibits the intrinsic apoptosis pathway. The intrinsic pathway leads to cell death by releasing caspase activating factors, such as cytochrome c, into the cytosol from the mitochondria.⁴³ Cytochrome c complexes with and activates apoptotic protease activating factor (APAF-1) beginning the cascade of proapoptosis proteins. The Bcl-2 protein works in a manner as yet incompletely understood to stabilize the mitochondrial membrane such that cytochrome c is not released even when stimuli are present. Elevated levels are not only associated with tumor cell resistance to normal apoptotic stimuli, but also to chemotherapeutic-induced apoptosis, suggesting a role in drug resistance.^{43,44} Overexpression of Bcl-2 has been associated with a poor prognosis in patients with low-grade NHL.^{44,45} The t(14;18) chromosomal translocation places the *Bcl-2* proto-oncogene under the regulation of the immunoglobulin heavy chain (IgH) E μ enhancer, resulting in dysregulated expression of the Bcl-2 protein.⁴⁶

Oblimersen sodium, or G3139 (Genta Inc.), is the first AS-ON molecule to be widely tested in patients. It is a fully phosphorothioated 18-mer AS-ON complementary to the first six codons of the open reading frame (ORF) of the Bcl-2 mRNA sequence. Oblimersen was identified as the most biologically active Bcl-2 antisense sequence from among a series of 40 AS-ONs designed.⁴⁷ This compound targeting positions 1–18 of the ORF reduced Bcl-2 mRNA expression to near the lower limit of detection within cancer cells.⁴⁸ Preclinical studies concerning the role of Bcl-2 in tumor cell lines and animal xenograft models have demonstrated. Oblimersen is biologically active, both as a single agent and in combination with standard chemotherapeutic agents.⁴⁸ Studies have demonstrated that AS-ON specifically downregulates Bcl-2 protein and induces apoptosis in

lymphoma cell lines. Separate work by Klasa and Waters has shown that human lymphoma xenografts treated with oblimersen resulted in prolonged median survival and cured some animals.^{49,50} When oblimersen was combined with other agents, such as cyclophosphamide or rituximab, the mice survived longer. These promising results lead to several clinical trials.

Two phase I trials were conducted to evaluate the safety and activity of oblimersen as a single agent in patients with NHL.^{51,52} The larger included 21 patients with Bcl-2-positive relapsed NHL who received a 14-day subcutaneous infusion.⁵² The median age was 54 years, nine had follicular NHL, eight had small lymphocytic NHL, three had large cell lymphoma, and one had mantle cell lymphoma. All patients had received multiple chemotherapy regimens and four patients had received high-dose chemotherapy and autologous stem cell transplantation. Oblimersen was delivered by a continuous subcutaneous infusion for 14 days at doses of 4.6–195.8 mg/m²/day. All patients experienced local skin inflammation at the sites of subcutaneous infusion. Dose limiting toxicities were observed at doses greater than 147.2 mg/m²/day and consisted of thrombocytopenia, fevers, and hypotension. Non-dose-limiting toxicities included hyperglycemia during the infusion, fatigue, and transient increases in liver enzymes, which subsequently normalized.⁵³ Three patients responded (one CR, two minor responses). The median overall survival for all patients was 13.4 months. The one patient in CR remained disease free at 36 months after treatment. Among the responding patients or those with stable disease, the median progression-free survival was 3.6 months. Ten of 18 patients had a significant reduction in Bcl-2 protein levels measured in peripheral blood mononuclear cells, bone marrow, in lymph node tissue. Based on this study, a dose of 110.4 mg/m²/day was recommended for further evaluation. Currently, a phase II study is underway at Royal Marsden Hospital using this dose in patients with relapsed NHL.

More recent studies have explored the use of oblimersen sodium in combination with other chemotherapeutic regimens in hopes of enhancing treatment-induced apoptosis when Bcl-2 is suppressed. In an interim analysis, a small cohort of ten chemotherapy naive patients have been treated with oblimersen and R-CHOP after failing to initially respond to six cycles of oblimersen.⁵⁴ Of these patients, two had a CR and four had a PR. The combination of these drugs did not appear to increase the toxicity of R-CHOP. Another study has combined oblimersen with rituximab in relapsed NHL. To date, 4 of 11 evaluable patients (36%) responded to the combination therapy.¹⁸ Single-agent use of oblimersen patients with chronic lymphocytic leukemia has demonstrated activity, but a unique toxicity emerged.⁵⁵ Patients developed severe hypotension at

doses well tolerated in other disease indications, and it is believed that the release of IL-8 at the time of the infusion may be responsible.⁵⁶ Additional studies are underway to further explore the activity of oblimersen in NHL and CLL.

GALLIUM NITRATE

Gallium Nitrate is one of the Group IIIa “near-metal” salts originally evaluated for antineoplastic activity by researchers at the National Cancer Institute during a full screening of all elements of the periodic table. When initially examined by Hart and colleagues, gallium was found to be the most active of the Group IIIa elements, inhibiting greater than 90% tumor growth in six of eight subcutaneous solid tumors tested in rodents, but less effect on leukemia.^{57,58} Later, phase I and phase II studies demonstrated the adverse effect of hypocalcemia, which led to FDA approval in the United States for the use of gallium nitrate for cancer-related hypercalcemia. Gallium has further been tested with encouraging results in patients with lymphoma, multiple myeloma,⁵⁹ uroepithelial cancer,⁶⁰ and ovarian cancer.⁶¹ The kinetics of gallium were initially established by Hall and colleagues in 1971.⁶² The initial half-life was 1 h, volume of distribution approximated total body water, and approximately 94% was excreted in the urine in the first 24 h.

A number of mechanisms have been proposed for the antineoplastic activity of gallium, including cellular deprivation of ferric iron by transferrin-dependent inhibition, inhibition of ribonucleotide reductase, induction of apoptosis, and interference with protein tyrosine phosphatases. Gallium binds to transferrin, although at lower affinity than iron, forming a Ga-Tf complex. It is well established that lymphoma cells express an increased number of transferrin receptors.⁶³ By absorbing Ga³⁺ instead of Fe³⁺, the cell up-regulates transferrin receptors, and therefore permits more incorporation of gallium into the cell. This inevitably starves the cell of iron, which may lead to cell death. There is also evidence that the Ga-Tf complex inhibits the intracellular release of iron, further leading to the iron deprivation.⁶⁴ This intracellular inhibition was found *in vitro* to be reversible by transferrin-iron complex, iron salts, or hemin.

A second mechanism of gallium is its interaction with ribonucleotide reductase. Chitambar et al.⁶⁵ demonstrated in L1201 leukemia cells that although inhibition of iron uptake indirectly inhibits the ribonucleotide reductase M2 subunit, gallium had a direct effect on the enzyme as well by inhibition of cytosine diphosphate (CDP) or (ADP). Further studies showed this interaction between gallium and ribonucleotide reductase was synergistic with hydroxyurea, a drug that also interacts with the M2 subunit of ribonucleotide reductase.⁶⁶

Initial studies with gallium nitrate in lymphoma involved bolus administration at a dose of 700 mg/m² every 2 weeks.^{67,68} The response rate was low (18%) and the toxicities included gastrointestinal toxicity, reversible renal insufficiency, and anemia. To decrease renal toxicity, Warrell et al. administered gallium nitrate by continuous 24-h i.v. infusion for 7 days every 3–5 weeks at doses of 200–400 mg/m² (Ref. 69). The maximum tolerated dose, defined by renal insufficiency, was 400 mg/m²/day. In the phase II study,⁶⁹ 47 patients who had previously failed conventional chemotherapy and who had bidimensionally measurable disease were evaluated. The patient population had a median of three prior therapies and many had extranodal involvement. The overall response rate was 34% (10% for Hodgkin's lymphoma and 43% for NHL patients), with two complete responses. The median duration of response was 2.5 months.

A further trial evaluated mitoguazone 600 mg/m² i.v. on days 1 and 10, etoposide 100–125 mg/m² i.v. on days 2–4, and continuous i.v. gallium nitrate on days 1–7, given every 3–4 weeks.⁷⁰ The patient population ranged from 19–77 years, with a median of two prior therapies and all had stage III or IV disease. The overall response rate was 52% but was higher (69%) for patients with diffuse large cell lymphoma. The toxicity of this regimen, however, was significant. Eighteen patients (42%) developed neutropenic fevers and three died. Other toxicities included mucositis (47%), keratitis and conjunctivitis (26%), diarrhea (21%), renal toxicity (16%), and optic neuritis (12%), which caused transient blindness in three of the five patients affected.

A third combination regimen with gallium was based on the *in vitro* studies demonstrating synergy between gallium and hydroxyurea.⁷¹ Chitambar and colleagues evaluated 14 patients with stage III or IV low- or intermediate-grade, refractory lymphoma. The age range was 53–80 years, with a median of three treatments and a median of six previous agents. Patients received doses of 200, 250, 300, or 350 mg/m² i.v. continuous infusion gallium for 7 days with either 500 mg or 1000 mg hydroxyurea concomitantly. Six of the 14 patients (43%) had a response, and the median response duration was 7 weeks. Further studies are underway to define the activity of gallium nitrate in patients with lymphoma.

PROTEOSOME INHIBITORS

Bortezomib is a dipeptidyl boronic acid proteasome inhibitor that effectively and specifically inhibits proteasome activity. The proteasome controls the stability of numerous proteins that regulate progression through the cell cycle and apoptosis, such as cyclins, cyclin-dependent kinases, tumor suppressors, and the nuclear factor- κ B.⁷² By altering the stability or activity of these proteins, proteasome inhibitors sensitize

malignant cells to apoptosis. In preclinical studies, bortezomib and other proteasome inhibitors have shown activity against a variety of B-cell malignancies, including multiple myeloma, diffuse large B-cell lymphoma, mantle cell lymphoma, and Hodgkin's lymphoma.^{73,74} Based on these findings, phase I clinical trials were conducted with bortezomib in various solid and hematologic malignancies. Phase II trials have been initiated for refractory chronic lymphocytic leukemia and non-Hodgkin's lymphoma.⁷⁵

HISTONE DEACETYLASE INHIBITORS

Histone deacetylase inhibitors are a new class of chemotherapeutic agents that induce growth arrest and apoptosis of neoplastic cells by binding to HDACs and modulating gene expression.

Depsipeptide, FR901228, is an HDAC inhibitor that has demonstrated potent *in vitro* and *in vivo* cytotoxic activity against murine and human tumor cell lines. In a phase I trial of depsipeptide conducted at the National Cancer Institute, three patients with CTCL had a partial response, and one patient with peripheral T-cell lymphoma, unspecified, had a complete response.⁷⁶ Another HDAC inhibitor, suberoylanilide hydroxamic acid (SAHA), has also demonstrated activity in patients with T-cell lymphoma. When administered intravenously in patients with advanced cancer, the maximal-tolerated dose of SAHA was 300 mg/m²/day \times 5 days for 3 weeks. An accumulation of acetylated histones in peripheral blood mononuclear cells and biopsied tumor tissue was demonstrated up to 4 h postinfusion. SAHA demonstrated clinical activity in patients with CTCL, and phase II clinical trials are being pursued. The activity of the HDAC inhibitors in B-cell NHL is currently under investigation.

TUMOR VACCINES

Tumor vaccines are an active immunotherapy in which the host is induced to generate an immune response against autologous tumor cells. The different types of vaccines are quite variable and include those directed at known tumor-specific antigens, such as the idotype vaccines and modified tumor cellular vaccines that attempt to enhance immunogenicity by introducing granulocyte macrophage colony-stimulating factor or other ligands, which improve or induce tumor antigen presentation into tumor cells. In addition, the use of primed antigen presenting cells, such as dendritic cells, to improve the immune response to the desired tumor antigens is also being explored.

B-cell lymphomas are clonal disorders with all tumor cells expressing the same tumor-specific immunoglobulin, the unique variable regions of which are termed an idotype (Id) that can serve as a

target for immunotherapy. The first clinical trial of idiotype vaccines in patients with follicular lymphoma was conducted by Dr. Levy's group at Stanford.^{77,78} Thirty-two patients with follicular lymphoma in first remission were treated with autologous purified Id protein chemically linked to keyhole limpet (KLH) as an immunologic adjuvant. An anti-Id humoral immune response to the vaccine developed in 14 patients. Another approach has been to use antigen-loaded dendritic cells that have been harvested from the patient and primed with the purified Id protein. Timmerman et al. treated 35 follicular lymphoma patients, 25 of whom were in first remission following cytoreductive chemotherapy.^{79,80} Out of the 25 patients treated in first remission, 23 demonstrated a T-cell or humoral anti-Id response to the dendritic cell vaccine. At a median follow-up of 43 months, 70% remain progression free. Response did not correlate with T-cell

response but favored those who mounted a humoral response; the difference however was not statistically significant. These data have formed the basis for two ongoing large randomized trials in patients with follicular lymphoma in first remission treated with a similar Id-KLH-pulsed dendritic cell vaccine.

Additional studies are underway to explore the use of anti-Id vaccines in patients who have been cytoreduced with chemotherapy. These studies require tumor biopsies for generation of the anti-Id vaccine, thus limiting accrual to patients with readily accessible tumor tissue. New advances in amplification and cloning of Id proteins using mammalian cells grown in tissue culture, recombinant bacteria, tobacco mosaic virus as a vector for engineering protein production in tobacco plants, naked DNA, and recombinant viruses are underway and may facilitate the availability of these therapies for an increased number of patients.

HODGKIN'S DISEASE

Chapter **69**

HODGKIN'S LYMPHOMA: EPIDEMIOLOGY AND RISK FACTORS

Brian J. Bolwell

HISTORY

The first description of Hodgkin's lymphoma (HL) occurred when Thomas Hodgkin described the clinical history and postmortem findings of seven patients who developed a massive enlargement of lymph nodes and spleen.¹ Hodgkin was not formally credited with this discovery, however, until 1865 when Sir Samuel Wilkes published a paper entitled "Cases of enlargement of lymph glands and spleen (or Hodgkin's lymphoma), with remarks."² Drs Carl Sternberg and Dorothy Reed are credited with the first definitive microscopic descriptions of HL.^{3,4}

DESCRIPTIVE EPIDEMIOLOGY

HL is an uncommon cancer, with approximately 8000 new cases diagnosed in the United States annually.⁵ Several large epidemiologic reports have noted that males have a slightly higher incidence of HL than do females; that whites are at higher risk than are blacks; and that HL seems to be more common in patients of higher socioeconomic class than in those of lower socioeconomic class.⁶⁻¹¹

HL is associated with a bimodal age-specific incidence distribution. The first peak occurs in early

adulthood, beginning at ages 10–14, peaking at ages 20–24, and decreasing at age 40–44. The second peak begins at age 50 and increases over time. Forty-one percent of cases are diagnosed in patients aged 20–34.⁶

Nodular sclerosing (NS) HL accounts for the majority of histologic subtypes of HL associated with the early-age incidence peak. NS HL has an essentially unimodal age-specific incidence, with a peak in young adults aged 20–24. The age-specific incidence rate for NS HL falls off by age 40–44, then remains relatively constant between the ages 45 and 64. Mixed cellularity HL has a unimodal age distribution, its incidence increasing slowly with age. By the age of 50, mixed cellularity has been reported to be the most common histologic subtype of HL.⁶ Lymphocyte-depleted HL is rare in younger patients, and progressively increases with age.

HL is more common in first-degree relatives.¹²⁻¹⁶ Some data suggest that siblings have a two- to fivefold increased risk of developing HL; same sex siblings may have up to a ninefold risk.¹⁶ When HL occurs in families, it is more likely to involve males. Some early reports suggested that HL may be contagious, particularly by airborne transmission, although subsequent studies conclusively refuted this possibility.¹⁷⁻¹⁹ Certain HLA antigens, particularly HLA-DP, have been associated with an increased incidence of HL and with clinical outcome.²⁰⁻²²

HODGKIN'S LYMPHOMA AND VIRUSES

THE POSSIBLE RELATIONSHIP OF EPSTEIN-BARR VIRUS TO HODGKIN'S LYMPHOMA

A Danish population-based study published in 1974 described over 17,000 people with a history of a positive Epstein-Barr (EBV) test, to determine if these patients were at risk for the development of subsequent malignancies. A significantly higher-than-expected incidence of HL in this patient population was discovered.²³

Since this observation, many investigators have employed increasingly sophisticated techniques attempting to determine not just a link but also a causal association between EBV and the development of HL. Between 19 and 40% of diagnosed cases of HL are generally reported to have detectable EBV viral genomes in Reed-Sternberg cells.²⁴ Other investigators have noted the following: pediatric cases of HL seem to have a higher proportion of EBV-associated HL than do those of adults; there is a higher incidence of mixed cellularity histologic subtype associated with EBV than of other HL histologic subtypes; and the association of EBV in HL may be stronger in less developed countries and in populations with lower socioeconomic status.²⁵⁻³⁰

A recent update of a vast population-based registry study from Denmark and Sweden involving over 38,000 infectious mononucleosis patients confirmed that only HL and skin cancers occurred in statistically significant increased numbers; no other cancer was associated with infectious mononucleosis/EBV.³¹ The conclusion was that the increased risk of HL appears to be a specific phenomenon.

However, many questions remain. The most obvious question is why are some cases of HL EBV positive and other cases EBV negative? Additionally, whether or not the presence of EBV viral genome Reed-Sternberg cells is a proof of causality is a very open question; most of the US population has been exposed to EBV, and one recent study found that the vast majority of small EBV-positive CD30⁻ cells carried somatically mutated V-region genes, indicating that in lymph nodes of patients with HL, as in the peripheral blood of healthy individuals, EBV persists in memory B cells.³² One might argue that EBV-negative HL is associated with other viruses; however, there is no significant evidence that this is the case.³³ Another theory suggests that EBV may be involved in all HL cases but may be undetectable only in some; EBV might infect the cell, transform it, and then it is eliminated (the hit-and-run theory), though this theory has been difficult to substantiate.

A large Danish and Swedish registry study comparing EBV-positive and EBV-negative HL has recently been published.³⁴ Over 17,000 patients with serologic evidence of EBV infection were compared to a cohort of over 24,000 individuals without known EBV infection. Tumor specimens from patients developing HL were tested for the presence of EBV. Fifty-five percent

of tumor specimens obtained from patients with infectious mononucleosis had evidence of EBV. There was no evidence of an increased risk of EBV-negative Hodgkin's lymphoma after infectious mononucleosis. In contrast, the risk of EBV-positive Hodgkin's lymphoma was significantly increased. The estimated median incubation time from mononucleosis to EBV-positive Hodgkin's lymphoma was 4.1 years. The risk of Hodgkin's lymphoma in the seropositive cohorts remains increased for two decades. The authors concluded that a causal association between infectious-mononucleosis-related EBV infection and the development of EBV-positive Hodgkin's lymphoma was likely. The authors also emphasized that in absolute terms, the risk of Hodgkin's lymphoma after infectious mononucleosis is only approximately 1/1000 persons; thus, other cofactors to explain the ultimately etiology of EBV-positive and EBV negative HL remain to be elucidated.

HODGKIN'S LYMPHOMA AND HIV

Although HL is not an AIDS-defining malignancy, there is a well-known increased risk for the development of HL in human immunodeficiency virus (HIV) infected individuals.³⁵⁻⁴¹ Some differences do exist between HIV associated HL and non HIV associated HL. HIV-associated HL is diagnosed at a more advanced stage than non-HIV-associated HL; has a higher incidence of extranodal involvement; and is more likely to have an underlying histology of mixed cellularity.³⁶⁻³⁸

One large series from France described 45 cases of HL in HIV-infected individuals. Forty-nine percent of patients presented with mixed cellularity histology, 75% with advanced stage, and 80% with B symptoms. Not only mediastinal involvement is a site of presentation in over 50% of patients with primary HL that this series described only 13% of HIV positive HL patients with mediastinal involvement. This study found that HIV-associated HL was preceded by an AIDS manifestation in only 11% of cases. Median CD4 cell count was 306/ μ L at diagnosis. With standard therapy, 79% of patients achieved a complete remission, but hematologic and infectious complications were frequent. Prognosis correlated with initial CD4 cell count.³⁵

Another large study from Italy described 114 cases of HIV-associated HL.⁴¹ As with other studies, the authors noted an increase in mixed cellularity histology, a high prevalence of advanced-stage disease, and extranodal involvement. The most powerful prognostic factor was the CD4 count at diagnosis; patients with a CD4 count of greater than 250/ μ L had a better prognosis. Eighteen patients could be studied for the presence of EBV viral genomes. Seventy-eight percent of patients were found to have EBV associated with their HL. This relationship of EBV-positive HL and HIV-associated HL was confirmed in a subsequent study, in which Reed-Sternberg cells of virtually all

studied HIV-associated HL patients expressed the EBV-encoded latent membrane protein 1.⁴⁰ Therefore, the association of HIV infection with HL may be part of the complex relationship between EBV infection and the development of HL.

Historically, clinical outcomes of patients with HIV-associated HL have been poor, with patients experiencing frequent infectious complications, and a more aggressive disease process. However, a recent report from Italy described 59 patients receiving combination chemotherapy with highly active retroviral therapy (HAART) and granulocyte colony-stimulating factor (G-CSF). Patients were treated with the Stanford V combination chemotherapy, which was well tolerated in 69% of patients completing treatment without dose reduction or delay in chemotherapy administration. Complete response was achieved by 81% of patients, and 56% were alive in remission with a median follow-up of 17 months. The authors concluded that in the era of HAART and G-CSF support, the delivery of combination chemotherapy to HIV-infected individuals is more feasible and more effective than seen previously.⁴²

POSSIBLE ASSOCIATION OF HODGKIN'S DISEASE WITH RHEUMATOLOGIC CONDITIONS TREATED WITH METHOTREXATE

Conflicting data exist describing a possible association of the development of lymphoproliferative disorders, including HL, with rheumatoid arthritis and other connective tissue disease.⁴³⁻⁴⁶ Case reports have described an association of HL with patients receiving mild doses of methotrexate to treat their underlying condition. This has led to the question of whether such patients receiving methotrexate, particularly those with rheumatoid arthritis, are at higher risk of developing lymphomas, including HL.

Over 25 years ago, Banks et al. published a retrospective review of all patients seen at the Mayo Clinic from 1965 to 1975 with a diagnosis of both a connective tissue disorder and a lymphoid malignancy.⁴⁷ Twenty-nine patients were identified, two with HL. There was no particular pattern of the type of lymphoproliferative disorder seen. There was also no mention of treatment for the underlying rheumatologic condition. However, the authors concluded that there was little evidence of an association between the two. The Mayo Clinic subsequently updated their data, describing 16,000 patients with rheumatoid arthritis seen from 1976 to 1992 that were cross-indexed with 21,000 patients who had hematologic malignancy and received a disease-modifying antirheumatic drug.⁴⁸ Thirty-nine patients fit this definition, four of which had HL. Twelve of the thirty-nine cases received methotrexate (two with HL). The lymphoid malignancies occurred at a median of 15 years

after the diagnosis of rheumatoid arthritis. There was no pattern to the lymphoproliferative disorder seen. The authors concluded that the data did not support a relationship between methotrexate and any particular type of hematologic malignancy.

A study from France analyzed 426 rheumatoid arthritis patients treated with methotrexate to determine whether or not there was an increased incidence of cancer, compared with both rheumatoid arthritis patients never treated with methotrexate (rheumatoid control) and the regional population.⁴⁹ The regional population consisted of over 800,000 individuals. After an extensive analysis, the authors concluded that methotrexate was not found to be responsible for the development of any particular type of cancer, including hematologic cancers.

The most recently published study investigating a possible association between rheumatoid arthritis patients treated with methotrexate and the development of lymphoma is a national study from France, consisting of 61 rheumatology departments treating and following 78,000 rheumatoid arthritis patients.⁵⁰ All new cases of lymphoma occurring in rheumatoid arthritis patients over a 3-year period from 1996 to 1998 were described. The incidence of the development of non-Hodgkin's lymphoma (NHL) and HL in the study group was compared to that of the general French adult population in 1998 (46 million individuals). Twenty-five new cases of lymphoid malignancy were discovered. The median age was 63 years. The median time from the diagnosis of rheumatoid arthritis to the development of a lymphoma was 16 years. The median duration of methotrexate therapy was 5 years. Of particular interest was the fact that in contrast to many case reports describing regression, and even resolution, of lymphoma when methotrexate therapy is discontinued, this report found that of 24 patients in whom methotrexate was stopped, only 3 patients developed a spontaneous remission and 2 later relapsed. The observed annual incidence of NHL in the study group did not significantly exceed the annual incidence of NHL in the general French population after adjustment for age and sex. Only seven patients developed HL, and these small numbers make any definitive conclusion problematic.

Several studies have pointed out another confounding variable concerning the possible association of lymphoproliferative disorders with methotrexate therapy for patients with rheumatologic arthritis. Any immunosuppressive therapy may increase the risk of viral infection, including EBV. Many reports have shown that patients developing HL while receiving methotrexate therapy have detectable EBV virus, and that the EBV viral genome can be detected within the malignant lymphoid cells.⁵¹⁻⁵⁴ It is far more likely that any association between connective tissue disorder patients receiving immunosuppressive therapy and the development of lymphoproliferative disorders,

especially HL, is related to the influence of EBV rather than an inherent susceptibility of patients with rheumatoid arthritis to the development of such cancers. The overall risk of the development of HL in patients with rheumatoid arthritis, even with immunosuppressive therapy, is still extremely low.

SUMMARY

Epidemiology data have shown that HL has a bimodal age-specific incidence peaking at ages 20–24

and decreasing after age 44. NS HL accounts for the majority of histologic subtypes associated with early-age incidence peak. HL is more common in first-degree relatives, although there is no evidence that HL is capable of airborne transmission. There is a clear association of EBV with HL in 20–40% cases. HIV has been associated with HL, but it is unclear whether the HIV virus itself plays an etiologic role in the pathogenesis of HL in these patients. There is little, if any, data to suggest that HL is associated with rheumatologic conditions treated with immunosuppressive therapy such as methotrexate.

Chapter 70

PROGNOSTIC FACTORS IN HODGKIN'S LYMPHOMA

Michel Henry-Amar

Since the beginning of the twentieth century, the concept has emerged that Hodgkin's lymphoma evolves through successive clinical stages associated with increasing disease spread and worsening clinical outcome. The validity of this concept has progressively been confirmed leading to the conception of staging classifications based on anatomic extent of the disease. In 1971, a consensus was reached at the Ann Arbor Workshop on the Staging of Hodgkin's lymphoma.¹ Thereafter, the so-called Ann Arbor classification was universally adopted and its prognostic significance confirmed through numerous publications, in particular one in which more than 14,000 cases from 20 cooperative groups or institutions were combined.² It is still used for the evaluation of patients presenting with the disease.

As time and data accumulated, it became obvious that the Ann Arbor staging could not be the sole prognostic tool in daily practice. In 1988, a modification of the Ann Arbor classification was advised by specialists attending the Cotswolds meeting in England.³ The major modification concerned the designation of the disease extent and bulk. However, this classification is not generally used.

A variety of other clinical and biological characteristics have been used and claimed to be of prognostic significance. Some of these characteristics, combined with others, have been applied to retrospective series and demonstrated their prognostic value. They are presently used by several cooperative groups or institutions in the design of clinical trials. An extensive review of the literature has been published by Specht and Hasenclever in 1999.⁴ Therefore, we will focus on the definition of prognostic factors and end points. We will also give examples specific for early and advanced stages. We will then discuss some issues that develop when using prognostic factors in the management of Hodgkin's lymphoma.

METHODOLOGICAL ISSUES

DEFINITION AND USE OF PROGNOSTIC FACTORS

Prognostic factors are variables measured in individuals that offer a partial explanation of the heterogeneity

observed in the outcome of a given disease.⁵ Prognostic factors may be used to predict the outcome of Hodgkin's lymphoma on a population (or a group of patients) basis, but not for individual patients.⁶ Prognostic factors can be used to define risk groups, thus playing a role in treatment selection. In the setting of a clinical trial, they can be used in the definition of eligibility criteria and for stratification before randomization. In the analysis of a trial's results, prognostic factors may allow adjustments to improve the value of statistical comparisons made. However, the use of prognostic factors will never justify the comparison of treatments described by nonrandomized studies.^{7,8}

TYPES

Prognostic factors can be tumor related or patient related. Tumor-related factors reflect the type of the tumor, the extent of the disease, and the characteristics related to the tumor growth. These characteristics can be measured on the tumor itself or may be surrogate measures such as serum markers. Patient-related factors more often correspond to demographic characteristics or patient physiologic reserve, such as performance status. Generally speaking, tumor as well as patient-related factors are important for outcome although one may keep them separate, especially when they are used in the selection of treatment.

Usually, prognostic factors are grouped according to the point in time at which they are recorded.⁶ Their values should be known at the point from which prognosis (i.e., time to response or more generally time to event) is measured. Such prognostic factors for which a single value is available (measured at diagnosis, before the start of treatment) are called fixed covariates. Other prognostic factors may be available only during treatment (e.g., received dose intensity, acute toxicity), or after the treatment is completed, or the study is closed (e.g., response to treatment, time to response). These prognostic factors are called time-dependent covariates.⁵ Their use is generally a source of difficulties because time-dependent covariates may be affected by the treatment and such variables should

never be used in statistical adjusted comparisons between treatments.

END POINTS

Prognostic factors that correlate with an outcome variable must have clearly defined end points.⁹ These may relate to treatment efficacy, such as response to therapy, acute toxicity, or treatment failure within a given time; they may also relate to long-term results, such as relapse-free survival for patients who reach a complete remission, disease-free survival, treatment failure-free survival, overall or cause-specific survival, or cumulative probability of late toxicity (e.g., secondary malignancies). Variables that correlate with survival in Hodgkin's lymphoma are often nonspecific, such as age at diagnosis and gender.

RELATIONS AMONG FACTORS

For a variable to qualify as a useful prognostic factor, it must be significant, independent, and clinically important.¹⁰ Many, if not all, variables are potentially of prognostic significance and many proved to be so in

univariate analysis. However, variables are likely to be highly interrelated and some may be partial substitutes for one another, and few present with independent prognostic value. Moreover, factors exist that predict for a given therapy only; some for a given stage and some in the context of the presence of other factors. The use of multivariate statistical analyses is needed to assess which factors are independently significant and which only correlate with known prognostic factors but are without independent prognostic significance. This last point dramatically highlights the limits of prognostic studies, either retrospective or prospective, since the results highly depend on the variables available for all cases enrolled and the statistical model used.

PROGNOSTIC FACTORS

FIXED COVARIATES

As previously mentioned, agreed prognostic factors have been assessed in various settings. Table 70.1 summarizes

Table 70.1 Prognostic factors shown to be independently significant

<p>In pathological stage I–II patients treated with radiotherapy alone</p> <ul style="list-style-type: none"> – Number of involved regions – Large tumor mass, <i>in particular mediastinal</i> – Tumor burden, i.e., combination of number of involved regions and tumor size in each region – B symptoms – Histologic subtype – Age – Gender 	<p>In advanced disease</p> <ul style="list-style-type: none"> – Stage IV disease – Tumor burden – Very large mediastinal mass – Inguinal involvement – B symptoms – Erythrocyte sedimentation rate – Anemia – Serum albumin – Serum alkaline phosphatase – Leukocytosis – Lymphocytopenia – Serum LDH – Serum β_2-microglobulin – Histologic subtype – Age – Gender
<p>In clinical stage I–II patients treated with radiotherapy alone</p> <ul style="list-style-type: none"> – Number of involved regions – Disease confined to upper cervical nodes – Large mediastinal mass – B symptoms – Erythrocyte sedimentation rate – Anemia – Serum albumin – Histologic subtype – Age – Gender 	<p>Prognostic factors for laparotomy findings in supradiaphragmatic clinical stage I–II</p> <ul style="list-style-type: none"> – Number of involved regions above the diaphragm – Disease confined to upper cervical nodes – Mediastinal involvement – B symptoms – Erythrocyte sedimentation rate – Histologic subtype – Age – Gender
<p>In clinical stage I–II patients treated with combined-modality therapy</p> <ul style="list-style-type: none"> – Number of involved regions above the diaphragm – Large mediastinal mass – B symptoms – Erythrocyte sedimentation rate – Age – Gender 	
<p>In clinical stage I–II patients treated with chemotherapy alone^a</p> <ul style="list-style-type: none"> – Number of involved regions – Tumor bulk – Age 	

^aFrom one series only.¹¹

factors shown to be independently significant on event-free survival (with event being relapse or treatment failure) in pathological stage I-II patients treated with radiotherapy alone, clinical stage I-II patients treated with radiotherapy alone, clinical stage I-II patients treated with combined-modality therapy, in those treated with chemotherapy alone (in one series only),¹¹ or in patients with advanced disease. Some of these factors have also proved to predict for laparotomy findings in supradiaphragmatic clinical stage I-II patients. Beside age and gender always mentioned, the number of involved regions, mediastinal involvement (more often bulky) or tumor burden, histologic subtype, B symptoms, and erythrocyte sedimentation rate are commonly reported over all settings. However, this data mostly concerns adult patients; very few are known in pediatric patients, thanks to the success obtained with combined-modality therapies since the late 70s.

TIME-DEPENDENT COVARIATES

Similarly, prognostic factors for outcome after relapse have been reported according to initial treatment type or to the treatment given for relapse or refractory disease. In relapsing patients after initial treatment with radiotherapy alone who are given chemotherapy, the extent of disease at relapse, the type of relapse (nodal or extranodal), histologic subtype, and older age at relapse have been shown of prognostic value. In contrast, time to relapse usually does not correlate with outcome. In relapsing patients after initial chemotherapy alone or combined-modality therapy, two factors have consistently been associated with poor outcome: the response to initial treatment (complete remission, partial remission, no remission) and the duration of initial remission. These factors were independent of the type of second-line treatment. Other factors reported are the extent of disease at relapse, extranodal relapse, B symptoms at relapse, histologic subtype, stage IV at original diagnosis, and age and performance status. In relapsing patients undergoing high-dose chemotherapy and stem cell transplantation for relapse or refractory disease, several factors have shown to influence the prognosis: the response to initial treatment, the duration of initial remission, the number of failed treatments before the given relapse, and response to high-dose chemotherapy before transplantation. Other factors also reported are the extent of disease before transplantation, extranodal relapse, pleural involvement or multiple pulmonary nodules at relapse, B symptoms at relapse, increased serum lactic dehydrogenase (LDH) before transplantation, and poor performance status.

PROGNOSTIC INDICES OR SCORES

As soon as factors have been identified to correlate with clinical outcome, investigators have combined all

or part of these factors with the aim of obtaining a score that can predict for outcome: the higher the score, the lower the probability of remission, relapse or treatment failure-free survival, or overall survival. Scores were built from data accumulated in early or advanced stage patient series, enrolled or not in randomized clinical trials, or were based on individual data from randomized clinical trials analyzed using the meta-analysis approach. Only prognostic scores based on large series of patients or derived from adequate statistical analysis are reviewed next.

PROGNOSTIC SCORES IN EARLY STAGES

British National Lymphoma Investigation (BNLI) index

In 1985, Haybittle and coworkers reported that age, gender, mediastinal involvement, pathologic grade based on histologic subtype, and erythrocyte sedimentation rate were independent prognostic factors on cause-specific survival in clinical stage I-IIA patients.¹² Using these factors, they derived a quantitative prognostic index based on the results of multivariate regression analysis performed on data from 743 patients. This index was expressed as follows:

$$I = 0.05 (\text{age in years}) + 1.0 (\text{mediastinal involvement, coded 1 for uninvolved mediastinum, 2 for involved mediastinum}) + 2.0 (\text{pathologic grade, coded 1 if lymphocyte predominant or nodular sclerosing type 1, or 2 if nodular sclerosing type 2 or mixed cellularity}) + 1.0 (\text{erythrocyte sedimentation rate, coded 1 if below 10 mm/1st hour, 2 if between 10 and 39 mm/1st hour, and 3 if 40 mm/1st hour or above}) - 1.2 (\text{gender, coded 1 for male, 2 for female}).$$

The index ranged from 2.5 for a young girl aged 15 without adverse factors to 11.5 for a man aged 70 with all adverse factors. In the BNLI series, the value of the index was $I < 5.0$ in 32% of patients, $5.0 \leq I < 7.5$ in 52%, and $I \geq 7.5$ in 16%. A high index value ($I \geq 7.5$) corresponded to high-risk patients, while patients with $I < 7.5$ had a low risk of cause-specific death whatever the level of the index.

German Hodgkin Study Group (GHSg) approach

The aim of the GHSg study was to adapt treatment in supradiaphragmatic clinical stage I-II patients according to their risk of occult infradiaphragmatic involvement. A retrospective multivariate analysis (logistic regression) was performed on pretherapeutic clinical characteristics of 391 laparotomized patients.¹³ Twenty one percent had subdiaphragmatic disease. Of the factors (clinical including nodal presentation and biologic) tested, four independently correlated with infradiaphragmatic disease: left cervical involvement, mediastinal involvement, Karnofsky performance status less than 10, and histologic subtype (mixed cellularity or lymphocytic depletion). The regression coefficients were then used to derive a quantitative estimate of the probability of infradiaphragmatic disease for individual

patients. It ended in defining two groups of patients at low or high risk. The low-risk group was composed of patients with no left cervical involvement, mediastinal involvement, and Karnofsky index equal to 10 (19% of patients), or with no left cervical involvement, mediastinal involvement, and lymphocyte predominant or nodular sclerosing histologic subtype (19% of patients), or with mediastinal involvement, Karnofsky index equal to 10 and lymphocyte predominant or nodular sclerosing histologic subtype (19% of patients). The high-risk group comprised of patients with left cervical involvement and mediastinal involvement (25% of patients), or with no mediastinal involvement and mixed cellularity or lymphocytic depletion histologic subtype (29% of patients). All other patients were considered with intermediate risk. The probability of infra-diaphragmatic disease was 8% in patients at low risk and more than 35% in patients at high risk.

European Organization for Research and Treatment of Cancer (EORTC) scoring system

Based on 25-year experience of the management of supradiaphragmatic early stage Hodgkin's lymphoma, the EORTC Lymphoma Group has defined treatment strategies based on prognostic factors with the objective of adapting the treatment aggressiveness (i.e., combined-modality therapy) to patients at high risk of treatment failure in order to avoid most treatment-related complications. In 1989, Tubiana and coworkers published the results of a multivariate analysis based on a total of 1579 patients enrolled into four successive randomized clinical trials over the 1964–1987 period.¹⁴ Six factors were proven to independently correlate with either disease-free survival or overall survival: age (<40, 40–49, ≥50 years), gender, number of nodal areas involved (1, 2 or 3, 4 or 5), histologic type (lymphocyte predominant or nodular sclerosing), B symptoms, and erythrocyte sedimentation rate (<30, 30–49, ≥50 mm/1st hour). The originality of the publication consisted in the discussion on the balance that exists between two types of risk—the risk of treatment failure because of too light treatment and that of long-term complications following extended field irradiation or combined-modality therapy using aggressive chemotherapy. After multivariate analysis, three prognostic groups were defined. The very favorable group included females aged 39 years or less, with stage I disease, lymphocyte predominant or nodular sclerosing histologic subtype, no B symptoms, and erythrocyte sedimentation rate less than 30 mm/1st hour. They represented 6% of all patients. A simulation was performed to help in defining the unfavorable group of patients. Three options were discussed. Option A concerned patients aged 50 years or more, or with three or more nodal areas involved, or with no B symptoms and erythrocyte sedimentation rate more than or equal to 50 mm/1st hour, or with B symptoms and erythrocyte sedimentation rate more than or equal to 30 mm/1st hour. Forty-nine percent of patients were option A. Option B

had the same definition as option A except that only patients with four or five nodal areas involved were considered. Option B would include 38% of all patients. In option C, patients aged 50 years or more, or with four or five nodal areas involved, or patients aged 40–49 years with no B symptoms and erythrocyte sedimentation rate more than or equal to 50 mm/1st hour, or those with B symptoms and erythrocyte sedimentation rate more than or equal to 30 mm/1st hour were considered. Option C concerned 19% of patients. All other patients not fitting with very favorable or unfavorable definitions were considered in the favorable group, i.e., 45, 56, or 75% of all patients according to option A, B, or C, respectively. Based on the projected probability of disease-free survival and overall survival, option B was selected in the design of the H7 trial.¹⁵ However, in this trial the presence of bulky mediastinal involvement qualified patients as an unfavorable prognostic group, although this factor was not included in the overall prognostic study performed because it was not recorded.¹⁶ The EORTC scoring system, still in use since the H7 trial start, in particular in the two following trials H8 and H9, is presented in Table 70.2.^{17–19}

Investigators who have defined a prognostic score they trust in are prone to use it in the design of the next study; they may also wait before its prognostic value is confirmed based on independent series. The design of the EORTC H7 trial was based on the newly defined EORTC scoring system; it also included an experimental strategy to test its validity. In the favorable group, patients were randomized to receive subtotal lymphoid and splenic irradiation (standard treatment) or six courses of EBVP (epirubicin, bleomycin, vinblastine, prednisone) followed by involved-field irradiation. In the unfavorable group, patients were randomized to receive six courses of MOPP/ABV (mechlorethamine, vincristine, procarbazine, prednisone, doxorubicin, bleomycin, vinblastine) hybrid and involved-field irradiation (standard treatment) or six courses of EBVP and involved-field irradiation. Beside the treatment comparison within each prognostic group, the trial design tested the prognostic value of the scoring system by comparing the two groups of patients treated with EBVP and involved-field irradiation. It is the only example of an experimental prospective design made to assess the value of a prognostic score.

PROGNOSTIC SCORES IN ADVANCED STAGES

St. Bartholomew's Hospital and Christie Hospital experience

Two series of patients with stage IIIB–IV were combined for a total of 301.²⁰ At both hospitals, patients were treated with combined-modality therapy. The end point was overall survival. Four factors emerged from multivariate analysis: age ≥45 years, male gender, absolute lymphocyte count less than $0.75 \times 10^9/L$, and stage IV. Three prognostic groups could be defined. The low risk group was composed of patients aged less than

Table 70.2 The European Organization for Research and Treatment of Cancer scoring system in supradiaphragmatic clinical stage I-II

Factor	Score according to code
Age ^a	< 40 = 0, 40–49 = 1, ≥50 = 9
Gender	Female = 0, male = 1
Clinical stage ^b	I = 0, II ₂₋₃ = 1, II ₄₋₅ = 9
B symptoms and ESR ^c	A and ESR < 50 = 0, B and ESR < 30 = 1 A and ESR ≥50 = 9 or B and ESR ≥ 30 = 9
Mediastinum ^d	Uninvolved or not bulky = 0, bulky involvement = 9
Histologic subtype	Lymphocyte predominant or nodular sclerosing = 0 Mixed cellularity or lymphocytic depletion = 1
Total score	0–38
0	Patient belongs to the <i>very favorable</i> prognostic group
1–4	Patient belongs to the <i>favorable</i> prognostic group
≥ 9	Patient belongs to the <i>unfavorable</i> prognostic group

^aIn years.

^bFive major nodal areas were defined as follows: the whole neck including the supraclavicular area (left and right); the axilla including the infraclavicular area (left and right); the whole mediastinum including the hilar nodes on both sides (one area)

II₂₋₃, stage II with two or three nodal areas involved

II₄₋₅, stage II with four or five nodal areas involved

^cErythrocyte sedimentation rate, in mm/first hour.

^dBulky mediastinal involvement if M/R ratio ≥ 0.35 where M/T ratio is defined as the largest diameter of the mediastinum/thoracic diameter at the T5-T6 level, in standing position.¹⁶

45 years with lymphocyte count more than 0.75×10^9 /L or female with stage IIIB (59% of patients). The high-risk group comprised male patients with stage IV disease, aged more than 45 years, or with lymphocyte count less than 0.75×10^9 /L (26% of patients). All other patients were included in the intermediate prognostic group (15% of patients). The difference in survival probability was highly significant ($P < 0.001$).

Memorial Sloan-Kettering Cancer Center (MSKCC) experience

The series concerned 161 patients with stage IIIB, IIIB, or IV disease who were treated between 1975 and 1984 according to two successive protocols.²¹ All patients received combined-modality therapy. The main end point was overall survival. With multivariate analysis, five factors were shown to have independent prognostic value: age ≥45 years, serum LDH > 400 UI/L, low (abnormal) hematocrit, inguinal involvement, and bulky mediastinal mass ≥0.45 of the thoracic aperture. Since the regression coefficients corresponding to the five factors were of the same magnitude (range 1.49–2.99), each of them was considered with equal significance. Therefore, the prognostic score was derived from the sum of adverse factors present, theoretically ranging 0–5. Patients who expressed none or only one adverse factor (60% of all patients) were considered at low risk of death, while those with two or more (40% of patients) were considered at high risk of death. The same five factors plus one, bone marrow involvement, were used to predict for disease progression. Again, patients who expressed none or only one adverse factor displayed significantly better progres-

sion-free survival rate at 4 years than those who expressed two or more factors.

Italian experience

Gobbi and coworkers attempted to predict expected median survival time (EMST) including deaths from all causes.²² Factors retained in the model were age, gender, clinical stage, histologic subtype, erythrocyte sedimentation rate, and serum albumin. A proposed equation was as follows: $EMST = [326.9 - 64.6 \text{ erythrocyte sedimentation rate} - 70.6 \text{ clinical stage} - 60.2 \text{ histologic type} - 40.4 \text{ age} - 29.9 \text{ serum albumin} - 24.3 \text{ gender}] \times 0.693$, that predicts a survival duration in months for a given individual.

European bone marrow transplantation (EBMT) experience

In 1996, Federico and coworkers reported the predictive value of an index based on the MSKCC scoring system applied to stage III-IV disease with overall survival as endpoint.²³ Patients were considered at high risk of death if they presented with at least two of the following factors: mediastinal mass ≥0.45, stage IV E+, high serum LDH, inguinal nodal involvement, low hematocrit, or bone marrow involvement.

International Prognostic Index (IPI)

The International Prognostic Factors Project for Advanced Hodgkin's lymphoma was initiated by the GHSG to propose a score that could predict for both freedom from progression of disease and overall survival.²⁴ Twenty-five cooperative groups or institutions participated and a total of 5141 cases treated with

combination chemotherapy for advanced Hodgkin's disease, with or without radiotherapy, were collected. The IPI score was calculated from the set of patients with complete data (31% of all patients) and partially validated on an additional 2643 patients (51%) with not all data available. Seven factors displayed independent prognostic value on progression-free survival: serum albumin less than 4.0 g/dL, hemoglobin less than 10.5 g/dL, male gender, stage IV disease, age more than or equal to 45 years, white-cell count more than or equal to 15,000/mm³, and lymphocyte count less than 600/mm³ or 8% of white-cell count. All seven factors were associated with coefficients of risk that were similar (range 1.26–1.49). Therefore, the IPI score was calculated as the sum of the factors present, ranging from 0 to 7. Among the “working” patient group (*N* = 1618), the score was equal to 0 in 7%, 1 in 22%, 2 in 29%, 3 in 23%, 4 in 12%, and more than or equal to 5 in 7%. In the validation patient group (*N* = 2643), these figures were 7, 25, 31, 22, 11, and 4%, respectively. The score highly predicted for progression-free survival, and a proposal was made that patients be subgrouped in those presenting with 0–2 factors and those presenting with more than or equal to three factors. The IPI score also predicted for overall survival: the higher the score, the lower the survival rate. Later, Bierman and coworkers reported that the IPI score predicts for both event-free survival and overall survival in patients with advanced Hodgkin's lymphoma treated with autologous hematopoietic stem cell transplantation.²⁵ The IPI score could be calculated for 579 of the 739 advanced-stage patients enrolled into the EORTC H34 trial.²⁶ Forty percent of patients had 0–2 factors and 60% three factors or more. The 5-year progression-free survival rates were 84% and 74% in the two groups, respectively (*P* = 0.002), while the 8-year overall survival rates were 85% and 64% (*P* < 0.001) (unpublished data). The applicability of the IPI score to early stage disease (I–II–IIIA) was tested by the GHSG.²⁷ The IPI score was applied to patients enrolled into two consecutive trials and could be calculated in 961 (70%) of all patients. In patients with unfavorable early stage disease (clinical stage I–II with one or more GHSG risk factors, or IIA without any risk factor), the IPI score (0–2 vs ≥ 3) predicted for disease-free survival while it was found of no prognostic value in favorable early stage disease patients.

PROGNOSTIC SCORES IN ALL STAGES

Experience of the Scotland and Newcastle

Lymphoma Group (SNLG) therapy working party

From 1979 to 1986, 723 Hodgkin's lymphoma patients were registered and detailed clinical and laboratory data were collected by the SNLG.²⁸ Sufficient information was available for 547 (76%) patients. Of these, 92 were used to develop a prognostic index and 455 for index validation. Almost half of the patients had stage III–IV disease. The end point used was overall survival.

