Ceramics are defined as the art and science of making and using solid articles that have as their essential component, inorganic nonmetallic materials [Kingery et al., 1976]. Ceramics are refractory, polycrystalline compounds, usually inorganic, including silicates, metallic oxides, carbides and various refractory hydrides, sulfides, and selenides. Oxides such as Al$_2$O$_3$, MgO, SiO$_2$, and ZrO$_2$ contain metallic and nonmetallic elements and ionic salts, such as NaCl, CsCl, and ZnS [Park and Lakes, 1992]. Exceptions to the preceding include covalently bonded ceramics such as diamond and carbonaceous structures like graphite and pyrolized carbons [Park and Lakes, 1992].

Ceramics in the form of pottery have been used by humans for thousands of years. Until recently, their use was somewhat limited because of their inherent brittleness, susceptibility to notches or micro-cracks, low tensile strength, and low impact strength. However, within the last 100 years, innovative techniques for fabricating ceramics have led to their use as "high tech" materials. In recent years, humans have realized that ceramics and their composites can also be used to augment or replace various parts of the

39-1

body, particularly bone. Thus, the ceramics used for the latter purposes are classified as *bioceramics*. Their relative inertness to the body fluids, high compressive strength, and aesthetically pleasing appearance led to the use of ceramics in dentistry as dental crowns. Some carbons have found use as implants especially for blood interfacing applications such as heart valves. Due to their high specific strength as fibers and their biocompatibility, ceramics are also being used as reinforcing components of composite implant materials and for tensile loading applications such as artificial tendon and ligaments [Park and Lakes, 1992].

Unlike metals and polymers, ceramics are difficult to shear plastically due to the (ionic) nature of the bonding and minimum number of slip systems. These characteristics make the ceramics nonductile and are responsible for almost zero creep at room temperature [Park and Lakes, 1992]. Consequently, ceramics are very susceptible to notches or microcracks because instead of undergoing plastic deformation (or yield) they will fracture elastically on initiation of a crack. At the crack tip the stress could be many times higher than the stress in the material away from the tip, resulting in a *stress concentration* which weakens the material considerably. The latter makes it difficult to predict the tensile strength of the material (ceramic). This is also the reason ceramics have low tensile strength compared to compressive strength. If a ceramic is flawless, it is very strong even when subjected to tension. Flawless glass fibers have twice the tensile strengths of high strength steel ($\sim$7 GPa) [Park and Lakes, 1992].

Ceramics are generally hard; in fact, the measurement of hardness is calibrated against ceramic materials. Diamond is the hardest, with a hardness index of 10 on Moh's scale, and talc ($Mg_3Si_3O_{10}COH$) is the softest ceramic (Moh's hardness 1), while ceramics such as **alumina** (Al_2O_3; hardness 9), quartz (SiO_2; hardness 8), and apatite ($Ca_5P_3O_{12}F$; hardness 5) are in the middle range. Other characteristics of ceramic materials are (1) their high melting temperatures and (2) low conductivity of electricity and heat. These characteristics are due to the chemical bonding within ceramics.

In order to be classified as a bioceramic, the ceramic material must meet or exceed the properties listed in Table 39.1. The number of specific ceramics currently in use or under investigation cannot be accounted for in the space available for bioceramics in this book. Thus, this chapter will focus on a general overview of the relatively bioinert, bioactive or surface reactive ceramics, and biodegradable or resorbable bioceramics.

Ceramics used in fabricating implants can be classified as nonabsorbable (relatively inert), bioactive or surface reactive (semi-inert) [Hench, 1991, 1993] and biodegradable or resorbable (non-inert) [Hentrich et al., 1971; Graves et al., 1972]. Alumina, zirconia, silicone nitrides, and carbons are inert bioceramics. Certain **glass ceramics** and dense **hydroxyapatites** are semi-inert (bioreactive) and **calcium phosphates** and calcium aluminates are resorbable ceramics [Park and Lakes, 1992].

39.2 Nonabsorbable or Relatively Bioinert Bioceramics

39.2.1 Relatively Bioinert Ceramics

Relatively bioinert ceramics maintain their physical and mechanical properties while in the host. They resist corrosion and wear and have all the properties listed for bioceramics in Table 39.1. Examples of relatively bioinert ceramics are dense and porous aluminum oxides, zirconia ceramics, and single phase calcium aluminates (Table 39.2). Relatively bioinert ceramics are typically used as structural-support

TABLE 39.1 Desired Properties of Implantable Bioceramics

1. Should be nontoxic
2. Should be noncarcinogenic
3. Should be nonallergic
4. Should be noninflammatory
5. Should be biocompatible
6. Should be biofunctional for its lifetime in the host

implants. Some of these are bone plates, bone screws, and femoral heads (Table 39.3). Examples of nonstructural support uses are ventilation tubes, sterilization devices [Feenstra and de Groot, 1983] and drug delivery devices (see Table 39.3).

39.2.2 Alumina (Al_2O_3)

The main source of high purity alumina (aluminum oxide, Al_2O_3) is bauxite and native corundum. The commonly available alumina (alpha, α) can be prepared by calcining alumina trihydrate. The chemical composition and density of commercially available "pure" calcined alumina are given in Table 39.4. The American Society for Testing and Materials (ASTM) specifies that alumina for implant use should contain 99.5% pure alumina and less than 0.1% combined SiO_2 and alkali oxides (mostly Na_2O) (F603-78).

Alpha alumina has a rhombohedral crystal structure ($a = 4.758$ Å and $c = 12.991$ Å). Natural alumina is known as sapphire or ruby, depending on the types of impurities which give rise to color. The single

crystal form of alumina has been used successfully to make implants [Kawahara, 1989; Park 1991]. Single crystal alumina can be made by feeding fine alumina powders onto the surface of a seed crystal which is slowly withdrawn from an electric arc or oxy-hydrogen flame as the fused powder builds up. Single crystals of alumina up to 10 cm in diameter have been grown by this method [Park and Lakes, 1992].

The strength of polycrystalline alumina depends on its grain size and porosity. Generally, the smaller the grains, the lower the porosity and the higher the strength [Park and Lakes, 1992]. The ASTM standards (F603-78) requires a flexural strength greater than 400 MPa and elastic modulus of 380 GPa (Table 39.5).

Aluminum oxide has been used in the area of orthopaedics for more than 25 years [Hench, 1991]. Single crystal alumina has been used in orthopaedics and dental surgery for almost 20 years. Alumina is usually a quite hard material, its hardness varies from 20 to 30 GPa. This high hardness permits its use as an abrasive (emery) and as bearings for watch movements [Park and Lakes, 1992]. Both polycrystalline and single crystal alumina have been used clinically. The high hardness is accompanied by low friction and wear and inertness to the *in vivo* environment. These properties make alumina an ideal material for use in joint replacements [Park and Lakes, 1992]. Aluminum oxide implants in bones of rhesus monkeys have shown no signs of rejection or toxicity for 350 days [Graves et al., 1972; Hentrich et al., 1971]. One of the most popular uses for aluminum oxide is in total hip protheses. Aluminum oxide hip protheses

with an ultra-high molecular weight polyethylene (UHMWPE) socket have been claimed to be a better device than a metal prostheses with a UHMWPE socket [Oonishi, 1992]. However, the key for success of any implant, besides the correct surgical implantation, is the highest possible quality control during fabrication of the material and the production of the implant [Hench, 1991].

39.2.3 Zirconia (ZrO$_2$)

Pure zirconia can be obtained from chemical conversion of zircon (ZrSiO$_4$), which is an abundant mineral deposit [Park and Lakes, 1992]. Zirconia has a high melting temperature ($T_m = 2953$ K) and chemical stability with $a = 5.145$ Å, $b = 0.521$ Å, $c = 5.311$ Å, and $\beta = 99°14$ in [Park and Lakes, 1992]. It undergoes a large volume change during phase changes at high temperature in pure form; therefore, a dopant oxide such as Y$_2$O$_3$ is used to stabilize the high temperature (cubic) phase. We have used 6 mole% Y$_2$O$_3$ as dopant to make zirconia for implantation in bone [Hentrich et al., 1971]. Zirconia produced in this manner is referred to as *partially stabilized* zirconia [Drennan and Steele, 1991]. However, the physical properties of zirconia are somewhat inferior to that of alumina (Table 39.5).

High density zirconia oxide showed excellent compatibility with autogenous rhesus monkey bone and was completely nonreactive to the body environment for the duration of the 350 day study [Hentrich et al., 1971]. Zirconia has shown excellent biocompatibility and good wear and friction when combined with ultra-high molecular weight polyethylene [Kumar et al., 1989; Murakami and Ohtsuki, 1989].

39.2.4 Carbons

Carbons can be made in many allotropic forms: crystalline diamond, graphite, noncrystalline glassy carbon, and quasicrystalline pyrolitic carbon. Among these, only pyrolitic carbon is widely utilized for implant fabrication; it is normally used as a surface coating. It is also possible to coat surfaces with diamond. Although the techniques of coating with diamond have the potential to revolutionize medical device manufacturing, it is not yet commercially available [Park and Lakes, 1992].

The crystalline structure of carbon, as used in implants, is similar to the graphite structure shown in Figure 39.1. The planar hexagonal arrays are formed by strong covalent bonds in which one of the valence electrons or atoms is free to move, resulting in high but anisotropic electric conductivity. Since the bonding between the layers is stronger than the van der Waals force, it has been suggested that the layers are *cross-linked*. However, the remarkable lubricating property of graphite cannot be attained unless the cross-links are eliminated [Park and Lakes, 1992].

The poorly crystalline carbons are thought to contain unassociated or unoriented carbon atoms. The hexagonal layers are not perfectly arranged, as shown in Figure 39.2. Properties of individual crystallites seem to be highly anisotropic. However, if the crystallites are randomly dispersed, the aggregate becomes isotropic [Park and Lakes, 1992].

The mechanical properties of carbon, especially pyrolitic carbon, are largely dependent on its density, as shown in Figure 39.3 and Figure 39.4. The increased mechanical properties are directly related to increased

density, which indicates that the properties of pyrolitic carbon depend mainly on the aggregate structure of the material [Park and Lakes, 1992].

Graphite and glassy carbon have a much lower mechanical strength than pyrolitic carbon (Table 39.6). However, the average modulus of elasticity is almost the same for all carbons. The strength of pyrolitic carbon is quite high compared to graphite and glassy carbon. Again, this is due to the fewer number of flaws and unassociated carbons in the aggregate.

A composite carbon which is reinforced with carbon fiber has been considered for making implants. However, the carbon–carbon composite is highly anisotropic, and its density is in the range of 1.4 to 1.45 g/cm^3 with a porosity of 35 to 38% (Table 39.7).

Carbons exhibit excellent compatibility with tissue. Compatibility of pyrolitic carbon-coated devices with blood have resulted in extensive use of these devices for repairing diseased heart valves and blood vessels [Park and Lakes, 1992].

Pyrolitic carbons can be deposited onto finished implants from hydrocarbon gas in a *fluidized bed* at a controlled temperature and pressure. The anisotropy, density, crystallite size and structure of the deposited carbon can be controlled by temperature, composition of the fluidized gas, the bed geometry, and the residence time (velocity) of the gas molecules in the bed. The microstructure of deposited carbon should be highly controlled, since the formation of growth features associated with uneven crystallization

12: 38.

can result in a weaker material (Figure 39.5). It is also possible to introduce various elements into the
fluidized gas and co-deposit them with carbon. Usually silicon (10 to 20 w/o) is co-deposited (or alloyed)
to increase hardness for applications requiring resistance to abrasion, such as heart valve discs.

Recently, success was achieved in depositing pyrolitic carbon onto the surfaces of blood vessel implants
made of polymers. This type of carbon is called ultra low temperature isotropic (ULTI) carbon instead
of low temperature isotropic **(LTI) carbon**. The deposited carbon has excellent compatibility with blood
and is thin enough not to interfere with the flexibility of the grafts [Park and Lakes, 1992].

The vitreous or glassy carbon is made by controlled pyrolysis of polymers such as phenolformaldehyde,
Rayon (cellulose), and polyacrylnitrite at a high temperature in a controlled environment. This process
is particularly useful for making carbon fibers and textiles which can be used alone or as components of
composites.

39.3   Biodegradable or Resorbable Ceramics

Although Plaster of Paris was used in 1892 as a bone substitute [Peltier, 1961], the concept of using synthetic
resorbable ceramics as bone substitutes was introduced in 1969 [Hentrich et al., 1969; Graves et al., 1972].
Resorbable ceramics, as the name implies, degrade upon implantation in the host. The resorbed material
is replaced by endogenous tissues. The rate of degradation varies from material to material. Almost all
bioresorbable ceramics except Biocoral and Plaster of Paris (calcium sulfate dihydrate) are variations
of calcium phosphate (Table 39.8). Examples of resorbable ceramics are aluminum calcium phosphate,
coralline, Plaster of Paris, hydroxyapatite, and tricalcium phosphate (Table 39.8).

39.3.1   Calcium Phosphate

Calcium phosphate has been used in the form of artificial bone. This material has been synthesized and
used for manufacturing various forms of implants, as well as for solid or porous coatings on other implants
(Table 39.9).