Five factors were independently associated with a high risk of death with multivariate analysis: age, clinical stage, hemoglobin level, absolute lymphocyte count, and tumor bulk more than 10 cm. A prognostic index, *I*, was calculated as follows: $I = 1.5858 - 0.0363 \text{ age} + 0.0005 (\text{age})^2 + 0.0683 \text{ clinical stage} - 0.086 \text{ lymphocyte count} - 0.0587 \text{ hemoglobin} [+ 0.3 \text{ if bulky disease present}]$, in which age is entered as an absolute figure, clinical stage is coded according to Ann Arbor classification (IA, IIA, IIIA coded 1, IB or IIB coded 2, IIIB coded 3, IV coded 4), absolute lymphocyte count is entered as a score (< 1.0 × 10⁹ /L coded 1, 1.0 – 1.5 × 10⁹ /L coded 2, > 1.5 – 2.0 × 10⁹ /L coded 3, > 2 × 10⁹ /L coded 4), and hemoglobin in g/dL is entered as an absolute figure. Bulky disease, if available, corresponds to the presence of a single node more than or equal to 5 cm or mediastinal to thoracic ratio more than 0.30. Applied to the patients in the validation group, the index demonstrated its ability to discriminate patients at high risk of death if *I* > 0.5. It was also able to discriminate patients with classical Ann Arbor stage IA and IIA disease with poor prognosis. Later, the SNLG index was used to select poor risk patients to receive intensive multiagent chemotherapy with or without autotransplant.²⁹

International Database on Hodgkin's lymphoma (IDHD) experience

In 1989, more than 14,000 cases were collected from 20 cooperative groups or institutions.³⁰ Data was used by Gobbi and coworkers to confirm the predictive equation that estimates for a given individual his/her EMST including deaths from all causes.^{22,31} Factors selected were roughly similar to those previously published (see earlier section): age, gender, clinical stage, histologic subtype, B symptoms, serum albumin, and distribution of involved areas. An equation was derived: $\text{EMST} = \text{Exp} [3.75 + 1.25 \text{ clinical stage I} + 0.77 \text{ clinical stage II} + 0.46 \text{ clinical stage III} - 0.00046 \text{ age}^2 + 0.85 \text{ histologic type} + 0.42 \text{ B symptoms} - \ln (\text{serum albumin in percentile}) - 0.25 \text{ gender} + 0.25 \text{ involved area distribution}]$, with EMST expressed in months.

EORTC Lymphoma Group experience

Of the nine randomized trials that the EORTC Lymphoma Group has conducted since 1964, five were selected that have tested modern therapies and provided similar results in term of event-free survival with treatment failure, progression, relapse, and death considered as events.^{15–17,26,32} Overall, 3141 cases were available including 347 (11%) cases with advanced stage disease and low IPI score (0–2 adverse factors present). The distributions of the clinical and biological patient characteristics were similar within the five series except for bulky disease and the number of nodal areas involved that were significantly more often present among stage III–IV cases. Factors considered in the multivariate analysis included age, gender,

topography, clinical stage, mediastinal involvement, bulky disease, B symptoms, erythrocyte sedimentation rate, leukocyte count, neutrophil count, hemoglobin, and histologic subtype. In the final model performed on 2775 cases with all information available, four factors remained significant after stratification on treatment type: age more than or equal to 50 years, male gender, B symptoms, and neutrophil count more than or equal to $8000/\text{mm}^3$. The corresponding coefficients ranged between 1.30 and 1.52, and a score was derived that considered the number of adverse factors present, i.e., 0–4. There were 23% of cases with no adverse factor, 45% with one factor, 25% with two factors, and 7% with three or four factors. The proportion of cases with three to four adverse factors was less than 1% in cases with early stage favorable prognostic features (1090 cases) according to the EORTC scoring system (Table 70.2), 12% in cases with early stage unfavorable prognostic features (1366 cases), and 11% in those with advanced stage and low IPI score (319 cases). While the progression-free survival curves of cases with zero, one, or two adverse factors did not significantly differ, that of cases with three to four factors was significantly lower. The 8-year progression-free survival rates were 86, 83, 80, and 68% in the four groups, respectively ($P < 0.001$) (unpublished data).

PROGNOSTIC SCORES IN CHILDREN

In the last years, three groups have reported results of trials from which prognostic scoring systems have been issued. The French Society of Pediatric Oncology reported that female gender, B symptoms, nodular sclerosing histologic subtype, low hemoglobin (< 10.5 g/dL), and the presence of two of the following biologic factors—erythrocyte sedimentation rate more than 40 mm/1st hour, leukocytes more than $12 \times 10^9/\text{L}$, fibrinogen more than 5 g/L, α_2 -globulin less than 10 g/L, or albumin less than 35 g/L—significantly correlated (univariate analysis) with clinical outcome in 202 children with low-stage disease.³³ Patients were found at high risk if they presented with hemoglobin less than 10.5 g/dL and nodular sclerosing histologic subtype and at least two of the other five biologic factors (prognostic scale derived from multivariate analysis).

Smith and coworkers have reported the results of a prognostic factor analysis based on three series of patients treated with combined-modality therapy at three institutions.³⁴ Overall, the data of 328 pediatric patients was analyzed. Five factors were found of prognostic value on disease-free survival: male gender, stage IIB–IIIB–IV, bulky mediastinal disease, leukocytes more than $13.5 \times 10^3/\text{mm}^3$, and hemoglobin less than 11 g/dL. Because the coefficients of all five factors ranged from 1.92 to 2.08, the score proposed was equal to the sum of the factors expressed by the patient. Patients were divided into four groups with significantly different prognosis. The disease-free survival rate was 94% in patients with zero to one factor present

(50% of all patients), 85% in those with two factors (23% of patients), 71% with three factors (16% of patients), and 49% with four or five factors (11% of patients). The overall survival rate ranged from 99% to 92% for patients with less than or equal to three factors present while it was only 72% for those with four to five factors.

The German-Austrian Pediatric Hodgkin's lymphoma Study Group reported the results of a retrospective study on factors that could predict for event-free survival.³⁵ Data from 552 children treated according to the HD-90 multicenter study was used. In this study, treatment was adapted to disease presentation, i.e., stage I–IIA, IIB–IIIA, and IIIB–IV. Significant univariate predictive factors were nodular sclerosing histologic subtype, B symptoms, number of involved regions and treatment. Using a multivariate regression model, only nodular sclerosing histologic subtype and B symptoms remained independent prognostic factors.

LIMITS OF PROGNOSTIC FACTORS

Several limits can be listed that mainly depend on the kind of a given prognostic factor. One can distinguish prognostic factors whether they are objective or not, a situation that interferes with their definition.

PROGNOSTIC FACTOR DEFINITION

Objective prognostic factors such as age, gender, height, weight, or biologic data can be estimated and their measure is generally not subjected to discussion. Automatic or validated instruments when available are very helpful. In biologic data measurement, knowledge of normal values according to either age or gender is required. However, nonobjective factors are more frequent than objective ones in the clinical research area. Histologic subtype and tumor bulk among many others can be selected as examples.

Assessment of histologic subtype depends on the experience of the pathologist and classification used. When a central review is organized involving senior experienced pathologists, very few discrepancies are noticed between diagnoses for a given case as well as few variations are observed in the distribution of various subtypes with time, i.e., within cohort of patients or studies. However, even when a central review exists, the prognostic value of pathology per se is controversial especially since the use of modern combined-modality therapy.

Tumor bulk is a recognized prognostic factor in Hodgkin's lymphoma. The way used in its evaluation, however, can very much influence the result. The Ann Arbor classification considers the number of lymph node regions involved, and their definition may vary from one study to the other. Some investigators include lung hilar nodes in the mediastinum, while others do not. In estimating mediastinal bulk, two

ways of calculation have been proposed that provide different estimations.^{16,36} Specht and colleagues have tried to precisely measure tumor burden and have demonstrated its prognostic value in early as well as advanced stages disease.³⁷⁻³⁹ They used both the number of involved regions and the tumor size in each region. This approach may, however, be much difficult to apply in daily practice and sensitive to clinician attention. A more direct method of estimation of tumor burden was assessed by Gobbi and colleagues.⁴⁰ It consists of using images of the lesions obtained through computed tomography for all deep sites of involvement and those obtained by ultrasonography for superficial lesions. The sum of the volumes of the lesions is used as an estimation of the absolute tumor burden. Its ratio to the patient's body surface area represents the relative tumor burden. The latter parameter was demonstrated to be the most prognostic among all classical factors tested. Again, this approach depends highly on the radiologists' experience and their attention paid in measuring the volume of the lesions.

ASSESSMENT OF PROGNOSTIC VALUE

While adequate statistical methods are now applied by most investigators, the material used varies from one series to the other. Prognostic factors were never assessed from a population-based series that are available from cancer registries only. The main reason is that data would be incomplete and heterogeneous and highly dependent upon the institution where the patients have been treated. Hospital-based series are biased and very often limited in number since Hodgkin's lymphoma is a rare disease. When a large single institution series is used, it generally includes patients treated over a long period of time during which treatments may have changed dramatically, leading to the loss of predictive power for most factors tested.⁴¹ To overcome this difficulty, large homogeneous series are needed that may come from cooperative groups; alternatively, the combination of data from clinical trials with the same objectives (i.e., meta-analysis approach) has proved to be effective.

The prognostic value of scoring systems should be confirmed using independent series of patients. This approach can be applied within series when the analysis is made using a random sample of patients and the validation made using the remaining.²⁴ Another possibility is to apply and/or compare various scoring systems using an independent series.⁴²⁻⁴⁴ Only factors or scoring systems that are consistently found of independent prognostic value in independent series should then be used.

APPLYING PROGNOSTIC SCORES

Prognostic scores previously described can be grouped into two categories. The first category includes those that are easy to calculate, i.e., without the help of a calculator. A simple adding of adverse factors present is generally sufficient to select patients at low or high risk.

Among these are the scores proposed by the GHSG, the EORTC Lymphoma Group, the St Bartholomew's Hospital & Christie Hospital team, the MSKCC, the EBMT, and the IPI, and all scores derived from pediatric data.^{13,15,20,21,23,24,33-35} The second category includes scores that necessitate more or less sophisticated calculation. It concerns the scores proposed by the BNLI, the SNLG, and by Gobbi et al.^{12,22,28,31} Prognostic scores belonging to the second category have probably no chance to be used by others in contrast to the IPI score, for example, that has been adopted by most groups involved in the management of advanced stage disease.

USE OF PROGNOSTIC FACTORS

IN CLINICAL TRIALS

The use of prognostic factors in clinical trials usually corresponds to three purposes: study definition, stratification before randomization, and analysis of the trial results. In the definition of the study, prognostic factors are used as entry or exclusion criteria. This attitude is often based on ethical considerations since eligible patients are those for whom the benefits and risks of treatments are uncertain enough to justify randomization. It is the case in deescalation trials or in those in which better results are expected from more aggressive therapy. However, the use of prognostic factors in selecting patients may bias the trial recruitment since patient inclusion lies with the responsible local investigator who could decide to exclude borderline cases from the trial. Even central randomization does not prevent such a bias. Therefore, prognostic factors must be simple, clearly defined, easy to assess, and well accepted by all investigators participating in the trial.

Randomization is the only method to ensure comparability of the treatment groups concerning known and unknown factors. Currently randomization techniques provide adequate distribution between treatment groups especially when large numbers of patients are included. In small randomized trials, stratified randomization is designed to balance treatment allocation within predefined subgroups. However, the number of strata should be limited to avoid overstratification.

Prognostic factors not only serve in the description of the study population, they also play a role in analysis of the trial results. The omission of important known or unknown prognostic factors may bias the estimate of the treatment effect or reduce the statistical power.⁴⁵ The analysis of the results of a trial should include both univariate and multivariate tests for treatment effect. Consistent results will make the conclusion more convincing.

IN DECISION ANALYSIS

Improvements achieved in the management and treatment of Hodgkin's lymphoma have been so important in the last 10-15 years that very few are expected in the

near future. The proportion of patients cured of the disease is 90% or more in early stages and 80% or more in advanced stages. As a consequence, hematologists progressively change their objectives from better survival alone, to better survival and less late treatment-related toxicity. This concept forms the basis of most treatment strategies worldwide. Treatment strategies are usually based on the combination of known prognostic factors. In order to help investigators in selecting patients who should be offered a given treatment or to participate in a given controlled clinical trial, other approaches have been developed. Among these, decision analysis represents a tool that has been applied since the late 70s.⁴⁶⁻⁴⁸ It is based on the use of definitions of patient risk groups (based on combinations of various prognostic factors) and on data derived from the literature. Applications have been made taking into consideration exploratory laparotomy and splenectomy, the use of stem cell transplantation, or the probability of late complications such as secondary malignancy, cardiac mortality, etc.⁴⁹⁻⁵⁵

CONCLUSIONS

A large number of parameters are of prognostic significance in Hodgkin's lymphoma. A majority are more or

less linked to the tumor mass itself. This is true not only for earlier mentioned factors but also for other biologic markers considered as putative prognostic factors, their prognostic significance having not yet been assessed using multivariate analysis applied to large series of cases.^{56,57} Currently prevailing wisdom is to adapt treatment strategy to the a priori patient's prognosis, limiting treatment aggressiveness in patients with "favorable" prognostic factors (i.e., patients at low risk of progression/relapse) to reduce late toxicity, and increasing treatment intensity in patients with "unfavorable" prognostic factors to increase their chance of cure.

In the absence of a general consensus, factors currently used by investigators at various centers or cooperative groups are likely to differ for historical, educational, or economic reasons. This makes comparisons difficult between series, and almost impossible large-scale analysis. Adding new biologic parameters in the panoply will make it even more complicated. However, as measurable events such as treatment failure and death become rare, a huge number of patients should be prospectively followed to allow the emergence of new prognostic factors including biologic markers.⁵⁷ A general consensus on what factors should be systematically used in clinical research and on what are still a matter of debate would certainly be highly valuable.

Chapter 71

CLASSIFICATION, PATHOLOGY, AND MOLECULAR GENETICS OF HODGKIN'S LYMPHOMA

James R. Cook and Eric D. Hsi

CELL OF ORIGIN AND EVIDENCE OF DISRUPTED B-CELL TRANSCRIPTION FACTOR EXPRESSION

The nature and cell of origin of Hodgkin's disease (HD) has been the subject of debate since the initial description of HD in 1830.¹ Not until the mid-1990s was it recognized that the Reed-Sternberg was derived from B-cells and was in most cases a monoclonal proliferation.²⁻⁵ These studies utilized single-cell polymerase chain reaction (PCR) from Reed-Sternberg cells to demonstrate monoclonal *IGH* rearrangements. In the pivotal study, Marafioti and colleagues examined 25 cases of HD by single-cell PCR with amplification of *IGH* or *IGK* genes. Twenty-four cases revealed gene rearrangements. Comparison of the PCR products showed that all cases were clonal and 75% of the cases had the capacity for productive rearrangements.⁵ Furthermore, while the immunoglobulin (*Ig*) genes were theoretically functional, there was no transcription of *Ig* genes due to defects in the *Ig* gene regulatory elements.⁵

Analysis of the *IGH* sequences of Reed-Sternberg cells showed a high load of somatic mutations. The presence of these mutations, which occurs in the germinal center in normal B-cells sets the germinal center B-cell as the stage of B-cell maturation for most Reed-Sternberg cells. This concept is supported by studies of composite Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma in which a common precursor to the two lymphomas can be traced by *IGH* sequence to a germinal center type B-cell.^{5,6} The results of these studies firmly establish HD as HL, a monoclonal B-cell proliferation of cells derived from germinal center or postgerminal center B-cells in the vast majority of cases.

More recent studies provide insight into the mechanisms for a disrupted B-cell transcriptional program.

Oct-2, Bob-1, and Pu.1 are important B-cell transcription factors that have all been shown to be down regulated in classical Hodgkin's lymphoma (cHL).⁷⁻¹⁰ While they are seen in nodular lymphocyte predominant HL (nLPHL) and other B-cell lymphomas, the absence of these transcription factors serves both as an explanation for lack of *Ig* transcription and expression in cHL lymphoma as well as a diagnostic marker for this lymphoma. This lack of *Ig* expression is somewhat problematic since in normal B-cell development, the lack of *Ig* expression leads to apoptosis. Therefore, other genetic mechanisms must be operative to protect the cell from this fate. One explanation is overexpression of NF κ B. This ubiquitous transcription factor has numerous functions in promoting cell survival and proliferation. Recent studies demonstrate the constitutive expression of activated (nuclear) NF κ B in HL and that defective I κ B α (an inhibitor of NF κ B) is a mechanism responsible for this.¹¹⁻¹³ With this as background, we proceed with the pathology and classification of HL.

CLASSIFICATION OF HODGKIN'S LYMPHOMA

The classification of HL has undergone substantial changes over the last decade, reflecting an improved understanding of the underlying biology of this neoplasm.¹⁴ In 1966, the Rye conference modified the earlier Lukes and Butler classification system to produce four histologic subtypes of HD: Lymphocyte predominance, nodular sclerosis, mixed cellularity, and lymphocyte depletion.^{15,16} This scheme was widely used for the next 30 years. The Rye classification was popular among pathologists for its simplicity and ease of use and was equally popular among clinicians because the individual subtypes were associated with prognostic differences when treated with then-current therapy.¹⁷

Table 71.1 Classification of Hodgkin's Lymphoma

Rye (1966)	REAL (1996)	WHO (2001)
Lymphocyte predominance	Lymphocyte predominance	Nodular lymphocyte predominance
Nodular sclerosis	Classical Hodgkin's Disease	Classical Hodgkin Lymphoma
Mixed cellularity	– Nodular sclerosis	– Nodular sclerosis
Lymphocyte depleted	– Mixed cellularity – Lymphocyte depleted	– Mixed cellularity – Lymphocyte depleted

As immunophenotypic studies became part of the standard practice of hematopathology, however, it became clear that many of the cases diagnosed as lymphocyte predominance HD displayed biologic and clinical features that separated these cases from all of the other forms of HD. In addition, with improvements in standard therapy, the earlier prognostic differences between the other subtypes of HD essentially vanished. To reflect these advances, the classification of HD was modified in the revised European-American lymphoma (REAL) classification of 1994 into two large categories: lymphocyte predominance HD and classical HD.¹⁸ The remaining histologic subtypes of the Rye classification were retained under the heading of classical HD. In addition, the term “lymphocyte-rich classical HD” was introduced to identify cases containing a lymphoid rich background, but an immunophenotype that was identical to the other forms of classical HD and to separate such cases from lymphocyte predominance HD (Table 71.1). The WHO classification of 2001 retained the overall organization of the REAL classification. However, the term “Hodgkin's disease” was replaced by “Hodgkin's lymphoma” to represent the now-definitive lymphoid histogenesis of this malignancy, and the characteristic nodular growth pattern of cases of lymphocyte predominant HL was explicitly acknowledged.¹⁹

CLASSICAL HODGKIN'S LYMPHOMA

In the WHO classification, four histologic subtypes of cHL are recognized.¹⁹ While each of these subtypes display similar immunophenotypes and molecular genetic features, there are characteristic differences in morphology and in association with the Epstein-Barr virus. The next section will first discuss the general features of cHL common to each of the subtypes, followed by descriptions of each of the subtypes that will discuss their more specific associations.

COMMON FEATURES IN ALL SUBTYPES

General

Classical Hodgkin's lymphoma is a neoplasm of B-cell origin that is histologically composed of multinucleate

Reed-Sternberg cells and mononuclear variants, known as Hodgkin cells.¹⁹ Cases of otherwise typical cHL have been described that appear to be of T-cell origin, but such cases are very rare, and their most appropriate classification is a subject of controversy.^{20–22} cHL is much more common than nLPHL, with cHL representing about 95% of all HL. There is a bimodal age distribution, with the first peak around 15–35 years of age, and a second peak in elderly populations. Patients typically present with nodal disease, most often involving the cervical region. Secondary involvement of extranodal sites may occur, but primary presentation at extranodal locations is unusual.

Pathology

The lymph nodes are effaced by a proliferation of Reed-Sternberg cells and mononuclear Hodgkin variants that is accompanied by an often extensive benign, inflammatory infiltrate. Reed-Sternberg cells are defined as large cells with abundant cytoplasm, and at least two distinct nuclear lobes, each of which contain a prominent eosinophilic nucleolus. The mononuclear Hodgkin variants are large cells with a usually round nucleus and prominent nucleolus. The Reed-Sternberg and Hodgkin cells generally constitute only a small minority of the cells present in histologic sections, and in some cases the malignant cells may be quite rare. In modern practice, a definitive diagnosis of HL cannot be established by morphologic features alone, but requires confirmation by immunohistochemistry.

Immunophenotype

The neoplastic cells in cHL are almost always positive for CD30,^{23,24} and a large percentage of cases coexpress CD15 (70–80%)^{24,25} and PAX5 (up to 90%) (Figure 71.1).^{26,27} cHL is usually negative for CD45 and J-chain. CD20 may be found in a subset of cases but is usually present on only a minority of the neoplastic cells and expressed with variable intensity. The finding of strong CD20 expression on a large percentage of Reed-Sternberg-like cells suggests the diagnosis of a B-cell lymphoma, such as T-cell rich large B-cell lymphoma.¹⁹ The B-cell transcription factors OCT-2 and/or BOB.1 are characteristically absent.⁹ Occasionally, other B-cell antigens such as CD79a may be present. Some cases may show aberrant expression of T-cell antigens, but the finding of multiple T-cell antigens should raise the possibility of a T-cell neoplasm, such as anaplastic large cell lymphoma.

Molecular genetics

Classical cytogenetic studies of cHL are often unsuccessful, or demonstrate only a normal karyotype. The failure of such studies to characterize the malignant cells likely is secondary to the difficulty in isolating the neoplastic cells, which typically represent only a small percentage of the cells present, combined with poor growth of the neoplastic cells in culture. When abnor-

Figure 71.1 Nodular sclerosis Hodgkin's lymphoma. The lymph node is effaced by a lymphoid proliferation that is separated into nodules by dense collagenous bands of fibrosis (upper left). The nodules contain numerous Reed-Sternberg cells and mononuclear variants (upper right). The neoplastic cells are positive for CD30 (lower left) and CD15 (lower right)

malities are identified, karyotypes are typically quite complex and hypertetraploidy is common.^{28,29} Specific recurrent abnormalities, however, have not been identified. Clonal rearrangements of the Ig heavy chain are present in the vast majority of cases, although highly specialized, nonstandard laboratory techniques such as microdissection or single-cell PCR studies may be required to demonstrate this finding as noted earlier in this chapter. Cases with clonal T-cell receptor rearrangements appear to be very rare, and the nature of such cases is a matter of controversy.¹⁹ In EBV positive cases, clonality of the Epstein-Barr virus (EBV) genome may also be identified.³⁰

NODULAR SCLEROSIS HODGKIN'S LYMPHOMA

General

Nodular sclerosis Hodgkin's lymphoma (NSHL) is defined as cHL where nodules of tumor cells are surrounded by bands of collagenous fibrosis. NSHL represents the most common subtype of cHL.¹⁹

Pathology

The malignant cells in NSHL include lacunar Reed-Sternberg cells, large neoplastic cells with abundant cytoplasm and characteristic retraction artifact when fixed in formalin. Bands of collagenous fibrosis surround a proliferation of Reed-Sternberg and Hodgkin cells admixed with small lymphocytes, large transformed cells, eosinophils, plasma cells, and other inflammatory cells (Figure 71.1). Some of the neoplastic cells demonstrate a shrunken, hyperchromatic appearance that has been described as "mummified" cells. When sheets of Reed-Sternberg and Hodgkin cells are present, the term "syncytial variant NHSL" has been employed.

Several grading systems have been proposed for NHSL based upon the number of Reed-Sternberg/Hodgkin

cells present. The most commonly used of these is the BNLI system, which divides cases into two grades.³¹ In grade 2 NSHL, sheets of Reed-Sternberg/Hodgkin cells are present in at least 25% of the nodules. Grade 1 cases, in contrast, contain fewer neoplastic cells. Although frequently used in research protocols, this grading scheme has not gained acceptance in routine clinical practice in the United States.

EBV association

The incidence of EBV positivity varies with the ethnic groups studied, but is approximately 20–40% in NSHL.^{30,32,33}

MIXED CELLULARITY HODGKIN'S LYMPHOMA

General

The mixed cellularity Hodgkin's lymphoma (MCHL) subtype is defined by the WHO as containing scattered classical Reed-Sternberg and Hodgkin cells in a diffuse or vaguely nodular mixed inflammatory background without nodular fibrosis. MCHL is the second most common type of cHL and represents approximately 20–25% of cases.¹⁹

Pathology

Histologic sections of MCHL demonstrate effacement of the lymph node architecture by scattered Reed-Sternberg cells and variants in a diffuse or vaguely nodular mixed inflammatory proliferation (Figure 71.2). Often, there are numerous small lymphocytes, plasma cells, eosinophils, histiocytes, or neutrophils, although the relative numbers of each of these cell types varies from case to case.

EBV association

Approximately 75% of cases are positive for EBV.^{30,32,33}

Figure 71.2 Mixed cellularity Hodgkin's lymphoma. A binucleate Reed-Sternberg cell is seen surrounded by small lymphocytes, eosinophils, and plasma cells

LYMPHOCYTE-RICH CLASSICAL HODGKIN'S LYMPHOMA

General

Lymphocyte-rich cHL (LRCHL) is defined as cHL containing Reed-Sternberg cells and variants in a nodular or diffuse background of numerous lymphocytes without prominent neutrophils and eosinophils.¹⁹ Establishing a diagnosis of LRCHL, and in particular, distinguishing such cases from nLPHL, requires immunohistochemical studies. LRCHL accounts for approximately 5% of HL overall.

Pathology

Cases of LRCHL typically display a nodular growth pattern with some of the nodules containing germinal centers. There are scattered Reed-Sternberg cells and variants, usually within the mantle zones surrounding germinal centers (Figures 71.3 and 71.4). Some of the

Figure 71.3 Lymphocyte-rich classical Hodgkin's lymphoma. At low power, there is a lymphoid-rich infiltrate with a predominantly diffuse growth pattern. A residual germinal center is seen (center right)

Figure 71.4 Lymphocyte-rich classical Hodgkin's lymphoma. At high power, a binucleate Reed-Sternberg cell is present surrounded by numerous small lymphocytes

malignant cells may show multiple folded nuclear lobes ("popcorn cells"), reminiscent of those seen in nLPHL. There is no nodular sclerosis. Although rare scattered eosinophils and neutrophils may be present, they are not a prominent feature.

EBV association

Most cases are EBV negative.^{30,32,33}

LYMPHOCYTE-DEPLETED CLASSICAL HODGKIN'S LYMPHOMA

General

The definition of lymphocyte-depleted classical Hodgkin's lymphoma (LDCHL) has changed dramatically over the years. Using WHO criteria, LDCHL is now defined as a diffuse proliferation of numerous Reed-Sternberg cells and variants (with an appropriate immunophenotype) without accompanying lymphocytes. Many of the cases that in the past were classified as lymphocyte depletion based upon hematoxylin and eosin morphology alone would currently be categorized as either non-Hodgkin's lymphomas (especially anaplastic large cell lymphomas) or so-called "syncytial variant" nodular sclerosis cHL. As currently defined, LDCHL is a rare entity, and there is little reliable data in the literature regarding such cases. In Western countries, this subtype appears to be somewhat more common in patients with HIV or other types of immunosuppression.

Pathology

LDCHL typically displays numerous Reed-Sternberg cells and variants, often present in sheets, raising a differential diagnosis that includes non-Hodgkin's lymphomas. In some cases, the neoplastic cells may be scattered in a background of diffuse fibrosis. In all cases, there are very few accompanying small lymphocytes.

EBV association

Most of the HIV-associated cases will be positive for EBV.^{34,35}

NODULAR LYMPHOCYTE PREDOMINANT HODGKIN'S LYMPHOMA

GENERAL

Nodular lymphocyte predominant HL is a neoplasm of germinal center B-cells that displays a growth pattern that is at least partially nodular. Whether an entirely diffuse form of LPHL exists has been controversial, and most cases formerly reported as diffuse LPHL are currently thought to represent either T-cell rich large B-cell lymphomas or LRCHL.¹⁹ Overall, nLPHL represents approximately 5% of all cases of HL.

An intriguing association between nLPHL and a form of benign hyperplasia known as progressive transformation of germinal centers (PTGC) has led to the suggestion that PTGC may represent a precursor lesion for nLPHL.³⁶ PTGC may be seen within the same lymph node containing nLPHL, or PTGC may be found in biopsies without evidence of malignancy obtained either before or after the diagnosis of nLPHL. It should be noted, however, that most patients with PTGC do not go on to develop nLPHL.³⁷

A small subset of patients, approximately 3–5%,¹⁹ will go on to develop a large B-cell lymphoma. Many of these cases display the morphologic features of T-cell rich large B-cell lymphoma (TCRLBL). In fact, although the clinical features of nLPHL and TCRLBL are quite distinct, it can be difficult in some cases to distinguish between these two entities based on morphologic and immunophenotypic findings.

Figure 71.5 Nodular lymphocyte predominant Hodgkin's lymphoma. A nodular proliferation of lymphocytes and histiocytes is present

Recognition of such cases with features overlapping nLPHL and TCRLBL has led to the suggestion that these two neoplasms may be biologically related.^{38,39}

PATHOLOGY

The neoplastic cells of nLPHL are large cells with vesicular chromatin, scant cytoplasm, and folded nuclear contours. Due to the characteristically extreme nuclear lobation, these cells are frequently described as “pop-corn cells.” These cells are also known as “L&H cells,” a holdover of terminology from the Lukes and Butler classification that defined such cases as “lymphocytic and histiocytic Hodgkin disease.”¹⁶ Prototypical cases of nLPHL show effacement of the lymph node architecture by a nodular lymphoid proliferation. The nod-

Figure 71.6 Nodular lymphocyte predominant Hodgkin's lymphoma. The neoplastic cells in nLPHL show multiple nuclear lobes with vesicular chromatin and prominent nucleoli (left). There is strong expression of CD20 (right)

ules consist of many small B-cells, with scattered L&H cells (Figures 71.5 and 71.6).^{17,40,41} Similar appearing diffuse areas may also be present. When diffuse areas are extensive, distinguishing nLPHL from TCRLBL may be quite difficult, especially in small biopsy specimens.

IMMUNOPHENOTYPE

Establishing a definitive diagnosis of nLPHL, and distinguishing such cases from cHL, requires immunophenotypic studies. The neoplastic cells are positive for CD20 (Figure 71.6) and CD45 (LCA) and are characteristically negative for CD15 and CD30.^{18,19,40} The L&H cells are also positive for the B-cell transcription factors, Oct-2 and BOB.1,⁹ and are typically positive for the Ig-joining segment known as J-chain.⁴² Approximately half of cases

are positive for epithelial membrane antigen (EMA).^{19,40} Another helpful phenotypic feature of nLPHL is that the neoplastic cells are typically ringed by small T-cells that often coexpress CD57.^{43,44} The presence of nodules of CD21 positive follicular dendritic cells also assists in the differential diagnosis with TCRLBL.⁴¹

MOLECULAR GENETICS

Functional, clonal Ig rearrangements are generally present in the neoplastic cells. However, clonal rearrangements are rarely detected by PCR or Southern blot studies of intact tissue and have usually been identified only after single-cell microdissection.¹⁹ Characteristic recurrent cytogenetic abnormalities have not been described.

Chapter 72

CLINICAL FEATURES AND MAKING THE DIAGNOSIS

Kristie A. Blum and Pierluigi Porcu

On the basis of differing morphologic, biologic, and clinical features described over the last 20 years, the currently accepted World Health Organization (WHO) Classification of Lymphoid Neoplasms recognizes two distinct clinical subtypes of Hodgkin's lymphoma (HL): classical HL and nodular lymphocyte-predominant HL.¹ Classical HL is a monoclonal lymphoid neoplasm composed of malignant Reed–Sternberg cells, which are multinucleated B cells that are CD30 and CD15 positive, surrounded by a mixed inflammatory infiltrate consisting of nonneoplastic lymphocytes, eosinophils, histiocytes, plasma cells, and fibroblasts. Four histologic subtypes of classical HL that differ in the morphology of Reed–Sternberg cells and composition of the reactive infiltrate have been identified: nodular sclerosis HL (NS HL), lymphocyte-rich HL (LR HL), mixed cellularity HL (MC HL), and lymphocyte-depleted HL (LD HL). While there is considerable overlap among these subtypes, unique clinical features have been noted with each.

Recognized as a separate entity in the WHO classification,¹ nodular lymphocyte-predominant HL is a monoclonal B-cell neoplasm characterized by a diffuse proliferation of large neoplastic cells [popcorn or lymphocytic and histiocytic (L&H) cells] that are CD20, CD79a, and CD45 positive and CD15 and CD30 negative, differing from Reed–Sternberg cells in classical HL.² These cells are frequently surrounded by a background infiltrate of nonmalignant small lymphocytes. This subtype comprises 3–8% of all HL,^{3,4} and has distinct clinical features and patterns of relapse in several different trials and case series.^{5–9}

CLASSICAL HODGKIN'S LYMPHOMA

EPIDEMIOLOGY

On the basis of data gathered by the Surveillance, Epidemiology, and End Results (SEER) program of the National Cancer Institute from 1975 to 2001, 7880 new cases of HL were expected in the United States in 2004, with 4330 cases in men and 3550 cases in women. From

1997 to 2001, the age-adjusted incidence rate reached 3.0/100,000 person-years, or 2.9/100,000 person-years in patients under the age of 65, and 4.3/100,000 person-years in patients 65 and older. The incidence is highest in Caucasian males, although females are commonly affected with the nodular sclerosing subtype. The median age at diagnosis is 36 years; however, as first described by MacMahon, a bimodal distribution of HL exists, with one peak in young adults (ages 15–34) and a second in patients older than 50.¹⁰ For patients aged 15–34, age-adjusted rates of HL range from 3.1 to 4.6 per 100,000 person-years and for patients older than 50, age-adjusted rates range from 2.8 to 3.8. Fortunately, the majority of patients with HL survive, with 5-year survival rates of 85% (88% in patients younger than 65, and 52% in patients 65 and older).

CLINICAL FEATURES

Classical Hodgkin's disease (HD) frequently presents with asymptomatic lymphadenopathy involving the cervical, supraclavicular, or mediastinal regions. Isolated subdiaphragmatic involvement is much less common, representing 3–10% of all HL cases.¹¹ Painful or tender lymphadenopathy is quite uncommon in HL and suggests an infectious etiology for the lymphadenopathy rather than HL. However, some patients will report pain induced by alcohol ingestion that localizes to the site of lymphomatous involvement. As the disease progresses and the nodal masses enlarge, some patients may develop dysphagia, tracheal compression, cough, hiccups, discomfort with movements of the shoulders, arms, or the neck, and skin irritation with redness or, rarely, ulceration.

While patients with cervical or supraclavicular lymphadenopathy frequently palpate an enlarged mass, patients with mediastinal presentations may complain of a persistent cough, dyspnea, or chest pain, which ultimately leads to further imaging and subsequent identification. Occasionally, patients with bulky mediastinal masses may demonstrate direct invasion of the chest wall, pleural or pericardial effusions, or superior vena caval syndrome. The

pleural and pericardial effusions may not necessarily be malignant, as documented by cytology, but may result from lymphatic or venous obstruction.

In the 1960s, Rosenberg et al. described a contiguous, predictable pattern of lymphatic involvement in patients with HD.¹² Specifically, in 100 consecutive surgically staged patients with newly diagnosed HD, the sites of involvement appeared to follow specific lymphatic channels, with patients presenting with cervical involvement frequently having additional involvement of the mediastinum, hilum, or axilla, with rare involvement of the abdomen unless mediastinal structures were also involved. It is unusual to find a patient with classical HD who has involvement of the neck and lower abdomen/inguinal nodes, without contiguous involvement of the mediastinum and upper abdomen. Also, involvement of the liver or bone marrow is unusual without involvement of the spleen. Occasional patients may have neck and upper abdomen involvement, bypassing the mediastinum, which may implicate direct spread via the thoracic duct. For patients with relapsed or primary refractory HL, the orderly progression of disease along contiguous lymphatic chains does not occur, and virtually any organ including the bone marrow may be involved at relapse.

Primary extranodal/organ involvement is uncommon in HL, unless related to direct extension. For example, while primary pulmonary presentations are rare, direct extension into the lung parenchyma is frequently observed, usually in the presence of adjacent mediastinal or hilar nodes. The lung is probably one of the most common nonlymphoid organs to be involved by HL, and such involvement may be manifested by linear infiltrates, pleural effusions, or nodular infiltrates demonstrated on chest X-ray or computed tomography (CT) scan. A rare patient may present with cough, wheezing, and endobronchial extension from an area of hilar lymphadenopathy. However, determination of pulmonary involvement can be quite problematic, as HL patients are predisposed to infectious complications including bacterial, viral, and atypical pneumonias. In addition, a history of granulomatous disease or fungal infection may be responsible for pulmonary scarring or nodules. The clinical setting, response to chemotherapy, and occasionally functional imaging techniques [positron emission tomography (PET) or gallium scanning] may help differentiate these abnormalities. Splenic involvement occurs frequently in HL, in approximately 30% of patients, and, as discussed later in this chapter, cannot be reliably detected with conventional imaging techniques. Splenic size alone is not adequate to determine involvement. Bone marrow involvement is quite unusual in HL and, when present, rarely results in cytopenias. Involvement is usually focal, and detection requires adequate bone marrow biopsy specimens. It should be remembered that flow cytometric analysis of bone marrow aspirates is usually

not helpful in classical HL, because Reed–Sternberg cells are infrequent and do not express surface immunoglobulins. Clonality cannot be established, and results generally reflect the background cell population. Diagnosis of bone marrow involvement, therefore, relies primarily on histopathologic analysis of an adequate core biopsy.

In addition to symptoms directly related to lymphadenopathy, patients may also complain of fevers, weight loss, night sweats, fatigue, or pruritus. B symptoms, defined as fever ($>38^{\circ}\text{C}$ or 100.4°F), unexplained weight loss ($>10\%$ body weight), or night sweats, are present in approximately 40% of patients. Since the presenting symptoms of classical HL are often nonspecific, including fatigue, cough, B symptoms, or pruritus, patients may describe these symptoms weeks to months prior to their diagnosis, and occasionally, only after persistent follow-up for these symptoms will a diagnosis be made. The Pel–Ebstein fever, an intermittent fever that recurs at variable intervals, has been associated with HL, although it is quite uncommon. The pruritus of HD can often be severe, leading to excoriations and hyperpigmentation from scratching, and may precede the diagnosis by months to years. A rare patient (typically an older male with a mixed cellularity type) will present with occult disease and fever of unknown origin. Systemic symptoms including weight loss, night sweats, and fevers may sometimes predominate, with minimal palpable adenopathy. Often only after extensive work-up, including imaging with CT scan, PET, or gallium scintigraphy, and/or bone marrow biopsy, will evidence of HL be detected. Other unusual presentations include pain related to bony involvement or nerve root compression from an epidural mass. Paraneoplastic syndromes including nephrotic syndrome, neurologic symptoms, or idiopathic thrombocytopenia purpura have also been reported and will be discussed later in this chapter.

Although the histologic subtype of HL does not appear to influence prognosis and does not alter therapeutic recommendations, each subtype is characterized by unique clinical characteristics that may guide the diagnostic evaluation as described below.

Nodular sclerosis Hodgkin's lymphoma

The nodular sclerosis subtype accounts for 70% of classical HL.¹³ This subtype is morphologically characterized by collagen bands that surround Hodgkin's or Reed–Sternberg cells. NS HL equally affects males and females and the median age at diagnosis is 28 years. At diagnosis, most patients present with stage II disease, with mediastinal involvement noted in 80% of patients, bulky disease (see Diagnostic Evaluation section for definition of bulky disease) in 54%, and splenic or lung involvement in only 10%.^{4,13}

Mixed cellularity Hodgkin's lymphoma

The mixed cellularity subtype is observed more frequently in patients with HIV disease, or in developing countries. It comprises 20–25% of classical HL cases, and is characterized by scattered Hodgkin's or Reed–Sternberg cells within a diffuse mixed inflammatory infiltrate without fibrosis.¹³ In contrast to NS HL, patients with MC HL are older (median age 37), predominantly male, and often with advanced-stage disease and B symptoms. Splenic involvement is reported in 30% of patients, bone marrow involvement in 10%, and liver involvement in 3%. Mediastinal presentations are uncommon.¹³

Lymphocyte-rich Hodgkin's lymphoma

This subtype comprises only 5% of classical HL, and again is seen most frequently in older males. Similar to MC HL, LR HL is pathologically characterized by Hodgkin's or Reed–Sternberg cells surrounded by an inflammatory infiltrate; however, these cells are primarily small lymphocytes with a notable absence of neutrophils and eosinophils.¹³ Most patients present with early-stage disease, in general with peripheral node involvement. Mediastinal involvement and B symptoms are uncommon.¹³

Lymphocyte-depleted Hodgkin's lymphoma

LD HL is the least common subtype of classical HL, often associated with HIV infection, composed of multiple, bizarre, large and small Hodgkin's or Reed–Sternberg cells in a fibrillary matrix with limited nonneoplastic inflammatory lymphocytes.¹³ Abdominal organs, retroperitoneal lymph nodes, and bone marrow involvement are favored, with relative sparing of peripheral nodes. Most patients with disease are male, with advanced-stage disease and B symptoms.¹³

Paraneoplastic syndromes

Classical HL is associated with the overexpression of a variety of cytokines and their receptors on Hodgkin's or Reed–Sternberg cells and in the surrounding inflammatory infiltrate. These cytokines, including interleukin 2 (IL-2), IL-5, IL-6, IL-7, IL-9, IL-10, IL-13, transforming growth factor β (TGF β), and lymphotoxin A (LT-A), may be responsible for the systemic symptoms of HL and for the rare paraneoplastic syndromes associated with HL. Nephrotic syndrome, idiopathic thrombocytopenia purpura, autoimmune hemolytic anemia, and cerebellar degeneration/ataxia have all been reported in patients with HL.^{14–18} Typically, nephrotic syndrome or neurologic symptoms precede a diagnosis of HL or herald a relapse, although occasionally high-dose steroids used to treat many of these syndromes may contribute to a delay in diagnosis.^{14,16} Idiopathic thrombocytopenia has been described in patients preceding the diagnosis of HL, at the time of relapse, and in patients in clinical remis-

sion for HL.^{17,18} Life-threatening complications of HL, including fulminant hepatic failure and lactic acidosis, have also been described,^{19,20} although these situations are quite rare.

DIAGNOSTIC EVALUATION

Initial diagnostic evaluation of HL is aimed at pathological confirmation, followed by additional evaluations to fully stage the patient. These assessments not only guide the patient's therapeutic management, but also impact prognosis. Patients with palpable lymphadenopathy should undergo an excisional biopsy in order to obtain an adequate diagnostic specimen. Fine needle aspirations are not sufficient to distinguish between classical HD and other CD30⁺ lymphomas including anaplastic T-cell lymphoma and diffuse large cell lymphoma. In addition, information regarding the subtype of HL (nodular sclerosing, mixed cellularity, lymphocyte rich, or lymphocyte depleted) may provide some guidance to expected clinical features.

The currently recommended diagnostic/staging work-up for patients with newly diagnosed HL is outlined in Table 72.1. The initial history and physical examination should address the presence or absence of B symptoms (defined as drenching night sweats, fever exceeding 38°C/100.4°F, or unexplained weight loss of

Table 72.1 Recommended diagnostic work-up for patients with HL

History and physical examination
B symptoms (The absence or presence of fever (>38°C), unexplained weight loss (>10% body weight), or night sweats)
EtOH intolerance
Pruritis
Fatigue
Performance status
Examination of nodes, Waldeyer's ring, liver, and spleen
Laboratory
CBC, differential, platelets

Lactate dehydrogenase (LDH)
Liver function tests (ALT, AST, bilirubin, alkaline phosphatase)
Albumin
BUN, creatinine
Serum/urine pregnancy test (in women of childbearing age)
HIV (if risk factors or unusual clinical presentation)
Imaging studies
Chest X-ray
CT chest/abdomen/pelvis (neck, in selected cases)
PET/gallium scanning (in selected cases)
Additional procedures
Bone marrow biopsy (bilateral, preferred)
Semen/oocyte cryopreservation

EtOH, ethanol; CBC, complete blood count; ALT, alanine transaminase; AST, aspartate transaminase; BUN, blood urea nitrogen, CT, computed tomography; PET, positron emission tomography.

at least 10% of the total body weight within the last 6 months), alcohol intolerance, pruritus, fatigue, performance status, and an examination of nodes, spleen, liver, and Waldeyer's ring. On physical examination, involved lymph nodes typically are nontender, rubbery, or firm. Large lymph nodes may coalesce, forming fixed, matted masses.

Initial laboratory testing should include a complete blood count with differential, erythrocyte sedimentation rate (ESR), lactate dehydrogenase (LDH), liver function tests, albumin, blood urea nitrogen (BUN), and creatinine. Elevated white blood cell count, lymphopenia, anemia, hypoalbuminemia, and an elevated ESR all have prognostic value in the treatment of HL (Table 72.2).^{21,22} In selected patients, HIV and pregnancy testing may also be indicated. Chest X-ray and CT scanning of the chest/abdomen/pelvis should be used to assess both the bulk and sites of disease at initial presentation. Patients presenting with signs or symptoms of naso-oropharyngeal involvement, such as the Waldeyer's ring, may require CT or magnetic resonance imaging (MRI) scans of the head and neck, to appropriately evaluate response. Bulky disease, usually defined as a mediastinal mass ratio (maximum

width of the tumor mass divided by maximum intrathoracic diameter) exceeding 1/3 or any single nodal/tumor mass exceeding 10 cm, is also an unfavorable prognostic factor. Other imaging techniques including PET or gallium scanning may be helpful, particularly in patients with large mediastinal masses or in the setting of indeterminate lesions on CT. These modalities will be discussed later in this chapter. Finally, bone marrow biopsy should be performed to complete the staging work-up. Bone marrow involvement has been reported in 5–15% of patients at diagnosis, and is frequently associated with the presence of B symptoms.^{23,24}

All patients should also be counseled regarding the risks of tobacco use during and after therapy, and fertility issues should be addressed. Specifically, with adriamycin, bleomycin, vinblastine, dacarbazine (ABVD) and Stanford V chemotherapy, there appears to be little effect on fertility, although this has not been studied exhaustively.^{25,26} However, intensive regimens including bleomycin, etoposide, adriamycin, cyclophosphamide, prednisone, procarbazine (BEACOPP) or other combination salvage therapies (including, but not limited to, ifostamide, carboplatin, etoposide (ICE), dexamethasone, cytarabine, cisplatin (DHAP), and etoposide, methylprednisolone, cytarabine, cisplatin (ESHAP)), followed by hematopoietic stem cell transplantation (SCT) for those patients who relapse, frequently affect fertility, and semen/oocyte cryopreservation is advised for those patients contemplating future parenthood. Finally, due to the high risk of second malignancies reported after combination chemotherapy and/or radiotherapy for classical HL,^{27,28} all patients should be advised about the need for continual follow-up and screening mammograms in the posttreatment period.

STAGING

Historically, staging of HL has followed the Ann Arbor staging system²⁹ (Table 72.3), although updated versions of this system incorporating a variety of prognostic factors exist (Table 72.4).³⁰ Overall, 55% of patients present with localized disease (Ann Arbor stage I–II).

The staging work-up for HD has evolved. Historically, lymphangiography, CT imaging, bone marrow biopsy, and staging laparotomy have been extensively used. Staging laparotomy evolved in an era where treatment for limited-stage (Ann Arbor stage I and II) HL consisted primarily of extended radiation therapy fields, and precise pathological staging was required to include all areas of involvement. With the detection of occult splenic or high retroperitoneal disease at the time of laparotomy in 20–30% of patients with clinical stage IA–IIA disease and 35% of patients with clinical stage IB–IIB disease,^{31,32} clinical staging alone was not accurate enough to predict which patients with early-stage HL were likely to attain a prolonged disease-free survival

Table 72.2 Prognostic factors in HL^{21,22}

Early-stage HL ²²	Advanced-stage HL ²¹
<i>EORTC criteria</i>	Albumin <4 g/dL
Large mediastinal mass	Hemoglobin <10.5 g/dL
Mediastinal mass ratio (MMR) >1/3	Male
Tumor/nodal mass >10 cm	Age ≥45 years
Age ≥50	Leukocytosis (WBC ≥15,000/mm ³)
ESR ≥50 without B symptoms or ≥30 with B-symptoms	Lymphopenia (Lymphocyte count <8% of WBC, or <600/mm ³)

Table 72.3 Ann Arbor staging system for Hodgkin's lymphoma²⁹

Stage I	Involvement of a single lymph node region or lymphoid structure, or involvement of a single extralymphatic site (I _E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm, which may be accompanied by localized contiguous involvement of an extralymphatic site or organ (II _E).
Stage III	Involvement of lymph node regions on both sides of the diaphragm, which may also be accompanied by involvement of the spleen (III _S) or by localized contiguous involvement of an extralymphatic site or organ (III _E)
Stage IV	Diffuse or disseminated involvement of one or more extralymphatic organs or tissues, with or without lymph node involvement.

Note: The absence or presence of fever (>38°C), unexplained weight loss (>10% body weight), or night sweats should be denoted by the suffix letters A or B, respectively.

with radiation therapy alone. Furthermore, even for patients with pathologically confirmed stage I and II disease, the recurrence rate after extended-field radiotherapy was approximately 20%. This led to the gradual abandonment of staging laparotomy for early-stage HL, in favor of a combined modality therapeutic approach. The addition of chemotherapy to the radiation regimen minimized the importance of detection of microscopic splenic involvement, and allowed the adoption of smaller radiation therapy portals (involved field), with significant improvements in toxicity and similar, if not better, outcomes. The elimination of staging laparotomy as part of routine staging also minimized the risk of postsplenectomy sepsis in patients with compromised immune function, and prevented prolonged treatment days associated with the hospitalization for surgical staging.