Calcium phosphate can be crystallized into salts such as hydroxyapatite and β-whitlockite depending
on the Ca : P ratio, presence of water, impurities, and temperature. In a wet environment and at lower
temperatures ($<900°$C), it is more likely that hydroxyl- or hydroxyapatite will form, while in a dry
atmosphere and at a higher temperature, β-whitlockite will be formed [Park and Lakes 1992]. Both forms
are very tissue compatible and are used as bone substitutes in a granular form or a solid block. The apatite
form of calcium phosphate is considered to be closely related to the mineral phase of bone and teeth.

The mineral part of bone and teeth is made of a crystalline form of calcium phosphate similar
to hydroxyapatite $[Ca_{10}(PO_4)_6(OH)_2]$. The apatite family of mineral $[A_{10}(BO_4)_6X_2]$ crystallizes into

hexagonal rhombic prisms and has unit cell dimensions $a = 9.432$Å and $c = 6.881$ Å. The atomic structure of hydroxyapatite projected down the c-axis onto the basal plane is shown in Figure 39.6. Note that the hydroxyl ions lie on the corners of the projected basal plane and they occur at equidistant intervals (3.44 Å) along the columns perpendicular to the basal plane and parallel to the c-axis. Six of the ten calcium ions in the unit cell are associated with the hydroxyls in these columns, resulting in strong interactions among them [Park and Lakes, 1992].

The ideal Ca : P ratio of hydroxyapatite is 10 : 6 and the calculated density is 3.219 g/cm^3. Substitution of OH with fluoride gives the apatite greater chemical stability due to the closer coordination of fluoride (symmetric shape) as compared to the hydroxyl (asymmetric, two atoms) by the nearest calcium. This is why fluoridation of drinking water helps in resisting caries of the teeth [Park and Lakes, 1992].
FIGURE 39.6 Hydroxyapatite structure projected down the *c*-axis onto the basal plane (From Posner A.S., Perloff A., and Diorio A.D. 1958. *Acta. Cryst.* 11: 308–309.)

Source: Park J.B. and Lakes R.S. 1992. *Biomaterials: An Introduction,* 2nd ed., p. 125. Plenum Press, New York.

The mechanical properties of synthetic calcium phosphates vary considerably (Table 39.10). The wide variations in properties of polycrystalline calcium phosphates are due to the variations in the structure and manufacturing processes. Depending on the final firing conditions, the calcium phosphate can be calcium hydroxyapatite or β-whitlockite. In many instances, both types of structures exist in the same final product [Park and Lakes, 1992].

Polycrystalline hydroxyapatite has a high elastic modulus (40 to 117 GPa). Hard tissue such as bone, dentin, and dental enamel are natural composites which contain hydroxyapatite (or a similar mineral), as well as protein, other organic materials, and water. Enamel is the stiffest hard tissue, with an elastic modulus of 74 GPa, and contains the most mineral. Dentin ($E = 21$ GPa) and compact bone ($E = 12$ to
FIGURE 39.7   Scanning electron micrograph ($\times$500) of a set and hardened hydroxyaptite (HA)-cysteine composite. The small white cysteine particles can be seen on the larger HA particles.

18 GPa) contain comparatively less mineral. The Poisson's ratio for the mineral or synthetic hydroxyapatite is about 0.27 which is close to that of bone ($\approx$0.3) [Park and Lakes, 1992].

Hontsu et al. [1997] were able to deposit an amorphous HA film on Ti, α-Al_2O_3, SiO//Si(100), and $SrTiO_3$ using a pulsed ArF excimer laser. Upon heat treatment the amorphous film was converted to the crystalline form of HA. The HA film's electrical properties were measured for the first time (Table 39.14).

Among the most important properties of hydroxyapatite as a biomaterial is its excellent biocompatibility. Hydroxyapatite appears to form a direct chemical bond with hard tissues [Piattelli and Trisi, 1994]. On implantation of hydroxyapatite particles or porous blocks in bone, new lamellar cancellous bone forms within 4 to 8 weeks [Bajpai and Fuchs, 1985]. Scanning electron micrograph (500$\times$) of a set and hardened hydroxyapatite-cysteine composite is shown in Figure 39.7. The composite sets and hardens on addition of water.

Many different methods have been developed to make precipitates of hydroxyapatite from an aqueous solution of $Ca(NO_3)_2$ and NaH_2PO_4. There has been successful use of modifications to Jarcho and colleagues wet precipitation procedure for synthesizing hydroxyapatites for use as bone implants [Jarcho et al., 1979; Bajpai and Fuchs, 1985], and drug delivery devices [Bajpai, 1992, 1994; Parker and Bajpai, 1993; Abrams and Bajpai, 1994]. The dried, filtered precipitate is placed in a high-temperature furnace and calcined at 1150°C for 1 h. The calcined powder is then ground in a ball mill, and the particles are separated by an automatic sieve shaker and sieves. The sized particles are then pressed in a die and sintered at 1200°C for 36 h for making drug delivery devices [Bajpai, 1989, 1992; Abrams and Bajpai, 1994]. Above 1250°C, hydroxyapatite shows a second precipitation phase along the grain boundaries [Park and Lakes 1992].

39.3.2 Aluminum–Calcium–Phosphate (ALCAP) Ceramics

Initially we fabricated a calcium aluminate ceramic containing phosphorous pentoxide [Hentrich et al., 1969, 1971; Graves et al., 1972]. Aluminum–calcium–phosphorous oxide ceramic (ALCAP) was developed later [Bajpai and Graves, 1980]. ALCAP has insulating dielectric properties but no magnetic or piezoelectric properties [Allaire et al., 1989]. ALCAP ceramics are unique because they provide a multipurpose crystallographic system where one phase of the ceramic on implantation can be more rapidly resorbed than the others [Wyatt et al., 1976; Bajpai, 1983; Mattie and Bajpai, 1988]. ALCAP is prepared from stock

powders of aluminum oxide, calcium oxide, and phosphorous pentoxide. A ratio of $50:34:16$ by weight of $AlO_2:CaO:P_2O_5$ is used to obtain the starting mixture for calcining at 1350°C in a high temperature furnace for 12 h. The calcined material is ground in a ball mill and sieved by an automatic siever to obtain particles of the desired size. The particulate powder is then pressed into solid blocks or hollow cylinders (green shape) and sintered at 1400°C for 36 h to increase the mechanical strength. ALCAP ceramic implants have given excellent results in terms of biocompatibility and gradual replacement of the ceramic material with endogenous bone [Bajpai, 1982; Mattie and Bajpai, 1988]. A scanning electron micrograph ($1000\times$) of sintered porous ALCAP is shown in Figure 39.8.

39.3.3 Coralline

Coral is a natural substance made by marine invertebrates. According to Holmes et al. [1984], the marine invertebrates live in the limestone exostructure, or coral. The porous structure of the coral is unique for each species of marine invertebrate [Holmes et al., 1984]. Corals for use as bone implants are selected on the basis of structural similarity to bone [Holmes et al., 1984]. Coral provides an excellent structure for the ingrowth of bone, and the main component, calcium carbonate, is gradually resorbed by the body [Khavari and Bajpai, 1993]. Corals can also be converted to hydroxyapatite by a hydrothermal exchange process. Interpore 200, a coral hydroxyapatite, resembles cancellous bone [Sartoris et al., 1986]. Both pure coral (Biocoral) and coral transformed to hydroxyapatite are currently used to repair traumatized bone, replace diseased bone, and correct various bone defects.

Biocoral is composed of crystalline calcium carbonate or aragonite, the metastable form of calcium carbonate. The compressive strength of Biocoral varies from 26 (50% porous) to 395 MPa (dense) and depends on the porosity of the ceramic. Likewise, the modulus of elasticity (Young's Modulus) of Biocoral varies from 8 (50% porous) to 100 GPa (dense) [Biocoral, 1989].

39.3.4 Tricalcium Phosphate (TCP) Ceramics

A multicrystalline porous form of β-tricalcium phosphate $[\beta$-$Ca_3(PO_4)_2]$ has been used successfully to correct periodontal defects and augment bony contours [Metsger et al., 1982]. X-ray diffraction
FIGURE 39.8   Scanning electron micrograph ($\times 1000$) of porous sintered ALCAP.
FIGURE 39.9   Scanning electron micrograph ($\times 500$) of a set and hardened TCP–cysteine composite. The small white cysteine particles can be seen on the larger TCP particles.

of β-tricalcium phosphate shows an average interconnected porosity of over 100 μm [Lemons et al., 1979]. Often tribasic calcium phosphate is mistaken for β-tricalcium phosphate. According to Metsger et al. [1982], tribasic calcium phosphate is a nonstoichiometric compound often bearing the formula of hydroxyapatite [$Ca_10(PO_4)_6(OH)_2$].

β-Tricalcium phosphate is prepared by a wet precipitation procedure from an aqueous solution of $Ca(NO_3)_2$ and NaH_2PO_4 [Bajpai et al., 1988]. The precipitate is calcined at 1150°C for 1 h, ground, and sieved to obtain the desired size particles for use as bone substitutes [Bajpai et al., 1988; Bajpai, 1990] and for making ceramic matrix drug delivery systems [Morris and Bajpai, 1989; Nagy and Bajpai, 1994; Moldovan and Bajpai, 1994]. These particles are used as such or pressed into cylindrical shapes and sintered at 1150 to 1200°C for 36 h to achieve the appropriate mechanical strength for use as drug delivery devices [Bajpai, 1989, 1992, 1994; Benghuzzi et al., 1991]. A scanning electron micrograph (500×) of a set and hardened TCP-cysteine composite is shown in Figure 39.9. The composite sets and hardens on the addition of water. TCP is usually more soluble than synthetic hydroxyapatite and, on implantation, allows good bone ingrowth and eventually is replaced by endogenous bone.

39.3.5 Zinc–Calcium–Phosphorous Oxide (ZCAP) Ceramics

Zinc is essential for human metabolism and is a component of at least 30 metalloenzymes [Pories and Strain, 1970]. In addition, zinc may also be involved in the process of wound healing [Pories and Strain 1970]. Thus zinc–calcium–phosphorous oxide polyphasic ceramics (ZCAP) were synthesized to repair bone defects and deliver drugs [Binzer and Bajpai, 1987; Bajpai, 1988, 1993; Arar and Bajpai, 1992]. ZCAP is prepared by a thermal mixing of zinc oxide, calcium oxide, and phosphorous pentoxide powders [Bajpai, 1988]. ZCAP, like ALCAP, has insulating dielectric properties but no magnetic or piezoelectric properties [Allaire et al., 1989]. Various ratios of these powders have been used to produce the desired material [Bajpai, 1988]. The oxide powders are mixed in a ball mill and subsequently calcined at 800°C for 24 h. The calcined ceramic is then ground and sieved to obtain the desired size particles. Scanning electron micrograph (500×) of a set and hardened ZCAP–cysteine composite is shown in Figure 39.10. The composite sets and hardens on addition of water. To date, ZCAP ceramics have been
FIGURE 39.10 Scanning electron micrograph ($\times 500$) of a set and hardened ZCAP–cysteine composite. The small white cysteine particles have blended with the ZCAP particles.

used to repair experimentally induced defects in bone and for delivering drugs [Binzer and Bajpai, 1987; Bajpai, 1993].

39.3.6 Zinc–Sulfate–Calcium–Phosphate (ZSCAP) Ceramics

Zinc–sulfate–calcium–phosphate polyphasic ceramics (ZSCAP) are prepared from stock powders of zinc sulfate, zinc oxide, calcium oxide, and phosphorous pentoxide [Bajpai, 1988]. A ratio of $15 : 30 : 30 : 25$ by weight of $ZnSO_4 : ZnO : CaO : P_2O_5$ is mixed in a crucible and allowed to cool for 30 min after the exothermal reaction has subsided. The cooled mixture is calcined in a crucible at $650°C$ for 24 h. The calcined ceramic is ground in a ball mill and the particles of the desired size are separated by sieving in an automatic siever. Scanning electron micrograph ($2000\times$) of set and hardened ZSCAP particles (45 to 63 μm) is shown in Figure 39.11. ZSCAP sets and hardens on addition of water. ZSCAP particles, on implantation in bone, set and harden on contact with blood and have been used to repair experimentally induced defects in bone [Scheidler and Bajpai, 1992].

39.3.7 Ferric–Calcium–Phosphorous–Oxide (FECAP) Ceramics

Ferric–Calcium–Phosphorous–Oxide polyphasic ceramic (FECAP) is prepared from powders of ferric (III) oxide, calcium oxide, and phosphorous pentoxide [Stricker et al.,1992; Fuski et al., 1993; Larrabee et al., 1993]. The powders are combined in various ratios by weight and mixed in a blender. Blocks of the mixture are then pressed in a die by means of a hydraulic press and calcined at $1100°C$ for 12 h. The calcined ceramic blocks are crushed and ground in a ball mill. The calcined ceramic is ground in a ball mill and the particles of the desired size are separated by sieving in an automatic siever. A scanning electron micrograph ($1000\times$) of a set and hardened FECAP-α ketoglutaric acid composite is shown in Figure 39.12. The composite sets and hardens on the addition of water. Studies conducted to date suggest complete resorption of FECAP particles implanted in bone within 60 days [Larrabee et al., 1993]. This particular ceramic could be used in patients suffering from anemia and similar diseases [Fuski et al., 1993].