Gallium scintigraphy/positron emission tomography

⁶⁷Gallium scintigraphy and PET are often used to both accurately stage HL and assess response to treatment. Conventional CT scanning has not proven to be very sensitive for occult abdominal disease during the staging evaluation of HL. In addition, assessment of a residual mediastinal mass at the completion of therapy can be problematic with this modality. ⁶⁷Ga scintigraphy has proven to be more sensitive than CT in the posttreatment evaluation of HL, provided that the patient has a gallium-avid tumor at diagnosis.^{33–35} The positive and negative predictive values of ⁶⁷Ga scintigraphy following treatment range from 92 to 100% and from 83 to 90%, respectively,^{36,37} compared to 48% and 83% with CT.³⁶ PET scan using the glucose analog 2-(¹⁸F)-fluoro-2-deoxy-D-glucose (¹⁸F-FDG) has emerged as a very useful tool in the evaluation and

Table 72.4 Cotswolds update of the Ann Arbor staging system³⁰

Stage	Description
Stage I	Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer's ring) or involvement of a single extralymphatic site (I _E)
Stage II	Involvement of two or more lymph node regions on the same side of the diaphragm (the mediastinum is a single site; hilar nodes, when involved on both sides, constitute stage II disease); localized contiguous involvement of only one extranodal organ or site and lymph node region on the same side of the diaphragm (II _E). The number of anatomic regions involved should be designated by a subscript (e.g., II ₃)
Stage III	Involvement of lymph node regions on both sides of the diaphragm, which may also be accompanied by involvement of the spleen (III _S) or by localized contiguous involvement of only one extranodal organ (III _E) or both (IIIS _E)
III1	With or without involvement of splenic, hilar, celiac, or portal nodes
III2	With involvement of para-aortic, iliac, and mesenteric nodes
Stage IV	Diffuse or disseminated involvement of one or more extranodal organs or tissues, with or without associated lymph node involvement
Designations applicable to any disease stage	
A	No symptoms
B	Fever (temperature >38°C), drenching night sweats, unexplained weight loss of more than 10% of body weight in the preceding 6 months
X	Bulky disease (>1/3 widening of the mediastinum or the presence of a nodal mass >10 cm)
E	Involvement of single extranodal site that is contiguous or proximal to known nodal site of disease

monitoring of response in HL. In terms of diagnostic evaluation, in a small study of 11 patients undergoing staging laparotomy, the sensitivity and specificity of ¹⁸F-FDG PET were both 100%, compared to 20% and 83%, respectively, with CT scans.³⁸ In a larger study of 45 patients with Hodgkin's and non-Hodgkin's lymphoma (NHL), PET scanning altered the staging in 16% of patients, although it understaged 7% of patients.³⁹ Even more data exist regarding the impact of PET imaging on response assessment. In 54 patients with HL (19 patients) or NHL (35 patients), all 6 patients with a positive ¹⁸F-FDG PET relapsed—a positive predictive value of 100%, compared to 42% with conventional CT.⁴⁰ The negative predictive value of ¹⁸F-FDG PET in this trial was 83%, with eight patients relapsing despite a negative study. In a second study in 48 patients previously treated for HL, the positive and negative predictive values of ¹⁸F-FDG PET were both equal to 92%.⁴¹ However, while ⁶⁷Ga scintigraphy and

¹⁸F-FDG PET may both guide staging and treatment decisions, false positives do occur. For example, in patients younger than 25 years, a regenerating thymus can be gallium- or ¹⁸F-FDG avid, following completion of treatment of HL.^{42,43} Therefore, these noninvasive radiographic modalities do have utility in the diagnostic and response evaluation of HL; however, the results need to be interpreted in conjunction with the clinical circumstances, other laboratory evaluations, and CT results. In situations where PET or ⁶⁷Ga scintigraphy results contradict the clinical picture or are inconclusive, biopsy may be warranted.

LYMPHOCYTE-PREDOMINANT HODGKIN'S LYMPHOMA

EPIDEMIOLOGY

Classified as a distinct subtype of HL by the WHO classification,¹ LP HL is a monoclonal B-cell neoplasm characterized by a nodular polymorphic infiltrate composed of small lymphocytes, histiocytes, and large neoplastic cells, referred to as popcorn and L&H cells, that differ morphologically and immunohistochemically from Reed–Sternberg cells. L&H cells usually have one large multilobated nucleus with limited cytoplasm. These cells, unlike Hodgkin's Reed–Sternberg cells, are frequently positive for CD20 and CD79a, while negative for CD30 and CD15. Several series have also described unique clinical features for this subtype of HL.^{5–9,44} LP HL represents 3–5% of all HLs and typically afflicts 30- to 50-year-old males.⁴

CLINICAL FEATURES

In a retrospective review of 219 LP HL cases, the majority of affected patients were male (74%) and most patients presented with stage I–II disease (81%).^{5,44} These patients typically present with isolated cervical, axillary, or inguinal node involvement, while mediastinal, splenic, or bone marrow involvement is uncommon.⁴⁵ Likewise, bulky disease and B symptoms are infrequent. In the same series, only 7% of patients presented with mediastinal involvement, and only 10–13% of patients had bulky disease or bone marrow involvement.^{5,44}

Patients with LP HL often experience multiple relapses, although the disease progresses slowly and is usually quite responsive to therapy at the time of relapse, leading to little impact on overall survival.^{44,45} The European Task Force on Lymphoma reported a 10-year overall survival exceeding 90% for patients with LP HL, compared to a 10-year progression-free survival of approximately 75%.^{5,44} In a second retrospective review of 50 cases of LP HL, 78% of patients presented with early-stage disease, and overall survival at 4 years reached 92%.⁸ Similar results were reported in a Stanford series of 59 patients with LP HL.⁹ Interestingly, some case series have reported a high rate of second malignancies, ranging from 12 to 14%,^{5,8} in patients with LP-HL, possibly attributable to either extended radiation fields or chemotherapy historically used in the treatment of this disease. In addition, transformation to diffuse large B-cell lymphoma has also been described.^{46–48}

DIAGNOSTIC EVALUATION/STAGING

The diagnostic and staging evaluation of LP HL is similar to that previously described for classical HL. Diagnosis should be confirmed by an excisional or core needle biopsy, as fine needle aspirations frequently do not yield enough tissue to visualize the typical L&H cells surrounded by the polymorphic, nodular (or nodular and diffuse) infiltrate of reactive lymphocytes and histiocytes. CD20, CD57, CD15, CD30, and CD3 staining should be performed on all specimens of LP HL. The clinical history and physical examination should again focus on the presence of B symptoms, fatigue, evaluation of performance status, and examination of nodal sites. CBC with differential, LDH, BUN, creatinine, liver function tests, and staging imaging studies should also be performed. Staging according to the Ann Arbor system (Tables 72.3 and 72.4) is again recommended. CT scan of the chest/abdomen/pelvis (neck in selected cases) and bone marrow biopsy should be performed for staging purposes. ¹⁸F-FDG PET and ⁶⁷Ga scintigraphy have not been extensively evaluated for patients with LP HL, but may prove to be useful for patients with equivocal CT scans. Finally, patients should again be counseled regarding fertility, smoking cessation, and risk of second malignancies, as therapy often consists of combination chemotherapy and/or radiotherapy as has been used in classical HL.

Chapter **73****TREATMENT APPROACH TO
CLASSICAL HODGKIN'S LYMPHOMA***Brian J. Bolwell and Toni K. Choueiri***INTRODUCTION**

The treatment of Hodgkin's Lymphoma (HL) has significant historical importance in the field of medical oncology. Despite being a rare malignancy, HL has represented a model for oncologic advances. HL was one of the first oncologic illnesses proved to be potentially medically cured. Radiation therapy has long been known to be curative for the majority of patients with limited stage HL. Additionally, the concept of dose intensity was demonstrated to have clinical validity in patients with HL, as a clear dose response curve in radiation therapy dose has been demonstrated. Combination chemotherapy is potentially curative for patients with advanced stage HL and represents a paradigm for combining different effective chemotherapeutic agents in a single regimen. More recently, long-term toxicities and complications of therapy, including secondary cancers, significant organ damage, and other toxicities, have been demonstrated in patients presumably cured from their HL as a result of therapy. Late toxicities have generated a spirited debate in recent years of the optimal way to treat classical HL. This chapter will present the "standard" recommendations for the treatment of HL and will also present a contrarian viewpoint.

**CLINICAL STAGE I AND II HL:
"STANDARD" PRINCIPLES OF THERAPY****INTRODUCTION**

Historically, treatment algorithms were designed to determine which patients could be cured with radiation therapy alone and which patients had a poor prognosis with radiation therapy and required combination chemotherapy. This is why staging laparotomies evolved: if one could prove that a patient had no pathologic evidence of disease below the diaphragm, then one might save the patient from the toxicity of combination chemotherapy and successfully treat the patient with radiation alone. There were

many reasons for this treatment strategy. Extended field radiation therapy was successful, with the majority of patients with stage I and II HL being cured. In the 1970s and 1980s, acute toxicities from combination chemotherapy were significant. Antiemetic therapy was poor; the use of MOPP (mechlorethamine, oncovin (vincristine), procarbazine, and prednisone) combination chemotherapy had a known leukemogenic risk; issues of sterility were a genuine concern; and the risk of neutropenic fever and serious infections were clinically important, especially in the era prior to the availability of hematopoietic growth factors. Additionally, it was commonly felt that if patients progressed after radiation therapy, the majority could be successfully salvaged at a later date with combination chemotherapy. Thus, a 25–30% incidence of relapse after radiation therapy was deemed to be less significant because of later successful salvage with combination chemotherapy. As a result, radiation therapy continues to this day to be a primary treatment modality for limited stage HL.

RADIATION THERAPY

A detailed description of various radiotherapy techniques is beyond the scope of this chapter. Briefly, when radiation therapy is used alone for limited stage HL, tumor doses of 150–200 cGy are generally given 5 days/week, with a total dose of 3,600–4,000 cGy delivered over approximately 5 weeks. "Boosts" of radiation therapy may be given to bulky disease sites. Given that limited stage HL is usually above the diaphragm, the most common field incorporated is the *mantle field*. The mantle field encompasses the mediastinal, hilar, subcarinal, axillary, infraclavicular, supraclavicular, cervical, and submandibular lymph nodes. The para-aortic field encompasses the para-aortic nodes to approximately the L5 vertebral body. Frequently, para-aortic radiation therapy also encompasses the splenic pedicle, where the spleen is still intact. The combination of mantle, para-aortic, and pelvic radiation therapy is known as total lymphoid irradiation; the para-aortic region and pelvic region is known as an *inverted Y*.

Radiation therapy alone

Staging laparotomy was part of the standard work up of patients with HL in the 1960s and 1970s, in part due to a lack of effective radiological techniques to evaluate abdominal and pelvic lymphadenopathy. Most patients therefore underwent pathologic staging. In contrast, at the present time few patients undergo pathologic staging. Computerized tomography and positron emission tomography (PET scanning) have led to the common practice of clinical staging. With this evolution, some of the data concerning radiation therapy in the treatment of HL is dated.

There are several studies comparing limited field radiation therapy with broader radiation fields as the sole form of therapy in patients with limited stage HL. These studies are summarized in Table 73.1. The EORTCH 5 Trial included patients of age 40 or younger with nonbulky pathologic stage I and II, who and were considered a favorable risk group. Patients received mantle and periaortic radiation therapy versus mantle radiation therapy alone; no differences in disease-free survival (DFS) were seen between the two treatment groups.⁴ Regional radiation therapy was compared to involved-field radiation therapy (IFRT) in a BLNI Trial for pathologic stage IA and IIA patients; again, there were no difference in freedom from relapse (FFR).¹

These data contrast two other studies that reported inferior outcome in pathologically staged patients when comparing limited field radiation therapy to broader fields. The Stanford trial compared subtotal lymphoid radiation therapy with IFRT in pathologically staged IA and IIA patients; FFR was significantly different (80% vs 32%), respectively.³ Significant differences in FFR was also found in the Collaborative clinical trial, favoring mantle/periaortic radiation therapy with IFRT.² The Collaborative clinical trial also

found an advantage to subtotal lymphoid irradiation versus involved-field radiation for clinical stage I and II patients, in which FFR was 59% versus 32%, which was a statistically significant difference.

The utility of clinical staging in the treatment of patients with HL without a staging laparotomy was documented by the EORTCH 6 Trial.⁵ In this study, favorable patients (defined as no more than two nodal sites; no B symptoms; no bulky disease; and an erythrocyte sedimentation rate <30 mm) were studied. These “favorable” patients (which constituted only 45% of patients with clinical stage I and II disease) were randomized to either subtotal nodal radiation therapy plus splenic radiation therapy versus staging laparotomy with treatment modified by the results of surgery and histology. If laparotomy was positive, patients received chemotherapy. Patients with a negative staging laparotomy, and lymphocyte predominant or nodular sclerosing histology, were treated with mantle radiation therapy alone, and other histologies received subtotal nodal radiation therapy plus splenic radiation therapy. In this study, DFS was not statistically different in the surgically staged group versus the clinically staged group. Note that 30% of patients had a positive staging laparotomy. Overall survival (OS), paradoxically, was slightly worse in the laparotomy arm (93% vs 89%). This may or may not have reflected acute or later complications as a result of surgery.

As clinical staging has become increasingly common, a majority of programs specializing in the care of lymphoma patients generally use subtotal lymphoid radiation therapy, or other modifications of extended field radiation therapy, when treating favorable stage I and II patients. Mantle radiation therapy alone is rarely used at the present time.

Radiation therapy versus radiation therapy plus chemotherapy

Clinical trials of limited stage HL have more recently focused on the use of radiation therapy versus combined radiation therapy and chemotherapy. Decades ago, the specific chemotherapy regimen usually employed was MOPP. Given that MOPP has been replaced in the treatment of HL by ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine), these pioneering studies are of only moderate relevance to today's practice. As a general statement, these studies included both pathologically staged and clinically staged patients, and generally compared subtotal lymphoid radiation therapy or total lymphoid radiation therapy versus MOPP (or a variant of MOPP) combined with limited or extended field radiation therapy. Table 73.2 shows a summary of these studies. Two studies found an advantage (FFR) in combined modality therapy (CMT), whereas the others did not. There was no difference in OS in any study. Other findings of studies of this era are important. Multiple sites of disease were associated with less favorable outcome.⁸ Several studies

Table 73.1 Limited versus extended radiation therapy for early stage HL

Author	Ref.	Year	Comment
Hope-Stone	1	1981	Regional vs IF for PS I-IIA; regional vs IF for CSI-IIA; no difference in PFS or OS
Fuller	2	1982	PS I-II: extended field XRT better DFS than IF (66% vs 51%, $P = 0.05$) CS I-II: EF better DFS than IF (52% vs 35%, $P = 0.02$)
Rosenberg	3	1985	PS IA and IIA: STLI/TLI vs IF FFR 80% vs 32%, $P = 0.0001$; OS identical
Carde	4	1988	PS I-II STLI vs M: no difference in FFR

XRT, radiation therapy; IF, involved field; PS, pathologic stage; CS, clinical stage; EF, extended field; STLI, subtotal lymphoid irradiation; TLI, total lymphoid irradiation; FFR, freedom from progression; M, mantle field.

Table 73.2 Selected early trials of extended radiation therapy versus extended radiation therapy + chemotherapy in early stage HL

Author	Ref.	Year	Comment
Jones	6	1982	PS I-II involved field XRT + MOPP vs extended field XRT—trend toward improved RFS with combined therapy ($P = 0.12$). No difference in OS. Predominant RFS effect on those patients with B symptoms ($P < 0.03$)
Nissen	7	1982	PS I-II randomized to extended field XRT or mantle XRT + MOPP. RFS better with combined therapy ($P < 0.05$). No difference in OS
Rosenberg	3	1985	PS IA—II B Randomized to IF XRT + MOPP vs extended field XRT. Combined better RFS but no difference in OS. PS IB- IIB TLI + MOPP vs TLI. No difference in RFS or OS
Tubiana	8	1989	PS I-II Randomized to MOPP + extended field XRT vs TLI DFS better in combined therapy, but no difference in OS

PS, pathologic stage; XRT, radiation therapy; IF, involved field; TLI, total lymphoid irradiation.

also concluded that large mediastinal masses (LMMs) were an adverse prognostic sign. In particular, patients with bulky mediastinal masses treated with radiation therapy alone had a high incidence of disease relapse, and most of these studies recommended CMT for this group of patients.^{9–14}

An additional early trial used a different approach, as patients with limited stage HL were randomized to

chemotherapy with cyclophosphamide, vinblastine, procarbazine, and prednisone (CVPP) alone or CVPP plus IFRT. The study found no differences in relapse-free survival (RFS) or OS. Additional prognostic factors were age more than 45 years and more than two lymph node areas involved with HL, as well as bulky disease.¹⁵

A meta-analysis of 3500 patients treated on randomized trials of more versus less extensive radiation therapy and trials comparing radiation therapy plus chemotherapy to radiation therapy alone was published in 1998.¹⁶ Adding chemotherapy reduced the risk of recurrence by 50% but did not improve OS. This was felt to be a result of an ability to salvage radiation therapy failures with subsequent chemotherapy.

Recent trials of CMT

A sample of the recently reported randomized trials of limited stage HL is shown in Table 73.3. The usual design of the studies is a comparison of extended field radiation therapy versus abbreviated chemotherapy, combined with either limited or extended field radiation therapy. In three studies, the control group was extended field radiation therapy and abbreviated courses of chemotherapy were given with either extended-field radiation therapy or IFRT. Freedom from progression was improved in the combined modality group in all three trials; OS was identical. Bonadonna et al. investigated the use of four full cycles of ABVD chemotherapy followed by either IFRT or extended-field radiation therapy. No differences in 12-year freedom from progression or OS were noted.

All of this data has led to the National Comprehensive Cancer Network (NCCN) practice guidelines for limited stage HL to focus on the use of extended field radiation therapy alone or CMT.²¹ For clinically staged patients with supradiaphragmatic presentation, the most common presentation of limited stage HL, the NCCN practice guidelines focused on three patient groups: those with no unfavorable factors, those with bulky disease, and those with nonbulky disease with an erythrocyte sedimentation rate (ESR) greater than 70 or three sites involved. The recommendations for

Table 73.3 Recent limited stage HL randomized trials

Author	Ref.	Year	Design	Comment
Hagenbeek	17	2000	543 pts. supradiaphragmatic CS I-II, age < 50 nonbulky, randomized to MOPP/ABV hybrid × 3 + IF XRT vs STLI	4y FFS better in combined arm: 99% vs 77% ($P < 0.0001$). OS 99% vs 95% ($P = 0.019$)
Press	18	2001	326 pts. supradiaphragmatic CS I-II randomized to STLI or 3 cycles ROXO + vlb + STLI	3y FFS better in combo arm: 94% vs 81% ($P < 0.001$). OS > 95% no difference
Sieber	19	2002	571 favorable CS I-II pts. randomized to ABVD × 2 + EF vs EF alone	2y FFP better in combo arm: 96% vs 84%, ($P < 0.05$). 2y OS 98% vs 98%
Bonadonna	20	2004	136 limited stage randomized to ABVD × 4 + IF XRT or STLI	No difference in FFP or OS

FFP, freedom from progression; CS, clinical stage; IF, involved field; EF, extended field; XRT, radiation therapy; STLI, subtotal lymphoid irradiation.

these three groups are as follows: for the favorable group, the recommendation is for subtotal lymphoid irradiation alone or CMT; for the group with bulky disease, CMT is recommended; for the nonbulky group with other high risk factors, either CMT (preferred) or subtotal lymphoid irradiation therapy is recommended. None of these recommendations for limited stage HL include chemotherapy alone.

Two recent studies have explored the use of ABVD alone for limited stage HL. A Canadian trial randomized 399 patients with nonbulky stage I-IIA disease, comparing four to six cycles of ABVD chemotherapy with extended field radiation therapy (in a high-risk group), or to two cycles of ABVD plus extended field radiation therapy (in a low-risk group). Five-year freedom from progression was slightly inferior in the ABVD group (87% vs 93%, $P = 0.006$). OS was the same, 96% (ABVD) versus 94% (standard therapy).²² Strauss et al. studied 152 untreated clinical stage I-III non-

bulky HL, comparing outcome to either six cycles of ABVD, or six cycles of ABVD followed by radiation therapy (involved-field or extended-field).²³ With five years follow-up, there was no difference in freedom from progression, or OS, in the two arms. Much smaller series have also described the clinical utility of ABVD alone in limited stage HL.^{24,25}

LATE EFFECTS AFTER PRIMARY THERAPY FOR HL

It is now known that secondary malignancies are a serious and potentially lethal consequence of primary HLe therapy. The combination of death from secondary malignancies and posttreatment cardiac mortality may result in more deaths for patients with favorable limited stage HL than does the HL itself.

Table 73.4 shows a summary of recently reported large studies examining the risk of secondary malignancies in patients who received therapy for HL. The vast majority of patients described in these studies received

Table 73.4 Secondary malignancy after HL therapy

Author	Ref.	Year	N	Follow-up	Findings
Bhatia	26	1996	1380	11.4 (median)	18-fold risk of all cancers. 7% absolute incidence at 15y. Breast cancer risk more than five times general population. BC risk associated with higher dose of radiation therapy. 46/47 solid tumor pts. received XRT ± chemotherapy.
Aisenberg	27	1997	111 women stage I-II HL treated with mantle XRT	18 y (median)	34% of pts. aged less than 20y developed breast cancer; 22% of those aged 20–29. No plateau in incidence with time.
van Leeuwen,	28	2000	1253	14y (median)	25y actuarial risk of malignancy 28%; risk of solid tumors higher for younger patients; no plateau in incidence with time; 27/27 breast cancer pts. received XRT ± chemo; 48/49 other solid tumor pts. received XRT ± chemotherapy.
Swerdlow	29	2000	5519	8.5y (mean)	20y cumulative risk of secondary malignancy 15%; 8% solid tumors. Relative risk of solid tumors (10y, 61, breast) greater for younger pts.
Metayer	30	2000	5925	10.5 (mean)	Sevenfold-increased risk of solid tumors, 27-fold risk of acute leukemia. 20y HL survivors have the following fold risk of developing cancers: breast—8; thyroid—38; cervix—11; GI—11. No secondary leukemic reported after 20 years, while risk of solid tumors continue. Vast majority of pts. in this cohort received XRT.
Ng	31	2002	1319	12 (median)	Fivefold-increased risk of secondary malignancy. Risk increased with increasing radiation field size. No plateau in risk after 20 years.
Dores	32	2002	32,591	8 (mean)	25y after HL therapy risk of developing a solid tumor 22%; no plateau in incidence; younger age has a higher relative risk of developing a solid tumor.

XTR, radiation therapy.

radiation therapy alone or radiation therapy in combination with chemotherapy. Several themes are apparent. Female patients receiving radiation therapy at a young age have a tremendously increased risk of developing breast cancer.²⁶⁻²⁸ Indeed, the relative risk of developing any solid tumor is higher if the patient is treated at a younger age.^{29,32} The risk of developing a solid tumor is increased if radiation therapy alone was used as opposed to chemotherapy alone.^{26,28,32} The risk of solid tumors continues with time; there is no plateau in the incidence of secondary solid tumors.³² As an example, with 25 years of follow-up, the risk of developing a secondary solid tumor is as high as 28%.²⁸ The risk of developing a hematologic malignancy is highest 5–10 years after therapy; there is no increased risk of hematologic malignancy after 20 years of therapy.³² The size of the radiation therapy field is associated with an increased risk of developing secondary solid tumors.³³ Additional studies have determined that the risk of breast cancer is associated with radiation therapy dose. The risk with radiation therapy dose appears to increase linearly, from at least 4–40 Gy.³³

A meta-analysis of over 8000 females diagnosed with HL between 1973 and 1999 was recently reported.³⁴ The purpose was to examine the influence of radiation therapy on the time interval to the development of breast cancer. Out of 8,036 women, 183 (2.3%) were subsequently diagnosed with breast carcinoma. The use of radiation therapy in the treatment of HL resulted in an increased risk of the development of breast carcinoma ($P < 0.01$). A regression model revealed that the use of radiotherapy had an adverse effect on long-term survival (relative risk = 1.84, $P = 0.01$).

Radiation therapy to the chest is also associated with an increased risk of ischemic coronary artery disease,

involving the carotid and/or subclavian arteries, and valvular cardiac disease. A sampling of recent studies examining the relationship of radiation therapy with the development of cardiac disease is shown in Table 73.5. Some common themes to these studies are given next. The risk of ischemic coronary artery disease increases with time: there is approximately a 5–7% risk at 10 years and a 10–20% risk at 20 years.^{36,39} The risk of death from ischemic heart disease is five times that of controls. The risk of ischemic death is 2–6% at 10 years and 10–12% at 20 years.^{36,38} There is an eightfold risk of developing symptomatic valvular heart disease, most commonly involving the aortic valve.³⁹ All of these risks are associated with higher doses of radiation therapy and larger radiation therapy fields.^{35,38,39} The addition of chemotherapy does not contribute to increased risk of any form of cardiac disease.^{36,39} The risk of developing cardiac disease in conjunction with mantle radiation therapy seems to be particularly observed in patients who have other known cardiac risk factors, such as hypertension and elevated lipid levels.

In summary, the risk of developing coronary artery disease is dramatically increased with the use of radiation therapy to the chest. The risk of the development of solid tumors is increased with radiation therapy as well. Both of these risks continue with time and show no evidence of a plateau in their incidence with follow-up beyond 20 years.

An important but sometimes neglected article was published years ago examining the incidence of second neoplasms after ABVD in HL.⁴⁰ Over 1000 consecutive patients with HL were studied. In contrast to MOPP chemotherapy, there is no increased incidence of secondary malignancy seen in patients treated with ABVD chemotherapy.

Table 73.5 Recent trials of treated HL and cardiovascular disease

Author	Ref.	Year	N	Follow-up	Comment
Hancock	35	1993	2232	9.5 (mean)	4% died of heart disease, 63% from CAD. Mediastinal XRT dose > 30 Gy associated with increased risk of death from MI increases with time.
Reinders	36	2000	258 treated with mantle XTR	14.2 (median)	12% developed ischemic heart disease. Actuarial risk at 25 years of cardiac death 10%.
Lee	37	2000	210 treated with mantle XTR	15-16 (median)	27% incidence of cardiovascular complication. Median time to cardiac event was 15 years.
Erikson	38	2000	157 mantle XTR	16 (median)	8% died from ischemic heart disease. Greater risk with larger volume fraction and higher XRT dose.
Hull	39	2003	415 chest XTR	11 (median)	10% developed ischemic heart disease at a median 9 years after treatment. 7% developed carotid and/or valvular dysfunction at a median of 22 years, most commonly aortic stenosis. Risk associated with higher XRT dose. Chemotherapy not associated with higher risk.

XRT, radiation therapy; MI, myocardial infarction; CAD, coronary artery disease.

THE CONTRARIAN APPROACH TO LIMITED STAGE HL

Virtually every textbook echoes the NCCN practice guidelines for HL in recommending radiation therapy in one form or another for limited stage disease. The radiation therapy is frequently coupled with chemotherapy, resulting in the now accepted combined modality approach. This approach has evolved for many reasons. First, it works fairly well; most patients with early stage HL are cured with this approach. Second, it builds on historical data. Initially, radiation therapy was much easier to administer to patients than was chemotherapy and resulted in generally good outcomes. Thirty years ago chemotherapy was something to avoid if at all possible. Additionally, when successful therapy for HL began there was no knowledge of long-term late effects of radiation therapy, because there was no long-term follow-up of successfully treated patients.

However, we now know that radiation therapy contributes to an increased risk of second malignancies, which continues to rise as the length of follow-up increases. Radiation therapy is also associated with cardiac toxicities that increase the risk of cardiac death in “successfully” treated patients. We also know that ABVD neither have a significant risk of secondary malignancies nor long-term cardiac toxicities (assuming that patients are monitored appropriately during the delivery of doxorubicin-based chemotherapy). Additionally, as described previously, we now have data on two recent studies examining the use of ABVD alone for limited stage HL, in which the clinical outcomes are outstanding.²³⁻²⁵ A logical question to ask is why should we give radiation therapy at all. The contrarian viewpoint in the treatment of early stage HL would answer this question as follows: given our current knowledge base, there is no reason to give radiation therapy in early stage HL; simply give everyone ABVD.

Dr. Dan Longo was a pioneer in the treatment of HL. He has written several editorials recently on this subject. In 2002 he wrote,

My fear is that we have ample evidence that radiation therapy is harmful and that it is no longer needed to treat most patients with Hodgkin's lymphoma. The safest and most effective way to manage patients with Hodgkin's lymphoma is to use clinical staging followed by six cycles of combination therapy. ABVD is probably the most effective available chemotherapy regimen we should be using radiation therapy more judiciously, rather than finding excuses to use it in every patient. The next generation and our patients will judge us harshly for failing to heed the obvious signs.⁴¹

In 2003 Dr. Longo wrote

The prevailing thinking seems to be as follows: if we give combined modality therapy we can cut back a

little on the radiation dose and cut back a little on the chemotherapy cycles and that should preserve the anti tumor effects and minimize the toxicity. Au contraire. No dose of radiation therapy is without life threatening late sequelae, and six cycles of ABVD chemotherapy alone appears to be extremely effective in all stages of Hodgkin's lymphoma without any reported life threatening toxicities.⁴²

Finally, in December 2004, Dr. Longo wrote an editorial and stated

Large cohorts of patients treated with radiation therapy have now been followed for many years and groups have reported that deaths related to radiation therapy treatment outnumbered deaths related to Hodgkin's lymphoma. Mediastinal radiation therapy is associated with a three fold increased risk of fatal myocardial infarction from accelerated coronary atherosclerosis. Furthermore, patients treated with radiation therapy have a risk of developing a secondary malignancy of about 25% in 25 years with no evidence that that risk is decreasing with time it is time to adopt a new approach to Hodgkin's lymphoma treatment: clinical staging followed by ABVD chemotherapy in all stages of disease. No life is without risk but such an approach removes the imminent threat posed by radiation exposure for the majority of patients.⁴³

Radiation therapy has significant late toxicities that seem to be largely ignored by the oncologic community. ABVD is an extremely effective treatment of HL and not associated with long-term toxicities. The vast majority of early stage HL patients should receive ABVD alone. The possible exceptions are those with LMMs who have a positive PET scan at the end of completion of chemotherapy. Such patients might benefit from radiation therapy, although this point has not been definitively proven.

CLINICAL STAGE III AND IV (ADVANCED) CLASSICAL HL: TREATMENT PRINCIPLES

INTRODUCTION

Many patients present with advanced stage HL.⁴⁴ In the 1960s, DeVita and colleagues from the National Cancer Institute (NCI) introduced a multiagent chemotherapy regimen known as MOPP that established cure in over 50% of patients with advanced disease.⁴⁵ Before this era, 5-year survival from advanced HL barely reached 5%. However, MOPP had significant short- and long-term toxicities. Investigators subsequently examined other regimens, such as ABVD. ABVD yields similar survival rates as MOPP but has fewer short- and long-term toxicities. What follows is a brief review of the historical development of chemotherapy regimens for advanced HL, a discussion of the “new” regimens used for higher-risk

patients, and an examination of the role of radiation therapy as part of CMT in the advanced disease setting.

CHEMOTHERAPY REGIMENS

MOPP and MOPP derivatives

The dosage, schedule, and frequency of MOPP chemotherapy are described in Table 73.6. Patients receive four drugs over a 2-week interval followed by a 2-week recovery period. A total of 4 weeks constitutes one cycle of treatment. Most patients receive six cycles. Historically, the dose of vincristine used in MOPP frequently exceeded the currently recognized dosage limit of 2 mg. Two updated mature studies with 10⁴⁵ and 14 years⁴⁶ follow-up, respectively, showed that 66% of patients have remained disease-free more than 10 years from the end of treatment. Forty-eight percent of advanced HL patients have survived between 9 and 21 years (median, 14 years) from the end of treatment. Nineteen percent of the complete remission cases have died of intercurrent illnesses, free of HL.^{45,46}

Unfortunately, acute and long-term toxicities of MOPP regimen were significant. These toxicities ranged from nausea to death. Overall mortality

approached 2.5% in the NCI series and 1.5% in smaller studies.⁴⁷ Hematologic toxicities, although reversible, were sometimes fatal, as hematopoietic growth factor compounds were not available at that time. Vincristine-associated neuropathy was clinically relevant with doses more than 2 mg. Procarbazine was associated with severe emesis, and a type I allergic reaction in rare cases.

Long-term toxicities were of even more serious concern. Most patients experienced infertility after treatment with MOPP. Males had at least an 80% risk of permanent azospermia after MOPP, while 50% of females experienced gonadal failure.^{47,48} The risk appeared lower with patients younger than 25 years of age; however, accelerated early menopause seemed to be the case in every female who did recover her menses after treatment.⁴⁶ At a time when sperm banking and oocyte cryopreservation were in their early stages, many young patients, though cured, experienced significant psychological repercussions due to their infertility.

Another major problem with MOPP was the observation of myelodysplastic syndrome (MDS) and acute leukemia in up to 6% of patients. These hematologic malignancies started 2 years after treatment, with a

Table 73.6 Main chemotherapy regimens used in advanced HL

Regimen	Dosage (mg/m ²)	Route	Schedule	Cycle duration
MOPP				28 days
Mechlorethamine	6	IV	Days 1, 8	
Vincristine ^a	1.4	IV	Days 1, 8	
Procarbazine	100	PO	Days 1–14	
Prednisone	40	PO	Days 1–14	
ABVD				28 days
Adriamycin	25	IV	Days 1, 15	
Bleomycin	10	IV	Days 1, 15	
Vinblastine	6	IV	Days 1, 15	
Dacarbazine	375	IV	Days 1, 15	
MOPP/ABV Hybrid				28 days
Mechlorethamine	6	IV	Day 1	
Vincristine ^a	1.4	IV	Day 1	
Procarbazine	100	PO	Days 1–7	
Prednisone	40	PO	Days 1–14	
Adriamycin	35	IV	Day 8	
Bleomycin	10	IV	Day 8	
Vinblastine	6	IV	Day 8	
Stanford V				28 days (total of three cycles)
Adriamycin	25	IV	Day 1, 15	
Vinblastine	6	IV	Day 1, 15	
Mechlorethamine	6	IV	Day 1	
Vincristine	1.4	IV	Day 8, 22	
Bleomycin	5	IV	Day 8, 22	
Etoposide	60	IV	Day 15, 16	
Prednisone	40	PO	Every other day	

^aVincristine dose capped at 2 mg.

peak around the fifth year, and were associated with an extremely poor prognosis, with a median survival of 6 months.⁴⁹ Although the risk of leukemia was mostly attributed to concomitant radiation, patients with MOPP therapy alone were at increased risk of leukemic transformation.^{49,50}

MOPP derivatives were introduced in the mid 1970s with the goal of similar efficacy with less toxicity. A prospective randomized trial by the Cancer and Leukemia Group B (CALGB) examined a new combination, BOPP (BCNU (carmustine), vincristine, procarbazine, and prednisone), derived from substitution of BCNU for nitrogen mustard in the MOPP regimen. BOPP was compared to MOPP and to 2 three-drug regimens, derived by removing the procarbazine in BOPP (BOP) or removing the alkylating agent (OPP). The four-drug programs resulted in significantly higher frequency of complete remissions (BOPP 67%, MOPP 63%) than the three-drug regimens (BOP 40%, OPP 42%), and a significantly longer duration of remission and survival. In addition, BOPP had less toxicity.⁵¹ Bakemeier et al. prospectively compared BCVPP (carmustine, cyclophosphamide, vincristine, procarbazine, and prednisone) to MOPP. Two hundred ninety-three patients were evaluable in the induction phase of this study. The complete remission rates of BCVPP and MOPP were similar. The duration of complete remissions for previously untreated patients given BCVPP was significantly longer than that for previously untreated patients given MOPP ($P = 0.02$). Although hematologic toxicities were similar, BCVPP caused less gastrointestinal ($P = 0.0001$) and neurological toxicity ($P = 0.01$) than MOPP. More importantly, previously untreated patients achieving complete remission with BCVPP had a better OS than those receiving MOPP ($P = 0.03$).⁵²

In other studies, alkylating agents such as cyclophosphamide or chlorambucil were used instead of the nitrogen mustard, resulting in similar efficacy but less treatment-related leukemia.^{53,54}

ABVD

In 1975, the ABVD regimen was introduced by Bonadonna et al. in an attempt to find a salvage treatment for MOPP failure. The dosage and schedule of this regimen are described in Table 73.6. The study involved a small number of patients (65 patients) and showed that ABVD was safe and could be used in cases of MOPP resistance. Moreover, it was well tolerated, with more than 85% of the intended dosage being delivered.⁵⁵

The same European group published a randomized trial in a larger cohort of 237 patients comparing the “new” ABVD regimen to the standard MOPP therapy. Three cycles of either combination chemotherapy preceded and then followed subtotal or total nodal radiation. The 7-year results indicated that ABVD was statistically superior to MOPP in terms of freedom from progression (80.8% vs 62.8%), RFS (87.7% vs 77.2%),

and OS (77.4% vs 67.9%). Gonadal toxicities and leukemia were only seen in patients receiving MOPP therapy.⁵⁶ Even with the clear benefits of ABVD over MOPP in this study, it was largely criticized due to the difficulty delivering the planned MOPP dosage after receiving extensive radiation.

A landmark US study from the CALGB in 1992 randomized 361 patients with advanced HL to receive MOPP, ABVD, or a combination of MOPP alternating with ABVD. Patients not achieving a complete response or who relapsed with either MOPP alone or ABVD alone were switched to the opposite regimen. Overall survival at 5 years was 66% for MOPP, 73% for ABVD, and 75% for MOPP-ABVD ($P = 0.28$ for the comparison of MOPP, with the anthracycline-containing regimens). While an improvement in OS did not occur, ABVD regimens did have a higher rate of complete response (82% vs 67%), less hematologic toxicity, and a higher rate of failure-free survival (FFS) at 5 years (61% vs 50%), when compared to MOPP. Patients with recurrent disease after ABVD subsequently received MOPP, with 61% achieving a second remission. In comparison, only 35% of those who suffered relapse after MOPP responded to ABVD. The alternating regimen (MOPP-ABVD) was not superior to ABVD and had more hematologic toxicity.⁵⁷ Patients did not receive radiation in this study, thus allowing a direct comparison of the three chemotherapy regimens. A long-term follow-up of this study over 15 years has recently been published, demonstrating a 45% to 50% progression-free survival (PFS) and a 65% OS rate for ABVD and MOPP/ABVD.⁵⁸

Due to the favorable outcomes associated with ABVD, it started to replace MOPP in most cases of advanced HL. Most patients were able to receive all of the planned treatments.⁵⁷ In addition, acute toxicities, such as bone marrow depression and neurotoxicities seen with MOPP, were much less frequent with ABVD. Long-term toxicities, including gonadal dysfunction, were encountered less frequently with ABVD than with MOPP, with reversibility in most of the cases.⁵⁹ In the European trial mentioned earlier,⁵⁶ no cases of therapy-related leukemia were seen with ABVD as compared with 6.5% with MOPP therapy, even with the use of radiation in both arms.

Anthracycline inclusion in the ABVD regimen were of concern initially, as doxorubicin is known to be associated with cardiomyopathy. However, six cycles of ABVD provide a total of 300 mg/m² of doxorubicin, which is well under the doses (450–500 mg/m²) usually associated with cardiac toxicities.⁶⁰ Although patients who receive mantle field radiation therapy have a threefold-increased risk of fatal myocardial infarction,³⁵ evidence is lacking to support an additive toxicity from concomitant anthracycline use.⁵⁶

Short- and long-term effects of bleomycin include pulmonary toxicity. In one trial, ABVD chemotherapy induced acute pulmonary toxicity that required

bleomycin dose modification in 37% of patients.⁶¹ The addition of radiation therapy resulted in a further decrease in vital capacity; however, this did not significantly affect normal daily activities. High-risk groups for bleomycin toxicity include children, patients with compromised respiratory status, or concomitant use of bleomycin and gemcitabine.^{62,63}

MOPP/ABV hybrid

This "hybrid" regimen is described in Table 73.6. Patients receive parts of a MOPP cycle combined with components of an ABVD cycle, over a 1-month period. An Eastern Cooperative Oncology Group (ECOG) trial showed a high response rate for this regimen coupled with an OS advantage when compared with sequential MOPP followed by ABVD regimen.⁶⁴ However, two other trials failed to show any FFS or OS benefit from the MOPP/ABV hybrid, when compared to an alternating regimen of MOPP/ABVD.^{65,66} These mixed results prompted the initiation of an intergroup trial comparing the hybrid regimen with the standard ABVD chemotherapy. Results from this trial showed no statistical difference in FFS and 5-year OS between the two arms.⁶⁷ However, the MOPP/ABV hybrid was associated with significant treatment-related deaths, secondary malignancies, and infections.⁶⁷ As ABVD has the same overall efficacy with less toxicity than the MOPP/ABV hybrid, it continues to be the "standard treatment" in advanced HL.

Stanford V

This regimen was introduced in 1995 with an objective of improving cure rate and limiting toxicities. Table 73.6 describes the schedule dosing of this regimen. Essentially, it is similar to the MOPP/ABV hybrid regimen but adds modest doses of Etoposide. Radiation therapy is an integral component of this regimen with 36 Gy radiation given to sites of bulky disease more than 5 cm in diameter. An initial report, followed recently by more mature data, showed an FFS of 86% with a 95% OS after 6.9 years of follow-up.^{68,69} These numbers remained consistent in patients with bulky mediastinal disease.⁷⁰ Secondary malignancies and infertility were reported to be less than 10%. This favorable toxicity profile, coupled with excellent efficacy, prompted interest in this regimen as a substitute for ABVD.⁷¹ However, a recent study from Italy showed an FFS inferiority for the Stanford regimen as compared to ABVD.⁷² This study compared three chemotherapy regimens: Stanford V, ABVD, and MOPP-EBV-CAD (MEC) (a combination regimen using mechlorethamine, CCNU, vindesine, alkeran, prednisone, epidoxorubicin, vincristine, procarbazine, vinblastine, and bleomycin). Although OS was not statically different, FFS, at 56 months follow-up, was 83% for ABVD, compared to 67% for Stanford V. However, an important point is that Stanford V is a combined modality regimen, with radiation therapy routinely given in up to

85% of the patients. The Italian trial used radiation therapy in only two-thirds of patients, and frequently at suboptimal dosages. Stanford V, with or without radiation therapy, is currently being compared to ABVD in advanced HL in an intergroup trial.⁷¹

BEACOPP regimen

The majority of patients with advanced HL are cured with standard anthracycline-based treatments. Approximately one-third of such patients fails to achieve a long-term remission and therefore may benefit from a more intensified initial regimen. An accurate prognostic algorithm is necessary to identify patients in whom standard treatment is likely to fail.

In 1998, a seven-factor prognostic scoring system that focused on 5-year rates of freedom from progression of disease was developed. This system, known as the international prognosis index (IPI), uses seven independent prognostic factors: serum albumin level of less than 4 g/dL; hemoglobin level of less than 10.5 g/dL; male sex; age of 45 years or older; stage IV disease (according to the Ann Arbor classification); leukocytosis (a white-cell count of at least 15,000/mm³); and lymphopenia (a lymphocyte count of less than 600/mm³, a count that was less than 8% of the white-cell count, or both). The score predicted the rate of freedom from disease progression with higher scores associated with increased risk of disease progression.⁷³ The IPI was incorporated in a major German trial where two "intense" regimens, known as BEACOPP (bleomycin, etoposide, adriamycin, cyclophosphamide, vincristine, procarbazine, and prednisone) were tested against COPP-ABVD, a combination that many experts find equivalent to ABVD.⁷⁴ A description of these two BEACOPP regimens (baseline and escalated) and COPP-ABVD is outlined in Table 73.7. The BEACOPP regimen was developed in an attempt to improve treatment results in advanced HL by dose and time intensification and addition of etoposide. It employs a schedule permitting a shortened 3-week cycle. With growth factor support, the dosages of cyclophosphamide, etoposide, and adriamycin were moderately escalated. The trial, known as the HL-9 trial, included more than 1000 patients with advanced disease. After a follow-up of more than 50 months, the rate of freedom from treatment failure at 5 years was 69% in the COPP-ABVD arm, 76% in the BEACOPP-baseline arm, and 87% in the escalated-arm BEACOPP arm ($P = 0.04$) for the comparison of the COPP-ABVD arm with the BEACOPP arms (both the baseline and escalated arms). The 5-year rates of OS were 83% with COPP-ABVD, 88% with BEACOPP-baseline, and 91% with BEACOPP-escalated. Only the comparison of BEACOPP-escalated and COPP-ABVD was statistically significant for OS. Taking into account the IPI, patients with poor risk factors (\geq four adverse factors) had a much more pronounced benefit from BEACOPP regimens compared to COPP-ABVD, with 5-year OS

Table 73.7 BEACOPP (baseline), BEACOPP escalated, and COPP/ABVD regimens

Regimen	Dosage (mg/m ²)	Route	Schedule	Cycle duration
BEACOPP (baseline)				21 days
Bleomycin	10	IV	Day 8

exceeding 80%, as compared to 67% in the COPP-ABVD arm.⁷⁴ On the other hand, in the group of patients with zero to one adverse prognostic factors, OS did not differ among the three arms. Unfortunately, this intensification in chemotherapy resulted in a higher incidence of side effects: bone marrow toxicity, including grade 3 and 4 anemia, thrombocytopenia, infections, azospermia, and mucositis. At a median follow-up of 7 years, secondary hematologic malignancies were 2.4% in the escalated BEACOPP arm, 1% in the BEACOPP-baseline group, and 0.4% in the COPP-ABVD arm.⁷⁵ Toxicities seemed to be more significant with advanced age, as a 21% mortality was noted in patients between 66 and 75 years old.⁷⁶ Studies are currently evaluating a shorter duration of the BEACOPP regimen (14 days) in addition to growth factors.⁷⁷ Another study is evaluating a “hybrid” regimen of escalated and standard BEACOPP, where patients get four cycles of each chemotherapy regimen in an attempt to reduce toxicity and maintain same cure rates.⁷⁵ These studies are ongoing.

ROLE OF RADIATION THERAPY IN ADVANCED HL

In addition to chemotherapy, radiation therapy presents a potentially attractive tool against advanced HL.

Early observations showed that the majority of relapses occurred in previously involved, nonirradiated sites. Retrospective studies from the early 1990s showed a 10-year DFS of 89% in-patients with advanced HL who received radiation, compared to 68% in-patients without radiation.⁷⁸ Similar results were reproduced in another retrospective study.⁷⁹ These encouraging results from CMT provided the basis for randomized controlled trials, summarized in Table 73.8.

A Southwest Oncology Group (SWOG) trial randomized 278 patients with stage III and IV HL to receive additional radiation therapy or observation after achieving complete remission (CR) with MOPP-based chemotherapy.⁸⁰ In an intention-to-treat analysis, RFS and OS at 8 years of follow-up were not statistically different. Another trial from a German group randomized patients in CR after six cycles of combined COPP-ABVD to receive one additional cycle of chemotherapy with COPP-ABVD versus radiation therapy to initially involved sites. Again, DFS and OS were not different in both groups.⁸¹ In a multicenter randomized French study, 559 patients with advanced HL were randomized to two regimens of anthracycline-based chemotherapy. Patients with an excellent response were then randomized to receive

Table 73.8 Trials of CMT for advanced HL

Author	Ref.	Year	N	Study	Median follow-up (months)	Comment
Fabian	80	1994	278	RCT	96	Based on an "intention to treat" analysis: No difference in OS or DFS between CMT and CT alone
Diehl	81	1995	288	RCT	72	After CR, randomized to one cycle of COPP-ABVD or 20 Gy of IFRT: No DFS or OS benefit
Ferne	82	2000	559	RCT	48	After CR, randomized to two cycles of the same CT or STNI: No OS or DFS difference
Brice	83	2001	82	RCT	48	Exclusively in LMM. After CR, randomized to two cycles of CT or STNI: RR superior in CMT but no difference in DFS or OS.
Loeffler	84	1998	1740	Meta-analysis	120	After CR, RT vs observation: RRTF reduced by 40% but no OS advantage, even in bulky disease. After CR, CT vs CMT: OS better in CT alone ($P = 0.045$)
Aleman	85	2003	739	RCT	79	After CR, two cycles of additional CT (hybrid) vs IFRT: no difference in EFS or OS
Laskar	86	2004	179	RCT	63	After CR with six cycles of ABVD, EFS and OS better with CMT than CT alone ($P = 0.01$ and 0.002 , respectively) <i>Caveats:</i> Less than 50% of patients have advanced HL or older than 15 years.
Diehl	87	2003 (Abstract)	1076	RCT	24	Third interim analysis: No difference in FTF or OS between CMT and CT alone.

RCT, randomized controlled trial; CT, chemotherapy; RT, radiation therapy; STNI, subtotal nodal irradiation; RRTF, relative risk of treatment failure; EFS, event-free survival; FTF, freedom from treatment failure.

either "consolidation" with extensive field radiation or an additional two cycles of the same chemotherapy. Five-year DFS and OS were not different for either consolidative regimen.⁸² The same authors published a subset study from the French trial that looked exclusively at patients with an LMM, a group believed by many experts to benefit from additional radiation. In this study, in patients with LMM who achieved a major response of at least 75% after six cycles of chemotherapy, consolidation radiotherapy did not add any survival benefit compared to two additional cycles of chemotherapy.⁸³

A meta-analysis tried to overcome the potential false-negative outcomes from smaller studies and involved 1700 patients with advanced HL from 14 different trials.⁸⁴ Additional radiation compared to observation decreased the relapse rate by 40% without affecting the 10-year OS. On the other hand, patients who had consolidative chemotherapy had an 8% better OS compared to those with consolidative radiation therapy. Although radiation seems to delay disease recurrence, its long-term toxicities (such as AML/MDS, other secondary solid tumors, and heart disease) appear to dampen any possible long-term OS benefit. This meta-analysis was largely criticized for two reasons: the chemotherapy used was primarily MOPP-based and IFRT was used in only 50% of cases. Patients with bulky disease features, a group who could poten-

tially benefit from radiation, were not carefully addressed in this meta-analysis.⁸⁴

Recently, two randomized studies were published, with mixed results. The first study from Europe randomized patients with advanced HL to receive two cycles of MOPP/ABV hybrid or IFRT to involved areas after six cycles of effective chemotherapy. IFRT did not add any DFS or OS benefit compared to the two additional cycles of MOPP/ABV. IFRT was of benefit in patients achieving only a partial response after chemotherapy, and resulted in a 5-year OS similar to patients in CR.⁸⁵

The second study, from India, explored the role of additional radiotherapy in patients achieving a CR after six cycles of ABVD. A significant difference in 8-year event-free-survival and OS was found when radiation was added to chemotherapy.⁸⁶ This was the first large, randomized study to show a survival advantage with consolidation radiation. However, this study is not widely accepted due to many limitations. More than 50% of patients had early-stage disease and were younger than 15 years. In addition, histology was in most of the cases a mixed-cellularity type, as compared to the nodular sclerosis type seen in most of the European and North American trials.