39.4   Bioactive or Surface-Reactive Ceramics

Upon implantation in the host, surface reactive ceramics form strong bonds with adjacent tissue. Examples of surface reactive ceramics are dense nonporous glasses, Bioglass and Ceravital, and hydroxyapatites (Table 39.11). One of their many uses is the coating of metal prostheses. This coating provides a stronger

bonding to the adjacent tissues, which is very important for protheses. A list of the uses of surface-reactive ceramics is shown in Table 39.12.

39.4.1 Glass Ceramics

Several variations of Bioglass and Ceravital glass ceramics have been used by various workers within the last decade. Glass ceramics used for implantation are silicon oxide based systems with or without phosphorous pentoxide.

Glass ceramics are polycrystalline ceramics made by controlled crystallization of glasses developed by S.D. Stookey of Corning Glass Works in the early 1960s [Park and Lakes, 1992]. Glass ceramics were first utilized in photosensitive glasses, in which small amounts of copper, silver, and gold are precipitated by ultraviolet light irradiation. These metallic precipitates help to nucleate and crystallize the glass into a fine grained ceramic which possesses excellent mechanical and thermal properties. Both Bioglass and Ceravital glass ceramics have been used as implants [Yamamuro et al., 1990].

The formation of glass ceramics is influenced by the nucleation and growth of small (<1 μm diameter) crystals as well as the size distribution of these crystals. It is estimated that about 10^{12} to 10^{15} nuclei/cm^3 are required to achieve such small crystals. In addition to the metallic agents already mentioned, Pt groups, TiO_2, ZrO_2, and P_2O_5 are widely used for nucleation and crystallization. The nucleation of glass is carried out at temperatures much lower than the melting temperature. During processing the melt viscosity is kept in the range of 10^{11} and 10^{12} Poise for 1 to 2 h. In order to obtain a larger fraction of the microcrystalline phase, the material is further heated to an appropriate temperature for maximum crystal growth. Deformation of the product, phase transformation within the crystalline phases, or redissolution of some of the phases should be avoided. The crystallization is usually more than 90% complete with grain sizes 0.1 to 1 μm. These grains are much smaller than those of conventional ceramics. Figure 39.13 shows a schematic representation of temperature–time cycle for a glass ceramic [Park and Lakes, 1992].

The glass ceramics developed for implantation are SiO_2–CaO–Na_2O–P_2O_5 and Li_2O–ZnO–SiO_2 systems. Two major groups are experimenting with the SiO_2–CaO–Na_2O–P_2O_5 glass ceramic. One group

varied the compositions (except for P_2O_5) in order to obtain the best glass ceramic composition for inducing direct bonding with bone (Table 39.13). The bonding to bone is related to the simultaneous formation of a calcium phosphate and SiO_2-rich film layer on the surface, as exhibited by the 46S5.2 type Bioglass. If a SiO_2-rich layer forms first and a calcium phosphate film develops later (46 to 55 mol % SiO_2 samples) or no phosphate film is formed (60 mol % SiO_2) then direct bonding with bone does not occur [Park and Lakes, 1992]. The approximate region of the SiO_2–CaO–Na_2O system for the tissue–glass–ceramic reaction is shown in Figure 39.14. As can be seen, the best region (region A) for good tissue bonding is the composition given for 46S5.2 type Bioglass (see Table 39.13) [Park and Lakes, 1992].

39.4.2 Ceravital

The composition of Ceravital is similar to that of Bioglass in SiO_2 content but differs somewhat in other components (see Table 39.13). In order to control the dissolution rate, Al_2O_3, TiO_2, and Ta_2O_5 are added

in Ceravital glass ceramic. The mixtures, after melting in a platinum crucible at 1500°C for three h, are annealed and cooled. The nucleation and crystallization temperatures are 680 and 750°C, respectively, each for 24 h. When the size of crystallites reaches approximately 4 Å and the characteristic needle structure is not formed, the process is stopped to obtain a fine grain structured glass ceramic [Park and Lakes, 1993].

Glass ceramics have several desirable properties compared to glasses and ceramics. The thermal coefficient of expansion is very low, typically 10^{-7} to 10^{-5}°C^{-1}, and in some cases it can even be made negative. Due to the controlled grain size and improved resistance to surface damage, the tensile strength of these materials can be increased by at least a factor of two, from about 100 to 200 MPa. The resistance to scratching and abrasion of glass ceramics is similar to that of sapphire [Park and Lakes, 1992].

A transmission electron micrograph of Bioglass glass ceramic implanted in the femur of rats for six weeks showed intimate contacts between the mineralized bone and the Bioglass (Figure 39.15). The mechanical strength of the interfacial bond between bone and Bioglass ceramic is on the same order of magnitude as the strength of the bulk glass ceramic (850 kg/cm^2 or 83.3 MPa), which is about three-fourths that of the host bone strength [Park and Lakes, 1992].

FIGURE 39.15   Transmission electron micrograph of well-mineralized bone (b) juxtaposed to the glass-ceramic (c) which fractured during sectioning. ×51,500. Insert a is the diffraction pattern from ceramic area and b is from bone area. (From Beckham C.A., Greenlee T.K. Jr, and Crebo A.R. 1971. *Calc. Tiss. Res.* 8: 165–171. With permission.)

A negative characteristic of the glass ceramic is its brittleness. In addition, limitations on the compositions used for producing a biocompatibile (or osteoconductive) glass ceramic hinders the production of a glass ceramic which has substantially higher mechanical strength. Thus glass ceramics cannot be used for making major load-bearing implants such as joint implants. However, they can be used as fillers for bone cement, dental restorative composites, and coating material (see Table 39.12). A glass ceramic containing 36 wt% of magnetite in a β-wollastonite- and $CaOSiO_2$-based glassy matrix has been synthesized for treating bone tumors by hyperthermia [Kokubo et al., 1992].

39.5   Deterioration of Ceramics

It is of great interest to know whether the inert ceramics such as alumina undergo significant static or dynamic fatigue. Even for the biodegradable ceramics, the rate of degradation *in vivo* is of paramount importance. Controlled degradation of an implant with time on implantation is desirable. Above a critical stress level, the fatigue strength of alumina is reduced by the presence of water. This is due to the delayed crack growth, which is accelerated by the water molecules [Park and Lakes, 1992]. Reduction in strength occurs if water penetrates the ceramic. Decrease in strength was not observed in samples which did not show water marks on the fractured surface (Figure 39.16). The presence of a small amount of silica in one sample lot may have contributed to the permeation of water molecules that is detrimental to the
FIGURE 39.16 Flexural strength of dense alumina rods after aging under stress in Ringer's solution. Lot 1 and 2 are from different batches of production. (From Krainess F.E. and Knapp W.J. 1978. *J. Biomed. Mater. Res.* 12: 245. With permission.)
FIGURE 39.17 Strain vs. number of cycles to failure (○ = absence of fatigue cracks in carbon film; ● = fracture of carbon film due to fatigue failure of substrates; □ = data from substrate determined in single-cycle tensile test). (From Shimm H.S. and Haubold A.D. 1980. *Biomater. Med. Dev. Art. Org.* 8: 333–344. With permission.)

strength [Park and Lakes, 1992]. It is not clear whether the static fatigue mechanism operates in single crystal alumina. It is reasonable to assume, that static fatigue will occur if the ceramic contains flaws or impurities, because these will act as the source of crack initiation and growth under stress [Park and Lakes, 1992].

Studies of the fatigue behavior of vapor-deposited pyrolitic carbon fibers (4000 to 5000 Å thick) onto a stainless steel substrate showed that the film does not break unless the substrate undergoes plastic deformation at 1.3×10^{-2} strain and up to one million cycles of loading. Therefore, the fatigue is closely related to the substrate, as shown in Figure 39.17. Similar substrate-carbon adherence is the basis for the pyrolitic carbon deposited polymer arterial grafts [Park and Lakes, 1992].

The fatigue life of ceramics can be predicted by assuming that the fatigue fracture is due to the slow growth of preexisting flaws. Generally, the strength distribution, σ_i, of ceramics in an inert environment
FIGURE 39.18 Plot of Ln Ln $[1/(1 - F)]$ vs. Ln S for Bioglass-coated alumina in a tris-hydroxyaminomethane buffer and liquid nitrogen. F is the probability of failure and S is strength. (From Ritter J.E. Jr, Greenspan D.C., Palmer R.A., and Hench L.L. 1979. *J. Biomed. Mater. Res.* 13: 260. With permission.)

can be correlated with the probability of failure F by the following equation:

$$\mathrm{LnLn}\left(\frac{1}{1 - F}\right) = m\mathrm{Ln}\left(\frac{s_i}{s_o}\right) \tag{39.1}$$

Both m and s_o are constants in the equation. Figure 39.18 shows a good fit for Bioglass coated alumina [Park and Lakes, 1992].

A minimum service life (t_{min}) of a specimen can be predicted by means of a proof test wherein it is subjected to stresses that are greater than those expected in service. Proof tests also eliminate the weaker pieces. This minimum life can be predicted from the following equation:

$$t_{min} = B\sigma_p^{N-2}\sigma_a^{-N} \tag{39.2}$$

Here σ_p is the proof test stress, σ_a is the applied stress, and B and N are constants.

Equation 39.2 after rearrangement, reads as follows:

$$t_{min}\sigma_a^2 = B(\sigma_p/\sigma_a)^{N-2} \tag{39.3}$$

Figure 39.19 shows a plot of Equation 39.3 for alumina on a logarithmic scale [Park and Lakes, 1992].

39.6 Bioceramic Manufacturing Techniques

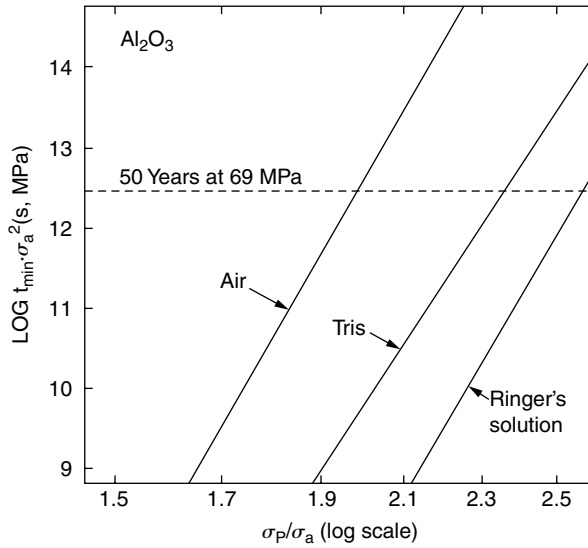
In order to fabricate bioceramics in more and more complex shapes, scientists are investigating the use of old and new manufacturing techniques. These techniques range from the adaptation of an age old pottery technique to the latest manufacturing methods for high temperature ceramic parts for airplane engines. No matter where the technique is perfected, the ultimate goal is the fabrication of bioceramic particles or devices in a desired shape in a consistent manner with the desired properties. The technique used to fabricate the bioceramic device will depend greatly on the ultimate application of the device, whether it is for hard tissue replacement or the integration of the device within the surrounding tissue.


FIGURE 39.19 Plot of Equation 39.3 for alumina after proof testing. $N = 43.85$, $m = 13.21$, and $\sigma_o = 55728$ psi. (From Ritter J.E. Jr, Greenspan D.C., Palmer R.A., and Hench L.L. 1979. *J. Biomed. Mater. Res.* 13: 261. With permission.)

39.6.1 Hard Tissue Replacement

Hard tissue replacement implies that the bioceramic device will be used for load bearing applications. Although it is desirable to have a device with a sufficient porosity for the surrounding tissue to infiltrate and attach to the device, the most important and immediate property is the strength of the device. In order to accomplish this, one must manufacture a bioceramic implant with a density and strength sufficient to mimic that of bone. However, if the bioceramic part is significantly stronger than the surrounding bone, one runs into the common problem seen with metals called *stress shielding.* The density of the bioceramic greatly determines its overall strength. As the density increases so does the overall strength of the bioceramic. Some of the techniques used to manufacture dense bioceramics are injection molding, gel casting, bicontinuous microemulsion, inverse microemulsion, emulsion, and additives.

Injection molding is a common technique used to form plastic parts for many commercial applications such as automobile parts. Briefly, the process involves forcing a heated material into a die and then ejecting the formed piece from the die. Injection molding allows for making complex shapes. Cihlar and Trunec [1996] found that by calcining (1273 K, 3 h) and milling the hydroxyapatite (HA) prior to mixing with a binder, an ethylene vinyl acetate copolymer (EVA)/HA mixture of 63% HA, they achieved 98% relative density with only 16% shrinkage using injection molding. The maximum flexural strength was 60 MPa for HA products sintered at 1473 K. However, this is still not strong enough for load bearing applications.

They also observed that HA decomposed to α-TCP at temperatures greater than 1573 K [Cihlar and Trunec, 1996].

In gel casting, HA is formed using the standard chemical precipitation. The calcium phosphate precipitant (30% w/v) is then mixed with glycerol and filtered. The "gel cake" is sintered at 1200°C for 2 h. This yielded a density of >99% and a highly uniform microstructure [Varma and Sivakumar, 1996].

Bicontinuous microemulsion, inverse microemulsion, and emulsion are all wet chemistry based methods to produce nanometer size HA powders. All three methods yield >97% relative density upon sintering at 1200°C for 2 h. The biocontinuous and inverse microemulsion resulted in the two smallest HA particle sizes, 22 and 24 nm respectively [Lim et al., 1997].