Currently, an ongoing German study (HL12) is using intensive regimens, such as like BEACOPP-type with or without IFRT, in patients with advanced HL. An interim analysis is supporting the hypothesis that

radiation can further be reduced substantially after effective chemotherapy.⁸⁷

CONCLUSIONS OF ADVANCED HL TREATMENT

Six to eight cycles of ABVD remains the treatment of choice for advanced stage HL at this time. Both the NCCN and NCI guidelines recognize ABVD as the gold standard regimen with a high level of evidence.^{88,89} Stanford V has a favorable toxicity profile, but it is not clear at this time whether it is as efficacious as ABVD. An intergroup trial is underway and will hopefully answer this question. BEACOPP regimens are gaining popularity, especially in high-risk disease; however, its toxicity profile is significant. The role of additional radiation after effective chemotherapy is at best con-

junctural, even in the bulky disease setting. Some patients with an LMM often receive additional radiation as part of initial therapy, although evidence supporting this practice is sparse. The conclusions from the current literature of the role of radiation added to chemotherapy in advanced HL is that it may have a beneficial impact when the preceding drug regimen is inadequate for effective tumor control, as occurs with patients who have a partial response. However, such patients have an inherently poor prognosis, and may be appropriate candidates for autologous stem cell transplant.

Future directions using new imaging techniques such as PET scan and gene expression profiling studies will hopefully identify accurate prognostic parameters to guide therapeutic decisions.

Chapter **74**

TREATMENT APPROACH TO NODULAR LYMPHOCYTE- PREDOMINANT HODGKIN'S LYMPHOMA

Brad Pohlman

INTRODUCTION AND PATHOLOGY

Nodular lymphocyte-predominant Hodgkin's Lymphoma (NLPHL) is a unique subtype of Hodgkin's lymphoma (HL), which accounts for approximately 5% of cases and has a morphology, immunophenotype, clinical presentation, natural history, and prognosis that are distinct from classical HL (CHL). This variant of HL was first described in the 1930s and recognized not only for its unique morphology but also its more indolent clinical behavior. Jackson and Parker coined the term "paragranuloma"—a term that is sometimes still seen in the literature.¹ Lukes and Butler used the term lymphocytic and histiocytic (L&H) and further divided this type into nodular and diffuse subtypes.² At the 1966 Rye conference, four types of HL were recognized: nodular sclerosis, mixed cellularity, lymphocyte depletion, and lymphocyte predominance (LP).³ Although the Rye classification combined the nodular and diffuse subtypes of LPHL, subsequent studies continued to analyze the pathological and clinical differences between these two variants.⁴⁻⁶ With advances in pathology and, in particular, immunohistochemistry, hematopathologists appreciated that a purely morphologic classification system was inadequate. In fact, the morphologic classifications of LPHL actually included at least two biologically distinct types of HL. This distinction was recognized in the 1994 Revised European-American Lymphoma (REAL) classification, which separated "lymphocyte predominance (paragranuloma)" from the other types of HL and added a provisional subtype of CHL, "lymphocyte-rich classical" (LRCHL).⁷ More recently, the World Health Organization (WHO) classification separated HL into two broad, pathologically and clinically distinct categories: NLPHL and CHL.^{8,9} The pathologic characteristics are detailed in Chapter 71. Briefly, NLPHL is a

monoclonal B-cell neoplasm characterized by a nodular, or a nodular and diffuse, polymorphous proliferation of scattered large neoplastic cells known as "popcorn" or "L&H" cells.⁹ Unlike the Reed-Sternberg cells of CHL, the L&H cell of NLPHL express the B-cell marker, CD20, but not CD15 or CD30. When the REAL/WHO criteria were applied to LPHL cases previously diagnosed by expert hematopathologists based on morphology alone, only three-quarters of the cases were still classified as LPHL.^{10,11} Most of the other cases were reclassified as CHL and, in particular, LRCHL.

CLINICAL FEATURES AND PROGNOSIS

PRE-REAL/WHO SERIES

Most publications prior to the combined morphologic and immunophenotypic classification included patients with both NLPHL and CHL. Both LPHL and CHL patients were eligible for the same clinical trials. Only a small minority had LPHL and many of them were undoubtedly misdiagnosed and actually had LRCHL. Even retrospective studies as recent as 1995, which purported to analyze the specific subset of patients with LPHL, still relied on now outdated and imprecise diagnostic criteria and, therefore, must have included a significant number of LRCHL patients.

Nevertheless, many large historical series of patients with LPHL (which predated the REAL/WHO criteria and clearly included patients with CHL and, in particular, LRCHL) recognized their distinct presentation and course.^{4-6,12-16} The patients were predominantly male, generally young, and frequently had asymptomatic, nonbulky, stage I or limited stage II disease involving peripheral lymph nodes. Although some series observed a pattern of frequent and sometimes late relapses, virtually all series recognized the

excellent overall survival. Many of these studies observed a disturbing pattern of deaths due to other, often treatment-related, malignancies and cardiovascular disease. Some of these series appreciated differences in long-term outcome between this subtype compared to other subtypes of HL.

The development of non-Hodgkin's lymphoma (NHL) in patients with CHL or LPHL has been well documented.^{12,17-24} A review from the International Data Base on Hodgkin's Disease appreciated a higher risk of NHL in patients with LPHL compared to those with CHL.²⁵ The NHL, primarily diffuse large B-cell lymphoma (DLBCL) and frequently the T-cell/histiocyte rich variant of DLBCL (TC/HR DLBCL), may occur simultaneously with, or sometimes years after, the diagnosis of LPHL even without any treatment.^{23,24} In many of these cases, a clonal progression from HL to NHL has been documented.^{24,26,27} Given the difficulty in sometimes distinguishing NLPHL and TC/HR DLBCL, some patients who actually had TC/HR DLBCL may have been initially misdiagnosed with NLPHL.^{11,24,27,28} Consequently, the risk of developing NHL may actually be overestimated. While the risk of NHL after HL may be higher in NLPHL compared to CHL patients, the absolute risk is still very low—probably less than 5%.

POST-REAL/WHO SERIES

Much of the available clinical information regarding NLPHL as currently defined is derived from the European Task Force on Lymphoma (ETFL) Project, which was initiated in 1994 and published in 1999.²⁹ In this large retrospective study, biopsies from cases diagnosed initially as LPHL at 17 European and American institutions were reviewed and reclassified using morphologic and immunohistochemical criteria according to a modified REAL classification. In addition, four other, relatively large, retrospective studies identified patients with NLPHL based on the REAL and/or WHO criteria.³⁰⁻³³ A summary of these five studies follows. Several other recent, relatively large, retrospective series were not included in this chapter because they included only children, included patients that were reported in a subsequent publication, and/or included immunohistochemistry for diagnosis in only some of the cases.^{10,34-38}

Patients with NLPHL in these five series accounted for 3–8% of all HL patients.²⁹⁻³³ The presenting characteristics of these patients are shown in Table 74.1. Like the historical publications, the patients in these series were primarily young males with early stage disease. Indeed, 51–63% of patients presented with stage I disease. Frequently, these patients presented with isolated peripheral adenopathy; mediastinal involvement was appreciated in only 0–15% of the patients. A significant minority (18–20%) of patients had clinical stage (CS) I–II infradiaphragmatic disease. Stage IV was rare and accounted for only 3–12% of patients. Less than 10% of

patients had B symptoms, and bulky disease was very uncommon. A concurrent diagnosis of DLBCL was documented in only one patient.³¹ The use of staging laparotomy in these retrospective series varied considerably (ranging from 0 to 88%), but results of staging laparotomy were provided in only one study.³⁰ In this study, only 4% of patients with CS I but 28% of patients with CS II were upstaged. Interestingly, six of eight patients with CS IIIA in this series were downstaged. The patients in these studies were diagnosed and treated over a period of many years. In general, they were treated no differently than patients with CHL of similar stage and risk factors according to standards of care at the time. Some of the patients were enrolled on clinical trials. The vast majority of patients received radiation therapy (RT) either alone or combined with chemotherapy. Some patients received radiation only to involved sites. Most received mantle or subtotal nodal irradiation (STNI). A few received total nodal irradiation. The specific chemotherapy regimens, sequence, and number of cycles varied considerably. With primary therapy, 93–98% of patients achieved a complete remission. The median follow-up in these five series ranged from 6.3 to 10.8 years. The freedom from relapse, freedom from progression, failure-free survival, or relapse-free survival ranged from 45 to 80% at 8–15 years. The HL-specific failure-free survival for the 219 NLPHL patients in the ETFL Project is shown in Figure 74.1.²⁹ In this series, failure-free survival was much worse for the minority of patients with stage IV disease (i.e., 24% at 8 years).²⁹ Relapses often occurred late; the median time to relapse was 39–53 months and ranged from 4 to 155 months. Three of these studies

NLPHL, nodular lymphocyte-predominant Hodgkin lymphoma; MDS, myelodysplastic syndrome; AML, acute myelogenous leukemia.

suggested a continuous pattern of relapse up to 10 years or more after diagnosis and treatment.^{29–31} Many patients had multiple relapses. One study suggested that patients with localized disease were less likely to relapse.³¹ Another found that relapses occurred more commonly outside the initial radiation field.³² In four of these series, subsequent NHL was documented in 0 of 71, 4 of 68, 6 of 219, and 1 of 42 patients.^{29–31,33} Despite the risk of relapse, the overall survival was extraordinarily good and ranged from 71 to 94% at 8–15 years. The HL-specific overall survival for the 219 NLPHL patients in the ETFL project is shown in Figure 74.1.²⁹ In this series, survival was worse for patients with stage IV disease (i.e., 41% at 8 years). Of 95 deaths reported in four of these series, only 16 were attributable to HL; most of the remaining patients were in remission at the time of death.^{29–31,33} Second malignancies and cardiovascular disease were the most common cause of death (Table 74.2).

TREATMENT OF EARLY STAGE DISEASE

PROSPECTIVE, CONTROLLED, RANDOMIZED, CLINICAL TRIALS

Several studies have defined the standard of care for patients with early stage CHL (see Chapter 73). Most, if not all, of these studies included patients with NLPHL. The German Hodgkin Lymphoma Study Group (GHSG) trial enrolled 1204 informative and eligible CS I or II patients with one or more risk factors or CS III without any risk factors.⁴⁰ A risk factor was defined as any of the following: large mediastinal mass (at least one-third of maximal thorax diameter), extranodal disease, massive splenic involvement (diffuse infiltrations or more than five focal lesions), erythrocyte sedimentation rate (ESR) ≥ 50 mm/h in patients without B symptoms, ≥ 30 mm/h in patients with B symptoms, or more than two lymph node areas of involvement. Patients with CS IIB were included on this study if they had an elevated ESR or more than two involved lymph node areas and none of the other risk factors. Patients were randomized to received four cycles of COPP (cyclophosphamide, vincristine, procarbazine, and

prednisone) alternating with ABVD (doxorubicin, bleomycin, vinblastine, and dacarbazine) followed by 30-Gy extended field (EF) plus 10 Gy to bulky disease or four cycles of COPP alternating with ABVD followed by 30-Gy involved field (IF) plus 10 Gy to bulky disease. Only 8% of patients had stage I disease and 1.4% had LPHL. The National Tumor Institute of Italy enrolled 136 eligible and assessable patients with “unfavorable” stage I or any stage IIA HL. Unfavorable was defined as having any of the following characteristics: bulky disease (mediastinal mass greater than one-third of the thoracic diameter and/or nodal disease >10 cm), pulmonary hilus involvement, or contiguous extranodal extent.⁴¹ Patients were randomized to receive either four cycles of ABVD followed by involved-field radiation therapy (IFRT) or four cycles of ABVD followed by STNI. Total radiation dose to previously involved sites was 36 Gy (in patients with confirmed complete remission following ABVD) and 40 Gy (in patients with unconfirmed complete remission or partial remission following ABVD). In patients randomized to receive STNI, the radiation dose to uninvolved sites was 30.6 Gy. Nodular sclerosis subtype accounted for 76% of the patients; the number of patients with NLPHL was not noted. Only 11% of the patients had stage I disease. In both the German and Italian studies, four cycles of chemotherapy followed by IFRT was equivalent to four cycles of chemotherapy followed by extended-field radiation therapy (EFRT). In a retrospective study of the HD1 and HD5 trials, the GHSG analyzed the outcome of CS or pathologic stage (PS) I–IIIA HL patients, who received four cycles of COPP alternating with ABVD followed by 40 Gy to areas of initially bulky disease and either 20, 30, or 40-Gy EFRT.⁴² LPHL accounted for only 1–5% of the patients in these two studies. They found no significant difference in complete response rate, freedom from treatment failure, or overall survival based on the administered RT and concluded that four cycles of chemotherapy followed by 20-Gy IF/EF is sufficient treatment for most patients with early stage, nonbulky HL.

Most studies of early stage HL have included RT (either with or without chemotherapy). Only five prospective, randomized studies have evaluated

chemotherapy alone for the treatment of patients with early stage HL. Two older studies in patients with early stage HL compared MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) chemotherapy to STNI and obtained conflicting results.^{43–45} LPHL patients accounted for only 6–7% of the patients randomized to receive chemotherapy. Recently the National Cancer Institute of Canada Clinical Trials Group and the Eastern Cooperative Oncology Group reported the preliminary results of a phase III study, which randomized 399 eligible patients with nonbulky, CS I–IIA HL to receive “standard therapy that includes RT” or chemotherapy alone.⁴⁶ Patients were stratified as either “low risk” or “high risk.” Low-risk patients were younger than 40 years and had nodular sclerosis or LPHL, ESR <50 mm/h, and involvement of three or fewer disease-site regions; all other patients were high risk. Patients randomized to the “standard” arm received STNI alone (if low risk) or two cycles of ABVD followed by STNI (if high risk). Patients randomized to the chemotherapy-only arm received four cycles of ABVD (if in complete remission after two cycles) or six cycles of ABVD (if not in complete remission after two cycles). Compared to “standard” therapy, patients that received chemotherapy alone had an inferior progression-free survival ($P = .006$, HR = 2.6, 5-year estimates 87% vs 93%) but the same overall survival (96% vs 94%). The number of patients with NLPHL was not provided. The Grupo Argentino de Tratamiento de la Leucemia Aguda randomized 277 untreated, CS I–II HL patients (including only 33 with LPHL) to receive six cycles of CVPP (cyclophosphamide, vinblastine, procarbazine, and prednisone) or six cycles of CVPP sandwiched with 30-Gy IFRT.⁴⁷ The prospective analysis showed an improved disease-free survival in favor of combined modality therapy but similar overall survival. In favorable patients with no risk factors (defined retrospectively by Cox multivariable analysis), the disease-free survival (75% vs 70%) and overall survival (92% vs 91%) at 84 months were similar. In unfavorable patients with one or more risk factors (age greater than 45 years, more than two lymph node area involved, or bulky disease), however, the combined modality patients had an improved disease-free survival (75% vs 34%, $P = 0.001$) but not a statistically significant different overall survival (84% vs 66%). Finally, Memorial Sloan Kettering Cancer Center randomized patients with nonbulky, CS or, in a small minority, PS I–IIA/B or IIIA HL to receive six cycles of ABVD chemotherapy with or without 36-Gy EFRT or, in a minority, IFRT.⁴⁸ The complete response duration, freedom from progression, and overall survival were the same in both groups. Fourteen (9%) of 152 enrolled patients had LPHL; six were randomized to receive chemotherapy only. Subset analysis of the entire group according to histology failed to detect significant differences in complete response duration ($P = .93$), freedom from progression ($P = .99$), or overall survival ($P = .51$).

On the basis of the results of these (as well as other) studies, most patients with early stage CHL are treated with four to six cycles of combination chemotherapy (e.g., ABVD) usually followed by 20–40-Gy IFRT. But NLPHL patients comprised only a small minority of the patients in these studies and many of the patients probably had LRCHL. Furthermore, many NLPHL patients were not eligible for these studies because they lacked the necessary risk factors. Therefore, it is unclear if the results from these studies are applicable to the “typical” NLPHL patient.

RETROSPECTIVE STUDIES OF LIMITED TREATMENT

In a recent review, Conners wrote, “. . . there is no definite evidence that LPHL is less curable than CHL . . .”⁴⁹ In another review, Diehl concluded, “there is no rationale for a less intensive treatment” of LPHL compared with CHL.³⁹ Yet he suggested that these “treatment strategies might be too intensive, particularly when late effects such as secondary malignancies and cardiac and pulmonary complications are taken into account.” Several authors have suggested that the management of these patients should try to minimize therapy-related complications.^{30,38,39,49} On the other hand, Diehl noted that the subsequent development of disease-related, rather than treatment-related, NHL in some patients suggests the need to retain (rather than reduce) currently effective primary therapy.³⁹ In fact, retrospective analyses support less intensive treatment at least for some patients.

Several groups have reviewed the outcome of LPHL patients treated with limited RT. In 1995, the Harvard Collaborative Oncology Group published the preliminary results of a combined prospective and retrospective analysis of 46 patients with PS I–IIA HL treated with mantle field RT alone between 1970 and 1993.⁵⁰ The prospective study was limited to patients with nodular sclerosis or LPHL and no risk factors (i.e., B symptoms, mediastinal mass greater than 1/3 of the thoracic diameter on a standing posteroanterior chest radiograph, and no subcarinal or hilar adenopathy). With a median follow-up of 32 (range 13–58) and 113 (range 56–296) months in the prospectively and retrospectively studied patients, respectively, none of the 16 LPHL patients had relapsed. The prospective study was recently updated.⁵¹ Between October 1988 and June 2000, 87 patients with PS IA–IIA HL received 30.6–44 Gy mantle field RT. After 1995, patients with PS IA mixed cellularity, CS IA LPHL, and females with CS IA nodular sclerosis HL were also enrolled. Of the 77 pathologically staged patients, 37 had PS IA and 40 had PS IIA disease. Six patients had CS IA disease. With a median follow-up of 61 (range 13–127) months, none of the 15 LPHL patients had relapsed. Wirth et al. retrospectively studied 261 Australian patients with CS I–II HL treated with 30–40 Gy mantle field RT alone between 1969 and 1994.⁵² With a median follow-up for surviving patients of 8.4 (range 1.8–27.4) years, the

10-year overall survival was 73%. On multivariable analysis for overall survival, age was the only important prognostic factor. The 10-year progression-free survival was 58%. On multivariable analysis, the progression-free survival was significantly better for patients with LP histology, nonmediastinal bulk less than 10 cm, three or fewer involved sites, no B symptoms, stage I, and performance status 0. The 10-year progression-free survival for 56 LPHL patients was 81% for stage I and 78% for stage II with no relapse or deaths beyond 10 years.

Patients with supradiaphragmatic CS IA LPHL have a very low probability of having disease detected below the diaphragm at staging laparotomy.^{53,54} And, as noted earlier, mediastinal involvement in NLPHL is very uncommon. These data suggest that patients with CS IA NLPHL might be candidates for very limited RT. Surprisingly, little data are available on the outcome of patients with LPHL (or NLPHL as defined by the REAL/WHO criteria), who were clinically staged with modern imaging studies and treated with limited RT. Early studies showed that IFRT alone was not adequate for unselected patients with early stage HL.^{55,56} Several studies, however, recognized the excellent outcome of young LPHL patients with PS or CS IA limited to suprahyoid cervical lymph node(s). Relapse following IFRT in this subset of patients is rare.^{14,57-59} Recently, Schlembach et al. reported the outcome of 36 NLPHL patients (retrospectively diagnosed according to the REAL/WHO criteria) with nonbulky, stage IA ($n = 27$) or IIA ($n = 9$) involving three or less nodal regions above ($n = 27$) or below the diaphragm ($n = 9$), who received a median of 40-Gy RT alone at the MD Anderson Cancer Center between 1963 and 1996.⁶⁰ The majority of patients received "limited-field," i.e., IF ($n = 3$), regional ($n = 18$), mantle or inverted Y +/- spleen ($n = 7$); the rest of the patients received EF, i.e., subtotal or total nodal irradiation ($n = 8$). For the 24 patients with PS IA ($n = 8$) or CS IA ($n = 16$) NLPHL who received IF or regional radiotherapy, the 5-year relapse-free and overall survival were 96% and 100%, respectively. The GHSG recently presented the preliminary findings from a study in which 89 patients with CS IA NLPHL and no risk factors were treated with IFRT ($n = 44$), two to four cycles of ABVD followed by 20-30 Gy IFRT ($n = 25$), ABVD chemotherapy alone ($n = 2$), or an unknown therapy ($n = 1$).⁶¹ Ninety-seven percent of the patients achieved a complete or unconfirmed complete remission. Two patients have relapsed and no patients have died. Follow-up, however, is relatively short.

Because of the excellent overall survival (regardless of the specific treatment) and the risk associated with treatment as well as the observations from a few reports, some authors have considered a "watch and wait" approach.^{13,29,62} In one study, 31 minimally staged patients, who were initially considered to have benign lymphadenopathy but were subsequently diagnosed

with LPHL, received no treatment following excision of the involved lymph node(s).¹² With median follow-up of 7 years, seven patients died 1-11 years after surgery—only one from HL and three from NHL, two from carcinoma, and two from other causes. In another study of 145 cases of LPHL, 24 stage I patients received no therapy following excision of the involved lymph node(s).¹³ Fifteen of these 24 patients relapsed but 9 remained free of disease for 7-14 years. In 1988, the French Society of Pediatric Oncology (FSOP) initiated a prospective, non-randomized study.³⁸ At the physician's discretion, 27 children with NLPHL were either observed following lymph node excision ($n = 13$) or received (according to FSOP protocols) chemotherapy with or without 20-Gy RT. Nine of 13 observed patients had no evidence of disease following lymphadenectomy. Seven of 13 observed patients progressed a median of 24 (range 4-120) months after surgery. With a median follow-up of 70 months, 12 of 13 patients are in first ($n = 7$), second ($n = 3$), third ($n = 1$), or fifth ($n = 1$) remission and all of the patients are alive.

TREATMENT OF ADVANCED-STAGE DISEASE

Several studies have defined the standards of care for patients with advanced-stage CHL and are discussed in Chapter 73. Based on the results of these studies, most patients in the United States are treated with ABVD, Stanford V (doxorubicin, vinblastine, vincristine, bleomycin, mechlorethamine, etoposide, and prednisone), or, less often, BEACOPP (bleomycin, etoposide, doxorubicin, cyclophosphamide, vincristine, procarbazine, and prednisone) with or without RT to sites of initially bulky disease.⁶³⁻⁶⁵ LPHL accounted for only 1-5% cases so the conclusions from these studies are not necessarily applicable to NLPHL patients.

On the basis of limited data and primarily individual institutional preferences, the National Comprehensive Cancer Network (NCCN) guidelines suggest that patients with advanced (as well as early) stage NLPHL requiring chemotherapy should receive "alkylator-based" regimens.⁶² Actually, very little published data are available on the most appropriate chemotherapy regimen in patients with NLPHL. In one retrospective study, 8 of 12 LPHL patients treated initially or at first relapse with MOPP or a MOPP-like regimen achieved a durable first or second complete remission, but only 2 of 6 patients treated initially or at first relapse with ABVD or EVA (etoposide, vinblastine, and doxorubicin) achieved a durable first or second complete remission.³⁰ A recently published study from the same institution retrospectively compared outcome of MOPP versus ABVD as salvage therapy in 100 HL patients who relapsed between 1980 and 1997 following primary RT.⁶⁶ Ninety-seven of the patients were stage I-II, and 10 had NLPHL. They observed no difference in freedom

from second relapse or survival between the two groups of patients and no difference in outcome based on histology.

The results from two recent publications suggest that rituximab, an anti-CD20 monoclonal antibody with activity in B-cell NHL, may have a role in the management of patients with NLPHL. These two prospective, phase II trials evaluated the potential efficacy of a standard 4-week course of rituximab in patients with NLPHL. Between May 1999 and March 2002, GHSG enrolled 10 patients (median age 41, range 23–49 years) with NLPHL in first ($n = 5$), second ($n = 2$), or third ($n = 2$) relapse, and a median of 8.5 (range 0.5–21) years after initial diagnosis.⁶⁷ Five patients had a complete response, four patients had a partial response, and one patient (who had relapsed 6 months after initial diagnosis and soon after completing BEACOPP) progressed. Two of the nine responding patients progressed at 12 months. The other seven patients remained in remission at 9+ to 26+ months. The other study enrolled 22 NLPHL patients (median age 45, range 18–63), who were previously untreated ($n = 12$) or were in first ($n = 6$), second ($n = 3$), or fourth ($n = 1$) relapse, and a median of 11.9 (range 1–33) years after initial diagnosis and a median of 9 (range 0.4–27) years after the prior treatment.⁶⁸ The complete and partial response rates were 46% and 54%, respectively. The response duration was relatively short. Six of 12 previously untreated and 3 of 10 previously treated patients relapsed a median of 9 months after the first rituximab infusion. Eight of the nine patients relapsed exclusively at the sites of prior disease. Five of these nine patients had a repeat biopsy. Two of the five patients (including one, who was previously untreated) relapsed with DLBCL.

GUIDELINES AND RECOMMENDATIONS

The optimal management of patients with NLPHL is uncertain and controversial. The NCCN guidelines for patients with NLPHL are complex and distinctly different than for patients with CHL; these recommendations are based on “lower-level” evidence including clinical experience, and are not always with uniform agreement among the panel members.⁶² For patients with CS IA NLPHL confined to the high neck (above the hyoid bone), the NCCN guidelines recommend IF or regional RT. For patients with CS I–IIA disease at other locations, the guidelines generally recommend IF or regional RT (with or without initial chemotherapy), while for patients with more advanced disease, the guidelines recommend chemotherapy with or without RT. For patients with CS III–IVA, observation is also offered as a management option. The National Cancer Institute/Physician's data query (NCI/PDQ) website suggests that patients with nonbulky, stage I LPHL presenting in a unilateral high neck (above the thyroid notch), epitrochlear, inguinal, or femoral locations require only IF or

“regional” RT; for all other patients, it recommends the same treatment for NLPHL and CHL patients.⁶⁹ The European Organization for Research and Treatment of Cancer (EORTC) and GHSG generally treat patients with CS I–II NLPHL and no risk factors with IFRT, while they treat patients with more advanced-stage disease (i.e., CS I–II with one or more risk factors or CS III–IV) the same as patients with CHL.⁷⁰

Based on the literature review in this chapter and the recommendations from European and American lymphoma experts, I offer the following guidelines. For patients with nonbulky, peripheral, stage IA or relatively limited, stage IIA disease, I recommend IF or regional RT. The optimal radiation dose is unknown; I recommend 30–36 Gy. For patients with bulky stage I or more advanced, stage II disease, I recommend four cycles of ABVD followed by 30 (if in complete remission) or 36-Gy (if in unconfirmed complete or partial remission) IFRT. Recent, and as yet unpublished, data from GHSG may allow some of these patients to receive as little as two cycles of ABVD and 20-Gy IFRT.⁷⁰ For patients with stage III or IV disease, I recommend six to eight cycles of combination chemotherapy (e.g., ABVD or BEACOPP). Given the poor failure-free and overall survival of stage IV NLPHL patients, standard or dose-escalated BEACOPP are particular attractive options. Recently presented, unpublished results from an Italian study, which enrolled patients with advanced-stage HL, suggested that Stanford V is inferior to ABVD.⁷¹ The current US intergroup study is comparing ABVD to Stanford V although enrollment is limited to advanced-stage CHL patients.

SUMMARY

NLPHL has a characteristic morphology, immunophenotype, presentation, and natural history. The clinician must recognize both its pathological and clinical characteristics and question the diagnosis if the two are discordant. Most of these patients have an excellent prognosis although long-term follow-up (i.e., greater than 10 years) in morphologically and immunophenotypically defined patients is limited. Based on the excellent 10-year survival and the relatively high risk of death from causes other than HL, therapy must not only adequately control, if not cure, the HL and ideally prevent the evolution to NHL, but also minimize both short- and long-term toxicities. This goal is perhaps even more important with NLPHL than with CHL. Future treatment strategies may incorporate anti-CD20 monoclonal antibodies, (e.g., rituximab). When relapse is suspected, a biopsy is mandatory to distinguish recurrent NLPHL from DLBCL and progressively transformed germinal centers (a benign lymphadenopathy that may occur before, after, or concurrently with NLPHL and is not necessarily indicative of disease relapse). Finally, these patients require indefinite follow-up since late relapses are possible.

Chapter **75****AUTOLOGOUS STEM CELL
TRANSPLANTATION FOR
HODGKIN'S LYMPHOMA***Craig Moskowitz and Daniel Persky*

The majority of patients with Hodgkin's lymphoma (HL) are cured with radiation therapy (RT) and/or combination chemotherapy. However, patients who relapse or those with primary refractory disease have a poor outcome with conventional-dose salvage regimens. Treatment results with these salvage regimens produce a low complete remission rate and minimal survival benefit. Long-term survival is poor when either MOPP or MOPP/ABVD is administered with curative intent in the salvage setting.^{1,2} Over the past two decades, results of many prospective clinical trials utilizing high-dose chemotherapy or chemoradiotherapy (HDT) with autologous stem cell transplantation (ASCT) in the salvage setting are reported, and approximately 40% of patients appear to be cured using this approach.³

Most early transplant studies included heavily pretreated patients receiving autologous bone marrow as the stem cell source, both of which influenced the morbidity and mortality of HDT.⁴⁻⁶ With the introduction of granulocyte colony-stimulating factor (G-CSF), peripheral blood progenitor cells, better transfusion practices, more effective antibiotics, and the omission of patients with disease progression pre-ASCT, the transplant-related mortality has decreased from 15% to less than 3% in most series. Despite these strides in supportive care, long-term freedom from treatment failure (FFTF) for the patients receiving HDT/ASCT has improved by less than 10% in recent series. There are a number of pretreatment and treatment-related prognostic factors that predict for outcome.⁷

**CHEMOSENSITIVE DISEASE IS REQUIRED
TO ACHIEVE BENEFIT FROM HDT/ASCT**

Two randomized studies comparing full-course salvage chemotherapy (SC) administered alone with curative intent with short-course SC followed by HDT and ASCT are reported. The British National Lymphoma

Investigation (BNLI) randomly assigned relapsed and primary refractory patients to either carmustine, etoposide, cytarabine, and melphalan (BEAM) HDT followed by ASCT or up to three cycles of mini-BEAM with standard support.⁸ The German Hodgkin's Lymphoma Study Group (GHSG) randomly assigned patients with relapsed HL to either two cycles of dexamethasone-BEAM (dexamethasone-BEAM) and BEAM and ASCT versus four cycles of dexamethasone-BEAM.⁹ Each study demonstrated a statistically significant improvement in FFTF for the patients treated on the HDT arms, but neither was powered to show an overall survival (OS) advantage.

The importance of pretransplant cytoreduction with SC is demonstrated in numerous previous reports.¹⁰⁻¹³ In 1993, the lymphoma service at Memorial Sloan Kettering Cancer Center (MSKCC) published results using high-dose chemoradiotherapy in patients with biopsy-confirmed relapsed and primary refractory HL in first-generation clinical trials (MSKCC protocols 85-97 and 86-86).^{14,15} The program utilized accelerated fractionation radiotherapy either as total lymphoid irradiation (TLI) or as involved field radiation (IFRT), followed by high-dose chemotherapy and ASCT. One hundred and fifty-six patients with relapsed or primary refractory disease were treated; chemosensitive disease to SC was not a requirement for subsequent HDT. At a median follow-up of 11 years, the FFTF was 45%. After the introduction of G-CSF, overall mortality of the program decreased from 18 to 6%. In this study, patients with chemosensitive disease to SC had a marked OS advantage: 61% versus 14%. These results demonstrated the feasibility of incorporating dose-intensive radiotherapy into HDT for HL and most importantly determined that patients with chemosensitive disease to SC had a marked improvement in FFTF compared to patients with refractory disease at the time of HDT.

As with aggressive non-Hodgkin's lymphoma (NHL), chemosensitive disease to SC is now suggested for transplant eligibility in the United States.¹⁶ There is limited

information regarding the optimal SC regimen. The requirements for an SC regimen are adequate cytoreduction in at least 75% of patients without extramedullary toxicity or severe bone marrow suppression, with subsequent ability to collect an adequate stem cell harvest.¹⁷ Specifically, in the phase III randomized German study described above, of the 161 patients enrolled, 13 could not be randomized secondary to dexamethasone-BEAM-related mortality (eight patients) or severe infection.

In 2001, we reported the results of a comprehensive program for the treatment of 82 patients with relapsed and primary refractory HL (MSKCC protocol 94-68).¹⁸ All patients received SC with ifosfamide, carboplatin, and etoposide (ICE) and only responders were subsequently offered HDT and ASCT. All patients in this trial had biopsy-proven relapsed or refractory disease, and our data were analyzed by intent to treat. The response rate to ICE was 90%; there was no severe ICE-related extramedullary (nonhematologic) toxicity. The median number of CD34⁺ cells/kg collected was 7×10^6 /kg. FFTE, at a median follow-up for surviving patients of 6 years, is 55%. In the subset of patients who received HDT/ASCT (75 of 82 patients), the FFTE is 61%.

Recently, two additional SC regimens were reported to have promising, although preliminary, results. Seventy-six patients with relapsed or refractory HL were treated on a phase I/II study with gemcitabine (G), vinorelbine (N, Vinorelbine), and liposomal doxorubicin (D) (GND). The objectives were to determine the maximally tolerated dose (MTD), response rates, and toxicity of this combination; 28 patients had a prior ASCT. At a planned interim analysis of the phase II portion of the study, the overall response rate was 58% [95% exact CI (0.34, 0.80)] for the first 19 patients without prior transplant [8 partial response (PR) 3 complete response (CR)] and 68% [95% exact CI (0.44, 0.87)] for the 19 patients with prior transplant (12 PR, 1 CR). The regimen was well tolerated and, importantly, is administered in the outpatient setting.¹⁹ IGEV consists of ifosfamide 2000 mg/m² i.v. days 1–4; gemcitabine 800 mg/m² i.v. days 1 and 4; vinorelbine 20 mg/m² i.v. day 1; prednisolone 100 mg/m² i.v. days 1–4, and G-CSF 300 µg s.c. days 7–12 or up to peripheral blood progenitor cell (PBPC) harvest. Therapy consisted of four IGEV cycles at 3-week intervals followed by HDT in responding patients. The overall response rate was 84%, and all patients but one mobilized an adequate amount of PBPC. Grade III–IV neutropenia occurred in 34% of all IGEV courses, and was dose limiting. Nonhematologic side effects were negligible.²⁰

DO PATIENTS WITH PRIMARY REFRACTORY DISEASE HAVE A SUBOPTIMAL OUTCOME WITH ASCT?

While response to SC is the major selection criteria to proceed to ASCT, other prognostic factors also predict

for long-term FFTE in patients with relapsed and refractory HL. Some groups have suggested that patients with primary refractory disease do less well than those patients who achieve an initial remission to front-line therapy. There are conflicting registry data in this regard.

The North American Autologous Blood and Bone Marrow Transplant Registry (ABMTR) reported on a series of 122 primary refractory patients having 3-year progression-free survival (PFS) and OS rates of 38 and 50%, respectively, using a variety of HDT regimens. Although chemosensitivity status was unknown in less than one-third of patients, it was concluded that only B symptoms at diagnosis and a poor performance status at the time of ASCT predicted for a poor outcome.

The Groupe d'Etudes des Lymphoma de l'Adulte (GELA) reported on a group of primary refractory patients defined as progression of disease on therapy, less than 50% response to front-line therapy, or persistent bone marrow involvement after four cycles of initial chemotherapy. These patients had poor outcomes with HDT and ASCT, with 5-year freedom from second failure of 23%, even though most patients (62%) had chemosensitive disease to SC.

The GHSB evaluated 206 patients with primary refractory disease defined as progression of disease on front-line therapy, or biopsy confirmation of active disease within 90 days posttherapy. While only 70 of these 206 patients actually received HDT and ASCT, the authors concluded that HDT was no better than standard chemoradiotherapy when the data were analyzed by intent to treat.^{21–24}

An underlying problem with these published refractory disease series is the lack of a uniform definition of this entity. Definitions range from progression of disease on upfront therapy to a partial response 3 months posttreatment. Moreover, the inclusion of patients with unconfirmed pathology may result in treatment of patients with aggressive NHL, with a nonmalignant disorder (infection, or sarcoid-like reactions), or with residual radiologic abnormalities but no active HL with an HDT program. These non-HL entities are often strongly positive on gallium or positron emission tomography imaging, thereby making histologic confirmation even more imperative.^{25–28}

We recently reported our data in primary refractory HL, which has longer median follow-up than any of the other reported series. This report is distinguished by a repeat biopsy confirming active HL in all patients. Among the 91 patients with primary refractory HL identified for this analysis, eight (9%) were found to have diffuse large B-cell lymphoma on the repeat biopsy. In these cases, the initial diagnosis of HL was confirmed by pathology review. The presence of an aggressive NHL has both prognostic significance and affects the choice of second-line therapy; for example, the use of anti-CD20-based therapy in patients with aggressive NHL may have a critical role (i.e., rituximab or high-dose radiolabeled anti-B1).²⁹ With a median follow-up of

Figure 75.1 Overall survival of transplanted patients with relapsed or primary refractory disease

10 years, results at many centers including data at memorial Sloan Kettering Cancer center indicate that HDT/ASCT should be considered as standard treatment for patients with primary refractory HL if chemosensitive disease to SC is established. This is summarized in Table 75.1.³⁰⁻³⁴ We found no difference in FFTF for patients with chemosensitive primary refractory versus chemosensitive relapsed disease³⁵ (Figure 75.1).

MULTIPLE FACTORS PREDICT SURVIVAL IN RELAPSED AND PRIMARY REFRACTORY HL

Many groups have reported that prognostic factors other than refractory disease can predict survival. In general these factors can be divided into four categories: (1) extent of disease (advanced stage or extranodal involvement); (2) B symptoms [or surrogate marker such as elevated erythrocyte sedimentation rate

or interleukin 10 (IL-10)]; (3) remission duration of less than 1 year; (4) significant disease burden after SC. In our study of ICE SC followed by HDT and ASCT discussed above, Cox regression analysis determined that there are three factors associated with a poor outcome pre-ICE: extranodal sites of disease (ENS) ($P < 0.001$), initial remission duration < 1 year ($P = 0.001$), and B symptoms ($P < 0.001$). Using this three-factor model, we identified three groups of patients with highly significant differences in outcome with this treatment approach. A favorable risk group having zero to one of these risk factors (56% of the patients) had FFTF of 80% measured from initiation of ICE therapy. Patients with two or three risk factors fared less well with an event-free survival (EFS) of 40%. (Figure 75.2)

This three-factor model was the basis of our third-generation risk-adapted comprehensive study. In this, study patients with no risk factor or one risk factor (ENS, initial response duration < 1 year, or B symptoms

Table 75.1 Outcome of patients with primary refractory disease based upon response to salvage therapy

Series	PTS	Median follow-up (months)	Biopsy proven (%)	PFS (%)	OS (%)	TD (%)	Chemosensitivity
Vancouver	30	42	55	42	30	18	NA
ABMTR	122	28	NA	38	50	12	NS

TD, toxic death; SFGM, French national registry.

Figure 75.2 Overall survival of transplanted patients with relapsed or primary refractory disease

at time of study enrollment), group A, were treated exactly the same as in the second-generation program; in that study FFTF was 80%. Patients with two risk factors, group B, received one dose of standard-dose ICE followed by a dose of augmented ICE second-line therapy as well as a more dose-intense transplant-conditioning regimen. Finally, patients with all three risk factors, group C, received a completely different regimen. Cytoreduction was done with transplant doses of ICE followed by stem cell support, which was followed by a second autotransplant. This three-arm study, however, uses one universal theme: patients must have chemosensitive disease to their “ICE” therapy—group A to standard doses of ICE, group B to augmented ICE, and group C to transplant doses of ICE. The median follow-up of the patients is now 30 months and patients with multiple risk factors have improved FFTF as compared to our previous report (unpublished data).

RATIONALE FOR USING RADIATION THERAPY IN THE SETTING OF HDT/ASCT

RT administered with curative intent in the salvage setting has been used alone or in combination with chemotherapy. Small single-institution series of highly selected patients report a significant local control rate and 5-year FFTF of approximately 30%. The strategy of incorporating RT into HDT is based on the premise that the pattern of relapse post-HDT is similar to relapse following front-line chemotherapy; i.e., it most commonly occurs at sites of initial nodal involvement and is therefore amenable to treatment with RT. Considering the excellent local control afforded by RT,

many institutions successfully incorporated RT into their second-line therapeutic approaches; however, there remains no random assignment data that support this strategy.

RT is most commonly given in two fashions: post-transplant consolidation or as part of pretransplant cytoreduction (Table 75.2).

CONSOLIDATIVE RADIOTHERAPY

The advantages of using RT in the post-ASCT setting include converting a CT-determined partial response to a complete response and reducing the size of the radiation field in patients with bulky disease by high-dose chemotherapy. It does not have the drawback of delaying the administration of high-dose chemotherapy or of overlapping pneumonitis, which can be seen with the combination of RT and carmustine-based HDT.^{36–40} Consolidative RT may, however, produce significant myelosuppression. This has largely been avoided by waiting for proper hematologic recovery and initiating RT within 3 months of ASCT. However, due to this selection bias, patients with early disease progression post-ASCT will not be eligible to receive consolidative RT with curative intent.

One of the earlier studies by Jagannath et al. at MD Anderson Cancer Center involved treatment of 61 patients with HDT/ASCT. Of 18 patients achieving a partial response, six were converted to a CR with local RT.⁴¹ Subsequently, Mundt et al. reported the experience at the University of Chicago with IFRT in 54 patients with relapsed/refractory HL. Forty-six percent of patients relapsed, two-thirds at sites of prior nodal

Table 75.2 Role of involved field radiotherapy as part of management in relapsed/refractory HL

Authors	Number of patients	Pre-ASCT	Post-ASCT	EFS/DFS/PFS	OS	Comments
Poen et al.	100	18	6	3 year EFS: 63% vs 55%, $P = 0.59$	3 year: 70% vs 61%, $P = 0.41$	Survival benefit in stages I–III
Pezner et al.	86	26	3	2 year DFS: 44%	2 year: 38%	IFRT impact not evaluated
Dawson et al.	13	13	0	2 year PFS: 50%	2 year: 84%	Prospective, phase I
Mundt et al.	54	7	13	5 year PFS: 38.9%	5 year (cause-specific): 46.5%	IFRT post-ASCT converted PR to CR in 10/10
Lancet et al.	70	0	27	5 year EFS: 44% vs 26%, $P = 0.0056$	5 year: 81% (not stratified)	

involvement. Of 13 patients receiving IFRT after ASCT, 10 were treated at sites of persistent disease and three for CR consolidation. IFRT significantly reduced the relapse at these sites (26.3% vs 42.8%, $P < 0.05$) and significantly improved local control. Most importantly, all 10 patients who received IFRT at sites of persistent disease, as defined by CT criteria, were converted to a CR and had improved FFTF (40% vs 12.1%, $P = 0.04$) that was comparable to patients achieving CR with ASCT alone (40% vs 60.0%, $P = 0.38$).⁴²

Lancet et al. described the experience at the University of Rochester with 27 of 70 patients who underwent ASCT receiving IFRT. Patients in CR, as defined by CT criteria, received 20 Gy to previous sites of disease while those achieving a PR posttransplant received 30 Gy within 4–8 weeks of ASCT. Five-year FFTF was significantly better in the consolidative IFRT group (44% vs 26%, $P = 0.006$). Consolidative RT has thus shown promise in its ability to convert some patients in PR, as defined by CT criteria, to CR with apparent long-term benefits.⁴³

PRE-ASCT CYTOREDUCTIVE RADIATION THERAPY

One of the main advantages of using RT as a part of cytoreductive therapy is maximizing response prior to HDT/ASCT, which, some groups have reported, is associated with a better outcome.¹⁷ It also eliminates any delay in RT administration, a modality that increasingly has been left out of front-line therapy for HL. In addition, hematologic toxicity secondary to RT in the post-ASCT setting is of little clinical importance when administered pre-ASCT. Conversely it contributes to mucositis and pneumonitis, particularly if mediastinal radiation is administered.

A Stanford series by Poen et al. included 100 consecutive patients of which 24 received IFRT, 18 as part of cytoreductive therapy and six in consolidative setting. In the 39 radiation-naïve patients in this study, IFRT improved OS (93% vs 55%, $P = 0.02$) with a trend toward improved FFTF. For the group as a whole, FFTF and OS did not improve survival, most likely due to the selection of patients eligible to receive IFRT.⁴⁴

In a series from the University of Toronto, Crump et al. treated 40 of 73 patients with extended-field RT to bulky sites of disease pre-ASCT. Univariate analysis determined that RT improved outcome, but this was not significant in multivariate analysis. Only disease status at transplant and relapse at irradiated sites was prognostic.⁴⁵ The same group later determined that treatment-related mortality in their series was worse in patients receiving thoracic RT, particularly if significant lung volume was irradiated or if given within 50 days of ASCT.⁴⁶

Pezner et al. published the City of Hope experience with cytoreductive IFRT in 29 of 86 patients, 17 of whom subsequently received conditioning regimens with total body irradiation. In-field recurrences developed in 7% of the patients. Two-year disease-free survival (DFS) was 44%. Interstitial pneumonitis occurred in only three patients. However, the utility of IFRT in this program was difficult to evaluate.⁴⁷

At MSKCC, we have used accelerated fractionated IFRT as part of cytoreduction for the past 20 years with or without total lymphoid radiation. Patients receive up to 36 Gy over a 10-day period administered in twice-daily fractions. Initially, in the pregrowth factor era, mortality with the entire program was excessive, but decreased to 6% after the introduction of G-CSF and now is 1% with the use of PBPC and more aggressive transfusion practices. Although univariate analysis

supports the use of IFRT, in multivariate analysis the use of IFRT is not significant because patients with widespread extranodal disease, a worse group of patients prognostically, rarely benefit from IFRT. Interestingly <15% of failures occurred at irradiated sites.^{14,18}

Recently, a small prospective study of IFRT administered pre-ASCT was reported by Dawson et al. from University of Michigan. Thirteen patients with HL received 20–36 Gy with excellent local control and a respectable 2-year FFTF of 50%, but there was a lack of association to dose or time interval pre-ASCT.⁴⁸

Cytoreductive RT continues to be frequently employed in HDT/ASCT regimens, based mostly on retrospective institutional series. Significant toxicity, primarily pulmonary, has limited most protocols to IFRT, with the addition of more extensive RT to RT-naïve patients.

Variability of RT doses and parameters, timing of administration, and study populations have limited the ability to compare the studies. Prospective studies will be needed to address these questions as well as concerns about late toxicity, including secondary myelodysplasia and acute leukemia.

SUMMARY

In conclusion, HDT with ASCT is standard therapy for patients with relapsed and primary refractory HL, provided chemosensitive disease to salvage chemotherapy is established. Future studies need to evaluate functional imaging in the transplant setting, standardize SC, and prospectively evaluate RT in a randomized fashion.^{42,49,50}

Chapter 76

HODGKIN'S LYMPHOMA: FOLLOW-UP CARE

Omer N. Koç

INTRODUCTION

The remarkable success in treatment of Hodgkin's Lymphoma (HL) creates the challenge of long-term management of patients who are, unfortunately, at risk for premature death. Despite excellent control of the disease, long-term outcome remains inferior to that of the general population. Excess mortality is, in general, due to HL itself during the first 5–10 years after diagnosis, but treatment-related complications affect survival 25–30 years after therapy. HL patients should be followed life long, and the schedule and the nature of this surveillance should be tailored to the temporal patterns of complications (Figure 76.1). While detection of recurrence may be most important during the first 5 years, detection and prevention of cardiac, thyroid, and pulmonary disease should be ongoing and screening for secondary malignancies should be employed when possible.

PATTERNS OF RELAPSE AFTER INITIAL TREATMENT OF HODGKIN'S LYMPHOMA

Although late relapses occur, most relapses are seen within the first 5 years of treatment. Relapse risk and location are significantly affected by stage at presentation, prognostic factors, and therapy given. Long-term follow-up for patients with Hodgkin's disease reveals that approximately 70% of the disease-related deaths occur during the first 5 years and virtually no disease-related deaths are seen after 10 years. There are no data to suggest that early detection of recurrences can necessarily improve survival. However, clinical trials suggest that salvage treatment for HL is more effective when patients have minimal disease than when they have bulky disease at recurrence. However, no trial has demonstrated an advantage for treatment when disease is detected by routine screening studies versus symptomatic relapse.^{1,2}

Figure 76.1 The actuarial risks of death from major disease categories. HD = Hodgkin's disease (From Ref. 1. Reprinted with permission from the American Society of Clinical Oncology)

Table 76.1 Suggested follow-up schedule for patients with Hodgkin's Lymphoma

	Years 0–2	Years 3–5	Years 5–10
Physical examination	Every 3–4 months	Every 6 months	Once a year
Routine blood work ^a	Every 3–4 months	Every 6 months	Once a year
TFT ^b , lipid profile	Once a year	Once a year	Once a year
Chest film	–	–	Once a year
CT scan	Every 3–4 months	Every 6 months	–
PET scan	Alternate CT/PET	Alternate CT/PET	
Breast cancer screen ^c	Treatment age ,17: 17–35:	Start at age 25 Start 8 years later	

^aRoutine blood work: Complete blood count, erythrocyte sedimentation rate, and liver function tests.

^bPatients who had neck radiotherapy.

^cFor women who had supradiaphragmatic irradiation. Annual breast MRI or ultrasound ages 25–29; annual mammogram ages 30 and above.

Despite lack of data showing a positive impact on outcome with aggressive posttreatment follow-up, many physicians utilize physical examination, blood work, and imaging studies fairly frequently during the first 2 years after therapy. This is usually followed by a less intensive schedule (Table 76.1). Typical follow-up consists of visits every 3–4 months during the first 2 years and every 6 months until year 5, and annually thereafter. These visits are generally used for physical examination, blood work, chest radiograph, and selected imaging studies. Despite such an intensive follow-up schedule, most of the relapses are detected in symptomatic patients. A study of 210 HL patients in complete remission after therapy revealed that 30 of 37 relapsed patients had symptoms of disease.³ Only four asymptomatic relapses were detected by routine evaluation. Widespread use of sensitive imaging methods such as FDG-PET (¹⁸F-fluorodeoxyglucose positron emission tomography) is likely to improve the early detection rate, although it is difficult to project whether such early detection will result in improved outcome. Imaging studies such as PET scanning, with or without computed tomography (CT) scanning, are used three to four times a year during the first 2 years of follow-up despite a lack of prospective studies evaluating their impact on outcome and their cost-benefit ratio.

FOLLOW-UP FOR LONG-TERM COMPLICATIONS OF HL TREATMENT

SECONDARY MALIGNANCIES

Numerous studies have demonstrated that the malignancy rate is significantly higher in survivors of HL than in the general population and these malignancies have poor prognosis. Solid tumors comprise the most common type of secondary malignancy, accounting for 60–80% of cases. The risk of developing a solid tumor is increased in patients receiving radiation therapy, compared to those

receiving chemotherapy alone. Secondary leukemia and non-Hodgkin's Lymphoma cases are fewer, but their relative risks are higher, since they are uncommon in the general population.^{4,5} The cumulative risk of solid tumors continuously increases until at least 25 years of follow-up. In contrast, the risk of acute leukemia is mostly confined to the first 10 years.

In a German Hodgkin's Lymphoma Study Group report from 2004, 127 patients out of a cohort of 5367 developed secondary cancers (2.4%) after a median follow-up of 72 months, with overall relative risk of 2.4.⁶ Of these, 24% were lung, 20% colorectal, and 10% were breast cancer. More than 50% of the patients with secondary cancers were treated with combined modality, including extended field radiotherapy. In a report from Royal Marsden Hospital, 77 second malignancies were detected out of 1039 patients (7.4%).⁷ The standardized incidence ratios (SIR) were as follows: 4 for stomach, 3.8 for lung, 26.5 for bone, 16.9 for soft tissue, and 3.9 for nonmelanoma skin cancers, 4.6 for non-Hodgkin's Lymphoma, and 31.3 for acute myeloid leukemia. Patients who received radiotherapy only had an SIR of 2.6, chemotherapy only 2.1, and combined modality therapy had an SIR of 3.1. Leukemia risk was related to chemotherapy exposure alone or with radiation. Unfortunately, the relative risk of solid tumors was greater in patients who were treated at the age of 25 or younger, compared to those treated at age 55 years or older. In the Dutch series, 1253 patients with HL treated before the age of 40 were analyzed. One hundred thirty-seven secondary cancers were detected in these patients compared to 19.4 cases expected in the general population.⁸ The 25-year actuarial risk of secondary cancer was 28%, and the relative risk of solid tumors increased in patients who were at a younger age during their first treatment. Most of the patients aged 20 years or younger developed second cancers before reaching 40 years and the risk appeared to decrease after 10 years. An updated Dutch series reported on 1261 patients with

a median follow-up of 17.8 years¹ (Figure 76.1). There were 534 deaths, 55% due to HL. Relative risk of death from all causes was 6.8 times greater than the risk observed in general population, and this risk remained high even 30 years after treatment due to secondary tumors and cardiovascular disease (relative risk of 6.6 and 6.3, respectively). The relative risks were significantly higher for patients treated before age 20, 14.8, and 13.6, respectively, for malignancy and cardiovascular deaths. As these patients grew older however, the secondary causes of mortality declined.

Except for breast cancer, there are no guidelines for screening HL survivors for secondary malignancy. The cumulative risk of developing breast cancer is estimated to be as high as one in three by 40 years of age for those receiving supradiaphragmatic irradiation in childhood (< 16 years) and one in five by age 50 years for those treated at age 20–29 years.⁹ The relative risk is increased mainly in those under the age of 30 years at the time of irradiation and is highest for those treated between the ages of 10 and 16 years. The relative risk is much lower in women aged 30–35 years (1–3.7). In comparison, the estimated risk for development of breast cancer by age 50 in the general population is one in 50. The median time to development of breast cancer after supradiaphragmatic irradiation was found to be about 15 years (range 4–20), although considerably shorter in those treated during childhood. There are no prospective trials of mammography or other screening methods in women at increased risk of breast cancer after supradiaphragmatic irradiation. In the absence of such data, clinicians have to tailor screening methods and frequency to the risk and the age of the patient at the time of treatment and the density of the breast tissue at the time of screening. Magnetic resonance imaging (MRI) scans may be more sensitive in younger women. Any method of screening should begin at a younger age than population screening for sporadic breast cancer. For those treated under the age of 17 years, screening from age 25 years is recommended; for those treated between 17 and 35 years, screening should begin 8 years after the completion of irradiation⁹ (Table 76.1).

The German Hodgkin's Lymphoma Study Group also investigated secondary myeloid leukemia and myelodysplastic syndromes in patients treated for HL.¹⁰ Forty-six patients out of a cohort of 5411 developed secondary acute myeloid leukemia/myelodysplastic syndromes (AML/MDS) after a median observation time of 55 months (1% incidence). Among these 46 patients, 30 had received cyclophosphamide, vincristine, prednisone, procarbazine/doxorubicin, bleomycin, vinblastine, dacarbazine (COPP/ABVD) or a similar regimen. There was only one patient who received ABVD alone. There were 11 patients who received Bleomycin, Etoposide, Doxorubicin, and COPP at standard or escalated doses. AML and MDS can be readily detected with a routine blood count in most patients. There may be an advantage to detect MDS early to maximize the

possibility of using allogeneic transplantation for this otherwise lethal complication. Discovery of cytopenia in an HL survivor should trigger an aggressive investigation with early examination of bone marrow morphology and cytogenetics.

CARDIAC COMPLICATIONS OF THERAPY

Cardiovascular mortality is the third main cause of death in patients with HL, after deaths due to HL and secondary malignancies. The relative risk of cardiac death is greatest in irradiated children and adolescents but the absolute risk increases with age at the time of irradiation. Cardiovascular deaths are mainly due to coronary artery disease accelerated by radiotherapy. Increased risks of cardiac events are particularly observed in patients who have known cardiac risk factors such as hypertension and hyperlipidemia. The addition of chemotherapy to radiation treatment does not appear to increase the coronary disease risk. Other late cardiac toxicities of radiation and chemotherapy include pericardial disease, cardiomyopathy, valvular defects, and conduction abnormalities.

The actuarial risk of developing symptomatic coronary artery disease is estimated to be 6% at 10 years and 10–20% at 20 years.^{11,12} The actuarial risk of death from cardiac ischemia is 2–6% at 10 years and 10–12% at 15–25 years. These rates are approximately five times the rates seen in the general population. In a single-center experience, 5.5% of 475 patients treated with mantle radiotherapy had a morbid cardiac event directly related to coronary artery disease.¹³ The mean interval from therapy to cardiac event was 13.1 years (range 4.4–27), and the mean age at the time of the event was 39.4 years (range 24–65). The relative risk of cardiac death was 2.8 (3.1 for males and 1.8 for females). Interestingly, in this group of patients, cardiovascular risk factors were, on average, higher than in the general population. Aggressive modification of cardiovascular risk factors should be an integral part of the follow-up management of HL survivors who had chest irradiation. The actuarial risk of other vascular events (e.g., carotid) reaches 7% at 20 years. The actuarial risk of valvular heart disease is about 5–6% with 20 years of follow-up, and the clinicians must stay alert to these complications.

THYROID AND GONADAL DYSFUNCTION

Subclinical and clinical thyroid disease is common after treatment of HL. In a series of 151 patients, 26 cases of subclinical, 12 cases of manifest clinical hypothyroidism, and 2 cases of hyperthyroidism were documented.¹⁴ Thyroid dysfunction was more frequent in patients who underwent mantle or neck radiotherapy. Hypothyroidism was often revealed after the sixth year of follow-up. A high incidence of thyroiditis was also reported in this group of patients. Annual monitoring of thyroid function should be incorporated in follow-up patients with HL, particularly in those treated with radiation involving neck.

The impact of therapy on fertility appears to be diminishing with judicious use of less gonadotoxic chemotherapeutics.¹⁵ In general, patients are advised to use an effective contraception for 6–12 months after chemotherapy. After this initial period, there is no reason to discourage pregnancy in female HL survivors, since there is no documented negative impact of pregnancy on their outcome.^{16,17} In addition, there appears to be no increase in the rates of stillbirths, low birth weight, congenital malformations, or early cancer development in the offspring of HL survivors.¹⁸

QUALITY OF LIFE

A number of studies investigated the health-related quality of life in long-term survivors of HL. In a study from Sweden, 121 survivors were compared to a control group of 236 individuals after a median of 14 years following therapy.¹⁹ Although their physical health was diminished, the overall quality of life was not inferior in HL patients. The German Hodgkin's Lymphoma Study Group obtained a quality-of-life questionnaire from 1981 patients at a median of 5.3 years after treatment completion.²⁰ Fatigue levels were much higher compared to the control population, even several years after completion of therapy. In an early-stage HL study comparing subtotal nodal radiation to combined modality therapy (CMT), there was a greater degree of symptom distress, fatigue, and poor quality of life with CMT at 6 months but the differences were not significant at 1 and 2 year time points.²¹ Again, fatigue was significantly higher before therapy and persisted after therapy in these patients compared to the general population. The recognition and acknowledgment of this excess fatigue may be reassuring to the patients and may motivate them to enter in fatigue reduction programs.

PATIENT EDUCATION

Probably the most important role of the physicians following patients with HL is the education they provide regarding recognition of potential medical problems

that may arise. A well-informed patient is more likely to seek medical attention with new symptoms. However, patient teaching must be done without causing excessive alarm or anxiety in the patient and their family members, and special attention must be paid to their psychosocial state. Routine physician visits by HL survivors are probably more valuable for the sense of comfort they provide to the patients than the detection of recurrent HL or treatment complications. During these visits, it is important to review and explain potential late complications of HL treatment, discuss the psychosocial impact of their disease, and promote health maintenance, including smoking cessation, cardiovascular risk reduction, and self-examination of skin and breast tissue. Although an occasional patient will present with asymptomatic physical or laboratory findings suspicious for recurrence or treatment-related complication, most of these will be detected in symptomatic patients who return for unscheduled visits.

CONCLUSIONS

Follow-up care of HL survivors is as important as their initial care, since they are under a constant threat of competing causes of morbidity and mortality. Although we know a great deal about relapse patterns and long-term complications of this disease, it is important to remember that there are no prospective data regarding utility of screening methods commonly used in follow-up. Therefore, all follow-up recommendations are based on clinical judgment and experience and the care paths of large cancer centers and must be tailored based on patient characteristics and the treatment given. Ongoing patient education remains an integral part of long-term follow-up of HL. Trends toward using minimally toxic and yet very effective therapy for HL are expected to reduce both recurrences and treatment complications and make follow-up simpler but not obsolete.

Chapter **77**

TREATMENT OF RELAPSED OR REFRACTORY HODGKIN'S LYMPHOMA AND NEW FRONTIERS IN HODGKIN'S LYMPHOMA THERAPY

Angelo M. Carella, Angela Congiu, Sandro Nati, and Ercole Brusamolino

INTRODUCTION

Hodgkin's lymphoma can now be cured in more than 80% of patients, irrespective of the anatomical stage of disease and of its histologic type. In spite of this great clinical success, some patients continue to experience either resistant disease or an early or late relapse. The need for an effective salvage strategy for these patients has been one of the most important problems to be addressed in this last decade. High-dose therapy followed by the autologous stem cell transplantation (ASCT) has proved to be the most effective therapy of resistant or relapsing patients.¹⁻²² High-dose chemotherapy, utilized as conditioning before ASCT, is generally preceded by the use of conventional-dose salvage chemotherapy regimens aimed at debulking the disease before high-dose therapy: such salvage chemotherapy is also used for patients who are not candidates for ASCT (advanced age, poor performance status (PA), and/or comorbidities).

As a general measure, a complete clinical restaging should be done in all cases at relapse; a new biopsy for tissue diagnosis should be done, when appropriate, in cases experiencing an early relapse, but it is mandatory in patients with a late relapse. Early relapses or relapses involving extranodal sites are associated with a worse outcome compared to late relapses or to recurrences in a single nodal station.

Several factors must be taken into account in the choice of a conventional salvage therapy. Because most of the patients with Hodgkin's lymphoma receive as first-line therapy anthracycline-based regimens (ABVD or ABVD-like regimens), subsequent chemotherapy should avoid these agents due to the risk of cumulative cardiac toxicity. In general, drugs with known cross-resistance with those used in first-line therapy should

be avoided. Lastly, in order to mobilize hematopoietic progenitor cells, an effective regimen should avoid drugs that may compromise stem cell mobilization, such as nitrosourea derivatives or selected alkylating agents (melphalan, busulphan, and mechlorethamine), and possibly should include drugs with high mobilizing capacity, such as cytarabine or gemcitabine.

What follows is a critical review of what has been achieved, so far, in the salvage therapy of Hodgkin's lymphoma, with a brief account of new perspectives in the therapy of resistant/relapsing patients.

RELAPSES AFTER RADIATION THERAPY ALONE

The prognosis of patients with Hodgkin's lymphoma, who relapse after being treated with radiotherapy alone, is generally very good. A number of studies have reviewed the outcome of conventional-dose salvage therapy in these patients.²³⁻³¹ These studies have evaluated potential prognostic factors, including disease characteristics at diagnosis and at relapse, time to relapse, and type of salvage chemotherapy. In the studies conducted in the 1980s, most of the patients relapsing after radiation therapy (RT) alone were treated with MOPP (mechlorethamine, vincristine, procarbazine, and prednisone) or similar chemotherapies.²⁴ A study from the Dana-Farber Cancer Institute indicated a 10-year freedom from progression (FFP) of 58% and an overall survival (OS) rate of 62%.²⁸ A similar analysis at Stanford University showed that the 10-year FFP and OS were both 57%²⁵; the International Database on Hodgkin's lymphoma reported a 10-year OS of 58% for clinical stage I-II and of 50% for pathological stage I-II patients.²⁹

The ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) regimen was initially introduced as second-line therapy for patients who had a poor response to, or relapsed after, irradiation and MOPP.³¹ ABVD has subsequently proved to be superior to MOPP for both early and advanced stage Hodgkin's lymphoma and to be less toxic in terms of lower risk of sterility and of subsequent leukemia.³² A study from the National Cancer Institute of Milan demonstrated the superiority of ABVD over MOPP, with a significantly higher FFP (73% vs 42%), relapse-free survival (RFS) (81% versus 54%), and OS (80% vs 44%).³² At variance, a study recently published from the Dana-Farber Cancer Institute has shown that the two regimens, MOPP and ABVD, had similar efficacy in patients with predominantly early-stage disease at initial RT.³³ The median follow-up was 12 years, and the 10-year FFP and OS were 70% and 89%, respectively; the type of salvage chemotherapy did not significantly influence FFP or OS; the only significant predictor for inferior FFP and OS was age greater than 50 years. The discrepancy between these two studies can be ascribed to the differences in the initial disease presentation. The results of salvage chemotherapy in more recent cohorts of patients are notably better³³ than those obtained in the earlier patients; this may be because patients who were treated in the earlier era were more likely to have presented with advanced disease or large mediastinal bulk that by current standards would have precluded the use of RT alone.^{34,35}

Given the risk of leukemogenesis and of irreversible gonadal toxicity associated with MOPP chemotherapy, ABVD should be considered the salvage regimen of choice after radiation therapy failure³⁶; this particularly applies to the patients given RT alone for prognostically unfavourable early-stage disease.

RECURRENT/RESISTANT DISEASE AFTER INITIAL CHEMOTHERAPY

The therapeutic options for patients with Hodgkin's lymphoma relapsed or refractory to first-line therapy include conventional-dose salvage chemotherapy, high-dose therapy followed by ASCT, and/or allogeneic stem cell transplant.³⁷⁻³⁹

The need to find a second-line effective treatment for Hodgkin's lymphoma is confined almost entirely to patients presenting with advanced stage lymphoma; among these patients, however, the failure to cure is not evenly distributed across all prognostic subgroups. The landmark study by the International Prognostic Factors Project on advanced Hodgkin's lymphoma has shown that the risk of resistant/relapsing disease is less than 20% for patients with a prognostic score 0-1 (30% of total), but that it exceeds 50% for those with four or more adverse prognostic factors (19% of total).⁴⁰

The choice of the best salvage approach should rely on the evaluation of prognostic factors and clinical characteristics of patients with recurrent or resistant disease. Since 1979, it has been observed that the length of remission after first-line therapy has a significant effect on the success of subsequent salvage treatment; thus, failures to chemotherapy can be classified as *primary resistant disease* [complete remission (CR) never achieved], as *early relapse* (within 12 months since remission), or as *late relapse* (beyond 12 months since remission). In a recent retrospective analysis of the German Hodgkin's Lymphoma Study Group on 513 patients, no patient with primary progressive disease, treated with conventional-dose chemotherapy survived more than 8 years; by contrast, the projected 20-year survival for patients with early or late relapse is 11% and 22%, respectively; thus, conventional-dose therapy has virtually no curative potential in resistant Hodgkin's lymphoma.⁴¹

In relapsing disease (either early or late), the most compelling evidence for the superiority of high-dose therapy over conventional-dose salvage therapy is derived from the British National Lymphoma Investigational (BNLI) and the European Blood and Marrow Transplantation (EBMT) groups.^{42,43} In the first trial, patients were treated with conventional-dose mini-BEAM (carmustine, etoposide, cytarabine, and melphalan) or high-dose BEAM with autologous stem cell transplant; the actuarial 3-year event-free survival (EFS) was significantly better in patients who received high-dose therapy (53% vs 10%).⁴² In the EBMT trial, patients who relapsed after chemotherapy were randomly assigned to four cycles of mini-BEAM + dexamethasone (dexamethasone mini-BEAM) or two cycles of dexamethasone followed by BEAM and ASCT; the final analysis showed an FFP significantly higher in the BEAM + ASCT group (55% vs 34%).⁴³ Subsequently, recent studies with high-dose therapy followed by ASCT have shown 30-65% long-term disease-free survival in selected patients with refractory and relapsed disease.^{10,19,39,44-49} In addition, the reduction of early transplant-related mortality from 10-15%, as reported in earlier studies, to less than 5% in more recent studies, has led to the widespread acceptance of this procedure. Therefore, there is now a general consensus that high-dose therapy and ASCT is the treatment of choice for relapsing or resistant Hodgkin's lymphoma.³⁹

The role of conventional-dose salvage therapy consists of achieving the maximum tumor reduction (debulking) prior to high-dose therapy. In nearly all reported series of ASCT in relapsed Hodgkin's lymphoma, patients received some cytoreductive therapy before high-dose therapy/ASCT. Patients who relapse after chemotherapy but not respond to standard-dose salvage chemotherapy constitute the bulk of long-term survivors in transplantation studies.^{6,45} Unfortunately, the design of these studies does not allow an accurate assessment of the role of cytoreduction, since many teams use a uniform standard-dose salvage chemotherapy followed by

high-dose therapy and ASCT. The ability to mobilize peripheral blood progenitor cells (PBPCs) is a critical requirement for a pre-ASCT cytoreductive chemotherapy regimen. The optimal number of CD34⁺ cells/kg needed for marrow reconstitution is undetermined but many studies have shown that $(2-3) \times 10^6$ CD34⁺ cells/kg are enough to achieve neutrophil and platelet engraftment and to shorten the length of hospital stay.⁴⁶

The choice of conventional salvage regimen should be also based on the evaluation of the potential cumulative risk of cardiac or pulmonary toxicity deriving from prior exposure to anthracyclines or bleomycin and on the absence of cross-resistance between the second-line drugs and those of first-line regimens (MOPP and MOPP-like, ABVD or ABVD-like regimens).

Historically, the ABVD regimen was developed when MOPP chemotherapy represented the standard first-line therapy for advanced Hodgkin's lymphoma; the ABVD combination cured about one fourth of the patients relapsing or refractory to MOPP.⁵⁰

In the last two decades, ABVD has been the standard first-line therapy in advanced Hodgkin's lymphoma; this has led to a search of new salvage regimens incorporating new drugs (Table 77.1). Many second-line standard-dose therapy regimens have been developed,^{52,62-65} several of which include platinum compounds such as cisplatin or carboplatin. While these regimens produce a fairly good overall response rate (from 50 to 80%), they are associated with substantial hematologic and nonhematologic toxicity, and hospitalization may be required either to administer the therapy or to manage complications. Overall response rates higher than 50% have been reported with the association of carmustine, etoposide, cytarabine, and melphalan (mini-BEAM)⁶⁴ and dexamethasone-BEAM (dexa-BEAM).⁶³ Unfortunately, both these regimens contain a nitrosourea and are poor mobi-

lizers of hematopoietic stem cells. Therefore, new drug combinations have been evaluated in order to provide sufficient disease control combined with moderate toxicity, and to allow a good PBPC mobilization for subsequent rescue after high-dose therapy. Either the combination of dexamethasone, cisplatin, and high-dose cytarabine (DHAP)⁶⁶ or that of etoposide, high-dose cytarabine, and cisplatin (ASHAP)⁶² has proved to have both characteristics (good efficacy and excellent PBPC-mobilizing capacity). Other salvage regimens consist of a backbone of ifosfamide and etoposide, in association with a platinum derivative. The mitoguazone, ifosfamide, vinorelbine, and etoposide (MINE) regimen⁵¹ was derived from the initial mitoguazone, ifosfamide, methotrexate, and etoposide (MIME) regimen.⁶⁷ In the group d'étude lymphoma (GELA) experience, among 100 patients with untreated relapses or induction failures, the MINE regimen produced an overall response rate of 75% (35% of CR); the CR response rate was 92% in patients with untreated relapses and 53% in those with induction failures; MINE was myelotoxic but was given on time at the calculated dose in 80% of patients and allowed an efficient harvest of PBPC.⁵¹

Recently, several variants of the ifosfamide-etoposide combination have been utilized and all these studies have confirmed that these drugs are able to produce good responses and can effectively mobilize hematopoietic progenitor cells into the peripheral blood. Two courses of VIP (etoposide, ifosfamide, and cisplatin) protocol⁵² produced an overall response rate of 67%, while a combination of etoposide, prednisolone, ifosfamide, and carboplatin (EPIC)⁵³ produced a response rate of 70%. Sixty-five consecutive patients, 22 with primary refractory and 43 with relapsed Hodgkin's lymphoma, were treated with two biweekly cycles of ifosfamide, carboplatin, and etoposide (ICE).⁵⁴ The response rate was 88% and the

CR, complete remission; PR, partial remission; PD, progressive disease; TRM, therapy-related death; NA: not available.

EFS rate for patients who underwent transplantation was 68%. Predictors for outcome included B symptoms, extranodal disease, and CR duration of ≤ 1 year. High-dose ifosfamide and vinorelbine produced an overall response rate of 83%, with 45% complete and 38% partial responses after a median of two cycles⁵⁵; the main toxic effect of these regimens was grade III–IV neutropenia, documented in 65% of cycles, with a median duration of 4–7 days. Almost all these standard-dose regimens were followed by PBPC collection and high-dose therapy with autologous stem cell rescue; after engraftment many patients received radiotherapy for residual disease. Of particular interest is the IEV (ifosfamide, epirubicin, and etoposide) combination⁵⁷; this regimen was highly effective in patients relapsing after first second-line chemotherapy. Responsive patients were subsequently treated with radiotherapy. In these advanced patients, IEV was able to induce OS, RFS, and FFP of 18, 44, and 22%, respectively.

More recently, gemcitabine, a new pyrimidine antimetabolite was shown to have remarkable activity against solid tumors such as those of pancreas, lung, and bladder and to be active in vitro against leukemia and lymphoma cell lines.⁶⁸ When used as a single agent, gemcitabine is active in Hodgkin's lymphoma^{58,59} and in a variety of histologic subtypes of non-Hodgkin's lymphoma, with a favorable toxicity profile compared with other cytotoxic agents.^{56,69} In phase II studies in relapsed/refractory Hodgkin's lymphoma the drug was given on days 1, 8, and 15 at a dose of 1200 mg/m², with a schedule every 28 days, for a total of six cycles.⁵⁹ The overall response rate was 39%, with 9% CRs. In another study,⁵⁸ the overall response rate was 43%, with 14% CR; the patients who relapsed after a remission longer than 12 months had a better OS rate than those who relapsed earlier (67% vs 25%). In both studies the major toxicity was hematologic, with a minority of patients experiencing a grade IV toxicity. In no study did treatment-related deaths occur. According to these results this drug has been included in several salvage regimens for resistant/relapsing Hodgkin's lymphoma.

The addition of cisplatin to gemcitabine has demonstrated synergistic activity in vitro and this combination has become the standard in the treatment of advanced bladder and non-small cell lung cancer.⁷⁰ Given the moderate toxicity observed with these drugs when used at conventional doses, both have been incorporated with dexamethasone into the gemcitabine, dexamethasone, cisplatin (GDP) regimen.⁷¹ The overall response rate achieved after the GDP regimen is 70%, (17% CRs); hematologic toxicity was mild (grade III neutropenia: 9%; grade III thrombocytopenia: 13%) and all patients successfully mobilized PBPC, with a median 10.6×10^6 CD34⁺ cells/kg.⁶⁰

Gemcitabine has also been associated with ifosfamide and vinorelbine in the IGEV combination. In the original experience in 17 heavily pretreated patients (chemo + radiotherapy), the overall response

rate was 94%⁶¹ and the median number of CD34⁺ cells collected was 10.9×10^6 /kg; in about 60% of patients, a single leukapheretic procedure was able to reach the number of CD34⁺ cells necessary for the transplantation procedure. No treatment-related death was observed. The experience with the IGEV regimen has been widely confirmed also for its acceptable toxicity.

FUTURE RESEARCH

Among the different experimental strategies in the treatment of Hodgkin's lymphoma, antibody-based constructs have given the most promising results in experimental Hodgkin's lymphoma models. Early clinical trials using immunotoxins and, more recently, monoclonal antibodies (MoAb) have demonstrated some clinical efficacy in patients with refractory Hodgkin's lymphoma.

Hodgkin's lymphoma can be a suitable candidate for MoAb-based therapy because Reed–Sternberg and Hodgkin's cells express specific surface antigens such as CD15, CD25, and CD30. So far, different approaches to eradicate tumor cells have been utilized using antibodies, including “naked” MoAb, and bispecific constructs that activate effectors cells of immune system against the target cell, immunotoxins that deliver a toxin linked to a specific antibody into the target cell, and different radioimmunoconjugates.

MONOCLONAL ANTIBODIES FOR TREATMENT OF THE LYMPHOCYTE-PREDOMINANT HISTOLOGY

The anti-CD20 monoclonal antibody rituximab has demonstrated clinical efficacy in lymphocyte-predominant Hodgkin's lymphoma (LPHL) where Hodgkin's cells express B-cell antigens such as CD20.⁷² Several multicenter phase II trials testing rituximab on refractory patients with LPHL are ongoing. In one study, 11 patients with CD20⁺ Hodgkin's lymphoma were treated with rituximab at the standard dose of 375 mg/m², weekly for 4 weeks; nine patients (82%) achieved a complete response for which median duration was 14 months.⁶⁰ Similar results have been obtained in a trial involving 22 patients with recurrent LPHL, with an overall response rate of 100%.⁷³

Treatment with rituximab was less successful in a series of 22 patients with classical Hodgkin's lymphoma, with an overall response rate of 23% and a median duration of response shorter than 8 months.⁷⁴

MONOCLONAL ANTIBODIES FOR TREATMENT OF CLASSICAL HODGKIN'S LYMPHOMA

Among the different target antigens on Reed–Sternberg cells, CD30 seems to be the most promising, since it is

expressed at very high levels.⁷⁵ So far, two anti-CD30 MoAbs have been developed, the humanized SGN-30⁷⁶ and the fully human MDX-60.⁷⁷ The SGN-30 chimeric anti-CD30 antibody has demonstrated antitumor activity in preclinical models of Hodgkin's lymphoma and anaplastic large cell lymphoma. In a phase I single-dose trial, SGN-30 MoAb showed minimal toxicity with doses from 1 to 15 mg/kg, and antitumor activity was documented in 15% of patients (2 of 13). In a phase I/II dose-escalation study of 6 weekly infusions of SGN-30 at doses of 2, 4, 8, and 12 mg/kg, the MOAb was very well tolerated up to 8 mg/kg, and it was associated with a moderate activity.⁷⁸

MDX-060 is a fully human IgG MoAb that recognizes CD30 and mediates killing of Reed–Sternberg cells in vitro and in xenograft tumor models. In a phase I/II dose-escalation study in patients with relapsed or refractory Hodgkin's lymphoma and other CD30⁺ lymphomas, MDX-060 was administered intravenously at dose levels of 0.1, 1, 5, 10, or 15 mg/kg, weekly for 4 weeks, with no dose-limiting toxicity. While the efficacy assessment has not been completed

yet in all patients, preliminary results indicate that MDX-060 is well tolerated and has a clinical activity.⁷⁹

Currently, humanized as well as fully human anti-CD30 MoAbs are being tested in clinical phase I/II studies. These MoAbs could engage the human immune system against Hodgkin's lymphoma and are capable of inducing apoptosis of Hodgkin's and Reed–Sternberg cells. In addition, these MoAbs could be combined with conventional chemotherapy and further improve the therapy of Hodgkin's lymphoma.

SUMMARY

It is more and more difficult to test new agents since Hodgkin's lymphoma is often cured by conventional and/or high-dose therapy.⁸⁰ Nevertheless patients experiencing tumor refractoriness or early/late relapse must be able to receive effective procedures for a second remission of the disease. Clinical investigators must continue to work together to harness the objective to cure all patients with Hodgkin's lymphoma.

SPECIAL TOPICS IN LYMPHOMA

Chapter **78**

EPIDEMIOLOGY OF SECOND MALIGNANCIES FOLLOWING LYMPHOMA THERAPY AND SCREENING RECOMMENDATIONS

Jonathan W. Friedberg and Andrea K. Ng

INTRODUCTION

Patients with Hodgkin's lymphoma and aggressive non-Hodgkin's lymphoma (NHL) have a relatively high cure rate compared with patients with other hematologic malignancies. Despite these cures, lymphoma survivors continue to have a higher mortality rate than age- and gender-matched peers who have not had the disease. Much of this excess mortality is from second malignancies, which are now recognized as a direct consequence of curative chemotherapy and radiation therapy, and frequently have a poor prognosis. Figure 78.1 shows the cumulative incidence of observed second tumors in a cohort of survivors of Hodgkin's disease and expected tumors in a matched population. Even more than 30 years after diagnosis, patients cured of Hodgkin's lymphoma experience elevated risks of second cancers. In one study, the relative risk of death from second malignancy was 5.1 compared with age-matched controls.¹ The recent appreciation of these often-fatal late effects of treatment has focused efforts in both screening and prevention.

SOLID TUMORS: INCIDENCE AND RISK FACTORS

The risk of solid tumors after treatment of lymphoma is most established in Hodgkin's lymphoma. However, as therapies for NHL improve and result in more survivors, it is expected that risks and risk factors for the development of solid tumors in this setting will be similar to those in Hodgkin's lymphoma. In the modern Hodgkin's lymphoma therapeutic era (post-mechlorethamine), lung and breast cancer, often appearing 15 or more years after completion of lymphoma therapy, have emerged as the most significant subtypes of second malignancy, accounting for the majority of cases.² Table 78.1 shows the types of solid tumors observed in a cohort of patients treated for Hodgkin's lymphoma at a single institution, representative of published experiences.

A recent study analyzed data from 32,591 patients with Hodgkin's lymphoma reported to 16 registries in North America and Europe.³ Importantly, this included 1111 25-year survivors. In this series, there were 1726 solid tumors, with cancers of the lung, digestive tract, and

Figure 78.1 Cumulative incidence of second tumors among patients with Hodgkin's lymphoma ($N = 1319$) treated at the Joint Center for Radiation Therapy, and the expected cumulative incidence of tumors among a matched population

breast the most common. After a progressive rise in relative risk of all solid tumors over time, there was an apparent downturn in risk at 25 years, emphasizing the importance of long-term surveillance in this population.

Radiation therapy is the most significant risk factor for developing solid tumors after lymphoma, with the majority of second cancers arising either within or at the edges of radiation fields. In the aforementioned series, temporal trends and treatment group distribution for cancers of the esophagus, stomach, rectum, breast, bladder, and thyroid all suggested a radiogenic effect. Three case-control studies have carefully evaluated the dose-response relationship between exposure to radiation therapies and the development of breast cancer and lung cancer, and demonstrated a significant trend of increasing risk of tumor development with increasing radiation dose.⁴⁻⁶

The contribution of chemotherapy alone to the risk of solid tumor development is less clear. In a cohort of patients with Hodgkin's lymphoma from the British Lymphoma Investigation Group, 31% of the population was treated with chemotherapy alone (predominantly with alkylating agents), and the relative risks of developing lung cancer after radiation therapy alone or chemotherapy alone were both significantly increased at 2.9 and 3.3, respectively.⁷ A nested case-control study of lung cancer after Hodgkin's lymphoma was subsequently performed, comparing 88 cases of lung cancer with 176 matched controls.⁸ Patients with a history of mechlorethamine treatment were at a significantly higher risk of developing lung cancer ($RR = 1.69$).

Two case-control studies on breast cancer after Hodgkin's lymphoma, however, showed a significantly

decreased risk of breast cancer after alkylating chemotherapy exposure.^{4,5} The relationship was dose related, with decreasing breast cancer risk with additional cycles of chemotherapy. Other data suggest the risk of breast cancer is significantly reduced in women who had premature menopause: the younger the age at menopause, the lower the risk of breast cancer.⁴ These studies do report that the radiation-related risk of breast cancer, however, does not diminish in the longest follow-up, again suggesting a need for lifetime surveillance and programs of patient and physician awareness.

Table 78.1 Tumor-type distribution of the 142 solid tumors observed in 1319 patients treated for Hodgkin's disease at the Joint Center for Radiation Therapy at a median of 12 years of follow-up

Solid tumor type ($N = 142$)	N	(%)
Breast	39	(27)
Lung	27	(19)
Gastrointestinal	25	(18)
Sarcoma	12	(8)
Genitourinary	12	(8)
Head and neck	9	(6)
Melanoma	8	(6)
Thyroid	5	(4)
Gynecologic	4	(3)
Central nervous system	1	(1)

Reports on the relationship between age at diagnosis and treatment of lymphoma and risk of second malignancy are conflicting. One consistent finding, however, is the increased risk of breast cancer for females treated for Hodgkin's lymphoma at a young age.^{2,4} The cutoff age ranges from 25 to 35, beyond which the risk of breast cancer appeared to be no longer significantly increased. A cohort of 1380 children with Hodgkin's lymphoma (median age of diagnosis was 11) was followed for a median of 17 years by the Late Effects Study Group.⁹ Two hundred twelve second cancers occurred in this group of patients, with breast cancer the most common malignancy. The cumulative incidence of second malignancy was 26% at 20 years. Risk factors for solid tumors clearly included young age at lymphoma diagnosis, and radiation-based therapy.

Several case-control studies have evaluated tobacco use as an additional risk factor for developing secondary neoplasms after therapy for lymphoma.^{6,8} In one study, in which the smoking history was known in 90% of the patient population, patients who smoked more than 10 pack-years after the diagnosis of Hodgkin's lymphoma were at a sixfold increased risk for lung cancer compared to those with a less than one pack-year history of smoking.¹⁰ The multiplicative effect between smoking and lymphoma therapy exposure is well described: patients who received both radiation therapy and alkylating agents were at a sevenfold increased risk of lung cancer; this risk increased to 49-fold in the setting of a greater than 10-year history of tobacco use.⁶

MYELODYSPLASTIC SYNDROME (MDS) AND ACUTE MYELOID LEUKEMIA (AML): INCIDENCE AND RISK FACTORS

Historically, myelodysplastic syndrome (MDS) and secondary acute myelogenous leukemia have been recognized as significant complications of alkylating-agent-based chemotherapy for both indolent NHL and Hodgkin's lymphoma.^{11,12} Topoisomerase inhibitors¹³ and purine analogs¹⁴ also clearly contribute to the risk of AML and MDS. With the recent introduction of alternative chemotherapy and immunotherapeutic modalities, autologous stem cell transplantation (ASCT) and radioimmunotherapy represent the lymphoma treatment modalities with the highest risk of developing MDS. In fact, MDS and AML have emerged as the major late complications of ASCT in patients with lymphoma.¹⁵ In this setting, these disorders have an exceedingly poor prognosis, and represent the leading cause of non-disease-related death in survivors of ASCT for lymphoma.

The true incidence of MDS after nonmyeloablative radioimmunotherapy with either iodine-131 tositumomab¹⁶ (Bexxar, GlaxoSmithKline, Philadelphia, and Corixa, Seattle) or Y-90 ibritumomab tiuxetan¹⁷ (Zevalin, BiogenIdec, Cambridge) remains to be defined. In an

analysis of 773 patients treated with I-131 tositumomab, 21 patients have developed MDS thus far, with an annualized incidence of 1.45%/year, which compares favorably to patients treated with alkylating agent chemotherapy.¹⁸ The incidence of MDS after Y-90 ibritumomab tiuxetan appears to be similar. However, long-term follow-up of large cohorts of patients is clearly required to definitively determine the incidence of this fatal complication in the modern treatment era of indolent lymphoma, and the degree to which radioimmunotherapy contributes to this risk.

There is a substantially greater understanding of clinical risk factors for subsequent development of MDS after ASCT for lymphoma. It is expected that these risk factors may be similar in patients treated with radioimmunotherapy. Acknowledging differences in methods used to identify cases and to estimate the cumulative incidence over time, up to 10% of NHL patients treated with ASCT may develop secondary MDS within 10 years of primary therapy.¹⁹ The majority of published studies are single-institution experiences. Important considerations in the interpretation of these studies are length and quality of patient follow-up, definition of MDS, and uniformity of treatment regimens. As expected, risk factors may differ between studies; however, the incidence over time in most studies is strikingly similar. Unlike secondary MDS from chemotherapy alone, the incidence post-ASCT appears to remain stable over time, without evidence of a plateau on the Kaplan-Meier curve.²⁰

A representative series from the Dana-Farber Cancer Institute evaluated the risks and outcome of MDS in 552 patients with NHL receiving a standard conditioning regimen of 1200–1400 cGy total body irradiation (TBI) and cyclophosphamide, followed by monoclonal-antibody-purged ASCT with marrow as graft source. In this series, 41 patients developed MDS, strictly defined, a median of 47 months (range 12–129) from ASCT.²¹ At the time of diagnosis of MDS, 29 patients were in remission and 12 patients had relapsed with NHL; the majority of these patients had not received further cytotoxic therapy since transplant. The absolute risk of developing MDS after ASCT for NHL was 7.4%. The cumulative risk of development of MDS was 14.5% at 10 years posttransplant.²² In a logistic regression model, low number of stem cells infused per kilogram and prior localized irradiation were the only significant predictors of developing MDS.

The specific role of TBI conditioning in the development of MDS has been assessed by several other studies. Almost 5000 patients with lymphoma have undergone ASCT in the European Bone Marrow Transplant Registry, with 68 patients developing MDS.²³ This incidence is lower than other series, perhaps as a consequence of underreporting of this complication. The median follow-up from the date of transplant was 6.7 years for patients who developed MDS, but only 2.9 years for the patients without MDS. Multivariate analysis revealed age at transplant, exposure to TBI in conditioning, long interval between diagnosis of lymphoma

and transplant, and indolent histology as independent variables predicting for subsequent MDS. For patients with Hodgkin's lymphoma, female gender was identified as a risk factor. The amount of previous chemotherapy, including cumulative alkylating agent exposure, was not found to be a significant factor.

In a case-control study of 56 patients with MDS/AML after ASCT for lymphoma, and 168 matched controls who also underwent ASCT for lymphoma but did not develop MDS/AML, the separate contributions of pretransplantation and transplantation-related therapy were assessed.²⁴ The intensity of pretransplant therapy did contribute to the risk of developing MDS. Transplant factors, including high-dose TBI, and peripheral blood stem cells as graft source also appeared to contribute to the risk of MDS.

It is therefore not possible to establish whether the increased risk of MDS in patients with lymphoma is truly a disease-related phenomenon, or secondary to other fac-

tors such as a tendency to use more TBI for conditioning, or exposure to high doses of alkylating agents pretransplant. The risk of MDS following ASCT for multiple myeloma²⁵, breast cancer,^{26,27} and germ cell tumors²⁸ appears to be less than that in similar populations of patients with NHL following ASCT. Reported risks of developing MDS after autotransplantation for Hodgkin's lymphoma are varied, with some studies suggesting a lower risk than in similar patients with NHL following ASCT,²⁹⁻³¹ and others reporting a similarly high risk.³² Confounding most of the studies of Hodgkin's lymphoma is the use of mechlorethamine prior to transplantation, which may have a more profound effect on the development of MDS than the transplant itself has.^{24,31} Standard, modern regimens for Hodgkin's lymphoma clearly have significantly less risk. Between 1981 and 1998, the German Hodgkin Study Group treated 5411 patients,³³ of whom only 46 patients developed MDS/AML at a median follow-up of 55 months. Similar

Table 78.2: MDS/AML after ASCT for NHL and HL

Institution	Diagnosis	Incidence	Median follow-up ^a	Risk factors
Dana-Farber ²¹	NHL	41/552	75 months	Prior XRT Low no. of cells infused
St. Bartholomew's ³⁴	NHL	27/330	72 months	Older patient age Prior fludarabine

French Cooperative Group ³⁰	HL	8/467	21 months	Splenectomy PBSCT

Abbreviations: XRT: localized radiotherapy; PBSCT: peripheral blood stem cell transplantation; TBI: total body irradiation; NHL: non-Hodgkin's lymphoma; HL, Hodgkin's lymphoma; EBMT: European Group for Blood and Marrow Transplantation.

to transplant patients, the prognosis of these patients was poor, with only four patients surviving.

Table 78.2 summarizes several experiences of MDS/AML after ASCT. In summary, the reported cumulative risk of MDS exceeds 10% in several series of patients undergoing autotransplantation for NHL, and is somewhat lower after transplantation for other histologies. Older patients with extensive prior chemotherapy, patients receiving localized radiotherapy, and those receiving TBI conditioning appear to be at the highest risk for this complication.

DETECTION OF SECOND MALIGNANCIES: STRATEGIES FOR SCREENING

The only screening test for early detection of secondary malignancies that has demonstrated benefit is mammography to detect breast cancer. In one study, 81% of 37 women with breast cancer after Hodgkin's lymphoma had mammographic abnormalities of a mass and/or microcalcifications.⁴¹ Diller et al. reported a high frequency of mammographically detected abnormalities, supporting the value of mammographic screening in 90 patients prospectively evaluated following treatment for Hodgkin's lymphoma.⁴² During the study period, 10 women developed 12 breast cancers, all of which were evident on mammogram. The role of other breast imaging modalities, including magnetic resonance imaging^{43,44} and FDG-PET,⁴⁵ have not been prospectively evaluated in women following treatment for lymphoma. Moreover, the effectiveness of tamoxifen or raloxifene as chemoprevention, although demonstrated in other high-risk patients,⁴⁶ is unclear in patients treated for lymphoma. It is probably reasonable to avoid estrogen replacement therapy in these women. At the present time, we recommend annual mammography beginning 7 years after completion of radiation therapy (in a field that includes the breast) for lymphoma. For women treated before age 20, screening should probably not begin until the patient reaches age 25.⁴⁷ We anticipate, however, that additional recommendations for chemoprevention or more elaborate screening algorithms may evolve over the next few years, as current trials mature.

Despite the prevalence of lung cancer after lymphoma therapy, there is no clear role for prospective imaging as screening. The role of chest CT as screening is currently being studied in a prospective randomized trial in other high-risk groups,⁴⁸ but survivors of lymphoma are not included in the study. There are no clear data suggesting a benefit to regular imaging. However, there should be a low threshold to image the chest for any signs or symptoms that could represent a thoracic malignancy. Given the clear increased risk of secondary malignancies in patients who smoke, we recommend counseling against tobacco use.

PREVENTION: TREATMENT REDUCTION

As outlined, the risk of both MDS/AML and solid tumors after lymphoma therapy is directly related to the cumulative treatment exposure, of both chemotherapy and radiation. A number of ongoing multi-institutional randomized trials are investigating different ways to reduce treatment for favorable prognosis Hodgkin's lymphoma, including the omission of radiation therapy, and the adoption of response-based therapy. However, longer follow-up time of these prospective randomized trials is needed to confirm to what degree the treatment reductions will translate into lower risk of second malignancy, and whether there is any trade-off with respect to failure-free survival. Even outside of a clinical trial, exposure to known stem cell toxins, including prolonged exposure to alkylating agents, purine analogs, and topoisomerase-II inhibitors, should be limited as much as possible in patients in whom ASCT or radioimmunotherapy may be considered as a treatment option. The introduction of novel biological treatment options for lymphoma, including monoclonal antibody therapy, proteasome inhibitors, and antisense therapy, may allow future minimization of such toxic therapies in many circumstances.

Clonal hematopoiesis pretransplant appears to increase the risk of subsequent MDS. There are at least five methods for assessing this risk, based on the presence of clonal abnormalities in hematopoietic cells, including standard cytogenetics, interphase fluorescence in situ hybridization, analysis for loss of heterozygosity, polymerase chain reaction for point mutations, and X-inactivation-based clonality assays.⁴⁹ Abnormalities in one of these assessments pretransplant, or before radioimmunotherapy, may represent relative contraindications to transplant. However, since no single mutation or gene rearrangement is sufficient for the development of MDS after transplant, and not all patients with cytogenetic abnormalities develop clinical MDS, these are imperfect assessments. The optimal "screening" modality has yet to be determined, and prospective studies are ongoing. However, most advocate serious consideration to deferring both radioimmunotherapy and autologous transplant in patients with clonal cytogenetic abnormalities.

Finally, to minimize the development of MDS after ASCT, chemotherapy-only conditioning regimens have similar response rates to TBI-containing regimens in most subtypes of NHL,^{38,50} and may decrease risk of MDS, particularly for those patients treated with localized radiotherapy.^{51,52}

CONCLUSIONS

Second malignancies have clearly evolved to be important causes of mortality in patients with curable lymphomas. As cure rates increase, and the cohort of

patients treated with aggressive autologous transplantation and novel radioimmunotherapy approaches grows, it is anticipated that the incidence of second cancers will increase significantly. Perhaps most concerning is the lack of an apparent plateau in the incidence curve, even 20–30 years after diagnosis of lymphoma.⁵³ For this reason, we feel it is critical that patients cured of lymphoma remain under care of medical and radiation oncologists attuned to these

risks, and undergo at least annual history and physical examinations, with appropriate screening tests for second cancers. Future emphasis needs to continue on minimizing toxic therapy to prevent this devastating cost of cure.

Chapter 79

THE APPROPRIATE USE OF PET AND GALLIUM SCANS IN LYMPHOMA

Rebecca Elstrom

INTRODUCTION

Radiologic imaging plays a critical role in the staging and follow-up of patients with lymphoma. The initial stage of disease helps to define appropriate therapeutic interventions, and the extent and location of disease have traditionally been established through the use of anatomic imaging, in addition to physical examination and bone marrow biopsy. Furthermore, as different patients show varying degrees of responsiveness to standard chemotherapy, imaging studies can help determine whether an individual patient is responding appropriately to therapy, and therefore whether continuation of that therapy is warranted. Finally, after completion of treatment, patients are followed for evidence of relapse or progression of disease through a combination of imaging and clinical follow-up. These studies help to establish the status of disease and therefore the appropriate intervention or observation.

Anatomic imaging, such as computed tomography (CT) and magnetic resonance imaging (MRI) have been used extensively in patients with lymphoma. However, these modalities are limited by their dependence on size abnormalities in defining areas of tumor involvement. This limitation renders anatomic imaging suboptimal for detecting small foci of disease or for differentiation of viable tumor from fibrosis in a residual mass following treatment.

Functional imaging modalities, in contrast to anatomic imaging, take advantage of cellular processes to identify tissues of interest. Two such functional imaging modalities, Gallium-67 (Ga-67) scintigraphy and positron emission tomography using 18-fluoro-2-deoxyglucose (FDG-PET), utilize tracers that are taken up via metabolic pathways, therefore resulting in enhancement of highly metabolic tissues, such as tumor foci. This characteristic allows identification of tumor sites based on cellular metabolic activity rather

than anatomic abnormalities, permitting detection of small foci of disease or differentiation of tumor from fibrosis. Both Ga-67 scintigraphy and FDG-PET have shown advantages in defining active lymphoma over classical imaging alone. However, the greater technical ease and apparent improved accuracy of FDG-PET imaging are contributing to its increasing acceptance as the functional imaging modality of choice in the care of lymphoma patients.