Another strategy to increase the density of ceramics is to use additives or impurities in small weight percents during sintering. The main disadvantages to this technique include (1) the possible decomposition of the original pure bioceramic and (2) results may end in all or portions of the bioceramic being nonbiocompatible.

Suchanek et al. [1997] studied the addition of several different additives to HA in 5 wt% amounts. The additives studied were K_2CO_3, Na_2CO_3, H_3BO_3, KF, $CaCl_2$, KCl, KH_2PO_4, $(KPO_3)_n$, $Na_2Si_2O_5$, $Na_2P_2O_7$, Na_3PO_4, $(NaPO_3)_n$, $Na_5P_3O_{10}$, and β-NaCaPO$_4$. HA has a fracture toughness of 1 MPa·m$^{1/2}$, whereas human bone has a fracture toughness of 2 to 12 MPa · m$^{1/2}$. One of the ways to improve the mechanical properties is to improve the densification of HA. Suchanek et al. [1997] found that the following additives (5 wt.%) did not improve the densification of HA: H_3BO_3, $CaCl_2$, KCl, KH_2PO_4, $(KPO_3)_n$, and $Na_2Si_2O_5$. The densification of HA was improved through the addition (5 wt.%) of K_2CO_3, Na_2CO_3, KF, $Na_2P_2O_7$, Na_3PO_4, $(NaPO_3)_n$, $Na_5P_3O_{10}$, and β-NaCaPO$_4$. However, H_3BO_3, $CaCl_2$, KH_2PO_4, $(KPO_3)_n$, $Na_2Si_2O_5$, K_2CO_3, Na_2CO_3, and KF produced the formation of β-TCP or CaO. The sodium phosphates used in this study were added to HA without the formation of β-TCP or CaO. The only compound that improved densification, did not cause formation of β-TCP or CaO, and provided a weak interface for HA was β-NaCaPO$_4$.

Another additive that has been investigated to improve the performance of HA is lithium (Li). The addition of lithium can increase the microhardness and produces a fine microstructure in HA. Fanovich et al. [1998] found that the addition of 0.2 wt% of Li to HA produced the maximum microhardness (5.9 GPa). However, the addition of high amounts of Li to HA results in abnormal grain growth and large pores. Furthermore, Li addition to HA results in the formation of β-TCP upon sintering.

Zirconia has been used as an additive to HA in order to improve its mechanical strength. Kawashima et al. [1997] found that addition of partially stabilized zirconia (PSZ) to HA can be used to increase the fracture toughness to 2.8 MPa · m$^{1/2}$. Bone has a fracture toughness of 2-12 MPa · m$^{1/2}$ [Suchanek et al., 1997]. PSZ was added to HA in different percentages (17, 33, 50 wt%) and it was found that 50 wt% PSZ had the highest fracture toughness. The surface energy of the PSZ-HA was not significantly different from HA alone. This suggests that the PSZ-HA composite could be biocompatible because of the similarity of the surface with HA [Kawashima et al., 1997].

39.6.2 Tissue Integration

The porosity is a critical factor for growth and integration of a tissue into the bioceramic implant. In particular the open porosity, that which is connected to the outside surface, is critical to the integration of tissue into the ceramic especially if the bioceramic is inert. Several methods have been developed to form porous ceramics, two of these are starch consolidation and drip casting.

In starch consolidation (Table 39.15), starch powders of a specific size are mixed with a bioceramic slurry at a predetermined weight percent. Upon heating, the starch will uptake water from the slurry mixture and swell. Upon sintering of the starch-bioceramic mixture, the starch is burned out and the pores are left in their place. Starch consolidation has been used to form complex shapes in alumina with ultimate porosities between 23 and 70 vol %. By controlling the starch content, one can control the ultimate porosity and resulting pore sizes. Large pores formed using starch consolidation in alumina were in the size range 10 to 80 μm whereas small pores varied between 0.5 and 9.5 μm [Lyckfeldt and Ferreira, 1998].

Liu [1996] used a drip casting technique (Table 39.15) to form porous HA granules with pore sizes from 95 to 400 μm. The granules had a total porosity from 24 to 76 vol %. The HA was made into a slurry using water and poly(vinyl butyral) powders. The slurry was then dripped onto a spherical mold surface. This technique is similar to that of drip casting by dripping an HA slurry into a liquid nitrogen bath. In both instances, calcining and sintering procedures are used to produce the final product [Liu, 1996].

39.6.3 Hydroxyapatite Synthesis Method

Prepare the following solutions:

Solution 1: Dissolve 157.6 g calcium nitrate tetrahydrate [Ca(NO$_3$)$_2$4H$_2$O] in 500 ml DI water. Bring the solution to a pH of 11 by adding ≈70 ml ammonium hydroxide [NH$_4$OH]. Bring the solution to 800 ml with DI water.

Solution 2: Dissolve 52.8 g ammonium phosphate dibasic [(NH$_4$)$_2$HPO$_4$] in 500 ml DI water. Bring the solution to a pH of 11 by adding ≈150 ml ammonium hydroxide [NH$_4$OH]. Add DI water until the precipitate is completely dissolved, 250–350 ml.

39.6.3.1 Special Note

If you use calcium nitrate [Ca(NO$_3$)$_2$nH$_2$O] instead of calcium nitrate tetrahydrate you need to recalculate the amount of calcium nitrate to add to make Solution 1 on the basis of the absence of the extra four waters. If you do not, you will have to add a large amount of ammonium hydroxide to pH the solution:

1. Add one-half of Solution 1 to a 2 l separatory funnel
2. Add one-half of Solution 2 to a 2 l separatory funnel
3. Titrate both solutions into a 4 l beaker with heat and constant stirring
4. Boil gently for 30 min
5. Repeat steps 1–4 for the rest of Solutions 1 and 2
6. Let cool completely allowing precipitate to settle to bottom of beaker
7. Pour contents of beaker into 250 ml polypropylene bottles
8. Centrifuge bottles for 10 min at (10,000 rpm) 16,000 g

9. Collect precipitate from the six bottles into two and resuspend with DI water
10. Fill the four empty bottles with the reaction mixture and centrifuge all six as before
11. Collect precipitant from the two bottles that were resuspended with DI water
12. Combine remaining four bottles into two bottles and resuspend with DI water
13. Repeat steps 10–12 as necessary
14. Dry precipitate for 24–48 h at 70°C
15. Calcine the precipitate for one hour at 1140°C
16. Grind and sieve product as desired

Defining Terms

Alumina: Aluminum oxide (Al_2O_3) which is very hard (Mohs hardness is 9) and strong. Single crystals are called sapphire or ruby depending on color. Alumina is used to fabricate hip joint socket components or dental root implants.

Calcium phosphate: A family of calcium phosphate ceramics including aluminum calcium phosphate, ferric calcium phosphate, hydroxyapatite and tricalcium phosphate (TCP), and zinc calcium phosphate which are used to substitute or augment bony structures and deliver drugs.

Glass-ceramics: A glass crystallized by heat treatment. Some of those have the ability to form chemical bonds with hard and soft tissues. Bioglass and Ceravital are well known examples.

Hydroxyapatite: A calcium phosphate ceramic with a calcium to phosphorus ratio of 5/3 and nominal composition $Ca_{1}0(PO_4)_6(OH)_2$. It has good mechanical properties and excellent biocompatibility. Hydroxyapatite is the mineral constituent of bone.

LTI carbon: A silicon alloyed pyrolitic carbon deposited onto a substrate at low temperature with isotropic crystal morphology. It is highly compatible with blood and used for cardiovascular implant fabrication such as artificial heart valve.

Maximum radius ratio: The ratio of atomic radii computed by assuming the largest atom or ion which can be placed in a crystal's unit cell structure without deforming the structure.

Mohs scale: A hardness scale in which 10 (diamond) is the hardest and 1 (talc) is the softest.

Acknowledgments

In Memory Of

In memory of Dr. P.K. Bajpai who left us early in 1998, I would like to share our lab's recipe for hydroxyapatite. Dr. Bajpai's lab and research at the University of Dayton have ended after 30 plus years, but I felt it would be fitting to share this recipe as a way to encourage other scientists to continue exploring the possibilities of bioceramics.

40.1   Introduction

Synthetic polymeric materials have been widely used in medical disposable supply, prosthetic materials, dental materials, implants, dressings, extracorporeal devices, encapsulants, polymeric drug delivery systems, tissue engineered products, and orthodoses as that of metal and ceramics substituents [Lee, 1989]. The main advantages of the polymeric **biomaterials** compared to metal or ceramic materials are ease of manufacturability to produce various shapes (latex, film, sheet, fibers, etc.), ease of secondary processability, reasonable cost, and availability with desired mechanical and physical properties. The required properties of polymeric biomaterials are similar to other biomaterials, that is, **biocompatibility**, sterilizability, adequate mechanical and physical properties, and manufacturability as given in Table 40.1.

     The objectives of this chapter are (1) the review of basic chemical and physical properties of the synthetic polymers, (2) the sterilization of the polymeric biomaterials, (3) the importance of the surface treatment for improving biocompatability, and (4) the application of the **chemogradient surface** for the study on cell to polymer interactions.

TABLE 40.1   Requirements for Biomedical Polymers

Properties	Description
Biocompatibility	Noncarcinogenesis, nonpyrogenicity, nontoxicity, and nonallergic response
Sterilizability	Autoclave, dry heating, ethylenoxide gas, and radiation
Physical property	Strength, elasticity, and durability
Manufacturability	Machining, molding, extruding, and fiber forming

Protein	$\begin{array}{c} O \quad H \\ \parallel \quad \vert \\ -C-N- \end{array}$

40.2   Polymerization and Basic Structure

40.2.1   Polymerization

In order to link the small molecules one has to force them to lose their electrons by the chemical processes of condensation and addition. By controlling the reaction temperature, pressure, and time in the presence of catalyst(s), the degree to which **repeating units** are put together into chains can be manipulated.

40.2.1.1   Condensation or Step Reaction Polymerization

During **condensation polymerization** a small molecule such as water will be condensed out by the chemical reaction. For example

$$\underset{\text{(amine)}}{\text{R-NH}_2} + \underset{\text{(carboxylic acid)}}{\text{R}'\text{COOH}} \rightarrow \underset{\text{(amide)}}{\text{R}'\text{CONHR}} + \underset{\text{(condensed molecule)}}{\text{H}_2\text{O}} \tag{40.1}$$
This particular process is used to make polyamides (Nylons). Nylon was the first commercial polymer, made in the 1930s.

Some typical condensation polymers and their interunit linkages are given in Table 40.2. One major drawback of condensation polymerization is the tendency for the reaction to cease before the chains grow to a sufficient length. This is due to the decreased mobility of the chains and reactant chemical species as polymerization progresses. This results in short chains. However, in the case of Nylon the chains are

polymerized to a sufficiently large extent before this occurs and the physical properties of the polymer are preserved.

Natural polymers, such as polysaccharides and proteins are also made by condensation polymerization. The condensing molecule is always water (H_2O).

40.2.1.2 Addition or Free Radical Polymerization

Addition polymerization can be achieved by rearranging the bonds within each monomer. Since each "mer" has to share at least two covalent electrons with other mers the monomer should have at least one double bond. For example, in the case of ethylene:

$$
n \ \{ \overset{\displaystyle H}{\underset{\displaystyle H}{C}} = \overset{\displaystyle H}{\underset{\displaystyle H}{C}} \} \ \rightarrow \ -\overset{\displaystyle H}{\underset{\displaystyle H}{C}} \left(\overset{\displaystyle H}{\underset{\displaystyle H}{C}} - \overset{\displaystyle H}{\underset{\displaystyle H}{C}} \right) \overset{\displaystyle H}{\underset{\displaystyle H}{C}} -
\tag{40.2}
$$
The breaking of a double bond can be made with an **initiator**. This is usually a free radical such as benzoyl peroxide ($H_5C_6COO–OOCC_6H_5$). The initiation can be activated by heat, ultraviolet light, and other chemicals. The free radicals (initiators) can react with monomers and this free radical can react with another monomer and the process can continue on. This process is called propagation. The propagation process can be terminated by combining two free radicals, by transfer, or by disproportionate processes. Some of the free radical polymers are given in Table 40.3. There are three more types of initiating species for addition polymerization beside free-radicals; cations, anions, and coordination (stereospecific) catalysts. Some monomers can use two or more of the initiation processes but others can use only one process as given in Table 40.3.

TABLE 40.3 Monomers for Addition Polymerization and Suitable Process

Monomer names	Chemical structure	Polymerization mechanism			
		Radical	Cationic	Anionic	Coordination
Acrylonitrile	$CH_2=CH$ $\vert$ $C\equiv N$	+	−	+	+
Ethylene	$CH_2=CH_2$	+	+	−	−
Methacrylate	$CH_2=CH$ $\vert$ $COOCH_3$	+	−	+	+
Methylmethacrylate	$CH_2=CCH_3$ $\vert$ $COOCH_3$	+	−	+	+
Propylene	$CH_2=CH$ $\vert$ CH_3	−	−	−	+
Styrene	$CH_2=CH$ $\vert$ C_6H_5	+	+	+	+
Vinylchloride	$CH_2=CH$ $\vert$ Cl	+	−	−	+
Vinylidenechloride	$CH_2=C$ $\vert$ Cl (above: Cl)	+	−	+	−

+: high polymer formed.–: no reaction or oligomers only.

FIGURE 40.1 Fringed-micelle model of a linear polymer with semi-crystalline structure.

40.2.2 Basic Structure

Polymers have very long chain molecules which are formed by **covalent bonding** along the backbone chain. The long chains are held together either by secondary bonding forces such as van der Waals and hydrogen bonds or primary covalent bonding forces through crosslinks between chains. The long chains are very flexible and can be tangled easily. In addition, each chain can have **side groups**, branches and copolymeric chains or blocks which can also interfere with the long-range ordering of chains. For example, paraffin wax has the same chemical formula as polyethylene (PE) $[(CH_2CH_2)_n]$, but will crystallize almost completely because of its much shorter chain lengths. However, when the chains become extremely long {from 40 to 50 repeating units $[-CH_2CH_2-]$ to several thousands as in linear PE} they cannot be crystallized completely (up to 80 to 90% crystallization is possible). Also, branched PE in which side chains are attached to the main backbone chain at positions normally occupied by a hydrogen atom, will not crystallize easily due to the **steric hindrance** of side chains resulting in a more noncrystalline structure. The partially crystallized structure is called semicrystalline which is the most commonly occurring structure for linear polymers. The semicrystalline structure is represented by disordered noncrystalline (amorphous) regions and ordered crystalline regions which may contain folded chains as shown in Figure 40.1.

The degree of polymerization (DP) is defined as an average number of mers, or repeating units, per molecule, that is, chain. Each chain may have a different number of mers depending on the condition of polymerization. Also, the length of each chain may be different. Therefore, it is assumed there is an average degree of polymerization or average molecular weight (MW). The relationship between molecular weight and degree of polymerization can be expressed as:

$$\text{MW of polymer} = \text{DP} \times \text{MW of mer (or repeating unit)} \tag{40.3}$$

The two average molecular weights most commonly used are defined in terms of the numbers of molecules, Ni, having molecular weight, Mi; or wi, the weight of species with molecular weights Mi as follows:

1. The number-average molecular weight, Mn, is defined by

$$\text{Mn} = \frac{\sum NiMi}{\sum NiMi} = \sum niMi = \frac{\sum Wi}{\sum (Wi/Mi)} = \frac{1}{\sum (wi\ Mi)} \tag{40.4}$$

2. The weight average molecular weight, Mw, is defined by

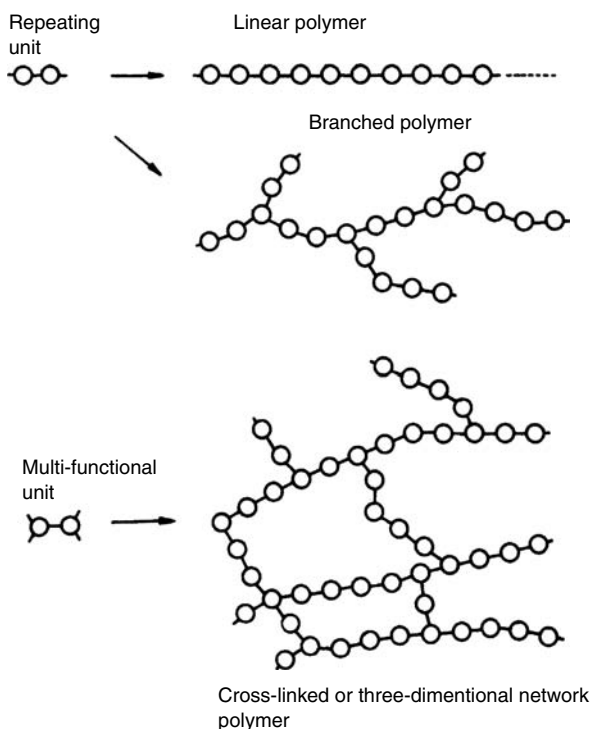
$$\text{Mw} = \frac{\sum WiMi}{\sum Wi} = \sum wiMi = \frac{\sum NiMi^2}{\sum NiMi} \tag{40.5}$$


FIGURE 40.2 Arrangement of polymer chains into linear, branched, and network structure depending on the functionality of the repeating units.

An absolute method of measuring the molecular weight is one that depends on theoretical considerations, counting molecules and their weight directly. The relative methods require calibration based on an absolute method and include intrinsic viscosity and gel permeation chromatography (GPC). Absolute methods of determining the number-average molecular weight (Mn) include osmometry and other colligative methods, and end group analysis. Light-scattering yields an absolute weight-average molecular weight (Mw).

As the molecular chains become longer by the progress of polymerization, their relative mobility decreases. The chain mobility is also related to the physical properties of the final polymer. Generally, the higher the molecular weight, the less the mobility of chains which results in higher strength and greater thermal stability. The polymer chains can be arranged in three ways; linear, branched, and a cross-linked (or three-dimensional) network as shown in Figure 40.2. Linear polymers such as polyvinyls, polyamides, and polyesters are much easier to crystallize than the cross-linked or branched polymers. However, they cannot be crystallized 100% as with metals. Instead they become semicrystalline polymers. The arrangement of chains in crystalline regions is believed to be a combination of folded and extended chains. The chain folds, which are seemingly more difficult to form, are necessary to explain observed single crystal structures in which the crystal thickness is too small to accommodate the length of the chain as determined by electron and x-ray diffraction studies. The classical "fringed-micelle" model in which the amorphous and crystalline regions coexist has been modified to include chain folds in the crystalline regions. The cross-linked or three-dimensional network polymers such as polyphenolformaldehyde cannot be crystallized at all and they become noncrystalline, amorphous polymers.

Vinyl polymers have a repeating unit $-CH_2-CHX-$ where X is some monovalent side group. There are three possible arrangements of side groups (X) (1) atactic, (2) isotactic, and (3) syndiotactic. In atactic arrangements the side groups are randomly distributed while in syndiotactic and isotactic arrangements they are either in alternating positions or on one side of the main chain. If side groups are

Random

Alternating

Block

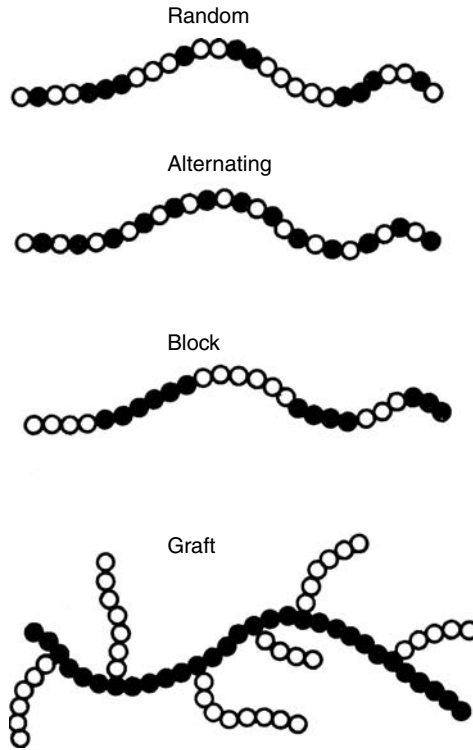
Graft


FIGURE 40.3   Possible arrangements of copolymers.

small like polyethylene (X $=$ H) and the chains are linear, the polymer crystallizes easily. However, if the side groups are large as in polyvinyl chloride (X $=$ Cl) and polystyrene (X $=$ C_6H_5, benzene ring) and are randomly distributed along the chains (atactic), then a noncrystalline structure will be formed. The isotactic and syndiotactic polymers usually crystallize even when the side groups are large.

Copolymerization, in which two or more homopolymers (one type of repeating unit throughout its structure) are chemically combined, always disrupts the regularity of polymer chains thus promoting the formation of a noncrystalline structure. Possible arrangement of the different copolymerization is shown in Figure 40.3. The addition of **plasticizers** to prevent crystallization by keeping the chains separated from one another will result in more flexible polymers, a noncrystalline version of a polymer which normally crystallizes. An example is celluloid which is normally made of crystalline nitrocellulose plasticized with camphor. Plasticizers are also used to make rigid noncrystalline polymers like polyvinylchloride (PVC) into a more flexible solid (a good example is Tygon® tubing).

Elastomers, or rubbers, are polymers which exhibit large stretchability at room temperature and can snap back to their original dimensions when the load is released. The elastomers are non-crystalline polymers which have an intermediate structure consisting of long chain molecules in three-dimensional networks (see next section for more details). The chains also have "kinks" or "bends" in them which straighten when a load is applied. For example, the chains of *cis*-polyisoprene (natural rubber) are bent at the double bond due to the methyl group interfering with the neighboring hydrogen in the repeating unit [$-CH_2-C(CH_3)=CH-CH_2-$]. If the methyl group is on the opposite side of the hydrogen then it becomes *trans*-polyisoprene which will crystallize due to the absence of the steric hindrance present in the *cis* form. The resulting polymer is a very rigid solid called gutta percha which is not an elastomer. Below the **glass transition temperature** (T_g; second-order transition temperature between viscous liquid and solid) natural rubber loses its compliance and becomes a glass-like material. Therefore, to be flexible,
FIGURE 40.4 Approximate relations among molecular weight, T_g, T_m, and polymer properties.

all elastomers should have T_g well below room temperature. What makes the elastomers not behave like liquids above T_g is in fact due to the cross-links between chains which act as pinning points. Without cross-links the polymer would deform permanently. An example is latex which behaves as a viscous liquid. Latex can be cross-linked with sulfur (**vulcanization**) by breaking double bonds (C=C) and forming C–S–S–C bonds between the chains. The more cross-links are introduced the more rigid the structure becomes. If all the chains are cross-linked together, the material will become a three-dimensional rigid polymer.

40.2.3 Effect of Structural Modification on Properties

The physical properties of polymers can be affected in many ways. In particular, the chemical composition and arrangement of chains will have a great effect on the final properties. By such means the polymers can be tailored to meet the end use.

40.2.3.1 Effect of Molecular Weight and Composition

The molecular weight and its distribution have a great effect on the properties of a polymer since its rigidity is primarily due to the immobilization or entanglement of the chains. This is because the chains are arranged like cooked spaghetti strands in a bowl. By increasing the molecular weight the polymer chains become longer and less mobile and a more rigid material results as shown in Figure 40.4. Equally important is that all chains should be equal in length since if there are short chains they will act as plasticizers. Another obvious way of changing properties is to change the chemical composition of the backbone or side chains. Substituting the backbone carbon of a polyethylene with divalent oxygen or sulfur will decrease the melting and glass transition temperatures since the chain becomes more flexible due to the increased rotational freedom. On the other hand if the backbone chains can be made more rigid then a stiffer polymer will result.

40.2.3.2 Effect of Side Chain Substitution, Cross-Linking, and Branching

Increasing the size of side groups in linear polymers such as polyethylene will decrease the melting temperature due to the lesser perfection of molecular packing, that is, decreased crystallinity. This effect is seen until the side group itself becomes large enough to hinder the movement of the main chain as shown in Table 40.4. Very long side groups can be thought of as being branches.

Cross-linking of the main chains is in effect similar to the side-chain substitution with a small molecule, that is, it lowers the melting temperature. This is due to the interference of the cross-linking which causes

TABLE 40.4   Effect of Side
Chain Substitution on Melting
Temperature in Polyethylene

Side chain	T_m (°C)
$-H$	140
$-CH_3$	165
$-CH_2CH_3$	124
$-CH_2CH_2CH_3$	75
$-CH_2CH_2CH_2CH_3$	−55
$-CH_2CHCH_2CH_3$ $\quad\quad\;CH_3$	196
CH_3 $\;\;\mid$ $-CH_2CCH_2CH_3$ $\;\;\mid$ $\;\;-CH_3$	350
FIGURE 40.5   Change of volume vs. temperature of a solid. The glass transition temperature (T_g) depends on the rate of cooling and below (T_g) the material behaves as a solid like a window glass.

decreased mobility of the chains resulting in further retardation of the crystallization rate. In fact, a large degree of cross-linking can prevent crystallization completely. However, when the cross-linking density increases for a rubber, the material becomes harder and the glass transition temperature also increases.

40.2.3.3   Effect of Temperature on Properties

Amorphous polymers undergo a substantial change in their properties as a function of temperature. The glass transition temperature, T_g, is a boundary between the glassy region of behavior in which the polymer is relatively stiff and the rubbery region in which it is very compliant. T_g can also be defined as the temperature at which the slope of volume change versus temperature has a discontinuity in slope as shown in Figure 40.5. Since polymers are non-crystalline or at most semicrystalline, the value obtained in this measurement depends on how fast it is taken.