GALLIUM-67 SCINTIGRAPHY

Gallium-67 citrate has been used since the 1970s for imaging of lymphoma and other tumors. Many malignant cells, including some lymphomas, take up large amounts of iron for use as a cofactor for ribonucleotide reductase, a key enzyme in DNA synthesis. Many malignant cells overexpress the transferrin receptor,¹⁻³ facilitating uptake of iron bound to transferrin. Gallium-bound transferrin binds the transferrin receptor and is therefore taken up into cells in a manner similar to iron. Ga-67 is administered intravenously and, following a distribution period of 1–2 days, can be imaged, with the best sensitivity and accuracy demonstrated by single photon emission computed tomography (SPECT).^{4,5}

Using Ga-67 SPECT and higher doses of tracer, Ga-67 scintigraphy has been studied in staging and in follow-up of patients with lymphoma. It was found to be beneficial following treatment for restaging and detection of recurrence.^{6,7} Different lymphoma grades and histologies have variable rates of detection, however. For example, while Ga-67 was sensitive and accurate in restaging of aggressive lymphomas, it was inadequate for detection of indolent lymphomas, and did not predict Richter's transformation in chronic lymphocytic leukemia (CLL).⁸ Baseline scanning is therefore critical to establish the utility of this modality in individual tumors.

In recent years, the emergence of FDG-PET has led investigators to compare the utility of these two imaging modalities in the evaluation of lymphoma. In both Hodgkin's lymphoma (HL) and non-Hodgkin's lymphoma (NHL), FDG-PET shows higher sensitivity for staging and follow-up after treatment.⁹⁻¹¹ In addition, FDG-PET detects indolent lymphomas with better accuracy than does Ga-67 scintigraphy. These findings, combined with a shorter half-life of FDG and more convenient imaging characteristics, have led to FDG-PET largely replacing Ga-67 scintigraphy where FDG-PET is available.

18-FLUORO-2-DEOXYGLUCOSE POSITRON EMISSION TOMOGRAPHY (FDG-PET)

It has been known for decades that cancer cells have altered metabolism relative to normal cells. In the 1920s, Warburg first described the fact that cancer cells take up large amounts of glucose, performing glycolysis at an elevated rate even in the presence of oxygen.¹² Warburg hypothesized that this high rate of aerobic glycolysis was a result of dysfunctional mitochondrial electron transport, decreased production of ATP via oxidative metabolism, and a compensatory increase in ATP production by glycolysis. Others have proposed that the increased glucose uptake and glycolysis seen in cancer cells may be a primary effect, with subsequent suppression of oxidative phosphorylation. Whatever the mechanism, many cancer cells, including most lymphomas, take up excess amounts of glucose. It is this increased glucose uptake that targets FDG to cancer cells and is the basis of FDG-PET imaging of cancer.

18-Fluoro-2-deoxyglucose is a labeled glucose analog that is taken up by cells in a manner and at a rate similar to glucose. Upon entry into the cell, the molecule is phosphorylated by hexokinase, therefore trapping it inside the cell. While glucose is subsequently metabolized via glycolysis, the 2-deoxyglucose analog cannot be further metabolized, resulting in accumulation of the labeled, phosphorylated molecule within highly metabolic tissues. The label can then be detected by PET.

While FDG-PET is increasingly used in the care of patients with cancer, the optimal role for this imaging modality is still under investigation. The following sections review the status of FDG-PET imaging in detection and initial staging, response assessment, and follow-up of patients with lymphoma.

DETECTION

The ability of FDG-PET to image lymphomas depends on the tumor's characteristic of high glucose uptake. However, the mechanisms by which this excess glucose uptake occurs, though currently under investigation,

are still not completely understood. While this increased glucose uptake could act as a compensatory mechanism for highly anabolic cells to obtain building blocks for growth and proliferation, an alternative possibility is that high glucose uptake is a fundamental property of malignant cells. In the former case, one would expect that FDG avidity would depend on tumor grade, while in the latter case, the avidity may be independent of grade. Several groups have investigated different subtypes of lymphoma in an attempt to define which of these may be reliably imaged by FDG-PET.

Varying results have been reported regarding the utility of FDG-PET in imaging indolent tumors. Leskinen-Kallio and colleagues, in an early study examining FDG uptake in NHL, found poor uptake in indolent tumors.¹³ In contrast, Newman et al. described comparable FDG uptake by both low- and intermediate-grade tumors.¹⁴

To evaluate this issue more decisively, investigators have studied the utility of FDG-PET in specific histologic subtypes of lymphoma. Elstrom and colleagues systematically evaluated specific World Health Organization (WHO) subtypes for their detectability by FDG-PET.¹⁵ While 93% of lymphoma patients overall had tumor detectable by PET, those tumors that were not reliably detected fell within specific WHO subtypes, including marginal zone lymphoma (MZL), peripheral T-cell lymphoma (PTCL), and cutaneous B-cell lymphoma (CBCL). One limitation of this study was poor representation of some histologic subtypes, such as small lymphocytic lymphoma (SLL). Jerusalem et al. investigated FDG-PET in indolent lymphomas and found that it has poor sensitivity in imaging SLL.¹⁶ Follicular lymphoma (FL), in contrast, including grade 1 tumors, was nearly uniformly detected in both of the above studies. These results suggest that tumor grade is not the most important predictor of FDG avidity, but rather that this avidity is based on other, as yet poorly defined, biological characteristics of the tumor.

Hoffmann and colleagues have further explored the situations in which FDG-PET imaging is useful in lymphoma. In one study they showed that, while 5 of 6 nodal MZLs were detected by FDG-PET, none of 14 extranodal MZL evaluated showed FDG avidity.¹⁷ In another study, an evaluation of eight cases of duodenal FL, a rare manifestation of this tumor, showed that none of these lymphomas could be imaged by FDG-PET.¹⁸ Of note, the one FL not detected by FDG-PET in the study by Elstrom et al. was an intestinal tumor. This raises the possibility that, even within broad WHO subtypes, subtle biological differences may define different imaging characteristics.

In summary, FDG-PET reliably detects most lymphomas. In the case of the most common aggressive NHL and HL, FDG-PET imaging represents an accurate assessment of disease activity. In these cases, FDG-PET can likely be used in follow-up of patients

even without a baseline scan to document utility. However, in some tumors, particularly SLL, extranodal MZL, and intestinal FL, FDG avidity should be documented prior to therapy if the clinician plans to use this imaging modality for follow-up. Further studies of these issues will further clarify the generalizability of these findings.

STAGING

Initial staging of disease presents a critical issue in the care of lymphoma patients, affecting prognosis and choice of therapy. Studies investigating the utility of FDG-PET in lymphoma have shown promising results for improving the accuracy of staging in these patients. Several groups have compared FDG-PET with traditional staging studies, such as CT, MRI, and bone marrow biopsy, in detecting specific sites of disease. In

general, these investigators report improved sensitivity and specificity using FDG-PET as compared to anatomic imaging studies in both NHL and HL. The results of selected studies are presented in Table 79.1.

In addition to anatomic imaging, evaluation of bone marrow involvement represents a critical issue in staging of lymphoma. Investigations of the ability of FDG-PET to accurately stage bone marrow involvement by lymphoma have yielded conflicting results. Some have shown improved detection of bone marrow disease by PET, particularly in cases of patchy bone marrow involvement.²⁵ Others, however, demonstrate poor sensitivity and specificity, with a significant incidence of both false-negative FDG-PET, especially in indolent lymphomas, and false-positive FDG-PET, often in the setting of B symptoms and benign bone marrow hyperplasia.^{15,26,27} At this point, FDG-PET is

Table 79.1 FDG-PET versus conventional imaging modalities (CIM) in staging lymphoma

Studies	Histology	Patients	Major findings	Comments
Naumann et al. ¹⁹	HL	88	PET Stage change in 20% Intensification of treatment in 10%	PET is especially useful in early stage
Partridge et al. ²⁰	HL	44	PET 41% upstaged 7% downstaged Treatment modification in 25%	
Jerusalem et al. ²¹	HL	33	PET 12% downstaged 1 false negative 9% upstaged	No changes in treatment based on PET

Delbeke et al. ²⁴	HL, NHL	45	PET 16% stage change 13% Treatment change CIM 7% stage change Accuracy 91% PET 84% CIM	PET and CIM are complementary

best used as a complementary study in evaluating bone marrow involvement, ideally with follow-up biopsy of any focal areas of uptake in the setting of a negative iliac crest biopsy.

A recurring difficulty in addressing the question of FDG-PET accuracy in staging is the lack of a clear gold standard. In most cases, systematic biopsy of questionable lesions is impractical, and therefore the true result is often defined by the clinical scenario or follow-up. In spite of this limitation, however, studies have repeatedly shown improved staging information with the addition of FDG-PET.

In summary, FDG-PET scanning at initial staging can add valuable information for the clinician. First, a pretreatment FDG-PET scan documents the FDG avidity of a patient's lymphoma, confirming the utility of this modality in follow-up. In addition, PET can refine staging results of anatomic imaging by upstaging through detection of small lesions or diffuse organ involvement. Alternatively, PET may identify patients with a lower stage than suggested by anatomic imaging. However, it is clear that FDG-PET can in some cases show both false-positive and false-negative results. Therefore, discrepancies in staging must be interpreted carefully. In cases of uncertainty, questionable lesions should be biopsied if possible, particularly in cases in which treatment would be altered.

RESPONSE ASSESSMENT

Response assessment following treatment for lymphoma provides an assessment of the adequacy of response to therapy and can help determine prognosis and the need for further therapy. Since patients who have not achieved a complete response to treatment have a poorer overall prognosis, identification of these patients early in the course of therapy may allow rapid institution of second-line therapy and, ideally, improve outcome. Unfortunately, traditional restaging modalities present pitfalls which can make accurate assessment of disease status difficult. For example, many patients retain residual anatomic abnormalities at sites of initial disease following treatment. These abnormalities may represent active lymphoma, but alternatively might represent fibrotic or necrotic tissue, in the absence of active disease. Distinguishing between these two scenarios is critical for deciding on further therapy in those patients for whom it is required, without subjecting patients for whom it is unnecessary to the toxicity of further therapy.

Potentially FDG-PET may accurately assess tumor response to therapy and therefore guide appropriate follow-up. Several investigators have studied the prognostic implications of FDG-PET following therapy, and these studies have provided promising data regarding the utility of PET in this setting. Zinzani and colleagues showed that of 44 NHL and HL patients evaluated, all 13 patients with residual abnormality on

FDG-PET relapsed, whereas only 1 of 24 with complete resolution of abnormal FDG uptake relapsed.²⁸ Similar results were found by Mikhaeel et al.,²⁹ who also studied a combined group of NHL and HL patients. Of 32 patients included in the study, nine had residual FDG uptake abnormalities following therapy, of which eight had relapsed at a median follow-up of 38 months. In contrast, only two of 23 patients without FDG-PET abnormalities relapsed in the same amount of time. Similarly, Jerusalem and colleagues studied a combined group of 54 NHL and HL patients,³⁰ showing that all patients with positive FDG-PET scan following first-line treatment relapsed within 1 year, whereas 86% of those with negative scans remained disease free at 1 year.

The utility of FDG-PET in predicting outcome following therapy in HL specifically has been investigated in several studies. Guay et al. studied 48 patients with HL following chemotherapy.³¹ Of 12 patients with residual abnormality on FDG-PET, 11 relapsed, with a median progression-free interval (PFS) of 79 days. In contrast, of 36 patients with negative scans, only three relapsed with a follow-up of 5 years. Spaepen et al. also studied patients with HL who were followed for a minimum of 1 year, and showed that all five with positive posttherapy scans relapsed, while only five of 55 with negative scans relapsed.³² In this study, the 2-year PFS was 91% in patients with a negative follow-up PET scan and 0% in those with a positive scan. Similar results were shown in a study by Dittman et al.³³ In contrast, the positive predictive value of FDG-PET was found to be only 46% in a study by de Wit and colleagues,³⁴ with 10 of 22 patients with positive scans relapsing.

For NHL, FDG-PET has shown similar predictive capability. Spaepen and colleagues studied a group of 93 patients with NHL with FDG-PET scans following first-line chemotherapy.³⁵ All 26 patients with a positive posttherapy PET scan relapsed, with a median PFS of only 73 days. In contrast, only 11 of 67 patients with a negative scan relapsed, with a much longer median PFS of 404 days. Mikhaeel et al. also showed high predictive power in a group of patients with aggressive NHL.³⁶ In this group of 45 patients, all nine with a positive posttreatment FDG-PET scan relapsed, whereas only six of 36 with negative scans relapsed at a median follow-up of 30 months. A third study, by Filmont and colleagues, also demonstrated the predictive power of FDG-PET in the posttreatment setting.³⁷ In this group of patients, the positive predictive power for relapse following a positive PET scan was 95%, whereas the negative predictive power was 83%. This study included a heterogeneous group of patients, including those undergoing first-line therapy as well as patients with relapsed disease.

In summary, FDG-PET scanning following therapy for HL and NHL contributes valuable information regarding prognosis. It appears to be most useful in

prediction of early relapse. This is consistent with the idea that PET scanning reveals residual active disease and therefore more accurately defines remission status than traditional restaging techniques. FDG-PET must be interpreted with caution, however, as nonmalignant processes may also lead to abnormal uptake. On this note, it is clear that benign thymic uptake may occur after therapy, particularly in younger patients with HL. Other inflammatory or infectious processes may also cause false-positive scans. Because of these issues, positive FDG-PET scans following treatment should not be used in isolation to justify further therapy, but rather should be supplemented by clinical information and further investigation, such as biopsy, to document residual active disease. Abnormal FDG uptake in an area not previously known to be involved by lymphoma should raise particular caution. In contrast, a negative FDG-PET scan following therapy in a patient with known FDG-avid disease provides strong evidence for a meaningful complete response and good prognosis.

EARLY RESPONSE EVALUATION

While it is clearly important to accurately assess response following treatment, an alternative approach of early evaluation during treatment could potentially identify patients who are destined to have a poor outcome with first-line therapy, allowing a change to more effective therapy while avoiding the toxicity of an ineffective chemotherapy regimen. Furthermore, an inadequate early response might predict for those patients who would benefit from immediate intensification of therapy.

The potential of FDG-PET scanning early in treatment to predict the ultimate outcome of that treatment has been investigated in several studies. Jerusalem et al. studied a group of 28 NHL patients, performing PET scans during treatment prior to completion of therapy.³⁸ They found that all patients with residual FDG uptake either failed to enter complete remission (CR) or relapsed, while all evaluable patients with negative scans entered CR. One third of those with negative scans subsequently relapsed during follow-up. A drawback to this study was inclusion of a heterogeneous group of patients, including multiple histologies as well as both front-line and salvage therapies. Furthermore, scans were performed at inconsistent times during treatment, after anywhere from two to five cycles of therapy. Zijlstra and colleagues evaluated the ability of PET to predict outcome in patients with aggressive NHL, when performed after 1–2 cycles of chemotherapy and found that, at 16 months follow-up, 64% of those with negative early PET remained free of disease, whereas only 25% of those with positive scans were disease free at the end of the study.³⁹ Kostakoglu and colleagues evaluated a mixed group of patients with either HL or NHL who had FDG-PET scans performed after one cycle of chemotherapy.⁴⁰

Thirteen of 15 patients with positive scans either did not enter CR or relapsed following treatment. In contrast, only two of 15 with negative scans relapsed. When compared to posttreatment scans, early FDG-PET scans showed improved power to predict outcome, suggesting that early scans could be a more useful approach to response monitoring.

Several caveats to these data must be mentioned. These studies included heterogeneous groups of patients with scans performed at varying times during therapy. Before these findings can be generalized, studies must be performed in a systematic fashion, using defined groups of patients and defined imaging protocols. Furthermore, we do not yet know how to apply this information. Although patients with a positive early treatment scan appear to have a poorer prognosis than those with a negative scan, it is unclear whether changing or intensifying therapy, for example by instituting early high-dose therapy with stem cell transplant, will improve these patients' long-term outcome. At this time, therefore, the use of FDG-PET early in treatment must be considered investigational.

PROGNOSIS IN STEM CELL TRANSPLANTATION

Autologous stem cell transplantation provides an opportunity for improved long-term survival or cure in many patients with relapsed lymphoma. However, it remains difficult to accurately predict which patients will benefit from this intensive and toxic therapy. Several groups have investigated the potential for FDG-PET performed in the pretransplant setting to predict ultimate outcome.^{41–44} In general, these studies have shown that a negative FDG-PET scan during or after salvage chemotherapy strongly predicts improved PFS after transplant, while those patients with a positive FDG-PET scan prior to transplant are significantly more likely to relapse early. While the data do not definitively rule out the benefit of transplantation for those patients who retain FDG-PET-positive lesions, it may be useful in overall discussions of potential risk and benefit. As more information becomes available regarding this issue, the role of FDG-PET in pretransplantation evaluation will become clearer.

LIMITATIONS OF FDG-PET

FDG-PET can add valuable information at several stages of care of lymphoma patients. However, this modality also has limitations which must be recognized in order to benefit optimally from its use. First, while the majority of lymphomas are detectable by FDG-PET scanning, some tumors fail to accumulate FDG, rendering them silent by this modality. While the likelihood of FDG avidity can be predicted by histology, exceptions do exist. For example, although the vast majority of FLs show FDG avidity, intestinal FLs are much less likely to take up the tracer.¹⁸ Because of these exceptions, at this point, a baseline scan should

Figure 79.1 Relapsed large B-cell lymphoma obscured by ureteral obstruction. A patient with a history of large B-cell lymphoma underwent FDG-PET scanning in follow-up. The intense uptake demonstrated in the right abdomen was interpreted as ureteral obstruction with no evidence of tumor. A CT scan demonstrated a mass compressing the ureter, and biopsy confirmed relapse of lymphoma

be done in patients for whom FDG-PET will be used in follow-up.

A second limitation of FDG-PET involves difficulties of interpretation in areas of high physiologic tracer accumulation. One major example of this issue is seen in the urinary tract, as FDG is excreted via the kidneys. Tumor localized near the kidney, ureter, or bladder may not be visualized due to masking of FDG accumulation by urinary collecting structures (Figure 79.1). Alternatively, abnormal accumulations of urine may be interpreted as tumor mass, for example in the case of ureter obstruction from a cause unrelated to tumor. Another anatomic area that may present difficulty in imaging and interpretation is the cardiac region. Patients fast for several hours prior to FDG administration, therefore suppressing insulin levels. This leads to a conversion from glucose metabolism to fatty acid metabolism in adaptable tissues such as cardiac muscle, reducing FDG uptake in these tissues. In up to a third of cases, however, the heart may still take up significant amounts of FDG. While the radiologist can usually identify this uptake as cardiac, it may mask areas of malignancy in the paracardiac mediastinum. These issues emphasize the importance of concurrent anatomic imaging for optimal interpretation of FDG-PET.

Inflammatory lesions can on occasion mimic tumor on FDG-PET. Under most circumstances, inflammation can be differentiated from malignancy by intensity of uptake and spatial characteristics. In some cases, however, inflammatory lesions may masquerade as malignancy. Cases of suspected residual or recurrent tumor

visualized by FDG-PET have been documented to be infection in multiple instances.^{45,46} Furthermore, postradiation inflammation may cause significant FDG accumulation. While the characteristics of uptake usually identify the process, the localization to a former site of tumor involvement can be misleading. Zhuang and colleagues have suggested that changes in FDG intensity over time may accurately differentiate tumor from inflammation, with tumor tissue continuing to increase in intensity and inflammatory lesions decreasing in intensity over the course of several hours.⁴⁷ These findings have yet to be confirmed in clinical practice.

Thymic uptake following chemotherapy, particularly in young patients with HL, is increasingly recognized as a possible cause of false-positive FDG-PET scans after therapy (Figure 79.2).⁴⁸ In an appropriate clinical setting, the clinician can recognize this phenomenon of thymic rebound as a benign event unrelated to residual tumor. However, the location of the thymus in the mediastinum, an area of frequent lymphomatous involvement, may at times make this interpretation problematic. Similarly, bone marrow may show increased uptake during or following chemotherapy due to recovery of normal hematopoiesis (Figure 79.3). Again, the clinical scenario should in most cases make interpretation of this phenomenon clear-cut.

Figure 79.2 Thymic rebound. An FDG-PET scan was performed 9 weeks following completion of therapy in a patient with Hodgkin's lymphoma. The mediastinal uptake is typical of benign thymic hyperplasia, and the patient remains in a complete remission

Figure 79.3 Physiologic uptake of FDG in a patient with large B-cell lymphoma. A patient with large B-cell lymphoma underwent baseline FDG-PET demonstrating uptake in mediastinal tumor (a). A scan performed during treatment to evaluate disease response showed resolution of FDG uptake in malignant tissues but an increase in uptake of the tracer in bone marrow, reflecting hematopoietic recovery (b). Following completion of therapy, no tracer uptake is detected in tumor or bone marrow, but physiologic cardiac uptake is demonstrated (c)

FUTURE DIRECTIONS

The field of functional imaging in the care of lymphoma patients is evolving rapidly. FDG-PET scanning has the potential to contribute to care of lymphoma patients in many new ways. We must, however, carefully and systematically evaluate how best to incorporate this modality in order to use it optimally. Several areas of investigation must be pursued for this aim to be realized.

Many studies have investigated the prognostic importance and treatment implications for patients with specific stages of lymphoma. However, these studies were done using conventional staging techniques. While it is reasonable to imagine that improved staging would refine our ability to predict prognosis and appropriately choose treatment, we do not at this time know how disease detected by FDG-PET will impact on these factors. For example, will low-volume disease detected only by PET, changing a patient's stage from 2 to 3, portend a worse prognosis?

A critical question for investigation is the appropriate use of FDG-PET scanning in prediction of treatment outcome. Although a positive FDG-PET scan after therapy completion would appropriately lead to investigation of the positive lesion and further treatment if confirmed to be active disease, the use of scanning during treatment is less clear. More systematic studies evaluating the outcome of patients undergoing FDG-PET scans early in treatment must be performed to define the role of this strategy in guiding treatment. Patients with specific histologies should be evaluated under defined circumstances, at a defined time during

treatment, in order to clarify whether this strategy can predict outcome with high enough accuracy to guide treatment changes. Furthermore, we do not know at this time what constitutes an appropriate treatment change. It is unclear if switching to another, possibly more intensive, treatment regimen will improve outcome in these patients, or instead whether a positive scan portends a poor prognosis whatever the treatment strategy. These questions can be answered only through well-designed, prospective clinical trials.

CONCLUSION

Functional imaging modalities have become valuable tools in the care of lymphoma patients. While Ga-67 scanning provided early benefits, the improved technical ease and greater accuracy of FDG-PET render Ga-67 scintigraphy less relevant in situations in which FDG-PET is available. FDG-PET provides important information in both initial staging of lymphoma and restaging following treatment, but its contribution appears to be dependent on tumor histology and location. Care must be taken in analysis of FDG-PET images, with the clinical scenario and characteristics of uptake guiding interpretation. Currently, FDG-PET should play a complementary role with other studies such as anatomic imaging, with biopsy and pathological confirmation of questionable lesions performed when possible. In the future, FDG-PET will provide increasingly more guidance in evaluation of prognosis and treatment effectiveness.

MULTIPLE MYELOMA

Chapter 80

EPIDEMIOLOGY AND RISK FACTORS OF MULTIPLE MYELOMA: INSIGHTS INTO INCIDENCE AND ETIOLOGY

Ashraf Badros

Multiple myeloma (MM) is characterized by proliferation of malignant plasma cells in the bone marrow, bone destruction, extramedullary plasmacytoma, renal failure, and, late in the disease course, marrow failure manifested as anemia, leukopenia, and thrombocytopenia.¹ MM is customarily portrayed as an uncommon cancer. Nevertheless, MM accounts for 10% of all hematologic malignancies and 1% of all cancers. There are an estimated 74,000 new cases of MM worldwide each year with a worldwide prevalence of over 200,000 cases. MM is responsible for 2% of all cancer deaths yearly, with an estimated 57,370 deaths worldwide.² In the United States, there were an estimated 15,270 new MM cases in 2004 and over 11,070 yearly deaths due to MM.³ The biology of MM suggests a multistep process as illustrated by the clinical progression from monoclonal gammopathy of unknown significance (MGUS) to the symptomatic phase of the disease. A B-cell precursor cell, after immunoglobulin gene rearrangement, is presumed to be the origin of the malignant clone in MM. The events that determine the susceptibility of B cells to undergo such malignant transformation are at best speculative.⁴ The racial differences in the disease, the increased risk of developing MM with certain human leukocyte antigen

(HLA) types, and the clustering of MM in certain families suggest that genetic susceptibility may predispose certain populations to develop MM. In this chapter, the biological, environmental, chemical, and familial factors and their contributions to the pathogenesis of MM are discussed.

DESCRIPTIVE EPIDEMIOLOGY

TIME TRENDS

The incidence and mortality rates for MM were not available until 1950, when the disease was removed from the category of "lymphoreticular malignancies" and assigned a unique ICD code.⁵ The international trends in MM rates vary significantly from country to country. There was an overall increased incidence between 1970 and 1990 with a plateau in the last decade. The incidence and prevalence of MM in selected world population is shown in Table 80.1.^{2,6} This increase was attributed to underreporting in the earlier years and to improved diagnosis and more intensive surveys, especially in the elderly, in the later years (diagnostic phenomenon) rather than an actual increase in incidence.⁷

Table 80.1 Multiple myeloma incidence, mortality, and prevalence worldwide

	Male				Female			
	Cases ^a	ASR ^b	Deaths	Prevalence ^c	Cases ^a	ASR ^b	Death	Prevalence ^c
World	39,480	1.5	30,392	74,315	34,463	1.12	26,978	69,262

^aCases: number of MM cases observed during a specific time.

^bASR: an age standard rate is a summary measure of the rate that a population would have if it had a standard age structure. Standardization helps to overcome the age difference between populations, as age significantly affects the incidence of MM. It is expressed per 100,000.

^cFive-year prevalence.

Modified from Ref. 2.

GENDER EFFECTS

The age-adjusted incidence rates for MM are higher in men (in the United States, 8090 cases were diagnosed in men versus 7180 cases in women, in the year 2004). This gender-related difference is noted across all age groups and is maintained worldwide in all reported age-specific incidence rates. This is despite the fact that MM is a disease of the elderly, and that women in general live longer than men. This gender-related difference is not only limited to the incidence of MM. There are indications that women may be more resistant than men to carcinogen exposure from occupation, radiation exposure, or smoking. In some studies, women have a better prognosis after therapy than do men.^{8–12}

RACIAL DIFFERENCE IN MM INCIDENCE

While many cancers (namely, those of the esophagus, cervix, stomach, pancreas, larynx, and prostate) have a higher rate among blacks than whites, within the hematopoietic system, MM is the only malignancy with a higher incidence among blacks. Asians have the lowest incidence rate of MM (less than

1/100,000). Table 80.2 and Figure 80.1 describe MM incidence in the US white and black males and females categorized by age at diagnosis.³ This difference in MM incidence is also reported in Jamaica and South Africa, where blacks are reported to have a higher incidence than that reported for US blacks.^{13,14} There is no definitive data to suggest that the higher incidence of MM in blacks is associated with biologically different disease. In some studies, black MM patients were, on average, 10 years younger than white patients and had higher incidence of fractures, paraplegia, and infections.¹⁵

Many explanations for the difference in incidence of MM between blacks and white have been proposed. Socioeconomic data showed that MM risk was significantly higher in the lowest categories of occupation, education, and income. In a population-based case-control study including 573 cases (206 blacks and 367 whites), low socioeconomic status was noted for 37% of MM in blacks and 17% in whites, and accounted for 49% of the excess incidence of MM in blacks.¹⁶

Differences in lifestyle between blacks and whites failed to show significant risks associated with cigarettes

Table 80.2 Multiple myeloma incidence in the United States: white and black males and females categorized by age at diagnosis

	Age category at diagnosis				
	30–39	40–49	50–59	60–69	70+
White male	0.4	1.8	7.3	16.3	35.6
Black male	1.4	6.4	18.9	36.8	66.8
White female	0.2	1.4	4.9	12.1	22.9
Black female	0.4	4.8	13.6	27.8	45.1

Note: The incidence rates were compared for males and females of all races diagnosed between 1973 and 1980 split by the age at diagnosis (30–39, 40–49, 50–59, 60–69, 70+). The *P*-value is zero to four decimal places, meaning that the trend is highly significant. The incidence rate of myeloma increases with aging across all groups. There is a higher incidence rate among male population than among females and is more in blacks than in whites.

Source: From Ref. 3. Rates are per 100,000 and age-adjusted to the 2000 US (19 age groups) standard.

or alcoholic beverages, and no consistent patterns with either intensity or duration of use of either were seen. These data are consistent with several studies indicating that smoking and drinking are not associated with MM.¹⁷ Another area of controversy is the difference of dietary

habits across different racial groups and its relation to the incidence of MM. The use of vitamin C supplements by whites and the higher frequency of obesity among blacks may explain part of the higher incidence of MM among blacks. However such conjecture cannot explain the noted worldwide racial disparity of MM.¹⁸

Whether genetic factors contribute to the high incidence of MM among blacks is another area of controversy. Serologic typing of HLAs was conducted for blacks (46 patients and 88 controls) and whites (85 patients and 122 controls). Black patients had significantly higher frequencies than black controls for Bw65, Cw2, and DRw14. White patients had higher frequencies than white controls for A3 and Cw2. Cw2 allele had a relative MM risk of 5.7 (95% CI 1.5–26.6) and 2.6 (95% CI 1.0–7.2) for blacks and whites, respectively.¹⁹ Some studies had reported a lower survival rate for blacks than for whites, though others did not find such a difference.²⁰ In a Southwest Oncology Group (SWOG) randomized trial, the survival for black patients was similar to that for white patients, both overall and adjusted for prognostic factors such as stage.²¹ Not all blacks have a high incidence rate of MM; the incidence of MM in blacks living in Caribbean island is the lowest compared to other countries. Again, the younger age and aggressive presentation were noted with overall poor survival.²²

ETIOLOGY OF MULTIPLE MYELOMA

Although the etiology of MM remains unknown, several environmental, occupational, and genetic factors have been associated with increased risk of developing MM. Although these risk factors are discussed disjointedly, it must be recognized that many factors contribute to the risk of each single case. In the search for factors that cause cancer, epidemiologists have used cohort and case-control studies. A defined population's "cohort" exposed to factors suspected of increasing the incidence of a cancer and a control "matched" group are followed for incidence of cancer. These factors are then investigated further if high incidence of a cancer is seen. Case-control studies begin with a cluster of cancer cases that are followed by investigating the exposure to various agents. Case-control studies are conducted quickly with fewer subjects. However, they are biased by selection and the ability of subjects to remember exposures.

MONOCLONAL GAMMOPATHY OF UNKNOWN SIGNIFICANCE

Incidence

MGUS indicates the presence of a monoclonal protein (M-protein) in persons without evidence of MM, macroglobulinemia, amyloidosis (AL), or related plasma cell disorders. MGUS can be associated with other disorders, including lymphoproliferative diseases, leukemia, connective tissue disorders, dermatologic diseases, and neurologic disorders.²³ MGUS is found in approximately 3% of persons older than 70 years and in about 1% of those older than 50 years. In the largest series of MGUS patients published to date that included 1384 patients from Mayo Clinic from 1960 through 1994, the risk of progression to MM was 1% per year. Patients were at risk of progression even after more than 25 years of a stable monoclonal gammopathy. The risk of developing MM was 25-fold higher when compared with a similar population (from SEER database). The concentration of the serum M-protein was the major independent predictor of progression. Patients with an immunoglobulin M (IgM) or an IgA monoclonal gammopathy had a higher risk of progression than those with an IgG monoclonal gammopathy. The presence of a urine M-protein or the reduction of one or more uninvolved immunoglobulins was not a risk factor for progression.²⁴ An early study that included 398 patients (270 whites and 128 blacks) showed that blacks had a two times (14.8%) higher incidence of MGUS than did whites (7.8%); this difference was statistically significant, and was noted across all age subgroups.²⁵ In a community-based study from the Duke Established Populations, of 1732 patients over age 70, 106 subjects (6.1%) had MGUS. There was a twofold difference in prevalence between blacks (8.4%) and whites (3.8%), $P < .001$. This biological

racial difference is associated with susceptibility to an early event in the carcinogenic process leading to MM.²⁶ In a study from Zaragoza, Spain, the yearly incidence of monoclonal gammopathy remained stable up to 1985; from that time on, a 30–40% yearly increase was noticed, which was mainly related to MGUS and is a reflection of improved diagnosis and more vigorous application of testing to the elderly.²⁷ The increased rate is also noted for patients diagnosed between 1976 and 1997 in Iceland. There was an increased incidence noted between 1976 and 1980 from 5.8 (men) and 4.9 (women) to 14.7 (men) and 12.5 (women) during 1992–1997. Incidence rates were very low under 50 years of age and increased with age from 11 and 17/100,000 at age 50–54, to 169 and 119/100,000 at age 80–84, for men and women, respectively.²⁸

Risk factors

A retrospective study of 285 cases of MGUS matched with 570 controls assessed risk factors for MGUS. MGUS was significantly increased in farmers ($P < 0.005$) and industry workers ($P < 0.025$), and in those with occupational exposure to asbestos, fertilizers, mineral oils and petroleum, paints and related products, and pesticides ($P < 0.05$). Chronic immune-stimulating conditions, when considered as a group, presented a significant ($P < 0.025$) risk of MGUS, but no specific disease has been significantly associated.²⁹ A retrospective study from the Nurses' Health Study showed that MGUS is not increased in women with breast implants.³⁰ Among 6737 atomic bomb survivors, 112 developed MGUS between 1985 and 2001. The crude incidence rate was 164/100,000 person-years in the overall study population, with a sharp increase in incidence after age 60. Among 75 patients with MGUS detected in 1985, 50 patients (67%) had died by 2001, and 16 (21%) of these deaths were due to MM. Transformation from MGUS to MM was faster in exposed persons than in non-exposed persons, though that was not statistically significant.³¹

IMMUNE STIMULATION AND MYELOMA

Chronic infections and eczema

Many medical conditions associated with chronic stimulation of the immune system, such as repeated infections, allergic conditions, or autoimmune disease, have been reported to increase the risk of MM. In a case-control study, past history was abstracted from medical records for leukemia, $n = 299$; non-Hodgkin's lymphoma (NHL), $n = 100$; and MM, $n = 175$ patients, and matched with 787 controls. Prior histories of eczema and musculoskeletal conditions were associated with higher risk for MM with no role identified for chronic antigenic stimulation in the etiology of leukemia or NHL.³² Another case-control study of 100 MM cases in whites showed no associations between MM and history of medical conditions that cause prolonged stimulation of the immune system, like

chronic infections, autoimmune disorders, allergy-related disorders, or lymphoid tissue surgery.³³

Gaucher's disease

Several case reports have long suspected an association between Gaucher's disease and gammopathy.^{34–39} There is a reported incidence of 20% polyclonal gammopathy in this disease with an unclear percentage of monoclonal abnormalities. It is suspected that lipid deposition in Gaucher's disease results in chronic stimulation of the humoral immune system with production of polyclonal immunoglobulins that under unclear circumstances become monoclonal with development of MGUS and/or MM.⁴⁰ The use of enzyme therapy to control Gaucher's disease decreased polyclonal immunoglobulin levels but had no effect on monoclonal gammopathy. The lack of correlation between disease activity and immunoglobulin levels means that the enzyme-sensitive process affecting lipid metabolism is not directly linked to immunoglobulin deregulation.⁴¹

Rheumatoid arthritis

MM has presented in patients with rheumatoid arthritis concurrently and in many cases masking the symptoms of arthritis.^{42–46} IgA isotype MM is more frequently reported in rheumatoid arthritis patients.⁴⁷ Several cytokines and inflammatory molecules like interleukin 6, C-reactive protein, and the adhesion molecules ICAM-1, VCAM-1, and CD44 theoretically link MM and autoimmune disorders.⁴⁸ A report from Sweden blamed the number of X-rays in arthritis patients for the increased risk of MM.⁴⁹

VIRAL INFECTIONS

Kaposi's sarcoma-associated herpesvirus

Human herpesvirus 8 (KSHV/HHV-8) was detected in the bone marrow dendritic cells of MM patients. This was considered an etiologic pathogen for MM, as it was not detected in normal individuals.⁵⁰ Unfortunately, subsequent confirmatory studies failed to establish a role of HHV-8 in the etiology of MM.^{51–56} Also several clinical studies from the United States and South Africa failed to establish a link between MM and KSHV.^{52,57}

Acquired immunodeficiency syndrome

AIDS has been associated with increased incidence of high-grade B-cell lymphoma and leukemia. Several reports have described MM in HIV-infected patients.^{58–68} These reports suggest that MM occurrence in AIDS patients is more than a coincidental event. Several authors suggested that MM should be considered another AIDS-associated neoplasm. In most of the reported cases, MM occurred in younger patients and had a fairly aggressive course with development of extramedullary disease, factors that may prompt physicians to publish their cases. The diagnosis of MM may be difficult in an AIDS population as renal failure, bone

marrow plasmacytosis, and hypergammaglobulinemia are attributed to HIV. The challenge in diagnosis and lack of a uniform reporting system for these patients probably underestimate the true incidence of MM in AIDS patients. Biologically, it is plausible that the antigen-driven response to the viral infection and the associated increased levels of cytokines (e.g., interleukin 6) and many angiogenic factors (e.g., vascular endothelial growth factor and basic fibroblastic growth factor) can sustain the malignant clone in MM.

Hepatitis C virus

Infection with hepatitis C virus (HCV), an RNA virus that can modulate the immune system, is associated with type II mixed cryoglobulinemia. Recently, a large case-controlled study confirmed that HCV-infected patients have a higher risk of B-cell NHL (OR = 3.7, 95% CI 1.9–7.4, $P = 0.0001$) and MM (OR = 4.5, 95% CI 1.9–10.7, $P = 0.0004$).⁶⁹ Other studies link HCV infection to Waldenstrom's macroglobulinemia and MGUS.^{70,71} However, the data remain speculative and when the incidence of MM is evaluated in the context of HCV, the association is less clear.^{72–74}

Human T-cell lymphotropic virus type 1

A recent report of increased cases of MM in West Indies with incidences similar to what is reported for Afro-Americans in the United States entertained a possible link between the endemic human T-cell lymphotropic virus type 1 (HTLV-1) infection and MM, though this correlation has not been confirmed.⁷⁵

RADIATION EXPOSURE

Ionizing radiation is the most recognized risk factor for hematologic malignancies. Detailed prospective and retrospective studies analyzed the risk of environmental, military, occupational, and medically related sources of radiation. The issue is described in more detail below.

Occupational exposure

The effects of low-grade protracted exposure to radiation in older age as seen in nuclear workers and individuals living in high-risk areas are at least intriguing. Several case-controlled studies reported an increased risk of MM among nuclear workers exposed to external penetrating ionizing radiation. In the international combined analyses of mortality data on 95,673 workers, more than 85.4% men, employed for at least 6 months in the nuclear industry in the United States, United Kingdom, and Canada, were monitored for external exposure to ionizing radiation. The analyses covered a total of 2,124,526 person-years at risk and 15,825 deaths, 3976 of which were due to cancer. Among the 31 specific types of cancers studied, a significant association was observed only for MM ($P = 0.037$; 44 deaths).⁷⁶ In the Sellafield British nuclear plant the cancer mortality and incidence among 14,282 workers employed between 1947 and 1975 were studied up to 1988.

Overall cancer mortality and incidence were 4% and 10%, respectively, less than that of the England and Wales populations. Among radiation workers there were significant positive correlations between accumulated radiation dose and mortality from cancers of ill-defined and secondary sites and for leukemia, but the association with MM was quite weak.⁷⁷ A study of workers at US Department of Energy facilities identified 98 MM cases/deaths and compared them to 391 age-matched controls selected from 115,143 workers at three sites. Cases were disproportionately African-American males; all were hired prior to 1948. Lifetime cumulative whole body ionizing radiation dose was not associated with MM; however, there was a positive association between MM risk and doses received at an older age.⁷⁸ The French Atomic Energy reviewed the cancer death for all workers between 1950 and 1968, after several deaths from cancer were reported in the mid 1980s. The cohort was followed up to 1990. The numbers of deaths from all causes and from all cancer sites were 44 and 21, respectively. No excess of cancer deaths was reported for the study period. The risk of death from all cancer sites increased with the duration of exposure to chemicals. The authors conclude, "the results do not justify the impression of an excess of cancer in workers of atomic facilities."⁷⁹

Residential exposure

In a report of all hematologic cancer cases in 489 towns within 30-km radius of Spain's seven nuclear power plants and five nuclear fuel facilities, cases of leukemia ($n = 610$), lymphoma ($n = 198$), and myeloma ($n = 122$) were matched to 477 control towns lying within a 50–100-km radius of each installation. Statistical testing revealed that with the exception of MM, none of the tumors studied showed evidence of a rise in risk with proximity to a nuclear installation.⁸⁰ Taking all these data together, it appears that high-grade exposures were associated with risk of leukemia and possibly NHL, while prolonged low-grade exposure as seen in factory workers and in those living near nuclear facilities increases the risk of MM.

OCCUPATIONAL HAZARDS

Many occupational exposures have been associated with MM; these include metals, rubber, wood, leather, paint, and petroleum. Several excellent reviews have discussed each occupation and its associated risks. The following is a brief summary of published studies for pertinent occupations.

Agriculture

Agricultural work (predominantly farming) is an occupation that has been most frequently associated with MM.⁸¹ Early reports from Iowa farmers in the 1970s showed a significantly higher mortality rate for MM and leukemia.⁸² A recent update of these data suggest that

association between farmers and MM is weaker than initially reported.^{9,83,84} Similar results were reported from Sweden. There were 568 MM cases among 254,417 men working in agriculture, with an estimated RR of 1.20 (95% CI 1.09–1.33).⁸⁵ Meta-analyses of peer-reviewed studies of MM and farming including 32 studies published between 1981 and 1996 confirmed a low risk of MM.⁸⁶ Other studies evaluated the work environment in agriculture and risk of MM. Farming has many potential carcinogenic exposures, such as animals and zoonotic viruses, grains, dust, fertilizers, pesticides, or benzene and engine fumes. In Italy, a case-controlled study for 71 cases of leukemia, lymphoma, and myeloma estimated the risk of hematologic malignancies for agricultural workers at 1.63 (95% CI 0.69–4.34) in males and 6.00 (95% CI 1.21–25.52) in females, with significantly increased risks after DDT exposure (OR = 4.11; 95% CI 1.16–14.55).⁸⁷ In another case-control study from Italy, MM risk was not increased among workers in agriculture as a whole (OR = 1.31, 95% CI 0.62–2.74), but was increased among workers cultivating apples and pears and with exposure to chlorinated insecticides.⁸⁸ In a large cohort of 120,000 male and 85,000 female farmers in Finland, 17,000 cancer cases were observed. Compared with the incidence of cancer in the Finnish population, both genders experienced a 17–18% decreased risk of cancer. The risks were low in smoking-related cancers. Cancers with higher incidence were lip cancer and Hodgkin's disease in males. Risk of Hodgkin's disease was highest in farms without animals (RR = 1.74, CI 1.12–2.59). MM was found in excess among farmers working in pig or poultry farms.⁸⁹ Other studies failed to link farm animals to MM.⁹⁰

Rubber

Excess death from MM was noted in rubber workers from Akron, Ohio.⁹¹ Similar findings were reported in a large study including 1352 white and 438 nonwhite male workers in rubber-manufacturing industry in the United States with excess bladder cancer (RR of 2.1), esophageal cancer (2.7), and MM (4.5).⁹² Exposure to butadiene was associated with an increased risk of leukemia and Hodgkin's disease, while MM and lymphomas are associated with exposure to styrene.⁹³ However, three large studies did not find MM to be one of the cancers affecting rubber workers.^{94–96}

Benzene and related exposures

Prior case series and epidemiologic studies linked industrial exposure to benzene to development of MM.^{97–100} It is accepted now that benzene exposure by itself is not a risk nor a causal factor for development of MM. This was recently reviewed in two excellent papers and is confirmed in several meta-analyses.^{101–105}

Other occupations

A recent review of 70 occupational cohort studies that addressed B-cell cancer risks in nine major industrial

categories explain the limitation and inconsistency in these studies.¹⁰⁶ The exposure of painters to chemical compounds is complex, for there are various dyes, pigments, and solvents, which are known to be mutagenic in paint. The specific agent(s), if any, associated with the increased risk of MM in painters has not been identified. Exposure to asbestos has been linked to an increased risk of myeloma in at least two case-control studies.^{33,105,107} In contrast, other case-control studies have not detected this association.¹⁰⁸ It will take further work to determine whether asbestos plays a role in the etiology of MM. An increased risk of MM in workers in wood, leather, and textile industries has been found in some studies, but the results are inconsistent and not universally confirmed by other investigators.^{109–116} Statistical associations have been made between employment as sheet metal workers and an increased risk of MM.^{113,117,118} The small numbers of cases and the lack of information on actual type and duration of exposures make it difficult to determine which occupational exposures are responsible for the elevated risks observed.

LIFESTYLE FACTORS

Socioeconomic status

Socioeconomic status has been debated as an important prognostic factor in MM patients. A low socioeconomic status has been described in association with shorter survival, advanced clinical stage, and less response to chemotherapy in MM.^{119–121} This is probably related to limited access to health care rather than an epidemiologic phenomenon.

Diet

As diet differs significantly in various racial groups, its contribution to MM has been suspected though not confirmed. The use of vitamin C supplements was reported to reduce MM risks in whites.¹⁸ The consumption of yogurt increased the risk of developing MM while vegetables decreased that risk.¹²²

Obesity

Recent data suggest that obesity increases the risk of MM. Excess body weight has been shown to increase the risk of death from various cancers and MM in a prospective studied population of more than 900,000 US adults. Some studies attributed the higher risk of MM in blacks to obesity, which is more common in blacks. However, recent studies showed that MM risk appears equal among black and white obese male veterans. As the prevalence of obesity and overweight worldwide increases, it is important to define its impact on cancer and to elucidate the mechanisms involved.^{123,124}

Smoking

Several studies have proven that smoking is not linked to an excessive risk of MM for both blacks and whites

of both gender, and no consistent patterns with either intensity or duration of use have been found.^{17,125–131}

Hair dyes

Use of permanent hair dye, especially dark dyes, contributes to death rates from MM, however the risk is small and unlikely to be a major contributor to MM.^{132–139}

GENETIC AND MOLECULAR FACTORS IN MULTIPLE MYELOMA

FAMILIAL PREDISPOSITION

Reports of familial cluster of MM suggest that genetic factors may play a role in the etiology of MM. As previously discussed, neither specific genetic factors nor environmental exposures have been clearly implicated.^{140–145} From these cases and other reviews, several observations have been made. First, there is no difference between familial and non-familial MM with regard to clinical presentation, laboratory data, and prognosis. Second, the earlier age of diagnosis in successive generations is a reflection of the genetic phenomenon of anticipation.¹⁴⁶ Third, individuals with familial MM appear to have a higher incidence of other hematologic malignancies. There is also a higher incidence of MGUS in many relatives of MM patients that puts them at a higher risk of developing MM.^{147,148} One report of HLA typing disclosed identical haplotypes (AW24, A26, B13, and BW55) in two sisters 58 and 56 years old, diagnosed 22 months apart.¹⁴⁹ Other studies of familial MM in twins showed identical isotypes and in some cases similar karyotypic abnormalities.^{150–152} A comprehensive family cancer database from several Swedish registries included 6 million persons. There were more than 30,000 cancers reported, and an increased cancer risk in offspring (1.1 times) was noted when the father had cancer. If both parents had cancer, the risk for sons was 1.4 and for daughters 1.3. MM was among the cancers with higher risks.¹⁵³ A population-based case-control interview study of 565 MM patients (361 whites and 204 blacks) and 2104 controls (1150 whites and 954 blacks) showed that family history of any cancer contributes to the risk of MM. The risk of MM was significantly elevated for patients who reported that a first-degree relative had MM (OR = 3.7, 95% CI 1.2–12.0) or any lymphoproliferative cancer (OR = 1.7, 95% CI 1.0–2.8), especially a sibling (OR = 2.3, 95% CI 1.1–4.5). The risk associated with familial occurrence of hematologic cancer was higher for blacks than for whites.¹⁵⁴ However, to date the question of genetic predisposition to MM remains unanswered.^{155–159}

POLYMORPHISM

Factors that regulate the metabolism of environmental and occupational carcinogens may be critical in

modifying MM risks in different individuals. The human xenobiotic metabolizing system is responsible for completing the detoxification of procarcinogens. The system comprises two classes of enzymes: phase 1 cytochrome P450 and phase 2 enzymes, including glutathione S-transferases (GST M1 and GST T1), paraoxonase 1 (PON1), and N-acetyltransferases (NAT) 1 and 2. Interindividual variability in the xenobiotic enzyme system can predispose certain racial groups to the carcinogenic effects of certain chemicals. In a case-control study using peripheral blood or bone marrow biopsy specimens from 90 Caucasian individuals and a control group consisting of 205 healthy Caucasian volunteer bone marrow donors, there was a significant increase in incidences of the GST T1 null; PON1 BB and NAT2 slow acetylation genotypes in MM cases compared with controls. Multivariate analysis revealed that GST T1 null was the most significant risk factor for MM. Interestingly the GST T1 enzyme has been identified as essential for benzene biodegradation. African Americans have an increased frequency of GST T1 null genotypes; this may explain the high incidence of MM. The study presents the evidence that inherited polymorphisms in genes are responsible for metabolizing carcinogens that can affect the individual risk for developing hematologic diseases.¹⁶⁰

GENE ARRAY DATA

The recent development of gene expression profiling has highlighted the sequential genetic change from normal plasma cell to a malignant one. The transformation of MGUS to MM provides an opportunity to better understand the genes involved and correlates these molecular changes with various environmental events. Recently, microarray analysis of plasma cells from 5 healthy donors, 7 patients with MGUS, and 24 MM patients established 380 genes differentially expressed between normal and MM, but a much smaller difference of only 74 genes that were differentially expressed between MGUS and MM samples. Differentially expressed genes included oncogenes/tumor-suppressor genes (LAF4, RB1, and disabled homolog 2), cell-signaling genes (RAS family members, B-cell signaling, and NF- κ B genes), DNA-binding and transcription-factor genes (XBP1, zinc-finger proteins, forkhead box, and ring-finger proteins), and developmental genes (WNT and SHH pathways).¹⁶¹ In a twin experiment, gene

profiling of MM cells allows us to overcome the individual genetic heterogeneity. A recent study compared the gene expression profile of MM cells from a patient's bone marrow with his genetically identical healthy twin. Two hundred and ninety-six genes were upregulated and 103 genes were downregulated at least twofold in MM cells versus the normal twin plasma cells (PCs). Highly expressed genes in MM cells included cell survival pathway genes such as mcl-1, dad-1, caspase 8, and FADD-like apoptosis regulator (FLIP); oncogenes/transcriptional factors such as Jun-D, Xbp-1, calmodulin, Calnexin, and FGFR-3; stress response and ubiquitin/proteasome pathway-related genes, and various ribosomal genes reflecting increased metabolic and translational activity. Several genes were downregulated in MM cells versus healthy twin PCs including RAD51, killer cell immunoglobulin-like receptor protein, and apoptotic protease activating factor. This study provides insights into the mechanisms involved in malignant transformation in MM.¹⁶² These new developments of the molecular mechanisms of MM will help us understand what causes the disease and develop effective preventive and treatment strategies.

SUMMARY

The increased incidence of MM in the last 50 years is indicative of improved diagnosis of the disease and the vigorous evaluation of the increasingly aging population rather than an actual increase in incidence. MM clinical presentations range from a benign disease requiring no therapy to an aggressive malignancy reflecting the complex processes involved in initiation and propagation of the malignant clone. Genetic abnormalities possibly represent initial events that are acquired or inherited and remain dormant until environmental factors promote the proliferation of the malignant clone. Then the clone is sustained through a network of cytokines and cellular elements in the bone marrow microenvironment. The contributions of race, sex, infection, various chemicals, and hereditary factors to this process remain under investigation. Despite extensive studies, the etiology of the disease remains elusive. The studies of the genetic background, using gene array and related technologies, have provided a new opportunity to correlate specific genes with the progress of the disease.

Chapter 81

MOLECULAR BIOLOGY, PATHOLOGY, AND CYTOGENETICS

*Silvia Ling, Lynda Campbell, Phoebe Joy Ho,
John Gibson, and Douglas E. Joshua*

INTRODUCTION

Although traditional morphology has played a secondary role to the rapid developments in molecular biology, cytogenetics, and new areas of therapy for patients with multiple myeloma, its importance cannot be underestimated. Furthermore, new cytogenetic and molecular data, which relate morphologic appearances to chromosomal translocations (i.e., the association of CD20 expression, t(11;14) translocations, and small mature plasma cell morphology),¹ have the potential to play considerable therapeutic roles in decision making about appropriate treatment for patients with myeloma.

MORPHOLOGY

NORMAL AND MALIGNANT PLASMA CELLS

Plasma cells are part of the normal cell population of the bone marrow. They comprise approximately 1% of the nucleated cells of normal marrow aspirates, and are equally distributed throughout the red marrow. Bone marrow findings of increased plasma cells, characteristic of myeloma, must always be taken together with other features before definite conclusions can be drawn, as high plasma cell numbers are seen in some reactive states, especially in HIV infection, autoimmune states, and liver disease. Aggregations of normal plasma cells usually occur in a perivascular distribution, with fewer than four or six cells clumped together. Normal plasma cells are of two major morphologic types. The classical “Marschalko” plasma cells are the predominant plasma cells in normal marrow. Such cells have abundant basophilic cytoplasm, paranuclear hof, and are usually devoid of nucleoli. The second appearance is of the lymphoplasmacytoid plasma cells, which are usually IgM secreting and are

the predominant cells in Waldenstrom’s macroglobulinemia. These cells are smaller than “Marschalko” plasma cells, with less eccentricity of the nucleus, and are more dispersed in the bone marrow without perivascular cuffing. Malignant plasma cells can be differentiated by aggregation along endosteal surfaces, large clumps, and the presence of nucleated plasmablasts or proplasmablasts. Binucleated plasma cells are occasionally seen in normal reactive marrow, and do not per se define malignancy. Electron microscopic appearances of normal plasma cells reveal peripheral chromatin condensation in an eccentric nucleus with well-developed paranuclear Golgi apparatus and cytoplasmic endoplasmic reticulum. Normal plasma cells have an even distribution of kappa and lambda staining, whereas malignant clones are light-chain restricted. Morphologic abnormalities, such as crystal formation, Russell bodies, and “flame” cells are not usually seen in normal marrows, but are by no means pathognomonic of malignancy, as they can occasionally be seen in reactive states.

THE MORPHOLOGIC DIAGNOSIS OF MULTIPLE MYELOMA

The morphologic diagnosis of multiple myeloma and its distinction from reactive plasmacytosis relies on both the quantity of plasma cells seen and the qualitative plasma cell abnormalities, as previously mentioned. In general terms, more than 30% of plasma cells in a marrow aspirate smears constitute a major diagnostic criterion for multiple myeloma, although such a percentage may occur in other conditions, such as rheumatic disorders, inflammatory reactions of the bone marrow, and in particular, HIV infection. The demonstration of light-chain isotype restriction has become a major criterion for distinguishing malignant from reactive cases. Nuclear-cytoplasmic asynchrony is more evident in malignant plasma cells. Recently, the international

myeloma working group has suggested criteria for the distinction of monoclonal gammopathy of unknown significance (MGUS), smoldering myeloma, and symptomatic myeloma. These criteria do not rely on strict morphologic criteria, but stress the clonal or light-chain isotype restriction of plasma cells.²

Despite attempts to define morphologic and or cytochemical features that distinguish neoplastic plasma cells from normal plasma cells, no morphologic criteria appear to be pathognomonic. Spindle-shaped crystal deposits and other cellular inclusions (see Figures 81.1 and 81.2) typical of myeloma can occasionally be seen in normal plasma cells. The diffuse eosinophilic pink staining at the cell periphery, the so-called “flame” cells (see Figure 81.3) seen mostly in IgA myeloma, can occur in other variants, as can Russell bodies which, while initially thought to be organisms, are now known to be immunoglobulin (Ig), have been seen in normal plasma cells. Variations in cell size, in multiple nucleolarity, and even cytochemical staining are not pathognomonic (see Figure 81.4). Most plasma cells stain positively for acid phosphatase, nonspecific esterase, and periodic acid-Schiff, but these are not specific for myeloma. The presence of plasmablasts (see Figure 81.5), nucleolated plasma cells often with less eccentricity and less intense staining of cytoplasm, is classical of myeloma. The number of plasmablasts has also been shown to correlate with prognosis. The presence of a large number of plasmablasts per se is probably the most important morphologic feature that distinguishes myeloma from reactive plasmacytosis, and a population of plasmablasts greater than 2% of plasma cells have been shown by the Mayo Clinic to be an adverse prognostic factor.³

In early myeloma, plasma cells distribute in an interstitial pattern. At a later stage, they form dense aggregates on endosteal surface, followed by nodules and sheets in advanced disease. These patterns correlate with

Figure 81.1 Bone marrow aspirate of a patient with myeloma. Needle-shaped, azurophilic crystalline inclusions in cytoplasm of plasma cells representing Ig inclusion material

Figure 81.2 Bone marrow aspirate of a patient with myeloma. Mott cells are plasma cells with multiple bluish cytoplasmic inclusion bodies

survival, as do other major prognostic factors: plasma cell labeling index and serum β_2 -microglobulin.⁴⁻⁶

The growth pattern of myeloma on trephine is also predictive of the type of skeletal defects and correlates strongly with magnetic resonance imaging findings. Nodules of plasma cells are associated with osteolytic lesions, whereas interstitial and “sarcomatous” types are associated with osteoporosis.⁷

The percentage of plasma cells on bone marrow aspirates is used as a diagnostic criterion for myeloma. According to the World Health Organization classification, major diagnostic criteria require 30% plasmacytosis, while minor criteria require 10–30% for the diagnosis of myeloma. For MGUS, marrow plasmacytosis is defined as <10%.

Monoclonality of myeloma can be demonstrated on trephine by kappa or lambda light-chain restriction by immunohistochemical stain. CD138/syndecan-1 is a useful immunohistochemical marker of normal and neoplastic plasma cells on bone marrow trephine.

IMMUNOPHENOTYPING OF PLASMA CELLS

Immunophenotyping is a valuable technique for differentiating myeloma and normal plasma cells, and the distinction is based on the presence of phenotypic aberrations in myeloma plasma cells (MPCs) that are absent in normal plasma cells.

Normal plasma cells meet the following criteria on phenotyping: high-intensity CD38 positive, CD138 positive, CD 56 negative, CD19 positive, CD20 negative, CD28 negative, CD33 negative, and CD117 negative. Plasma cells in patients with myeloma may demonstrate other abnormalities; for example, positive CD20, CD40, and CD56, and negative CD19.⁸⁻¹¹

Thus, although plasma cells are usually defined by high-intensity fluorescent CD38 and are CD45 negative, CD45⁺ populations of plasma cells have also been studied, and these correlate with plasma cell matrixity

Figure 81.3 Bone marrow aspirate of a patient with IgA myeloma. “Flame” cells are typically associated with IgA myeloma. They are plasma cells which stain eosinophilic pink in the periphery of the cytoplasm due to the accumulation of Ig

and proliferative capacity. Immature plasma cells are CD38⁺⁺, CD45⁺⁺, have high labeling indices, and correlate with the clinical behavior of the disease.¹² Mature malignant plasma cells are CD45 negative, have lower labeling indices, a lower incidence of P-glycoprotein expression, and oncoprotein abnormalities.¹³

DEVELOPMENT OF PLASMA CELLS

CELLULAR DEVELOPMENT

Lymphoid cells are derived from a common lymphoid progenitor which has the capacity to develop into a T, B, or natural killer cell.¹ The first recognizable B-cell type is a pro-B cell, which develops under the influence of transcription factors essential for B-cell commitment. The pro-B cell expresses the characteristic B-

Figure 81.5 Plasmablasts with prominent nucleoli in a patient with plasma cell leukemia

cell surface marker CD19, but not cytoplasmic μ immunoglobulin. It undergoes rearrangement of the Ig heavy-chain (IgH) genes, the product of which associates with that of the variable pre-beta and lambda 5 genes, which encode proteins forming the surrogate light chain. Subsequent rearrangement of true light-chain genes enables expression of surface IgM. The immature B cell thus expresses CD19, as well as cell surface IgM associated with kappa or lambda light chains, i.e., the B-cell receptor. A virgin B cell is an IgM⁺, IgD⁺ cell that circulates in the peripheral blood in the G₀ phase of cell cycle. It may be activated to proliferate and produce plasma cells and memory B cells. Such activation requires contact with T cells.

B cells with high-affinity receptors receive survival signals from antigen stimulation on dendritic cells and differentiate into memory B cells or plasmablasts, which subsequently migrate to the bone marrow and develop into plasma cells. These bone marrow plasma cells have a long life span and produce the majority of secreted Ig in the plasma. They are considered to be the normal, nonmalignant counterpart of the MPC.

MOLECULAR ASPECTS OF PLASMA CELL DEVELOPMENT

IgH gene rearrangements and V gene usage in myeloma

Maturation of normal B-cell precursors to mature plasma cells involves rearrangement of the Ig genes with subsequent somatic mutation of the variable (V) region. The variable region of the Ig heavy chain is derived from three distinct gene segments encoded by the variable (V), diversity (D), and joining (J) region sequences. For the light chain, the variable region is composed of variable kappa or lambda gene segments linked to the joining segments. V gene rearrangement is dependent on the protein products of recombinase activating genes. Within the variable regions of both the Ig heavy- and light-chain genes, there are three

hypervariable or complementary determining regions (CDR). These unique segments can be used as markers to detect minimal residual disease in B-cell tumors. CDR3 is the most variable portion of the Ig molecule, and is the principal site for somatic mutation and antibody affinity maturation of the Ig molecule.¹⁴

After variable region recombination, the isotypes of the heavy chains are determined by a process known as isotype switching. Many of the chromosomal translocations seen in multiple myeloma occur in these switch regions. The process of VDJ rearrangement and class switching allows a single B-cell clone to produce antibodies of different heavy-chain classes to the same antigenic epitope. The rearrangement of Ig genes during B-cell development is sequential, occurring at distinct stages of development. Heavy-chain genes undergo rearrangement before the light-chain genes. The product of successful heavy-chain VDJ joining activates rearrangements of the kappa locus, which precedes lambda rearrangement.

In myeloma, the malignant plasma cells have already undergone somatic mutation within the germinal center, and no ongoing mutation occurs with progressive disease. Thus, the mutation mechanism is no longer active in the malignant clone.^{15,16} Analysis of the variable genes has indicated that the majority of the malignant population is derived from a post-antigen-selected plasma cell. However, less mature, minor B-cell populations of identical variable gene sequences may coexist in the circulation, both in the postswitch and pre-switch populations.¹⁷

ORIGIN OF THE MALIGNANT PLASMA CELL

Myeloma is characterized by proliferation of a monoclonal population of plasma cells. It is a tumor of a postgerminal center, mature B cell that has undergone antigen selection, and somatic hypermutation.^{15,16,18} However, the origin of the MPC remains controversial.

Molecular studies have cast some insights into the stage of differentiation and the clonal nature of myeloma. Polymerase chain reaction and sequence analysis of the IgV_H genes have shown that clonal proliferation occurs in a cell that has undergone somatic hypermutation.¹⁵ Consequently, the unique IgH VDJ rearrangement, somatic hypermutation in the CDR regions (in particular, the hypervariable CDR3 region), becomes the signature of the malignant clone. This malignant population is intraclonally homogeneous and stable in spite of disease progression.^{16,19}

Phenotypic characterization of myeloma “stem cells” has recently been proposed,²⁰ suggesting they are CD138⁺ B cells that self-replicate and differentiate into malignant CD138⁺ plasma cells. These subsets are small (<5%), highly clonogenic, and express CD20⁺ and surface IgM. They are inhibited by anti-CD20 monoclonal

antibody. It was suggested that the therapeutic effect of CD20 antibodies will not be immediate and cannot be measured by standard response criteria, because they target the precursor and not the mature plasma cells that produce the clinical effects.²⁰

CYTOGENETIC ABNORMALITIES IN MYELOMA

Chromosome studies in multiple myeloma have become an important part of the management of myeloma patients. Early investigations were based on conventional karyotype analysis, with the detection of recurrent abnormalities, such as monosomy 13 and t(11;14). In recent years, developments in molecular cytogenetics ranging from metaphase and interphase fluorescent in situ hybridization (FISH) to multicolor spectral karyotyping (M-FISH) and comparative genomic hybridization (CGH) have greatly increased the range and number of detectable cytogenetic abnormalities (Figure 81.6). These techniques have overcome some limitations of conventional cytogenetics (CC) in myeloma, including (1) low mitotic index of myeloma cells; (2) multiple complex chromosomal abnormalities of myeloma complicating the identification of specific chromosomes; and (3) telomeric locations of translocational breakpoints and deletional sites, especially in 14q23.

DELETION OF CHROMOSOME 13Q

Deletion of chromosome 13q is the most common recurrent chromosomal abnormality in myeloma. It is detected in 15–20% of myeloma by CC,²¹ 50% of cases by interphase FISH in newly diagnosed myeloma patients,²² and 30–45% of cases of MGUS.^{23,24} The prognostic significance of loss of 13q identified by FISH alone has been the subject of considerable debate. Several studies based on molecular cytogenetics have shown that this abnormality is strongly associated with an unfavorable prognosis.^{23,25–32} It correlates with advanced stage, elevated β_2 -microglobulin, increased percentage of plasma cells, increased proliferative rate, and reduced overall survival. However, a multivariate analysis identified t(4;14), t(14;16), and the deletion of 17p13 as independent predictors of survival, while loss of 13q was found to be of only borderline significance.³³

Chromosome 13 abnormalities are frequently associated with other chromosomal aberrations. It was observed that, while all patients carrying translocations involving the IgH locus, such as t(4;14) and t(14;16), also had loss of chromosome 13, del(13q), the reverse was not true.^{24,34} This suggests the possibility that del(13q) occurred before the IgH translocation events, perhaps as an early oncogenic change. A role for monosomy 13 in the transformation of MGUS to myeloma has also been proposed, supported by a higher incidence of monosomy 13 in myeloma cases

Figure 81.6 Multiple myeloma karyotype: Top panel shows G-banded karyotype with extra copies of chromosomes 5, 7, 9, 15, and 19, loss of the Y chromosome, monosomy 13, and complex unbalanced rearrangements involving chromosomes 16, 17, and 20. The complex *der(16)* and cryptic *t(8;21)* were identified only on M-FISH (shown in the bottom panel). The *t(8;21)* breakpoint on 8q is at the site of the *MYC* gene

with preexisting MGUS (70%) compared with those cases without such a history (31%).³⁵ Moreover, in 18 asymptomatic, untreated patients with MGUS studied serially with both CC and FISH over 6–72 months (median 30 months), *del(13q14)* was identified in 5 patients over the course of the study, but in only 1 of these patients was the *del(13q)* detected at diagnosis. All five patients proceeded to develop multiple myeloma (MM) 6–12 months after 13q deletion identification, whereas only 2/13 patients without evidence of *del(13q)* transformed to MM.

The majority of chromosome 13 abnormalities (92%) are complete monosomies,²² with the remaining being partial deletions.

IGH SWITCH TRANSLOCATION

The most common structural chromosomal abnormality in myeloma is IgH switch translocation, involving the IgH gene locus on chromosome 14q32. Using

interphase FISH, its incidence is 50% in MGUS, 60–75% in multiple myeloma, and more than 80% in plasma cell leukemia.^{35–38} There is a large array of non-immunoglobulin translocation partners, with the most common ones being 11q13, 4p16.3, 16q23, and 6q23. Cloning of the breakpoints of these genes has shown that they contain candidate oncogenes. As the oncogenes are translocated to *der(14)*, they may be activated while under the control of IgH enhancers.

Chromosome 11q13

t(11;14) is observed in 15–20% of myeloma by FISH.^{39,40} In particular, it is much more common in IgM, IgE, and nonsecretory myeloma. The breakpoints are widely scattered over a region 100–330 kb centromeric to *cyclin D1*, in contrast to mantle cell lymphoma, where the breakpoints are tightly clustered within 110 kb upstream of *cyclin D1*.⁴¹ Cyclin D is likely to be a candidate oncogene, as supported by its being overexpressed in myeloma patients and cell lines with *t(11;14)*.

Early studies suggested that *t(11;14)* was associated with a poor prognosis.^{24,25,40,42} However, subsequent studies by interphase FISH have not confirmed the prognostic relationship.⁴⁰ A *t(11;14)* has been associated with a specific plasma cell morphology. Robillard et al. described an association between CD20 positivity, small mature plasma cell morphology, and *t(11;14)*.¹ Another study showed an association between *t(11;14)* and a lymphoplasmacytoid morphology.⁴³ There also appeared to be a link between this morphologic subtype of MM, the *t(11;14)*, and nonsecretory MM.⁴³

Chromosome 4p

t(4;14)(p16;q32) is present in about 15% of myeloma patients and 2–6% of patients with MGUS.^{44,45} It is detectable only by molecular cytogenetics due to its extreme telomeric position. Consequent to this translocation, *FGFR3* (fibroblast growth factor receptor 3) from *der(14)* and *MMSET* from *der(4)* localized in the breakpoint regions are overexpressed.^{46,47} *FGFR3* is a member of fibroblast growth factor receptor tyrosine kinases. Its mutation is shown to cause constitutive activation of the receptor in neonatal thanatropic dysplasia.⁴⁸ Similarly, in myeloma with *t(4;14)*, it is constitutively activated.⁴⁷

The second putative oncogene in *t(4;14)* is *MMSET/WHSC1*. It is a candidate gene for a multiple malformation syndrome known as Wolf–Hirschhorn syndrome. Among myeloma patients with *t(4;14)*, approximately 32% lack *FGFR3* expression, yet express *MMSET*, supporting its role in oncogenesis.^{49,50}

The *t(4;14)* has been shown to confer a poor prognosis. Fonseca et al.³³ reported that patients in whom this translocation had been identified, using *cIg-FISH*, had a significantly shorter survival (26 months vs 45 months). However, Rasmussen et al. did not find any

correlation between outcome and FGFR3 overexpression,⁵¹ and FGFR3 overexpression was identified in only 74% of patients with t(4;14) by Keats et al.⁵⁰ In the latter study, t(4;14) predicted poor survival, irrespective of FGFR3 expression.

Chromosome 16p

t(14;16)(q32;23) occurs in about 5% of myeloma.^{52,53} Its breakpoint is dispersed in a region centromeric and telomeric to the candidate oncogene *c-maf*, which is shown to be overexpressed in myeloma cell lines with this particular translocation.⁵⁴

Chromosome 6p

The t(6;14)(p25;q32) is present in 18% of myeloma cell lines and 5% of primary myeloma tumors.⁵⁵ This translocation places the IgH locus close to the MUM1 (multiple myeloma oncogene 1)/interferon regulatory factor 4 (IRF4) gene, which is overexpressed in myeloma cell lines. MUM1/IRF4 belongs to the family of interferon regulatory factors (IRF) that regulate B-cell proliferation and differentiation, and have in vitro oncogenic activity.

Other chromosomal partners

Other recurrent chromosome partners in switch translocation include chromosome 8q24, 1q, and 9p13, with their corresponding potential candidate oncogene *c-myc*, IRA1 and 2, and *Pax 5*. *Pax 5* acts as a transcriptional activator and repressor, and is essential in B-cell development.⁵⁶

Switch translocations—implication for pathogenesis

Thirty to fifty percent of multiple myeloma is preceded by MGUS. As indicated earlier, the incidence of the chromosome 14q23 translocation increases from 47% in MGUS, to 60% in intramedullary myeloma and 70–80% in plasma cell leukemia.^{35,38} It occurs in the premalignant stage (MGUS) and is stable within the myeloma population of each tumor. It is proposed to be the primary translocation that initiates oncogenesis.⁵⁷ Conversely, changes such as complex *c-myc* translocations that do not occur in MGUS and tend to be heterogeneous within tumors are probably secondary/late events that contribute to disease progression.

NUMERICAL CHANGES

Numerical changes are common in myeloma, occurring in 89–90% of cases using conventional and molecular cytogenetics.²⁶ They are divided into “hypodiploid/pseudodiploid” and “hyperdiploid” changes. “Hypodiploidy” is associated with a poor prognosis, and the common ones are loss of chromosomes 8, 13, 14, and X, with the most prevalent one being monosomy 13. The common “hyperdiploidy” identified by both CC and FISH includes trisomies 1, 3, 5, 7, 9, 11, 15, 19, and 21.^{21,58,59} Hyperdiploidy is associated with a good prognosis.

C-myc REARRANGEMENT

C-myc rearrangement has been found in about 15% of myeloma and primary plasma cell leukemia in a large cohort of patients examined by interphase FISH,⁶⁰ in 50% of advanced myeloma,⁶¹ and in 55–95% of myeloma cell lines.^{60,61} Those that involve the Ig loci, i.e., t(8;14) and t(8;22), account for only 25%, with the remaining being highly complex and heterogeneous rearrangements with nonreciprocal translocations, multiple deletions, and duplications. *C-myc* rearrangements correlate with elevated β_2 -microglobulin, which is a poor prognostic indicator. Its incidence in MGUS (3%) and smoldering myeloma (4%) is much lower than in active disease.⁶⁰ For these reasons, it is reasonable to suggest that the *c-myc* rearrangement is a secondary/late oncogenic event.

OTHER MOLECULAR ABERRATIONS NOT AFFECTING THE Ig LOCI

These include chromosomes 11q and 8 rearrangements; duplication of 1q21-31; reciprocal translocation of 1q with 15p, 16p, and 5q; *p53*, *N-ras*, and *K-ras* mutation; complex translocations involving three or more chromosomes, and whole arm translocations.

Aberrations of *p53*, the tumor suppressor gene on chromosome 17p13, have been postulated to play a role in myeloma pathogenesis, with *p53* deletions found to be a predictor of poor survival.⁶² The *p53* tumor suppressor gene is involved in the control of normal cellular proliferation, differentiation, and apoptosis, as well as DNA replication and repair. Although previous CC studies indicated a low frequency of *p53* mutations and deletions in myeloma, 3–9%,⁶² molecular cytogenetic studies have demonstrated a much higher incidence. Monoallelic deletions of chromosome 17p involving *p53* have been detected by FISH in approximately one-third of newly diagnosed myeloma patients, and were also associated with reduced survival.⁶³ Many of these abnormalities are small interstitial deletions that are detectable only by FISH.⁶³ The higher frequency of *p53* mutations in plasma cell leukemia and relapsed disease, as compared with myeloma at diagnosis, may indicate their role as a late molecular aberration in myeloma progression.⁶⁴

N-ras and *K-ras* mutation are rare in MGUS, indolent disease, and solitary plasmacytomas, but have been reported to occur in 10–40% of patients with active disease, and even higher in advance disease. With the more sensitive allele-specific amplification method, the frequencies are higher: 55% at diagnosis and 81% at relapse.

PROGNOSTIC SIGNIFICANCE—AN OVERVIEW

Even early CC studies demonstrated the adverse prognostic significance of abnormal karyotypes in myeloma.⁶⁵ Patients with abnormal karyotypes are more likely to have features of aggressive disease: lower hemoglobin, higher β_2 -microglobulin, higher

labeling index, and higher percentage of plasma cells in the marrow ($P < .0001$)⁶⁶ and, in long-term follow-up, patients with the best outcome are those with no evidence of cytogenetic abnormalities at either diagnosis or relapse.³¹

By CC, the most consistent chromosomal abnormality associated with poor prognosis is del(13q), including both complete and partial deletions.^{25,27} This finding has since been confirmed in most molecular cytogenetics series.^{23,29,31,33} Conventional karyotyping has also demonstrated the poor prognostic significance associated with chromosome 11q translocations, including t(11;14) translocation and reciprocal translocations with chromosomes 8, 9, and 12.^{25,42} However, this was not confirmed by molecular cytogenetics.⁴⁰ The combination of aberrations of both chromosomes 11 and 13 results in a dismal outcome.²⁵

The hyperdiploid group, comprising 30–40%, is usually considered to carry a favorable prognosis, whereas hypodiploidy is associated with a poor prognosis.

EPIGENETIC EVENTS

An epigenetic event is defined as a genetic modification without alterations of DNA nucleotide sequences. Hypermethylation is an epigenetic event that is frequently associated with myeloma. It leads to the inactivation of genes, including death-associated protein kinase (*DAPK*), *SOCS1*, *p15*, and *p16*.

Hypermethylation of *p15* and *p16* was observed in 75 and 67% of one group of myeloma patients, respectively.⁶⁷ Hypermethylation of *p15* and *p16* was associated with blastic disease in myeloma, and may be causally related to plasmacytoma development.⁶⁷ Hypermethylation of *p16* was also shown to correlate with an increased proliferative rate of plasma cells, shorter survival, and poor outcome, albeit not as an independent prognostic factor.⁶⁸ In MGUS, the frequencies of *p15* and *p16* hypermethylation were similar to myeloma patients, suggesting an early genetic change rather than a late transformation event.⁶⁹

GENE EXPRESSION PROFILING

The unique gene expression profile of myeloma has allowed the identification of multitudes of genes that could be involved in the pathogenesis of myeloma, and that might become potential therapeutic targets. Myeloma can be distinguished accurately from normal plasma cells based on gene expression profiling of 120 genes; however, it is indistinguishable from MGUS by this approach. Myeloma can be subdivided molecularly into four groups (MM1–MM4) by an unsupervised hierarchical clustering, with the MM4 group being the highly proliferative myeloma cell lines and the MM1 group consisting of MGUS and normal plasma cells. The main difference lies in the high expression of genes involved in cell cycling and DNA metabolism in the MM4 subgroup,^{70,71} and correlates

with a high incidence of karyotypic abnormalities, increased β_2 -microglobulin, and increased creatinine, all of which are features of high-risk disease.

MYELOMA MICROENVIRONMENT

Cytogenetics and molecular studies have indicated that multiple genetic events are implicated in the pathogenesis of myeloma. In particular, IgH switch translocations are proposed to be the primary event in MGUS, with additional events contributing to transformation of the malignant clone to intramedullary myeloma. During this phase, myeloma cells produce factors that create a bone marrow microenvironment that is essential for survival, growth, and differentiation. Subsequently, secondary translocations or dysregulation of oncogenes lead to growth independent of the bone marrow milieu and a clinical course that is aggressive with frequent extramedullary manifestation.

INTERLEUKIN 6

Interleukin 6 (IL-6) is involved in the proliferation and differentiation of plasmablastic cells^{72–74} into Ig-secreting mature plasma cells.^{75–77} This process is also dependent on the interaction between fibronectin, produced by bone marrow stromal cells (BMCLs), and receptor VLA-4 and VLA-5 on bone marrow Ig-secreting plasma cells.⁷⁷

In multiple myeloma, IL-6 is a major autocrine and paracrine growth factor.^{78–82} This is based on in vitro and in vivo studies, which have shown that anti-IL-6 antibody almost completely inhibits proliferation of myeloma cells. Bone marrow stroma is the predominant source of IL-6 and its secretion is upregulated by transforming growth factor β , IL-1 β , and IL-10, which is produced by BMCLs and myeloma cells.⁸³ IL-6 correlates with disease activity in plasma cell dyscrasia.^{84,85} Higher levels of serum IL-6 and soluble IL-6 receptors are associated with disease progression and poor prognosis.^{84–86} Soluble IL-6 receptor/IL-6 complex activates gp130 and increases the IL-6 sensitivity of myeloma cell lines.⁸⁷

Activation of the gp130 IL-6 transducer is a key signal for myeloma proliferation. It mediates the IL-6 as well as other myeloma growth factors/cytokines including leukocyte inhibitory factor, OSM, IL-11, and CNTF.

Other cytokines interact with IL-6 and influence myeloma growth. IL-1 α , IL-2, IL-4, and IL-10 induce partial differentiation of B cells to normal plasmablastic cells. Interferon alpha has differing effects on myeloma, depending on the surface receptors on myeloma cells. It stimulates IL-6-dependent proliferation in some myeloma cell lines, but prolongs the plateau phase in patients responsive to therapy. Interferon gamma is a potent inhibitor of myeloma proliferation via downregulation of IL-6 receptor complex.

TUMOR NECROSIS FACTOR ALPHA

The major effect of tumor necrosis factor alpha (TNF- α) is stimulation of IL-6 production in BMSCs. It upregulates the adhesion molecules on myeloma and BMSCs, and hence triggers IL-6 secretion from BMSCs via activation of NF- κ B.^{88,89} TNF- α induces modest proliferation of myeloma cells via mitogen-activated protein kinase (MAPK)/ERK activation and not Stat3. It is possibly through the inhibition of the TNF- α pathway that proteasome inhibitors and thalidomide have their therapeutic effects. It also protects myeloma cells against drug-induced apoptosis.⁹⁰

VASCULAR ENDOTHELIAL GROWTH FACTOR

Neovascularization is an important pathogenetic factor of myeloma. Increased bone marrow angiogenesis correlates with disease progression.^{18,91–98} Vascular endothelial growth factor (VEGF) plays an important role in neovascularization of myeloma. It regulates endothelial cell function, vessel budding, and tube formation. In particular, it stimulates migration and proliferation of myeloma cells in an autocrine and paracrine loop.⁹⁹

VEGF is produced by myeloma cells and BMCLs that are adhered to myeloma cells. It also augments the secretion of IL-6 by BMCLs.

INSULIN GROWTH FACTOR-I

Insulin growth factor is an autocrine growth factor and migratory factor of myeloma cells. It activates predominantly the phosphoinositol 3-kinase (PI-3K) signaling pathway, with some contribution to the MAPK pathway. It stimulates proliferation, inhibits apoptosis, and enhances migration through endothelial cells and BMCLs.^{100–102}

MACROPHAGE INFLAMMATORY PROTEIN-1 ALPHA

Macrophage inflammatory protein-1 alpha (MIP-1 α) is a chemokine that belongs to the RANTES (regulated on activation, normal T expressed and secreted) family of chemokines. Its role in myeloma lytic lesions is well described. More recently, it is shown that it has been correlated with tumor burden and survival in myeloma patients.^{103,104}

Chapter 82

CLINICAL FEATURES AND MAKING THE DIAGNOSIS OF MULTIPLE MYELOMA

Yi-Hsiang Chen

Multiple myeloma is, with rare exceptions, a systemic disease. The neoplastic plasma cells cause various organ dysfunctions through tumor cell invasion and, more importantly, through the pathologic effects of the monoclonal immunoglobulins (Ig) and/or free Ig light chains. In addition, myeloma cells secrete, and stimulate normal stromal cells in the bone marrow microenvironment to secrete, a host of cytokines that mediate various biologic effects. Thus, patients with multiple myeloma may exhibit an array of clinical manifestations.

PRESENTING FEATURES

Despite increasing awareness of this disease entity and advances in the diagnostic technology that have led to early diagnosis, the major presenting features in most patients remain remarkably consistent. Table 82.1 summarizes the initial findings in groups of patients seen at various periods of time in the last three to four decades.¹⁻³ The findings in a small group of young and older patients are also included for comparison.^{4,5} The most frequent presentations are symptoms arising from myeloma involvement of bone and the bone marrow.

BONE PAIN

Bone pain is the most frequent presenting symptom. It may precede the diagnosis for months. It most commonly begins in the back and lower chest, less often in the ribs or extremities. Back pain is usually insidious, and is aggravated by weight bearing and movement. Acute exacerbation of back pain often occurs with compression fractures of the vertebrae. The chest pain from rib lesions is generally mild, aggravated by movement and position, but may be pleuritic and associated with dyspnea, particularly when rib fracture or pleural effusion develops. Bone pain may become severe when pathologic fracture occurs spontaneously or with trivial trauma. Physical examination may illicit bone tenderness of the affected regions. Radicular pain

and paresthesia along the dermatome distribution may precede the onset of motor weakness or loss of sphincter control from spinal cord or nerve root compression, and are important warning signs to look for clinically.

SYSTEMIC SYMPTOMS AND SIGNS

Weakness, fatigue, anorexia, palpitation, and dyspnea on exertion are common symptoms of anemia. The onset is insidious. The symptoms are generally mild, but worsen with the development of renal insufficiency. Symptoms of renal failure may supervene, including periorbital and dependent edema. In *hypercalcemic* patients, nausea, vomiting, constipation, polyuria, polydipsia, headache, and lethargy may develop.

FEVER AND INFECTION

Fever from myeloma occurs in <1% of patients.^{1,2} Its presence demands workup for infection. Infection occurs in about 10% of patients, but the incidence almost doubles in those older than 75 years.⁵ Recurrent pneumonia, sinusitis, and urinary tract infections may precede the diagnosis. In untreated patients with infection, Gram-positive organisms predominate.

RENAL FAILURE

Renal insufficiency (serum creatinine >2 mg/dL) is present in 20–30% of patients at diagnosis.¹⁻⁷ This may be an underestimation. In a study of more than 1300 newly diagnosed patients, the frequency of renal failure increased from 31 to 49%, when the creatinine clearance was also measured.⁶ Renal failure affected 24% of patients with IgG, 31% with IgA, 100% with IgD, and 52% with light-chain myeloma. Advanced age, late disease stage, heavy light-chain proteinuria, and hypercalcemia were identified as risk factors.⁶ Occasionally, severe acute renal failure is the first manifestation of myeloma. This is often precipitated by confounding events, such as dehydration, infection, and hypercalcemia.⁸⁻¹⁰ Over the course of the disease,

Table 82.1 Changing presenting features in multiple myeloma

Clinical features	1960–71 (1) ^a	1985–98 (2)	1972–86 (3)	1987–90 (3)	Age <40 (4)	Age >75 (5)
Symptoms

Creatinine >2mg/dL	30	19	14	10	29	35
Previous MGUS	–	20	–	–	–	–
Incidental diagnosis	–	–	14	34	–	–

^aNumbers in parentheses in the first row indicate references.

over 50% of patients will develop renal failure from myeloma. Renal failure may also be due to hypertension, diabetes, or other comorbid conditions in older patients. Detailed urinalysis is required to differentiate various forms of myeloma renal diseases. Myeloma cells may be detected in the urine sediment.¹¹

LESS COMMON PRESENTATIONS

Bleeding manifestations and symptoms related to polyneuropathy, hyperviscosity, and amyloidosis are present occasionally at diagnosis.

CLINICAL MANIFESTATIONS AND PATHOPHYSIOLOGY

Multiple myeloma may involve practically every organ system. Myeloma cells, originating from postgerminal center B lymphocytes (see Chapter 81), proliferate primarily in the bone marrow microenvironment. Thus, hematopoietic tissues and the skeletal system are uniformly affected at the earliest stage of disease.

BLOOD AND BONE MARROW CHANGES

Anemia is present in 60–80% of patients at presentation.^{1–5} It is usually mild to moderate in severity and is normocytic, normochromic in morphology. The anemia has the characteristics of anemia of chronic inflammation (formerly anemia of chronic disease) with low serum iron, decreased transferrin saturation, and elevated ferritin. The reticulocyte count is low, reflecting a hypoproliferative state. A bone marrow examination commonly reveals erythroid hypoplasia and a varying

degree of myeloma cell infiltration. The pathogenetic mechanisms of anemia in myeloma are beginning to be elucidated. Inflammatory cytokines, including interleukin-1 (IL-1), tumor necrosis factors (TNFs), and IL-6, often elevated in myeloma patients, suppress hematopoiesis.¹² Within the bone marrow microenvironment, myeloma cells, expressing high levels of cell surface Fas-L and TNF-related apoptosis-including ligand (TRAIL), induce apoptosis of the surrounding immature erythroblasts by binding to the respective death receptors on erythroblasts.¹³ The increased level of IL-6 induces excessive hepatic production of hepcidin, which inhibits the intestinal iron absorption and release of iron from reticuloendothelial cells, thus interfering with the iron use.¹⁴ In addition, inappropriate erythropoietin response, seen in 25% of patients (and more often as the disease progresses), contributes to the development of anemia, which frequently responds to erythropoietin treatment.^{15,16} In addition to inflammatory cytokines, hyperviscosity may be a cause of the blunted erythropoietin response.^{12,17} Finally, in some patients, the degree of anemia is accentuated because of an expanded plasma volume,¹⁸ which in turn is likely a consequence of an increased level of IL-6.¹⁹

Severe anemia can occur particularly in patients who have renal failure. Macrocytic anemia with an elevated mean corpuscular volume is seen in up to 20% of patients.²⁰ A few patients may have concomitant folate or vitamin B₁₂ deficiencies, but most have macrocytosis of unknown cause.²⁰ On the other hand, microcytic, iron-deficiency anemia can develop from gastrointestinal (GI) bleeding in patients who have amyloid involvement of the GI tract. RBC rouleaux formation and high

erythrocyte sedimentation rate are characteristically seen in patients with high monoclonal protein. Rarely, Howell–Jolly bodies may be present in patients with massive amyloid infiltration of the spleen.

Leukopenia and thrombocytopenia occur in 10–15% of patients at diagnosis. In some, thrombocytosis develops, presumably from the thrombopoietic effect of IL-6.^{1,2,21} This occurs more often in patients with osteosclerotic myeloma. Occasional plasma cells or plasmacytoid lymphocytes can be seen in the peripheral blood smear. A marked increase in plasma cells, 20% of leukocytes or $\geq 2000/\mu\text{L}$, is seen in rare cases of primary plasma cell leukemia and more commonly in the terminal phase of myeloma.²²

The bone marrow shows myeloma cell infiltration that varies from 10% to total replacement. Myeloma cells are morphologically monomorphic with large, round nuclei and an open chromatin pattern. This is in contrast to reactive plasmacytosis, in which a heterogeneous population of plasma/plasmacytoid cells with variously sized nuclei and condensed chromatin is seen. In some cases, plasmablastic morphology may predominate and predicts a poorer outcome.²³ On the bone marrow section, the pattern of myeloma cell infiltration may be diffuse, interstitial, or focal. These patterns appear to be of prognostic significance.²⁴ Some degree of fibrosis, unaccompanied by characteristic features of myeloid metaplasia, is found in up to 10% of patients but has no apparent effect on the clinical course of disease.^{24,25} With special staining, increased microvascular density can be seen in patients with advanced disease and is a poor prognostic factor.²⁶

BLOOD CHEMISTRIES

Abnormalities in blood chemistries reflect various organ dysfunctions and metabolic derangements and include elevated blood urea nitrogen, serum creatinine, calcium, and hepatic enzymes. Serum albumin level is often depressed consequent to specific transcriptional downregulation of the albumin gene by IL-6 and other inflammatory cytokines.^{27,28} The severity of hypoalbuminemia, correlated with the stage of disease, is an important prognostic factor.²⁹ C-reactive protein, a surrogate marker for IL-6, and β_2 -microglobulin, a marker for myeloma tumor load, are increased in some patients.³⁰ Elevated levels of serum lactic dehydrogenase, seen in 11% of untreated patients and more frequently in patients with high tumor mass, predict for chemoresistance and a shorter survival.³¹ A large amount of paraprotein in the serum causes reduced anion gap, “spurious” hyponatremia, and rarely, “spurious” hypercalcemia due to the binding of calcium by paraproteins.³²

HEMOSTATIC DEFECTS

Prothrombin time and partial thromboplastin time are generally normal. A prolonged thrombin time, however, is the most frequent abnormal coagulation finding in patients with myeloma.³³ It is occasionally associated

with bleeding diathesis, manifested as epistaxis, ecchymosis, hematoma, or postsurgical bleeding, but more often it is asymptomatic. The underlying cause is the interference of fibrin monomer polymerization by paraproteins.^{34,35} A heparin-like anticoagulant, unrelated to monoclonal protein, was also reported in some patients.³⁶ Rarely, specific inhibitors to coagulation factors, such as factor VIII, and reduced plasma concentration of fibrinogen, factors II, V, VII, VIII, X, and XI were reported.^{33,37} Acquired factor X deficiency, due to absorption and rapid clearance of factor X by the amyloid fibrils, was seen in a few patients with amyloid light chain (AL) amyloidosis.³⁸ Bleeding time may be prolonged, and platelet aggregation, adhesion, and platelet factor III activity may be reduced, possibly from the coating of paraprotein on platelet surface. This abnormality is clinically significant in patients with paraprotein concentration in excess of 5 g/dL.³⁹ Rarely, an acquired von Willebrand syndrome may develop. Monoclonal proteins either bind to von Willebrand factor itself, or interfere with its binding to platelet glycoprotein, or inhibit the binding of fibrinogen to platelets.^{40,41}

MYELOMA BONE DISEASE AND HYPERCALCEMIA

Hypercalcemia occurs in 20–30% of patients at diagnosis, often in association with skeletal system involvement. In a recent large series, radiographs at diagnosis were abnormal in 79% of patients, with discrete lytic lesions in 66% and diffuse osteoporosis in 22%. Osteosclerotic lesions occurred in about 0.5% of patients and are associated with POEMS syndrome in some patients.^{2,42}

MYELOMA RENAL DISEASES

The renal failure in myeloma may take one of several forms (Table 82.2) and is often multifactorial in an individual patient. Specific myeloma-related processes affect renal tubular and/or glomerular functions. Direct invasion of renal parenchyma by myeloma cells occurs rarely and mostly in the terminal phase of the disease.

TUBULAR DYSFUNCTION

Free light chains (Bence Jones protein) play a crucial role in causing renal damage in myeloma patients. The nephrotoxicity of certain light chains has previously been demonstrated. Incubation of light chain with renal cortical tissue slides inhibited organic ion trans-

Table 82.2 Renal dysfunctions

Reversible	Irreversible (mostly)

Pyelonephritis	

port, gluconeogenesis, and ammonia formation,⁴³ while microperfusion of nephrons with light chain isolated from myeloma patients with renal failure, but not those with normal renal function, led to obstruction of the distal tubules and cast formation.⁴⁴ Furthermore, intraperitoneal injection of light chains from myeloma patients with a variety of renal lesions reproduced similar lesions in mice in 22 of 27 cases. Light chains from patients without renal disease were much less likely (4/13) to induce renal lesions.⁴⁵ Thus, the properties of any particular light chain dictate the nature of renal damage in myeloma renal diseases.

Myeloma cast nephropathy

Myeloma cast nephropathy (MCN) is the most common form of myeloma renal disease and frequently progresses to chronic renal failure. It is often precipitated by dehydration, hypercalcemia, and use of diuretics or nonsteroidal anti-inflammatory drugs, all causing a reduction in glomerular filtration. Renal failure is reversible in about 50% of patients.^{8–10,46} The physical basis for light-chain nephrotoxicity has not been elucidated. The initial finding that the isoelectric point of light chain was the determinant for its nephrotoxicity has not been confirmed.^{45,47} Nevertheless, coprecipitation of light chain and Tamm-Horsfall protein in distal tubules leads to obstructing cast formation, tubular atrophy, disruption of the basement membrane, interstitial inflammation and fibrosis and eventually nephrosclerosis, all features characteristic of “myeloma kidney”.^{46,48}

Acquired Fanconi syndrome

Acquired Fanconi syndrome occurs rarely. It may precede overt myeloma for years.^{46,49} Patients may have azotemia and various degrees of proteinuria, glycosuria, aminoaciduria, and phosphaturia. On renal biopsy, the damaged proximal tubular cells show atrophic changes and contain crystalline cytoplasmic inclusions without overt lesions of cast nephropathy. This syndrome is almost always associated with κ light-chain proteinuria. Recent analysis of light chains in these patients showed a preferential involvement of V κ 1 subgroup of limited germline origin. This light-chain V domain contains unusual hydrophobic sequences that are resistant to proteolysis by lysosomal cathepsin B. The accumulation of indigestible nephrotoxic light chains in proximal tubular cells provides a plausible explanation for the functional impairment.⁵⁰

Distal tubular dysfunction

Distal tubular dysfunction with impairment in urinary acidification and concentration may occur as a part of renal failure or rarely as an isolated defect.^{46,49}

GLOMERULAR DYSFUNCTION

Monoclonal immunoglobulin deposition disease

Direct deposition of monoclonal light chain and/or, more rarely, fragments of heavy chain may lead to

renal failure in myeloma patients.^{51–53} Renal biopsy reveals nodular sclerosing glomerulopathy. Glomeruli are enlarged with a diffuse and nodular expansion of the mesangial matrix, with little thickening in glomerular basement membrane (GBM). Variable degrees of tubular basement membrane (TBM) thickening, tubular atrophy, and interstitial fibrosis are also present. Immunofluorescent staining shows linear monoclonal light-chain deposit in GBM and TBM in light-chain deposition disease (LCDD). In heavy-chain deposition disease (HCDD) or mixed light/heavy-chain disease (LHCDD), heavy-chain fragment and complement deposits are also present. In about 80% of LCDD, the light chain is of κ isotype.⁵⁴ Both κ and λ are seen in HCDD, while CH1 constant domain appears to be deleted in the deposits of heavy-chain fragment.⁵⁵ Commonly, a mixed picture of LCDD and MCN is present. Compared with MCN, monoclonal immunoglobulin deposition disease (MIDD) is more likely to lead to nephrotic syndrome, and may precede the diagnosis of myeloma. Systemic light-chain deposition in other organs may occur in some patients.⁵¹ The incidence of LCDD appears low. However, in a series of 118 myeloma patients with renal failure who underwent renal biopsy, LCDD was found in 19%.⁵³

Renal amyloidosis (see also Chapter 90)

Amyloidosis occurs in 7–10% of patients with myeloma.¹ The most common renal manifestation is nonspecific proteinuria, although microscopic hematuria may occur. About 25% of patients with AL amyloidosis have serum creatinine values >2 mg/dL. The glomerular filtration rate may be reduced in 50% of patients. About 15% of patients show clinical nephrotic syndrome.⁵⁶ Among 118 myeloma patients with renal failure and a renal biopsy, renal amyloidosis was found in 25%.⁵³ The kidney size is usually normal or slightly enlarged on imaging studies, but small, contracted kidneys can be seen. Renal biopsy shows amyloid deposition in glomerular mesangium and GBM. Amyloid material stains with Congo red and exhibits apple-green birefringence on polarized light. Electron micrographs reveal characteristic nonbranching fibrils with a distinct diameter of 7.5–10 nm.⁵⁷

NEUROLOGIC MANIFESTATIONS

Neurologic dysfunctions in patients with myeloma may result directly from tumor invasion or indirectly from the effects of myeloma proteins. In addition, metabolic derangements, hypercalcemia, hyperviscosity, and uremia affect neurologic functions (Table 82.3).

SPINAL CORD COMPRESSION AND RADICULOPATHY

Extension of vertebral body plasmacytoma and collapse of bony structures lead to compression of the spinal cord or dorsal roots by epidural tumors. Occasionally, paravertebral tumor invades the spinal canal through intervertebral foramina. The incidence

Table 82.3 Neurologic complications

Metabolic encephalopathies: hypercalcemia, hyperviscosity syndrome, uremia
Cord compression, radiculopathy
Meningeal plasmacytosis/CNS plasmacytoma
Cryoglobulinemia (vasculitis)
Peripheral polyneuropathies
POEMS syndrome/osteosclerotic myeloma
Amyloid neuropathy
Polyneuropathy associated with myeloma
Polyneuropathy associated with cryoglobulinemia

of this complication is about 15%.^{58,59} The thoracic spine is more commonly involved. IgA myeloma and extensive cortical bone involvement appear to pose a greater risk.⁵⁹ Plain radiographs of the spine may reveal vertebral collapse and/or vertebral or paravertebral masses. Uncommon neurologic manifestations may occur with cranial plasmacytoma, either as a part of multiple myeloma or as a solitary lesion.