TABLE 40.5 Biomedical Application of Polymeric Biomaterials

Synthetic Polymers	Applications
Polyvinylchloride (PVC)	Blood and solution bag, surgical packaging, IV sets, dialysis devices, catheter bottles, connectors, and cannulae
Polyethylene (PE)	Pharmaceutical bottle, nonwoven fabric, catheter, pouch, flexible container, and orthopedic implants
Polypropylene (PP)	Disposable syringes, blood oxygenator membrane, suture, nonwoven fabric, and artificial vascular grafts
Polymethylmetacrylate (PMMA)	Blood pump and reservoirs, membrane for blood dialyzer, implantable ocular lens, and bone cement
Polystyrene (PS)	Tissue culture flasks, roller bottles, and filterwares
Polyethylenterephthalate (PET)	Implantable suture, mesh, artificial vascular grafts, and heart valve
Polytetrafluoroethylene (PTFE)	Catheter and artificial vascular grafts
Polyurethane (PU)	Film, tubing, and components
Polyamide (Nylon)	Packaging film, catheters, sutures, and mold parts

40.3 Polymers Used as Biomaterials

Although hundreds of polymers are easily synthesized and could be used as biomaterials only ten to twenty polymers are mainly used in medical device fabrications from disposable to long-term implants as given in Table 40.5. In this section, the general information of the characteristics, properties, and applications of the most commonly used polymers will be discussed [Billmeyer, 1984; Park, 1984; Leininger and Bigg, 1986; Shalaby, 1988; Brandrup and Immergut, 1989; Sharma and Szycher, 1991; Park and Lakes, 1992; Dumitriu, 1993; Lee and Lee, 1995; Ratner et al., 1996].

40.3.1 Polyvinylchloride (PVC)

The PVC is an amorphous, rigid polymer due to the large side group (Cl, chloride) with a T_g of 75 to 105°C. It has a high melt viscosity hence it is difficult to process. To prevent the thermal degradation of the polymer (HCl could be released), thermal stabilizers such as metallic soaps or salts are incorporated. Lubricants are formulated on PVC compounds to prevent adhesion to metal surfaces and facilitate the melt flow during processing. Plasticizers are used in the range of 10 to 100 parts per 100 parts of PVC resin to make it flexible. Di-2-ethylhexylphthalate (DEHP or DOP) is used in medical PVC formulation. However, the plasticizers of trioctyltrimellitate (TOTM), polyester, azelate, and phosphate ester are also used to prevent extraction by blood, aqueous solution, and hot water during autoclaving sterilization.

   PVC sheets and films are used in blood and solution storage bags and surgical packaging. PVC tubing is commonly used in intravenous (IV) administration, dialysis devices, catheters, and cannulae.

40.3.2 Polyethylene (PE)

PE is available commercially in five major grades: (1) high density (HDPE), (2) low density (LDPE), (3) linear low density (LLDPE), (4) very low density (VLDPE), and (5) ultra high molecular weight (UHMWPE). HDPE is polymerized in a low temperature (60–80°C), and at a low pressure ($\sim$10 kg/cm^2) using metal catalysts. A highly crystalline, linear polymer with a density ranging from 0.94 to 0.965 g/cm^3 is obtained. LDPE is derived from a high temperature (150–300°C) and pressures (1000–3000 kg/cm^2) using free radical initiators. A highly branched polymer with lower crystallinity and densities ranging from 0.915 to 0.935 g/cm^3 is obtained. LLDPE (density: 0.91–0.94 g/cm^3) and VLDPE (density: 0.88–0.89 g/cm^3), which are linear polymers, are polymerized under low pressures and temperatures using metal catalysts with comonomers such as 1-butene, 1-hexene, or 1-octene to obtain the desired physical properties and density ranges.

HDPE is used in pharmaceutical bottles, nonwoven fabrics, and caps. LDPE is found in flexible container applications, nonwoven-disposable and laminated (or coextruded with paper) foil, and polymers for packaging. LLDPE is frequently employed in pouches and bags due to its excellent puncture resistance and VLDPE is used in extruded tubes. UHMWPE (MW $>2 \times 10^6$ g/mol) has been used for orthopedic implant fabrications, especially for load-bearing applications such as an acetabular cup of total hip and the tibial plateau and patellar surfaces of knee joints. Biocompatability tests for PE are given by ASTM standards in F981, F639, and F755.

40.3.3 Polypropylene (PP)

PP can be polymerized by a Ziegler-Natta stereospecific catalyst which controls the isotactic position of the methyl group. Thermal (T_g: $-12°C$, T_m: 125–167°C and density: 0.85–0.98 g/cm^3) and physical properties of PP are similar to PE. The average molecular weight of commercial PP ranges from 2.2 to 7.0×10^5 g/mol and has a wide molecular weight distribution (polydispersity) which is from 2.6 to 12. Additives for PP such as antioxidants, light stabilizer, nucleating agents, lubricants, mold release agents, antiblock, and slip agents are formulated to improve the physical properties and processability. PP has an exceptionally high flex life and excellent environment stress-cracking resistance, hence it had been tried for finger joint prostheses with an integrally molded hinge design [Park, 1984]. The gas and water vapor permeability of PP are in-between those of LDPE and HDPE. PP is used to make disposable hypothermic syringes, blood **oxygenator** membrane, packaging for devices, solutions, and drugs, **suture**, artificial vascular **grafts**, nonwoven fabrics, etc.

40.3.4 Polymethylmetacrylate (PMMA)

Commercial PMMA is an amorphous (T_g: 105°C and density: 1.15 to 1.195 g/cm^3) material with good resistance to dilute alkalis and other inorganic solutions. PMMA is best known for its exceptional light transparency (92% transmission), high **refractive index** (1.49), good weathering properties, and as one of the most biocompatible polymers. PMMA can be easily machined with conventional tools, molded, surface coated, and plasma etched with glow or corona discharge. PMMA is used broadly in medical applications such as a blood pump and reservoir, an IV system, membranes for blood dialyzer, and in *in vitro* diagnostics. It is also found in contact lenses and implantable ocular lenses due to excellent optical properties, dentures, and maxillofacial prostheses due to good physical and coloring properties, and **bone cement** for joint prostheses fixation (ASTM standard F451).

Another acrylic polymer such as polymethylacrylate (PMA), polyhydroxyethyl-methacrylate (PHEMA), and polyacrylamide (PAAm) are also used in medical applications. PHEMA and PAAm are **hydrogels**, lightly cross-linked by ethyleneglycoldimethylacrylate (EGDM) to increase their mechanical strength. The extended wear soft contact lenses are synthesized from PMMA and N-vinylpyrollidone or PHEMA which have high water content (above 70%) and a high oxygen permeability.

40.3.5 Polystyrene (PS) and Its Copolymers

The PS is polymerized by free radical polymerization and is usually atactic. Three grades are available; unmodified general purpose PS (GPPS, T_g: 100°C), high impact PS (HIPS), and PS foam. GPPS has good transparency, lack of color, ease of fabrication, thermal stability, low specific gravity (1.04–1.12 g/cm^3), and relatively high modulus. HIPS contains a rubbery modifier which forms chemical bonding with the growing PS chains. Hence the ductility and impact strength are increased and the resistance to environmental stress-cracking is also improved. PS is mainly processed by injection molding at 180–250°C. To improve processability additives such as stabilizers, lubricants, and mold releasing agents are formulated. GPPS is commonly used in tissue culture flasks, roller bottles, vacuum canisters, and filterware.

Acrylonitrile–butadiene–styrene (ABS) **copolymers** are produced by three monomers; acrylonitrile, butadiene, and styrene. The desired physical and chemical properties of ABS polymers with a wide range of functional characteristics can be controlled by changing the ratio of these monomers. They are resistant

to the common inorganic solutions, have good surface properties, and dimensional stability. ABS is used for IV sets, clamps, blood dialyzers, diagnostic test kits, and so on.

40.3.6 Polyesters

Polyesters such as polyethyleneterephthalate (PET) are frequently found in medical applications due to their unique chemical and physical properties. PET is so far the most important of this group of polymers in terms of biomedical applications such as artificial vascular graft, sutures, and meshes. It is highly crystalline with a high melting temperature (T_m: 265°C), hydrophobic and resistant to hydrolysis in dilute acids. In addition, PET can be converted by conventional techniques into molded articles such as luer filters, check valves, and catheter housings. Polycaprolactone is crystalline and has a low melting temperature (T_m: 64°C). Its use as a soft matrix or coating for conventional polyester fibers was proposed by recent investigation [Leininger and Bigg, 1986].

40.3.7 Polyamides (Nylons)

Polyamides are known as nylons and are designated by the number of carbon atoms in the repeating units. Nylons can be polymerized by step-reaction (or condensation) and ring-scission polymerization. They have excellent fiber-forming ability due to interchain **hydrogen bonding** and a high degree of crystallinity, which increases strength in the fiber direction.

The presence of –CONH– groups in polyamides attracts the chains strongly toward one another by hydrogen bonding. Since the hydrogen bond plays a major role in determining properties, the number and distribution of –CONH– groups are important factors. For example, T_g can be decreased by decreasing the number of –CONH– groups . On the other hand, an increase in the number of –CONH– groups improves physical properties such as strength as one can see that Nylon 66 is stronger than Nylon 610 and Nylon 6 is stronger than Nylon 11.

In addition to the higher Nylons (610 and 11) there are aromatic polyamides named aramids. One of them is poly (*p*-phenylene terephthalate) commonly known as **Kevlar®**, made by DuPont. This material can be made into fibers. The specific strength of such fibers is five times that of steel, therefore, it is most suitable for making composites.

Nylons are hygroscopic and lose their strength *in vivo* when implanted. The water molecules serve as plasticizers which attack the amorphous region. Proteolytic enzymes also aid in hydrolyzing by attacking the amide group. This is probably due to the fact that the proteins also contain the amide group along their molecular chains which the proteolytic enzymes could attack.

40.3.8 Fluorocarbon Polymers

The best known fluorocarbon polymer is polytetrafluoroethylene (PTFE), commonly known as **Teflon®** (DuPont). Other polymers containing fluorine are polytrifluorochloroethylene (PTFCE), polyvinylfluoride (PVF), and fluorinated ethylene propylene (FEP). Only PTFE will be discussed here since the others have rather inferior chemical and physical properties and are rarely used for implant fabrication.

PTFE is made from tetrafluoroethylene under pressure with a peroxide catalyst in the presence of excess water for removal of heat. The polymer is highly crystalline (over 94% crystallinity) with an average molecular weight of 0.5–5×10^6 g/mol. This polymer has a very high density (2.15–2.2 g/cm^3), low modulus of elasticity (0.5 GPa) and tensile strength (14 MPa). It also has a very low surface tension (18.5 erg/cm^2) and friction coefficient (0.1).

Standard specifications for the implantable PTFE are given by ASTM F754. PTFE also has an unusual property of being able to expand on a microscopic scale into a microporous material which is an excellent thermal insulator. PTFE cannot be injection molded or melt extruded because of its very high melt viscosity and it cannot be plasticized. Usually the powders are sintered to above 327°C under pressure to produce implants.

40.3.9 Rubbers

Silicone, natural, and synthetic rubbers have been used for the fabrication of implants. Natural rubber is made mostly from the latex of the Hevea brasiliensis tree and the chemical formula is the same as that of *cis*-1,4 polyisoprene. Natural rubber was found to be compatible with blood in its pure form. Also, cross-linking by x-ray and organic peroxides produces rubber with superior blood compatibility compared with rubbers made by the conventional sulfur vulcanization.

Synthetic rubbers were developed to substitute for natural rubber. The Ziegler-Natta types of stereospecific polymerization techniques have made this variety possible. The synthetic rubbers have rarely been used to make implants. The physical properties vary widely due to the wide variations in preparation recipes of these rubbers.

Silicone rubber, developed by Dow Corning company, is one of the few polymers developed for medical use. The repeating unit is dimethyl siloxane which is polymerized by a condensation polymerization. Low molecular weight polymers have low viscosity and can be cross-linked to make a higher molecular weight, rubber-like material. Medical grade silicone rubbers contain stannous octate as a catalyst and can be mixed with a base polymer at the time of implant fabrication.

40.3.10 Polyurethanes

Polyurethanes are usually thermosetting polymers: they are widely used to coat implants. Polyurethane rubbers are produced by reacting a prepared prepolymer chain with an aromatic di-isocyanate to make very long chains possessing active isocyanate groups for cross-linking. The polyurethane rubber is quite strong and has good resistance to oil and chemicals.

40.3.11 Polyacetal, Polysulfone, and Polycarbonate

These polymers have excellent mechanical, thermal, and chemical properties due to their stiffened main backbone chains. Polyacetals and polysulfones are being tested as implant materials, while polycarbonates have found their applications in the heart/lung assist devices, food packaging, etc.

Polyacetals are produced by reacting formaldehyde. These are also sometimes called polyoxymethylene (POM) and known widely as **Delrin®** (DuPont). These polymers have a reasonably high molecular weight ($>2 \times 10^4$ g/mol) and have excellent mechanical properties. More importantly, they display an excellent resistance to most chemicals and to water over wide temperature ranges.

Polysulfones were developed by Union Carbide in the 1960s. These polymers have a high thermal stability due to the bulky side groups (therefore, they are amorphous) and rigid main backbone chains. They are also highly stable to most chemicals but are not so stable in the presence of polar organic solvents such as ketones and chlorinated hydrocarbons.

Polycarbonates are tough, amorphous, and transparent polymers made by reacting bisphenol A and diphenyl carbonate. It is noted for its excellent mechanical and thermal properties (high T_g: 150°C), hydrophobicity, and antioxidative properties.