MENINGEAL INVOLVEMENT

Meningeal myelomatosis occurs rarely. Limited reports have recently been reviewed.⁶⁰ Patients may experience headache, mentation changes, multiple cranial nerve palsies, and speech and gait disturbances.⁶¹ IgD and IgA myelomas appear to be overrepresented in these cases. Advanced stage with high tumor-labeling index, and, in particular, plasma cell leukemia (19%) are common causes of central nervous system (CNS) disease. Specific laboratory findings include the presence of myeloma cells⁶² and paraprotein in the cerebrospinal fluid (CSF).⁶³

PERIPHERAL NEUROPATHIES

Peripheral polyneuropathy develops in 1–8% of patients with myeloma.^{64,65} The true incidence may be higher because of a high proportion of subclinical disease as suggested by electrodiagnostic studies.⁶⁶ The neuropathy may be sensory, motor, or sensorimotor, and consists of a heterogeneous group of disorders detailed below.

Osteosclerotic myeloma and POEMS syndrome

Osteosclerotic bone lesions are seen in about 3% of patients with multiple myeloma.^{67,68} Patients with *osteosclerotic myeloma* are on average about 10 years younger than those with classic myeloma, with a mean age at diagnosis of 55 years. Male gender predominates. The incidence of anemia, renal failure, hypercalcemia, and bone pain is lower than in classic myeloma. Monoclonal protein concentration is usually low. Osteosclerotic bone lesions are often limited in number, and bone marrow plasmacytosis is mild or absent. Peripheral polyneuropathy, however, occurs in 40–50% of patients and may precede other symptoms of myeloma.^{65,68} Similarly, multiple myeloma that is

associated with polyneuropathies occurs at a younger age with a male predominance. In about 50% of cases, pure osteosclerotic or mixed sclerotic/lytic bone lesions are seen, although pure lytic lesions occur in about 25% of patients.^{42,69} In both groups, the monoclonal IgG or IgA are almost exclusively associated with λ light-chain isotype. Clearly, these two groups of patients exhibit similar and overlapping features. Other unusual clinical manifestations, variably expressed in these patients, include organomegaly, endocrinopathy, and skin lesions. This constellation of clinical features is emphasized by the designation of an acronym, POEMS (plasma cell dyscrasia with polyneuropathy, organomegaly, endocrinopathy, M protein, and skin changes) syndrome.^{70,71} For uniform diagnosis, it was recently proposed that a diagnosis of POEMS be made when a patient meets two major criteria—polyneuropathy and monoclonal plasmaproliferative disorder—and one of the minor criteria—sclerotic bone lesions, Castleman's disease, organomegaly (liver, spleen, lymph nodes), endocrinopathy (adrenal, thyroid, pituitary, gonads, parathyroid, pancreas), skin changes (hyperpigmentation, hypertrichosis, plethora, hemangiomas, white nails), and papilledema.⁷² The POEMS syndrome is associated with various plasma cell dyscrasias. The incidence was 1.4% in 2714 patients with plasma cell dyscrasias, excluding myeloma.⁷³ Five to 20% of POEMS syndrome occurs in patients with typical myeloma with significant bone marrow plasmacytosis. Osteosclerotic or mixed sclerotic/lytic bone lesions occur in 90%. In about 45% of patients, the bone lesion is solitary.⁷⁴ The neuropathy in POEMS syndrome, form extensive demyelination with various degree of axonal degeneration, resembles chronic inflammatory demyelinating polyneuropathy. In the great majority, it is a chronic, distal sensorimotor neuropathy with symmetrical numbness and dysesthesia of legs, progressively extending proximally, accompanied by ascending weakness. Reflexes are severely depressed. Cranial nerves are spared, and autonomic involvement is very rare.^{75,76}

Osteolytic myeloma

Peripheral polyneuropathy also occurs in typical myeloma and resembles paraneoplastic neuropathy associated with other neoplasia. It is mostly a mild sensorimotor neuropathy from axonal degeneration, with some degree of segmental demyelination.⁷⁶ Distal numbness, tingling, and weakness affect the legs more than the arms. The autonomic system is not involved.

Amyloid neuropathy

Systemic amyloidosis complicates the course of myeloma in 7–10% of patients. Amyloid neuropathy occurs in about 15% of patients with systemic AL amyloidosis.^{56,77} In the nervous system, amyloid may be deposited, often focally, in epineurial and endoneurial connective tissues and vessel walls of peripheral

nerves, dorsal ganglia, and autonomic ganglia.⁷⁸ Sural nerve biopsy reveals axonal degeneration with a lesser degree of demyelination, affecting mostly unmyelinated or lightly myelinated fibers.⁷⁹ The absence of blood–nerve barrier in dorsal root and sympathetic ganglia may predispose these sites to amyloid deposition.⁸⁰ Electrodiagnostic studies show decreased action potential amplitude, reduced sensory responses, and normal or mildly reduced conduction velocity.⁸¹ The neuropathy is progressive, sensory dominant, with prominent pain and temperature sense loss. The most common initial presentation is burning or painful paresthesia with mild weakness of lower extremities. Symptoms of autonomic dysfunction include orthostatic hypotension, impotence, and urinary retention.

Carpal tunnel syndrome

The deposition of amyloid in the flexor retinaculum entraps the median nerve. Carpal tunnel syndrome is the most common neurologic finding in systemic amyloidosis. Electrodiagnostic studies show diminished sensory action potential, prolonged distal latency, and denervation of abductor pollicis brevis. Hand and wrist pain and numbness and paresthesia of the middle and radial fingers are common. Thenar muscle atrophy may occur in severe, chronic case.

Cryoglobulinemia

About 6% of myeloma proteins are cryoglobulins.⁸² Cryoglobulins, especially type II and III, have been associated with neuropathy. *Mononeuropathy* or *mononeuropathy multiplex* may occur as a consequence of vasculitis. *Polyneuropathy*, possibly due to ischemic demyelination, has also been reported.^{83,84} In eight cases of myeloma with cryoglobulinemia, one patient was reported to have polyneuropathy, which improved transiently with plasmapheresis and chemotherapy.⁸²

SYSTEMIC AMYLOIDOSIS (SEE ALSO CHAPTER 90)

AL amyloidosis complicates the course of myeloma in 7–10% of patients.^{1,85} It is more commonly associated with myeloma of λ light-chain type. Amyloidogenic light chains preferentially involve certain V_k and V_A germline genes. The specific V gene is often associated with a propensity for a specific pattern of organ infiltration, suggesting an organ tropism of amyloidogenic light chain.^{86,87} Amyloid protein may deposit in many organs in the body.⁸⁸ Serious organ dysfunctions develop when the kidneys, peripheral nervous system, and heart are involved. Cardiac amyloidosis results in arrhythmia, conduction defect, and restrictive cardiomyopathy. Involvement of the GI tract may produce mobility disorders and malabsorption. Pulmonary amyloidosis precipitates respiratory failure. Amyloid angiopathy causes spontaneous skin and mucosal bleeding. Amyloid may also deposit in the skin, endocrine organs, joints, and other tissues, occa-

sionally producing a pressure effect. Rarely, cortical bone involvement by amyloid results in pathologic fracture.

IMMUNE DYSFUNCTION

The susceptibility to bacterial infections in patients with myeloma has long been recognized.⁸⁹ Infection may be the presenting feature in 10% of patients. Patients at the initiation of treatment and at relapse are at higher risk for infection.^{90–92} Other risk factors are decreased polyclonal Ig and renal failure. Gram-positive infections are common before chemotherapy, while Gram-negative organisms predominate after chemotherapy.⁹²

Multiple defects in the immune system have been identified. The deficiencies of the uninvolved polyclonal Ig correlate with higher infection risks and are likely to be the major cause of infection.⁹³ This *secondary antibody deficiency (or functional hypogammaglobulinemic state)* is mainly due to defective antibody production in the immune responses to antigenic stimulation, particularly in the primary immune responses,^{90,94} though the accelerated concentration-dependent catabolism of IgG may also be a factor.⁹⁵ The underlying mechanism has been extensively studied in patients and in a murine plasmacytoma model. In human disease, lower numbers of peripheral blood and bone marrow B lymphocytes and plasma cell precursors, repeatedly observed in myeloma patients, indicate a suppression of B-cell proliferation and maturation. This suppression appears reversible when myeloma is effectively treated.^{96,97}

HYPERVISCOSITY SYNDROME

Hyperviscosity syndrome occurs in fewer than 5% of IgG and in 5–10% of IgA myeloma patients.^{98,99} The type of monoclonal immunoglobulin and the plasma concentration are the main determinants for the development of hyperviscosity. In one study of IgG myeloma, hyperviscosity occurred in 4.2% of 238 patients, and in 22% of 46 patients with serum IgG level above 5.0 g/dL.⁹⁸ The IgG₃ subtype, with a tendency for aggregation, and unusually asymmetrical IgG molecules with a high axial ratio, pose higher risks.^{100,101} Similarly, myeloma patients with polymeric IgA are much more likely to develop hyperviscosity syndrome than those with the monomeric form.^{99,102} Hyperviscosity has also been reported in unusual cases of light-chain myeloma.¹⁰³

The circulatory disturbances resulting from hyperviscosity lead to various clinical manifestations. Headache, blurred vision, reduced visual acuity, and drowsiness are common. Occasionally, patients may present with dementia or psychosis.¹⁰⁴ Progressive, severe CNS dysfunction results in obtundation, vertigo, seizure, gait ataxia, and coma. Dyspnea may precede overt congestive heart failure. Bleeding occurs most commonly as epistaxis, ecchymosis, and sometimes GI

bleeding. Fundoscopic examination, revealing characteristic retinal flame-shaped hemorrhages, engorged, tortuous, segmented retinal veins (“box-caring”), and papilledema, should be performed initially and repeatedly during the course of treatment.

EXTRAMEDULLARY PLASMACYTOMA

Primary extramedullary plasmacytoma occurs rarely and involves most commonly the upper air passages and paranasal sinuses (90%), though a variety of organ involvement has been reported.¹⁰⁵ The clinical manifestations depend on the sites of involvement. In the head and neck region, painless or painful mass may be the first sign. Nasal obstruction, discharge, epistaxis, hoarseness, or hemoptysis may occur. Less commonly involved sites include lung, GI tract, lymph nodes, and the thyroid gland. Only about 20% of patients will have serum monoclonal proteins, and the bone marrow is not involved. Diagnosis is made by histologic or cytologic demonstration of myeloma cells in the biopsied specimen. Establishment of monoclonality, by specific antibody staining for cytoplasmic immunoglobulin to show light-chain restriction or immunoglobulin gene rearrangement, is sometimes necessary to differentiate this entity from reactive plasmacytosis. A bone survey is necessary to exclude bone involvement, and magnetic resonance imaging (MRI) or ¹⁸F-fluorodeoxyglucose positron emission tomography (¹⁸F-FDG PET) may be used to detect other soft tissue involvement.¹⁰⁶

More commonly, extramedullary plasmacytomas develop at the terminal phase of myeloma. A wide variety of organs have been shown to be invaded in postmortem examination.⁸⁵ With increasingly effective chemotherapy, more patients develop extramedullary plasmacytoma during the late phase of their disease.

SOLITARY PLASMACYTOMA OF BONE

Solitary plasmacytoma of bone occurs in 3–5% of myeloma patients. It is more common in men (male-to-female ratio 2:1) and at a younger age (50 vs 65 years). It involves mainly the axial bones, particularly vertebrae. Local bone pain and occasionally pathologic fracture may be the presenting feature. Anemia, hypercalcemia, and renal impairment are absent. A serum monoclonal immunoglobulin, usually of low concentration, is detected in about 50% of patients. The bone marrow is not involved, by definition. A bone survey should be done to exclude more extensive disease.

The diagnostic criteria for solitary plasmacytoma of the bone and solitary extramedullary plasmacytoma are not well defined. Because a fraction of these patients, presumably those with truly localized disease, appear curable with radical radiotherapy,¹⁰⁷ stringent criteria that allow precise diagnosis of a potentially curable disease are needed. Questions have been

raised as to the need for using sensitive molecular techniques to assess marrow involvement and for advanced imaging methods, such as MRI or PET, to exclude disseminated diseases. Guidelines on the diagnosis and treatment have recently been proposed.¹⁰⁷

UNCOMMON MYELOMA: IgD AND IgE MYELOMA

Patients with IgD myeloma have a higher rate of renal failure, extramedullary lesions, amyloidosis, and leukemic manifestation. Serum paraprotein is low, often difficult to detect, and is associated with λ light chain in more than 80% of patients. Rare IgE myeloma also shows a tendency for developing into plasma cell leukemia.¹⁰⁸

CLINICAL EVALUATION

The diagnosis of myeloma may not be obvious even in a “typical” case, as the presenting symptoms are not specific. Increasingly, patients are referred for evaluation after seeking medical attention for unexplained anemia, neuropathy, or renal failure. Incidental finding of a monoclonal serum protein is also becoming more frequent. A comprehensive evaluation of patients suspicious for a diagnosis of myeloma starts with thorough history and physical examination. The clinical findings help to direct further investigations for the precise diagnosis and quantification of the extent of disease.

LABORATORY INVESTIGATION

Laboratory investigations are directed at defining various organ dysfunctions due to myeloma, and a number of studies, required for establishing a diagnosis and staging, should be routinely included.¹⁰⁹

HEMATOLOGIC EVALUATION

A complete blood count with differential is required. Optional determinations for serum iron, transferrin saturation, and ferritin are done for patients with microcytic indices, while serum folate and vitamin B₁₂ level are evaluated for those with macrocytic indices.

BIOCHEMICAL EVALUATION

Serum blood urea nitrogen, creatinine, electrolytes, and serum calcium are required tests. Serum albumin, lactate dehydrogenase, β_2 -microglobulin, and C-reactive protein (CRP) are useful prognostic markers.

IMMUNOGLOBULIN MEASUREMENTS

Serum protein electrophoresis is required for detecting monoclonal Ig. Cellulose acetate or agarose gel electrophoresis is commonly used. The latter was shown to be more sensitive.¹¹⁰ A monoclonal immunoglobulin (M spike) is identified as a discrete, homogeneous band on electrophoresis or as spikes in the γ , β , or α_2 region of the densitometer tracing. Two M proteins may occur

rarely (biclonal gammopathy). Immunofixation is then used to determine the isotype of the paraprotein, using specific antibodies to γ , α , μ , δ , and/or ϵ heavy-chain isotypes and to κ and λ light-chain isotypes. Typing for IgD and IgE is not routinely done and should be requested when IgD or IgE myeloma is suspected.

Urinary protein electrophoresis should be performed on an 80–100 \times concentrated random sample. Immunofixation electrophoresis more sensitive for detecting proteins in low concentration, should also be performed. If monoclonal free light chain is identified, a 24-h urine collection should be sent for quantifying daily excretion of light chain and other proteins, especially albumin. The urine dipstick is not sensitive to Bence Jones protein. Urinary light chains that occasionally form multiple, equally spaced bands (“ladder pattern”) are generally polyclonal.¹¹¹

BONE MARROW EXAMINATION (SEE ALSO CHAPTER 81)

A bone marrow aspiration and core biopsy are required for determining the extent and the histologic pattern of myeloma cell infiltration. The percent myeloma cells in the marrow should be enumerated. In selected cases, immunocytological studies, most commonly using immunoperoxidase staining, are performed for demonstrating light-chain restriction in monoclonal plasma cells. Other markers, such as Ki-67,¹¹² can be assessed. Optional flow cytometric study of the bone marrow is helpful in detailed characterization of the malignant myeloma cells. The nuclear ploidy, S-phase fraction, the expression of B-cell differentiation antigens, adhesion molecules, and occasionally the myeloid markers are of some prognostic interest. If available, a plasma cell labeling index, usually by bromodeoxyuridine labeling, should be obtained for its prognostic importance.³⁰ Cytogenetic and fluorescence in situ hybridization analyses for numeric and structural abnormalities and for specific rearrangement of chromosomes should be requested whenever possible. The cytogenetic analysis of myeloma cells has significant prognostic value and provides a basis for a molecularly based classification of myeloma (Chapters 80 and 81). Abnormalities in chromosome 13 are particularly ominous.¹¹³

IMAGING STUDIES

Plain X-ray

A skeletal survey is required and should include lateral and anteroposterior views of the skull, cervical, thoracic, and lumbar spines, chest, pelvis, femurs, and humeri. Radiographs of focal lesions are needed when clinically indicated. Myeloma involves most frequently the axial bones, the sites of red marrow. On X-ray, multiple, osteolytic lesions may be present, and are characteristically “punched out.” Extensive erosion

of the cortex in weight-bearing bones needs to be identified and may require urgent preventive measures to avoid pathologic fracture.

Radionuclide scans

Diphosphonate Conventional diphosphonate radionuclide bone scans, depending on the osteoblastic activity of the lesion, have a sensitivity of only 40–60% and thus are of limited use.^{114,115}

Tc 99m MIBI

Scanning with Tc 99m 2-methoxyisobutylisonitrile, a lipophilic, cationic agent accumulated in metabolically active tissues and extruded from the cells through MDR-1 p-glycoprotein, has recently been shown to have a higher sensitivity. Diffuse bone marrow uptake or focal enhanced bone lesions may be detected. The latter lesions are concordant with radiographic bone lesions in about 70% of the cases. It was suggested that the lesions detected by Tc 99m MIBI represented active disease sites, and the intensity of radionuclide uptake correlated with the disease activity, as reflected by high levels of disease markers, such as β 2-microglobulin and CRP.^{116–118} Its clinical utility is still experimental.

¹⁸F-FDG PET

Whole-body ¹⁸F-FDG-PET also detects diffuse and/or focal increased uptake of radionuclide in myeloma patients. In a study of 66 patients, a positive scan was obtained in all 16 untreated patients with active myeloma, including four (25%) who had a negative radiographic bone survey.¹⁰⁶ Extramedullary plasmacytoma was detected and verified by histologic examination. Importantly, tests for MGUS were negative, and new lesions were found in relapsed patients. A comparative study with Tc 99m MIBI and FDG-PET suggests the former reflects more the extent of disease, while the latter is more sensitive to active proliferative lesions.¹¹⁹ The validity of FDG-PET has yet to be determined.

COMPUTED TOMOGRAPHY

Computed tomography (CT) detects bone destruction similar to plain radiographs, but with higher sensitivity.

MAGNETIC RESONANCE IMAGING

MRI is useful in detecting myelomatous involvement of the bone marrow. The patterns of infiltration can be focal, diffuse, or mixed.¹²⁰ In a study of 77 patients examined with MRIs of the thoracic and lumbar spines, three stages of bone disease could be graded: stage I, no focal or diffuse infiltration; stage II, ≤ 10 foci or mild diffuse infiltration; and stage III, > 10 foci or strong diffuse infiltration. This MRI staging correlates strongly with survival and can be used as a bone lesion scale in Durie–Salmon staging system.¹²¹ MRI is also useful in following bone lesions after treatment, as plain radiographs may not show significant changes,

Table 82.4 Diagnostic criteria for (symptomatic) multiple myeloma

(1) Tumor criteria: Monoclonal plasma cells in the bone marrow >10% and/or Biopsy-documented plasmacytoma Monoclonal protein in serum and/or urine
(2) End organ damages, one or more of the following C alcium elevation in the blood (serum calcium >10.5 mg/dl or upper limit of normal) R enal insufficiency (serum creatinine >2 mg/dl) A nemia (hemoglobin <10 g/dl or 2 g/dl < normal) B one disease: lytic lesions or osteoporosis Others: symptomatic hyperviscosity, amyloidosis, recurrent bacterial infections (>2 episodes in 12 months)

For patients with a solitary bone lesion or osteoporosis without fracture as the sole defining criteria, $\geq 30\%$ bone marrow plasmacytosis is required for the diagnosis of systemic myeloma. For monoclonal protein, no specific level is required and it is absent in non-secretory myeloma.

even in responsive disease.¹²² MRI is the current imaging of choice in evaluating spinal cord compression.

Imaging studies, other than plain radiography, are not routinely used. MRI and PET appear promising, and further investigations may find them useful in detecting focal or residual disease and in better quantifying the extent of disease.¹²³

DIFFERENTIAL DIAGNOSIS

The required investigations detailed above assure the gathering of sufficient information for making the diagnosis. In most patients with symptomatic, progressive myeloma, the diagnosis is readily made by the presence of marked bone marrow plasmacytosis, monoclonal protein in serum and/or urine, and osteolytic bone lesions, all the major criteria for myeloma. Minor criteria, including anemia, hypercalcemia, renal insufficiency, and suppression of nonparaproteins, help establish the diagnosis in cases where bone disease is not obvious.¹²⁴ The myeloma-related disorders, however, are a heterogeneous group, including multiple

myeloma, smoldering myeloma, indolent myeloma, MGUS, solitary plasmacytoma of the bone, extramedullary plasmacytoma, and plasma cell leukemia. In addition, systemic AL amyloidosis, Waldenstrom's macroglobulinemia, and heavy-chain diseases also share the features of the neoplasia of Ig-secreting cells (see Chapters 88 and 90). The distinction among some of these disorders is not precise, and the diagnostic criteria used vary among experts. A number of classification systems are often used, including that by Durie-Salmon,¹²⁵ by the Mayo group,^{2,126} the Southwest Oncology Group (SWOG),¹²⁷ and by the British Columbia Cancer Agency.¹²⁸ A comparison of these classification systems in 157 patients with plasma cell dyscrasias showed that 80% of the cases could be classified by all systems, and in 64%, the diagnosis was concordant. Not unexpectedly, the discrepancies occurred primarily among the smoldering myeloma, indolent myeloma, and multiple myeloma stage I groups.¹²⁴ Thus, currently, the selection of a particular diagnosis and classification system makes relatively little difference in treatment approach.

Recent efforts by international groups aim at simplifying the classification for uniform application.^{123,129} Recognizing that myeloma-related disorders have a wide spectrum of overlapping features, the proposed classification emphasizes the importance of myeloma-related organ or tissue impairment (end-organ damage) in the clinical course of patients and in decision making for systemic therapy. The proposed diagnostic criteria, not greatly different from current classifications, have greater clarity.^{123,129} Tables 82.4–82.6 list the criteria for (symptomatic) multiple myeloma, MGUS, smoldering (indolent or asymptomatic) myeloma, nonsecretory myeloma, solitary plasmacytoma of the bone, and extramedullary plasmacytoma. In addition, plasma cell leukemia is defined by the presence of monoclonal plasma cells of $\geq 2000/\mu\text{L}$ in the peripheral blood and $\geq 20\%$ plasma cells in WBC differential count.

The biological basis for various classifications of myeloma-related disorders is unclear. Molecular studies have shown that similar genetic alterations occur in all variants of myeloma,¹³⁰ and in gene expression profiling, MGUS is not distinguishable from early

Table 82.5 Diagnostic criteria for monoclonal gammopathy of undetermined significance (MGUS), smoldering or indolent or asymptomatic myeloma (SM), and non-secretory myeloma (NSMM)

	MGUS	SM	NSMM
(1) Monoclonal plasma cells in the bone marrow	<10%	$\geq 10\%$	$\geq 10\%$
(2) M-spike: serum IgG or serum IgA or urine Bence Jones protein	<3.0 g/dl <2.0 g/dl; <1.0 g/24 h	≥ 3.0 g/dl ≥ 2.0 g/dl ≥ 1.0 g/24 h	absent ^a absent ^a absent ^a
(3) End organ damage	absent	absent	presnet

^aby immunofixation.

Presence of all three criteria are required for diagnosis, except in SM where only one of (1) and (2) criteria is sufficient.

Table 82.6 Solitary plasmacytoma of the bone, solitary extramedullary plasmacytoma

	Solitary plasmacytoma of the bone	Solitary extramedullary plasmacytoma
Biopsy-documented plasmacytoma	Bone, single site ^a	Extrasosseous, single site ^a
Monoclonal plasma cells in the bone marrow	<10%	Normal bone marrow
M protein in serum and/or urine	Absent ^b	Absent ^b
End-organ damage	Absent	Absent

^aX-ray and MRI and/or FDG-PET imaging (if performed) should be negative outside of the primary site.

^bLow concentration of M protein may be present in some patients (and may decrease after local treatment).

myeloma.^{131,132} Nevertheless, the classification provides a useful framework for clinical approach to patients with these disorders.

CONCLUDING REMARKS

Past investigations in myeloma and its related diseases have been fruitful in delineating the pathophysiologic processes of these disorders, and in elucidating the

basic biology of the immune system. Continued research in this area promises to refine our understanding of these disorders and, more importantly, will identify molecular targets for the next generation of effective therapeutics.

Acknowledgment

The help of my wife, Yu-His Chen, MD, in preparing this manuscript is acknowledged with gratitude and affection.

Chapter 83

INITIAL TREATMENT APPROACH TO MULTIPLE MYELOMA

Jeffrey A. Zonder

INTRODUCTION

Most of the 15,000 people per year in the United States who develop multiple myeloma (MM)¹ require some form of treatment at the time of diagnosis. Combination regimens incorporating alkylating agents, corticosteroids, and/or anthracyclines have been used for decades, with little overall progress during that time in terms of survival or cure rate.^{2,3} High-dose chemotherapy with autologous stem cell support (HDC/ASCS), shown in some studies to offer a modest survival benefit, is nonetheless noncurative (summarized below, and in greater detail in Chapter 90). Thalidomide plus dexamethasone (TD) has recently emerged as the most widely used front-line regimens in the United States, and other thalidomide-containing combinations, as well as ones incorporating bortezomib (Velcade; PS-341) or lenalidomide (Revlimid; CC-5013), are currently being studied. New regimens are often difficult to compare to more established therapies for a variety of reasons. The most important endpoint of therapy, survival, is not known for many newer regimens. Additionally, with the exception of Melphalan-Prednisone-Thalidomide (MPT), newer combinations have not been compared in a randomized fashion to standards like Melphalan-Prednisone (MP) or Vincristine-Doxorubicin (Adriamycin)-Dexamethasone (VAD) (described in detail below, Tables 83.1 and 83.2). Increasingly, surrogate endpoints are being used to assess new agents and combinations, with some debate as to the best indicator of clinical efficacy. Though it is widely held that complete response (CR) rate is the best predictor of long-term survival,^{4,5} some investigators have shown other endpoints such as time to disease progression may correlate more strongly.⁶ There is the least amount of data to support the use of partial reduction in serum or urine M-protein concentration as a surrogate efficacy endpoint, but it is often used in Phase II studies where the goal is often to determine if a regimen has enough “promise” to warrant larger-scale Phase III trials. For further discussion regarding response assessment, please refer to Chapter 91.

When treatment for a patient with newly diagnosed MM is being considered, the first question the clinician must ask is, “Does the patient require *any* treatment right now?” Definite indications for therapy include bone pain or the presence of multiple lytic skeletal lesions, cytopenias or renal dysfunction without other identifiable causes, hypercalcemia, or a high serum or urine M-protein level. Less common manifestations, such as amyloidosis or paraprotein-related hyperviscosity, also represent indications to initiate systemic therapy. Recently published management guidelines emphasize that asymptomatic newly diagnosed myeloma (formerly termed indolent or smoldering myeloma) should *not* be treated with cytotoxic therapy.⁷ It is clear that many of these patients can be followed for an extended period of time without intervention or complications.⁸ At least two randomized studies have addressed this point. In the first, a group of Swedish investigators randomized 50 patients with asymptomatic MM to either immediate or deferred therapy with MP.⁹ There were no differences in response rate, response duration, or survival, despite the fact that therapy was started on average a year later in the deferred-therapy arm. Riccardi et al. also found no differences in response rate or overall survival (OS) amongst 145 patients enrolled on a prospective study with a similar design.¹⁰ In contrast to the Swedish experience, patients treated at the time of disease progression had a shorter duration of response. Thalidomide, 200–800 mg/day, has been investigated as treatment of asymptomatic MM in a group of 29 patients at the Mayo Clinic.¹¹ Although the majority of patients exhibited reduction in M-protein levels, 37% of patients progressed to symptomatic myeloma by 2 years, and 28% experienced grade 3–4 drug toxicity. It is thus premature to recommend the use of thalidomide in this setting outside of a clinical trial designed to assess whether it retards the time to progression to overt disease compared to observation alone. Initiation of bisphosphonates in patients with asymptomatic MM in an effort to prevent the development of symptomatic skeletal disease is also being

Table 83.1 Combination chemotherapy regimens for multiple myeloma

Regimen	Drugs	Doses	Frequency
MP	Melphalan Prednisone	8–9 mg/m ² PO, days 1–4 60 mg/m ² (or 100 mg) PO, days 1–4	q 28 days
M2 (VBMCP) ³¹	Vincristine Carmustine (BCNU) Melphalan Cyclophosphamide Prednisone	0.03 mg/kg IVP, day 1 1 mg/kg IVPB, day 1 0.1 mg/kg PO, days 1–7 1 mg/kg IVPB, day 1 1 mg/kg PO, days 1–7	q 28 days
VMCP/VBAP ³⁴	Vincristine Melphalan Cyclophosphamide Prednisone (alternating with) Vincristine Carmustine (BCNU) Doxorubicin Prednisone	1 mg IVP, day 1 5–6 mg/m ² PO, days 1–4 100–125 mg/m ² PO, days 1–4 60 mg/m ² PO, days 1–4 1 mg IVP, day 1 30 mg/m ² IVPB, day 1 30 mg/m ² IVP, day 1 60 mg/m ² PO, days 1–4	q 28 days
ABCM ⁷⁷	Doxorubicin Carmustine (BCNU) Cyclophosphamide Melphalan	30 mg/m ² IVP, day 1 30 mg/m ² IVPB, day 1 100 mg/m ² PO, days 22–25 6 mg/m ² PO, days 22–25	q 5–6 weeks
EDAP ⁴⁴	Etoposide Dexamethasone Cytarabine (Ara-C) Cisplatin	100 mg/m ² /day, CIV, days 1–4 40 mg/day IV / PO, days 1–4 1 g/m ² IVPB, day 5 25 mg/m ² /day, CIV, days 1–4	q 28 days
DCEP ^{111,162}	Dexamethasone Cyclophosphamide Etoposide Cisplatin	40 mg/day, IV / PO, days 1–4 400 mg/m ² /day, CIV, days 1–4 40 mg/m ² /day, CIV, days 1–4 10 mg/m ² /day, CIV, days 1–4	q 28 days
MOCCA ¹⁶³	Methylprednisolone Vincristine Lomustine (CCNU) Cyclophosphamide Melphalan	0.8 mg/kg PO, days 1–7 0.03 mg/kg IVP, day 1 40 mg PO, day 1 10 mg/kg IVPB, day 1 0.25 mg/kg PO, days 1–4	q 35 days

explored,¹² but there is insufficient data to support routine use at present,¹³ particularly in light of the recently recognized association between long-term bisphosphonate use and the uncommon but potentially serious problem of osteonecrosis of the jaw (ONJ).^{14, 15}

CONVENTIONAL REGIMENS FOR INITIAL THERAPY OF MULTIPLE MYELOMA

MELPHALAN AND OTHER ALKYLATING AGENTS

Melphalan, usually in combination with prednisone (the “MP” regimen, Table 83.1), has been used to treat MM since the 1960s. A small randomized study comparing different schedules of melphalan, with or without prednisone, showed a distinct advantage in favor of intermittent (“pulse”) melphalan with prednisone as compared to either pulse or daily melphalan alone,¹⁶ though not all subsequent studies have con-

firmed superiority of this schedule.^{17, 18} In the MP regimen, the initial dose of oral melphalan is 8–9 mg/m² daily along with prednisone 100 mg/day (or 60 mg/m²/day) for four consecutive days, approximately every 4 weeks. While the oral administration of melphalan is convenient, absorption can sometimes be unpredictable,¹⁹ and therefore the dose may need to be titrated upward in subsequent cycles, until modest myelosuppression (i.e., absolute neutrophil count ~1000/MM³ weeks after the start of the cycle) is seen. Also, in patients with renal insufficiency, pronounced cytopenias can develop with full melphalan dosing, and a starting dose of 4–6 mg/m²/day for 4 days is recommended, with careful monitoring of hematologic toxicity. Objective responses, usually occurring within the first two to three cycles of MP, can be expected in 50–60% of patients and last on average 1.5–2 years.²⁰ Because of the low toxicity and ease of administration of oral MP, it is often selected as the initial therapy in

Table 83.2 Dosage schedules for VAD and related regimens

Regimen	Drugs	Doses	Frequency
VAD ³⁷	Vincristine Doxorubicin Dexamethasone	0.4 mg/day, CIV, days 1–4 9 mg/m ² /day, CIV, days 1–4 40 mg/d, days 1–4, 9–12, 17–20 (odd cycles) days 1–4, 14–18 (even cycles) (alternatively, DEX on days 1–4 and 14–18 every cycle, using a q 28 day schedule)	q 28–35 d
Bolus VAD ¹⁶⁴	Vincristine Doxorubicin Dexamethasone	0.4 mg/day, CIV, days 1–4 9 mg/m ² /day, CIV, days 1–4 40 mg/day, days 1–4, 9–12, 17–20 (odd cycles) days 1–4, 14–18 (even cycles)	q 28–35 d
DVd ⁴⁹	Liposomal Doxorubicin (Doxil) Vincristine Dexamethasone	40 mg/m ² , IVPB, day 1 2 mg IVP, day 1 40 mg/day, PO/IV, days 1–4	q 28 days
VAMP ⁴² (C-VAMP)	Vincristine Doxorubicin Methylprednisolone (add Cyclophosphamide)	0.4 mg/day, CIV, days 1–4 9 mg/m ² /day, CIV, days 1–4 1 g, IV/PO, days 1–5 (500 mg/m ² IVPB, days 1, 8, 15)	q 28 days
MOD ⁴¹	Mitoxantrone Vincristine Dexamethasone	9 mg/m ² /day, CIV, days 1–4 0.4 mg/day, CIV, days 1–4 40 mg/day, days 1–4, 9–12, 17–20	q 35 days
VND ⁴³	Vincristine Mitoxantrone Dexamethasone	0.4 mg/day, CIV, days 1–4 3 mg/m ² /day, CIV, days 1–4 40 mg/day, days 1–4	q 28 days
VECD ⁵⁰	Vincristine Epirubicin Cyclophosphamide Dexamethasone	1.5 mg IVP, day 1 20 mg/m ² IVP, days 2, 3 200 mg/m ² IVPB, days 1–3 20 mg/m ² PO/IV, days 1–5	q 28 days
VID ⁵⁴	Vincristine Idarubicin (oral) Dexamethasone	1.6 mg/m ² IVP (max: 2 mg), day 1 10 mg/m ² PO, days 1–4 40 mg/d PO/IV, days 1–4, 9–12, 17–20	q 28 days
Z-Dex ⁵³	Idarubicin (oral) Dexamethasone	10 mg/m ² PO, days 1–4 40 mg/d PO/IV, d 1–4	q 28 days

elderly patients and other patients not going on to HDC/ASCS (see discussion below).

Oral cyclophosphamide (Cytoxan), with or without steroids, has been shown to be equally effective as oral melphalan.^{21, 22} Intravenous (IV) cyclophosphamide, 600–1200 mg/m² every 3–6 weeks, is effective therapy and is also a viable alternative to oral melphalan.^{23, 24} More intensive IV cyclophosphamide dosing, such as 600 mg/m²/day for four consecutive days, is feasible²⁵ but not typically considered because of the effectiveness of less-toxic lower doses. Very high-dose IV cyclophosphamide (i.e., 4–7 g/m² followed by G-CSF or GM-CSF) is often used after induction to mobilize stem cells for collection prior to HDC/ASCS.^{26–28} It is likely that high-dose cyclophosphamide priming provides additional antimyeloma effect beyond that achieved by prior induction therapy,²⁹ though there is no evidence that this results in any benefit over priming with growth factors alone in terms of transplant outcome.³⁰

Many alkylator-based combination chemotherapy regimens have been evaluated and compared to MP. A meta-analysis showed no difference in response duration or OS in more than 6600 patients participating in 27 randomized trials,²⁰ but two particular regimens warrant comment. The M2 regimen (see Table 83.1) generated interest in the United States after an Eastern Cooperative Oncology Group (ECOG) randomized trial demonstrated modest superiority over MP.³¹ Objective responses occurred in more than 70% of patients receiving M2, but 5-year OS was an unimpressive 26%. In contrast, a European study comparing VAD and M2 did not demonstrate superior response rate or OS for the 46 patients treated with M2.³² Interest in this regimen may be revived somewhat by the recent report of the US Intergroup study comparing VAD followed by two cycles of M2 versus VAD followed by HDC/ASCS in more than 800 patients, discussed in detail below, in which patients treated with

M2, had equivalent overall outcomes to those getting HDC/ASCS.³³ VMCP alternating with VBAP (VMCP/VBAP, Table 83.1) was used in the positive IFM 90 HDC/ASCS study.³⁴ All patients received VMCP/VBAP induction, and then patients randomized to conventional therapy received additional cycles of the same regimen. In a SWOG study comparing VMCP/VBAP to MP, the alternating regimen demonstrated a superior response rate (53% vs 32%) and median OS (43 months vs 23 months).³⁵ Another randomized study comparing these regimens, however, did not demonstrate either a response rate or survival advantage for VMCP/VBAP.³⁶

VAD AND RELATED REGIMENS

With no overall improvement in outcome seen with the alkylator-based combination regimens developed in the 1970s and 1980s, regimens utilizing anthracyclines administered by continuous infusion were developed, with the rationale that continuous drug exposure would more effectively target slowly cycling plasma cells. One such regimen is VAD: vincristine 0.4 mg/day and doxorubicin (Adriamycin) 9 mg/m²/day as a continuous infusion, with pulses of dexamethasone (orally or IV intravenously) 40 mg/day on days 1–4, 9–11, 17–20 in repeating 28- to 35-day cycles.³⁷ Approximately two-thirds of previously untreated patients will respond to VAD, usually within two to three cycles.^{38–40} Unfortunately, despite the continuous infusion of chemotherapy in VAD and other regimens^{41–43} (see Table 83.2), the majority of these responses are partial,^{38–40, 42, 44} as seen with earlier bolus regimens. Also, long-term survival of nontransplanted myeloma patients treated with VAD is not significantly better than that seen with MP.^{3, 20} VAD is a reasonable option in patients with renal insufficiency because, in contrast to melphalan, neither vincristine nor doxorubicin requires dosage adjustment for impaired creatinine clearance. The widespread popularity of VAD since its advent in the 1980s until the last few years is accounted for by another factor as well: the dramatic increase in the use of HDC/ASCS. Several groups have reported a clear negative impact on stem cell mobilization and subsequent engraftment (particularly platelets) from prior melphalan therapy.^{45–47} Accordingly, VAD (two to four cycles) was often the initial regimen used in patients for whom HDC/ASCS was planned. More recently, TD has supplanted VAD as the most widely used regimen in such patients.

Central line placement and use of an ambulatory pump for regimens like VAD are inconvenient and are associated with infections and thrombotic complications. This, and the recognition that infusional regimens have not changed the overall course of MM compared to MP, has led to interest in more convenient bolus or oral variations on VAD (see Table 83.2). Randomized studies have shown that both “bolus

VAD,” with the standard doses of each drug given as an IV injection on days 1–4, and also the DVd regimen have similar efficacy to traditional VAD.^{48, 49} DVd consists of pegylated doxorubicin (Doxil™) 40 mg/m² IVPB on day 1, Vincristine 2 mg IVP on day 1, and dexamethasone 40 mg/day on days 1–4. In a Phase II study, DVd induced major responses in 88% of newly diagnosed patients and was well tolerated overall.⁴⁹ It is noteworthy that grade 3–4 palmar-plantar erythrodysesthesia, a Doxil-related toxicity not seen with traditional VAD, occurred in approximately 20% of patients. The VECD protocol, using bolus injections of vincristine 1.5 mg day 1 and epirubicin 20 mg/m² days 2 and 3 with 1-hour infusions of cyclophosphamide 200 mg/m² days 1–3 and oral dexamethasone 20 mg/m² days 1–5, is yet another regimen with comparable efficacy to VAD.⁵⁰ Bolus VAD or VECD are less expensive than either standard infusional VAD⁵¹ or DVd. In a preliminary cost analysis, DVd was shown to be less costly than VAD if the latter was administered on an inpatient basis.⁵² Given the significantly higher drug costs associated with DVd,⁵² this might not hold true at centers where both regimens are given in the outpatient setting.

Oral VAD variants have also been developed, and these are likely to have similar efficacy to traditional VAD.^{53, 54} The lack of availability of oral anthracyclines in the United States at present makes these less relevant for standard practice, however.

HIGH-DOSE DEXAMETHASONE MONOTHERAPY

Dexamethasone, 20 mg/m²/day on days 1–4, 9–12, and 17–20, induces responses in previously untreated patients with MM 40–50% of the time,^{55, 56} suggesting that dexamethasone accounts for most of the benefit derived from VAD and TD (described below). Dexamethasone monotherapy may be preferred for frail patients, since the toxicity is generally less than that seen with VAD or TD. Still, primary pulse dexamethasone treatment is somewhat more toxic than MP,⁵⁷ and patients should be monitored closely for specific side effects, including hyperglycemia, gastrointestinal bleeding, mood disorder, insomnia, weight gain, increased susceptibility to infections, and rarely pancreatitis.⁵⁸

THALIDOMIDE AND DEXAMETHASONE

Thalidomide has activity against relapsed and refractory myeloma as a single agent^{59–65} and in combination with pulse dexamethasone,^{66, 67} with responses noted in 25–55% of patients in various trials. In two large Phase II studies of TD in previously *untreated* patients, response rates of 64% and 72% were reported.^{68, 69} Investigators from the Mayo Clinic treated 50 patients with 200 mg of thalidomide daily with dexamethasone 40 mg/day on days 1–4, 9–12, and 17–20.⁶⁸ In the other study, 40 patients at M.D. Anderson Cancer Center (MDACC) were started on

thalidomide 100–200 mg daily with dose increase to 400 mg/day allowed (median maximum dose achieved was 200 mg/day), and dexamethasone 20 mg/m² on the same schedule as in the Mayo trial.⁶⁹ As would be predicted from trials involving patients with relapsed/refractory MM,^{65, 66} thalidomide therapy caused neuropathy, sedation, and constipation. Thrombotic complications occurred in 12% and 15% of patients treated in these two induction trials. In the MDACC study, a 25% thrombosis rate was observed in the first 24 patients treated, despite prophylaxis with 1 mg of coumadin daily. The next 16 patients received therapeutic doses of coumadin or low-molecular-weight heparin and no thrombotic events occurred.⁶⁹ Based on the results of these Phase II trials, a randomized study comparing TD to dexamethasone alone was undertaken by ECOG. In this study, after four cycles of randomized therapy, patients with at least stable disease were given the option of proceeding to HDC/ASCS. Although a statistically higher response rate was observed in the patients treated with TD (63% vs 41%), they also experienced more toxicity (including thrombotic complications), without any difference in survival.⁷⁰ TD induction has no negative effect on stem cell collection and quality of subsequent engraftment in patients treated with going on to HDC/ASCS.^{68, 70, 71} Conclusions regarding the long-term outcome for patients treated with TD *without* subsequent HDC/ASCS on this ECOG study are limited because almost all patients went on to high-dose therapy. The overall duration of response and survival for the 21 patients continuing TD beyond four cycles were 18 and 21 months, respectively,⁷² similar to the rates noted in the initial report of a large randomized trial of dexamethasone ± thalidomide without HDC/ASCS (TTP: 17 months, OS: 25 months).⁷³ These results are very similar to what one can expect from traditional cytotoxic regimens such as VAD. This, plus the fact that this convenient oral regimen can be used safely prior to HDC/ASCS or in the setting of renal insufficiency,⁷⁴ has made TD the most widely used induction regimen in the United States.

HIGH-DOSE CHEMOTHERAPY AND AUTOLOGOUS STEM CELL SUPPORT

The role of HDC/ASCS is somewhat controversial at present. Many clinicians consider HDC/ASCS to be the “standard of care” for suitable candidates early in the course of their treatment, typically after two to four cycles of induction therapy. The data available from published studies has recently been summarized in overviews and management guidelines,^{7, 55, 75} and will be reviewed here briefly (also, refer to Chapter 90).

A randomized trial from the Intergroupe Francophone du Myélome (IFM) comparing HDC/ASCS to nonmyeloablative therapy (VMCP/VBAP) demonstrated a supe-

rior outcome for those patients treated with intensive therapy.³⁴ In this trial involving 200 patients aged 65 years or less, the myeloablative preparative regimen consisted of melphalan 140 mg/m² plus 8 Gy total body irradiation. The response rate, 5-year event-free survival (EFS) and 5-year OS were all higher in the transplant arm of the trial (81% vs 55%, 28% vs 10%, and 52% vs 12%, respectively). The median OS for the HDC/ASCS arm was just over 1 year longer (57 months vs 44 months). A similar 1-year OS advantage (54 months vs 42 months) was also demonstrated in the more recent Medical Research Council (MRC) VII trial,⁷⁶ which involved 401 patients randomized to either HDC/ASCS or a conventional chemotherapy (“ABCM,”⁷⁷ Table 83.1). The fact that the transplanted patients in the MRC study did not do any better than those in the IFM trial is disappointing, since the patients in the MRC study received stem cells instead of bone marrow, and generally received a transplant preparative regimen (melphalan 200 mg/m² (MEL 200)) proven to be superior to that used in the IFM study.⁷⁸

Two nonrandomized studies comparing the outcome of HDC/ASCS to historical controls also suggest survival benefit from transplant. The Arkansas group compared outcome for 123 patients treated with the “Total Therapy I (TTI)” tandem transplant regimen with that of matched historical controls treated on prior Southwest Oncology Group (SWOG) with conventional chemotherapy.⁷⁹ Median EFS and OS were 49 and 62 months in the TTI group versus 22 and 48 months in the conventionally treated group. The Nordic Myeloma Study Group compared the results of therapy in 274 patients treated with HDC/ASCS and 274 matched historical controls who would have met current criteria for HDC/ASCS.⁸⁰ The intensive therapy group had a 3-year OS of approximately 70% versus 55% in the nontransplant group. Log-rank comparison of the survival curves showed a difference that was highly statistically significant. Based on the preceding data, several experts in the field of MM have concluded that HDC/ASCS offers some benefit over standard regimens and it should be considered standard therapy for suitable patients.^{7, 55}

In contrast to the results of the above-mentioned studies, a preliminary report from the PETHEMA investigators of a randomized trial comparing continued conventional chemotherapy to HDC/ASCS (MEL 200) in more than 200 patients who responded to initial conventional chemotherapy showed a similar median OS of approximately 5.5 years for both groups.⁸¹ It is possible that the exclusion of patients who did not respond to initial chemotherapy influenced the outcome of this study, making the results difficult to compare with those of the IFM and MRC studies. The Dutch–Belgian Hemato-Oncology Cooperative Study Group (HOVON) also conducted a randomized study in which patients received either HDC/ASCS or

“intermediate dose melphalan” (140 mg/m²). EFS and OS were the same for each arm (21 vs 22 months, and 50 vs 47 months, respectively).⁸²

More recently, the preliminary results of a US Intergroup randomized study were reported, and as in the PETHEMA trial, no survival benefit was observed.⁸³ Following VAD induction and high-dose cyclophosphamide with stem cell collection, patients received either HDC/ASCS (MEL 140 + 12 Gy TBI) or two cycles of the M2 regimen. Eight hundred and four patients started VAD, but only 510 were randomized after induction. For nearly all of the almost 300 patients who did not proceed with randomization, the reason was failure to respond to induction therapy. Thirty-nine patients on this trial with matched sibling donors underwent allogeneic stem cell transplant before this arm of the study was closed due to a high (but not surprising) treatment-related mortality of 39% in the first year. In the other two arms, there was no difference in the response rate, 7-year progression free survival (17% for HDC/ASCS vs 16% for chemotherapy), or 7-year OS (37% vs 42%). Interestingly, despite the early mortality seen in the small group of patients who underwent allogeneic transplantation, there was a 7-year OS of approximately 40% (very similar to that for the other groups), with an apparent survival curve plateau suggesting possible cures in some cases.³³ Reasons offered by the investigators for the lack of benefit with HDC/ASCS include unexpectedly good outcome in the conventional therapy arm compared to prior experience and the fact that over half of the patients progressing after M2 went on to be treated with HDC/ASCS.³³ A previously published French randomized study demonstrated equivalent survival for patients randomized to treatment with HDC/ASCS as rescue therapy upon progression, versus immediately following conventional therapy,⁸⁴ lending some credence to the latter assertion. It is possible that improved supportive measures and postprogression use of newer antimyeloma agents such as thalidomide or bortezomib could have contributed to the longer-than-expected survival seen in this study, as well. Regardless of the reason(s), the equivalent results with nonmyeloablative therapy and HDC/ASCS in this large, well-conducted study will likely complicate decision making for patients and clinicians.

It has become evident that the subset of MM patients with deletion of all or part of chromosome 13 (Δ 13), detected by either standard cytogenetic techniques or by fluorescence in situ hybridization (FISH), have inferior outcome compared to patients lacking Δ 13.^{85–87} Even with tandem melphalan-based autologous transplants, the 5-year OS for patients with Δ 13 is only 16%,⁸⁵ slightly *inferior* to the 22% observed for similar patients treated in another trial with the nonmyeloablative VBMCP regimen.⁸⁸ With poor outcome despite HDC/ASCS consistently demonstrated, other treatment options ought to be explored. At our center,

we have offered patients under age 60 with Δ 13 HDC/ASCS followed by a nonmyeloablative (“mini”) allogeneic transplant. The rationale for this is to try and gain “graft-versus-myeloma” benefit^{89, 90} without the excessive early mortality seen with standard allogeneic transplantation.^{91, 92} There is published anecdotal evidence that patients with Δ 13 can enjoy extended benefit after such treatment.^{93, 94} Variations on this approach have been described in several published reports.^{94–96} Large studies more formally evaluating the strategy of HDC/ASCS “conditioning” followed by nonmyeloablative allogeneic stem cell transplant are currently underway.