40.3.12 Biodegradable Polymers

Recently, several biodegradable polymers such as polylactide (PLA), polyglycolide (PGA), poly(glycolide-*co*-lactide) (PLGA), poly(dioxanone), poly(trimethylene carbonate), poly(carbonate), and so on are extensively used or tested on a wide range of medical applications due to their good biocompatibility, controllable biodegradability, and relatively good processability [Khang et al., 1997]. PLA, PGA, and PLGA are bioresorbable polyesters belonging to the group of poly α-hydroxy acids. These polymers degrade by nonspecific hydrolytic scission of their ester bonds. The hydrolysis of PLA yields lactic acid which is a normal byproduct of anaerobic metabolism in the human body and is incorporated in the tricarboxylic acid (TCA) cycle to be finally excreted by the body as carbon dioxide and water. PGA biodegrades by a combination of hydrolytic scission and enzymatic (esterase) action producing glycolic acid which can

either enter the TCA cycle or is excreted in urine and can be eliminated as carbon dioxide and water. The degradation time of PLGA can be controlled from weeks to over a year by varying the ratio of monomers and the processing conditions. It might be a suitable biomaterial for use in tissue engineered repair systems in which cells are implanted within PLGA films or scaffolds and in drug delivery systems in which drugs are loaded within PLGA microspheres. PGA (T_m: 225–230°C, T_g: 35–40°C) can be melt spun into fibers which can be converted into bioresorbable sutures, meshes, and surgical products. PLA (T_m: 173–178°C, T_g: 60–65°C) exhibit high tensile strength and low elongation resulting in a high modulus suitable for load-bearing applications such as in bone fracture fixation. Poly-p-dioxanone (T_m: 107–112°C, T_g: ~10°C) is a bioabsorbable polymer which can be fabricated into flexible monofilament surgical sutures.

40.4 Sterilization

Sterilizability of biomedical polymers is an important aspect of the properties because polymers have lower thermal and chemical stability than other materials such as ceramics and metals, consequently, they are also more difficult to sterilize using conventional techniques. Commonly used sterilization techniques are dry heat, autoclaving, radiation, and ethylene oxide gas [Block, 1977].

In dry heat sterilization, the temperature varies between 160 and 190°C. This is above the melting and softening temperatures of many linear polymers like polyethylene and PMMA. In the case of polyamide (Nylon), oxidation will occur at the dry sterilization temperature although this is below its melting temperature. The only polymers which can safely be dry sterilized are PTFE and silicone rubber.

Steam sterilization (autoclaving) is performed under high steam pressure at relatively low temperature (125–130°C). However, if the polymer is subjected to attack by water vapor, this method cannot be employed. PVC, polyacetals, PE (low-density variety), and polyamides belong to this category.

Chemical agents such as ethylene and propylene oxide gases [Glaser, 1979], and phenolic and hypochloride solutions are widely used for sterilizing polymers since they can be used at low temperatures. Chemical agents sometimes cause polymer deterioration even when sterilization takes place at room temperature. However, the time of exposure is relatively short (overnight), and most polymeric implants can be sterilized with this method.

Radiation sterilization [Sato, 1983] using the isotopic ^{60}Co can also deteriorate polymers since at high dosage the polymer chains can be dissociated or cross-linked according to the characteristics of the chemical structures, as shown in Table 40.6. In the case of PE, at high dosage (above 10^6 Gy) it becomes a brittle and hard material. This is due to a combination of random chain scission cross-linking. PP articles will often discolor during irradiation giving the product an undesirable color tint but the more severe problem is the embrittlement resulting in flange breakage, luer cracking, and tip breakage. The physical properties continue to deteriorate with time, following irradiation. These problems of coloration and changing physical properties are best resolved by avoiding the use of any additives which discolor at the sterilizing dose of radiation [Khang, 1996c].

40.5 Surface Modifications for Improving Biocompatability

Prevention of **thrombus** formation is important in clinical applications where blood is in contact such as hemodialysis membranes and tubes, artificial heart and heart–lung machines, prosthetic valves, and artificial vascular grafts. In spite of the use of anticoagulants, considerable platelet deposition and thrombus formation take place on the artificial surfaces [Branger, 1990].

Heparin, one of the complex carbohydrates known as mucopolysaccharides or glycosaminoglycan is currently used to prevent formation of clots. In general, heparin is well tolerated and devoid of serious consequences. However, it allows platelet adhesion to foreign surfaces and may cause hemorrhagic complications such as subdural hematoma, retroperitoneal hematoma, gastrointestinal bleeding, hemorrage

into joints, ocular and retinal bleeding, and bleeding at surgical sites [Lazarus, 1980]. These difficulties give rise to an interest in developing new methods of hemocompatible materials.

Many different groups have studied immobilization of heparin [Kim and Feijen, 1985; Park et al., 1988] on the polymeric surfaces, heparin analogues and heparin-prostaglandin or heparin-fibrinolytic enzyme conjugates [Jozefowicz and Jozefowicz, 1985]. The major drawback of these surfaces is that they are not stable in the blood environment. It has not been firmly established that a slow leakage of heparin is needed for it to be effective as an immobilized antithrombogenic agent, if not its effectiveness could be hindered by being "coated over" with an adsorbed layer of more common proteins such as albumin and **fibrinogen**. Fibrinolytic enzymes, urokinase, and various prostaglandins have also been immobilized by themselves in order to take advantage of their unique fibrin dissolution or antiplatelet aggregation actions [Ohshiro, 1983].

Albumin-coated surfaces have been studied because surfaces that resisted platelet adhesion *in vitro* were noted to adsorb albumin preferentially [Keogh et al., 1992]. Fibronectin coatings have been used in *in vitro* endothelial cell seeding to prepare a surface similar to the natural blood vessel lumen [Lee et al., 1989]. Also, algin-coated surfaces have been studied due to their good biocompatibility and biodegradability [Lee et al., 1990b; 1997b].

Recently, plasma gas discharge [Khang et al., 1997a] and corona treatment [Khang et al., 1996d] with reactive groups introduced on the polymeric surfaces have emerged as other ways to modify biomaterial surfaces [Lee et al., 1991; 1992].

Hydrophobic coatings composed of silicon- and fluorine-containing polymeric materials as well as polyurethanes have been studied because of the relatively good clinical performances of Silastic®, Teflon®, and polyurethane polymers in cardiovascular implants and devices. Polymeric fluorocarbon coatings deposited from a tetrafluoroethylene gas discharge have been found to greatly enhance resistance to both acute thrombotic occlusion and embolization in small diameter **Dacron®** grafts.

Hydrophilic coatings have also been popular because of their low interfacial tension in biological environments [Hoffman, 1981]. Hydrogels as well as various combinations of hydrophilic and hydrophobic monomers have been studied on the premise that there will be an optimum polar-dispersion force ratio which could be matched on the surfaces of the most passivating proteins. The passive surface may induce less clot formation. Polyethylene oxide coated surfaces have been found to resist protein adsorption and cell adhesion and have therefore been proposed as potential "blood compatible" coatings [Lee et al., 1990a]. General physical and chemical methods to modify the surfaces of polymeric biomaterials are listed in Table 40.7 [Ratner et al., 1996].

TABLE 40.7 Physical and Chemical Surface Modification Methods for Polymeric
Biomaterials

To modify blood compatibility	Octadecyl group attachment to surface
	Silicon containing block copolymer additive
	Plasma fluoropolymer deposition
	Plasma siloxane polymer deposition
	Radiation-grafted hydrogels
	Chemically modified polystyrene for heparin-like activity
To influence cell adhesion and growth	Oxidized polystyrene surface
	Ammonia plasma-treated surface
	Plasma-deposited acetone or methanol film
	Plasma fluoropolymer deposition
To control protein adsorption	Surface with immobilized polyethyelenglycol
	Treated ELISA dish surface
	Affinity chromatography particulates
	Surface cross-linked contact lens
To improve lubricity	Plasma treatment
	Radiation-grafted hydrogels
	Interpenetrating polymeric networks
To improve wear resistance and corrosion resistance	Ion implantation
	Diamond deposition
	Anodization
To alter transport properties	Plasma deposition (methane, fluoropolymer, siloxane)
To modify electrical characteristics	Plasma deposition
	Solvent coatings
	Parylene coatings

Another way of making antithrombogenic surfaces is the saline perfusion method, which is designed to prevent direct contacts between blood and the surface of biomaterials by means of perfusing saline solution through the porous wall which is in contact with blood [Park and Kim, 1993; Khang et al., 1996a, b]. It has been demonstrated that the adhesion of the blood cells could be prevented by the saline perfusion through PE, alumina, sulfonated/nonsulfonated PS/SBR, ePTFE (expanded polytetrafluoroethylene), and polysulfone porous tubes.

40.6 Chemogradient Surfaces for Cell and Protein Interaction

The behavior of the adsorption and desorption of blood proteins or adhesion and proliferation of different types of mammalian cells on polymeric materials depends on the surface characteristics such as wettability, hydrophilicity/hydrophobicity ratio, bulk chemistry, surface charge and charge distribution, surface roughness, and rigidity.

Many research groups have studied the effect of the surface wettability on the interactions of biological species with polymeric materials. Some have studied the interactions of different types of cultured cells or blood proteins with various polymers with different wettabilities to correlate the surface wettability and blood- or tissue-compatibility [Baier et al., 1984]. One problem encountered from the study using different kinds of polymers is that the surfaces are heterogeneous, both chemically and physically (different surface chemistry, roughness, rigidity, crystallinity, etc.), which caused widely varying results. Some others have studied the interactions of different types of cells or proteins with a range of methacrylate copolymers with different wettabilities and have the same kind of chemistry but are still physically heterogeneous [van Wachem et al., 1987]. Another methodological problem is that such studies are often tedious, laborious, and time-consuming because a large number of samples must be prepared to characterize the complete range of the desired surface properties.
FIGURE 40.6 Schematic diagram showing corona discharge apparatus for the preparation of wettability chemogradient surfaces.

Many studies have been focused on the preparation of surfaces whose properties are changed gradually along the material length. Such chemogradient surfaces are of particular interest in basic studies of the interactions between biological species and synthetic materials surfaces since the affect of a selected property can be examined in a single experiment on one surface preparation. A chemogradient of methyl groups was formed by diffusion of dimethyldichlorosilane through xylene on flat hydrophilic silicone-dioxide surfaces [Elwing et al., 1989]. The wettability chemogradient surfaces were made to investigate hydrophilicity-induced changes of adsorbed proteins.

Recently, a method for preparing wettability chemogradients on various polymer surfaces was developed [Lee et al., 1989, 1990; Khang et al., 1997b]. The wettability chemogradients were produced via radio frequency (RF) and plasma discharge treatment by exposing the polymer sheets continuously to the plasma [Lee et al., 1991]. The polymer surfaces oxidized gradually along the sample length with increasing plasma exposure time and thus the wettability chemogradient was created. Another method for preparing a wettability chemogradient on polymer surfaces using corona discharge treatment has been developed as shown in Figure 40.6 [Lee et al., 1992]. The wettability chemogradient was produced by treating the polymer sheets with corona from a knife-type electrode whose power was gradually changed along the sample length. The polymer surface gradually oxidized with the increasing power and the wettability chemogradient was created. Chemogradient surfaces with different functional gruops such as –COOH, –CH$_2$OH, –CONH$_2$, and –CH$_2$NH$_2$ were produced on PE surfaces by the above corona treatment followed by vinyl monomer grafting and substitution reactions [Kim et al., 1993; Lee et al., 1994a, b]. We have also prepared chargeable functional groups [Lee et al., 1997c, d, 1998a], comb-like polyethyleneoxide (PEO) [Jeong et al., 1996; Lee et al., 1997a] and phospholipid polymer chemogradient surfaces [Iwasaki et al., 1997] by the corona discharge treatment, followed by the graft copolymerization with subsequent substitution reaction of functional vinyl monomers as acrylic acid, sodium p-sulfonic styrene and N, N-dimethyl aminopropyl acrylamide, poly(ethyleneglycol) mono-methacrylate, and ω-methacryloyloxyalkyl phosphorylcholine (MAPC), respectively.

The water contact angles of the corona-treated PE surfaces gradually decrease along the sample length with increasing corona power (from about 95° to about 45°) as shown in Figure 40.7. The decrease in contact angles, that is, the increase in wettability along the sample length was due to the oxygen-based polar functionalities incorporated on the surface by the corona treatment. It was also confirmed also by fourier-transform infrared spectroscopy in the attenuated total reflectance mode and electron spectroscopy for chemical analysis (ESCA).

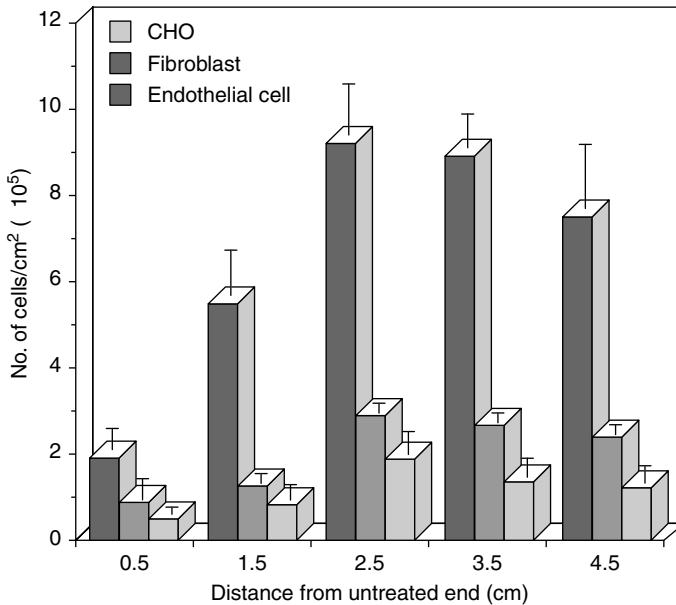
In order to investigate the interaction of different types of cells in terms of the surface hydrophilicity/hydrophobicity of polymeric materials, Chinese hamster ovaries (CHO), fibroblasts, and bovine aortic endothelial cells (EC) were cultured for 1 and 2 days on the PE wettability chemogradient surfaces. The maximum adhesion and growth of the cells appeared around a water contact angle of 50 to 55°
FIGURE 40.7 Changes in water contact angle of corona-treated PE surface along the sample length. Sample numbers, $n = 3$.


FIGURE 40.8 CHO, fibroblast, and endothelial cell growth on wettability chemogradient PE surfaces after 2 days culture (number of seeded cells, $4 \times 104/cm^2$). $n = 3$.

as shown in Figure 40.8. The observation of scanning electron microscopy (SEM) also verified that the cells are more adhered, spread, and grown onto the sections with moderate hydrophilicity as shown in Figure 40.9.

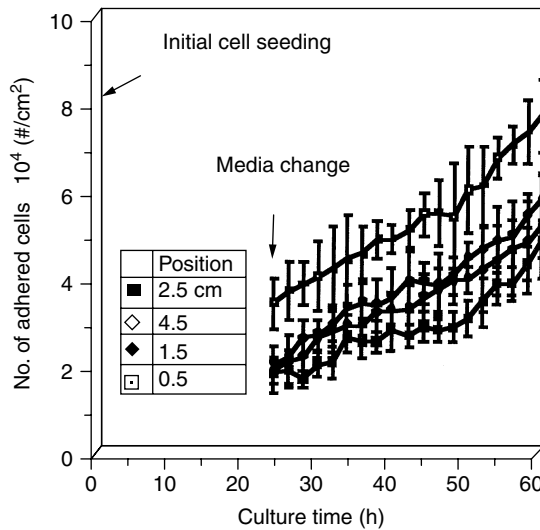
To determine the cell proliferation rates, the migration of fibroblasts on PE wettability chemogradient surfaces were observed [Khang et al., 1998b]. After the change of culture media at 24 h, cell growth morphology was recorded for 1 or 2 h intervals at the position of 0.5, 1.5, 2.5, and 4.5 cm for the counting
FIGURE 40.9 SEM microphotographs of CHO, fibroblast, and endothelial cells grown on PE wettability chemogradient surface along the sample length after 2 days culture (original magnification; ×400).


FIGURE 40.10 Fibroblast cell proliferation rates on wettability chemogradient PE surfaces (24 to 60 h culture).

of grown cells and the observation of cell morphology with a video tape recorder. The proliferation rates of fibroblast cells were calculated from the slopes of Figure 40.10 as given in Table 40.8. The proliferation rates on the PE surfaces with wettability chemogradient showed that as the surface wettability increased, it increased and then decreased. The maximum proliferation rate of the cells as 1111 cells/h · cm^2 appeared at around the position 2.5 cm.

TABLE 40.8 Proliferation Rates of Fibroblast Cells on Wettability Gradient PE Surfaces

Positions (cm)	Contact angle (°)	Cell proliferation rate (#cell/h cm^2)
2.5	55	1111
4.5	45	924
1.5	67	838
0.5	85	734

Note: 24 to 60 h culture.
FIGURE 40.11 Serum protein adsorption on PE wettability chemogradient surface (1 h adsorption). $n = 3$.

To observe the effect of serum proteins on the cell adhesion and growth behaviors, fetal bovine serum (FBS), which contains more than 200 kinds of different proteins, was adsorbed onto the wettability gradient PE surfaces for 1 h at 37°C. Figure 40.11 shows the relative adsorbed amount of serum proteins on the wettability gradient surfaces determined by ESCA. The maximum adsorption of the proteins appeared at around the 2.5 cm position, which is the same trend as the cell adhesion, growth, and migration behaviors. It can be explained that preferential adsorption of some serum proteins, like fibronectin and vitronectin from culture medium, onto the moderately wettable surfaces may be a reason for better cell adhesion, spreading, and growth. Proteins like fibronectin and vitronectin are well known as cell-adhesive proteins. Cells attached on surfaces are spread only when they are compatible on the surfaces. It seems that surface wettability plays an important role for cell adhesion, spreading, and migration.

Also investigated were (1) platelet adhesion on wettability chemogradient [Lee and Lee, 1998b], (2) cell interaction on microgrooved PE surfaces (groove depth, 0.5 μm; groove width, 0.45 μm; and pitch, 0.9 μm) with wettability chemogradient [Khang et al., 1997c], (3) detachment of human endothelial under flow from wettability gradient surface with different functional groups [Ruardy et al., 1997], (4) cell interaction on microporous polycarbonate membrane with wettability chemogradient [Lee et al., 1998c], and (5) cell interaction on poly(lactide-*co*-glycolide) surface with wettability chemogradient [Khang et al., 1998a].

During the last several years, "chemogradient surfaces" have evolved into easier and more popular tools for the study of protein adsorption and platelet or cell interactions continuously which relate to

the surface properties such as wettability, chemistry and charge, or dynamics of polymeric materials. In many studies, different kinds of polymeric materials with widely varying surface chemistries are used and the explanation of the results is often in controversy due to the surface heterogeneity. In addition, these studies are tedious, laborious, and time-consuming, and biological variations are more likely to occur. The application of chemogradient surfaces for these studies can reduce these discomforts and problems, and eventually save time and money. Also, chemogradient surfaces are valuable in investigating the basic mechanisms by which complicated systems such as proteins or cells interact with surfaces, since a continuum of selected and controlled physical–chemical properties can be studied in one experiment on the polymeric surface.

The possible applications of chemogradient surfaces in the near future are (1) separation devices of cells and/or biological species by different surface properties, (2) column packing materials for separation, (3) biosensoring, etc.

Defining Terms

Acetabulum: The socket portion of the hip joint.

Addition (or free radical) polymerization: Polymerization in which monomers are added to the growing chains, initiated by free radical agents.

Biocompatibility: Acceptance of an artificial implant by the surrounding tissues and as a whole. The implant should be compatible with tissues in terms of mechanical, chemical, surface, and pharmacological properties.

Biomaterials: Synthetic materials used to replace part of a living system or to function in intimate contact with living tissue.

Bone cement: Mixture of polymethylmethacrylate powder and methylmethacrylate monomer liquid to be used as a grouting material for the fixation of orthopedic joint implants.

Branching: Chains grown from the sides of the main backbone chains.

Chemogradient surface: The surface whose properties such as wettability, surface charge, and hydrophilicity/hydrophobicity ratio are changed gradually along the material length.

Condensation (step reaction) polymerization: Polymerization in which two or more chemicals are reacted to form a polymer by condensing out small molecules such as water and alcohol.

Copolymers: Polymers made from two or more monomers which can be obtained by grafting, block, alternating, or random attachment of the other polymer segment.

Covalent bonding: Bonding of atoms or molecules by sharing valence electrons.

Dacron®: Polyethyleneterephthalate polyester that is made into fiber. If the same polymer is made into a film, it is called Mylar®.

Delrin®: Polyacetal made by Union Carbide.

Elastomers: Rubbery materials. The restoring force comes from uncoiling or unkinking of coiled or kinked molecular chains. They can be highly stretched.

Embolus: Any foreign matter, as a blood clot or air bubble, carried in the blood stream.

Fibrinogen: A plasma protein of high molecular weight that is converted to fibrin through the action of thrombin. This material is used to make (absorbable) tissue adhesives.

Filler: Materials added as a powder to a rubber to improve its mechanical properties.

Free volume: The difference in volume occupied by the crystalline state (minimum) and non-crystalline state of a material for a given temperature and a pressure.

Glass transition temperature: Temperature at which solidification without crystallization takes place from viscous liquid.

Grafts: A transplant.

Heparin: A substance found in various body tissues, especially in the liver, that prevents the clotting of blood.

Hydrogel: Polymer which can absorb 30% or more of its weight in water.

Hydrogen bonding: A secondary bonding through dipole interactions in which the hydrogen ion is one of the dipoles.

Hydroquinone: Chemical inhibitor added to the bone cement liquid monomer to prevent accidental polymerization during storage.

Initiator: Chemical used to initiate the addition polymerization by becoming a free radical which in turn reacts with a monomer.

Ionic bonding: Bonding of atoms or molecules through electrostatic interaction of positive and negative ions.

Kevlar®:   Aromatic polyamides made by DuPont.

Lexan®:   Polycarbonate made by General Electric.

Oxygenator: An apparatus by which oxygen is introduced into blood during circulation outside the body, as during open-heart surgery.

Plasticizer: Substance made of small molecules, mixed with (amorphous) polymers to make the chains slide more easily past each other, making the polymer less rigid.

Refractive index: Ratio of speed of light in vacuum to speed of light in a material. It is a measure of the ability of a material to refract (bend) a beam of light.

Repeating unit: Basic molecular unit which can represent a polymer backbone chain. The average number of repeating units is called the degree of polymerization.

Repeating unit: The smallest unit representing a polymer molecular chain.

Semi-crystalline solid: Solid which contains both crystalline and noncrystalline regions and usually occurs in polymers due to their long chain molecules.

Side group: Chemical group attached to the main backbone chain. It is usually shorter than the branches and exists before polymerization.

Steric hindrance: Geometrical interference which restrains movements of molecular groups such as side chains and main chains of a polymer.

Suture: Material used in closing a wound with stitches.

Tacticity: Arrangement of asymmetrical side groups along the backbone chain of polymers. Groups could be distributed at random (atactic), one side (isotactic), or alternating (syndiotactic).

Teflon®:   Polytetrafluoroethylene made by DuPont.

Thrombus: The fibrinous clot attached at the site of thrombosis.

Udel®:   Polysulfone made by General Electric.

Valence electrons: The outermost (shell) electrons of an atom.

van der Waals bonding: A secondary bonding arising through the fluctuating dipole-dipole interactions.

Vinyl polymers: Thermoplastic linear polymers synthesized by free radical polymerization of vinyl monomers having a common structure of $CH_2=CHR$.

Vulcanization: Cross-linking of a (natural) rubber by adding sulfur.

Ziegler–Natta catalyst: Organometallic compounds which have the remarkable capacity of polymerizing a wide variety of monomers to linear and stereoregular polymers.

Composite Biomaterials

Roderic S. Lakes
University of Wisconsin-Madison

Composite materials are solids which contain two or more distinct constituent materials or phases, on a scale larger than the atomic. The term "composite" is usually reserved for those materials in which the distinct phases are separated on a scale larger than the atomic, and in which properties such as the elastic modulus are significantly altered in comparison with those of a homogeneous material. Accordingly, reinforced plastics such as fiberglass as well as natural materials such as bone are viewed as composite materials, but alloys such as brass are not. A foam is a composite in which one phase is empty space. Natural biological materials tend to be composites. Natural composites include bone, wood, dentin, cartilage, and skin. Natural foams include lung, cancellous bone, and wood. Natural composites often exhibit hierarchical structures in which particulate, porous, and fibrous structural features are seen on different micro-scales [Katz, 1980; Lakes, 1993]. In this segment, composite material fundamentals and applications in biomaterials [Park and Lakes, 1988] are explored. Composite materials offer a variety of advantages in comparison with homogeneous materials. These include the ability for the scientist or engineer to exercise considerable control over material properties. There is the potential for stiff, strong, lightweight materials as well as for highly resilient and compliant materials. In biomaterials, it is important that each constituent of the composite be biocompatible. Moreover, the interface between constituents should not be degraded by the body environment. Some applications of composites in biomaterial applications are (1) dental filling composites, (2) reinforced methyl methacrylate bone cement and ultra-high molecular weight polyethylene, and (3) orthopedic implants with porous surfaces.

41.1 Structure

The properties of composite materials depend very much upon *structure*. Composites differ from homogeneous materials in that considerable control can be exerted over the larger scale structure, and hence

over the desired properties. In particular, the properties of a composite material depend upon the *shape* of the heterogeneities, upon the *volume fraction* occupied by them, and upon the *interface* among the constituents. The shape of the heterogeneities in a composite material is classified as follows. The principal inclusion shape categories are (1) the particle, with no long dimension, (2) the fiber, with one long dimension, and (3) the platelet or lamina, with two long dimensions, as shown in Figure 41.1. The inclusions may vary in size and shape within a category. For example, particulate inclusions may be spherical, ellipsoidal, polyhedral, or irregular. If one phase consists of voids, filled with air or liquid, the material is known as a cellular solid. If the cells are polygonal, the material is a honeycomb; if the cells are polyhedral, it is a foam. It is necessary in the context of biomaterials to distinguish the above structural cells from biological cells, which occur only in living organisms. In each composite structure, we may moreover make the distinction between random orientation and preferred orientation.

41.2 Bounds on Properties

Mechanical properties in many composite materials depend on structure in a complex way, however for some structures, the prediction of properties is relatively simple. The simplest composite structures are the idealized Voigt and Reuss models, shown in Figure 41.2. The dark and light areas in these diagrams represent the two constituent materials in the composite. In contrast to most composite structures, it is easy to calculate the stiffness of materials with the Voigt and Reuss structures, since in the Voigt structure the strain is the same in both constituents; in the Reuss structure the stress is the same. The Young's modulus, E, of the Voigt composite is:

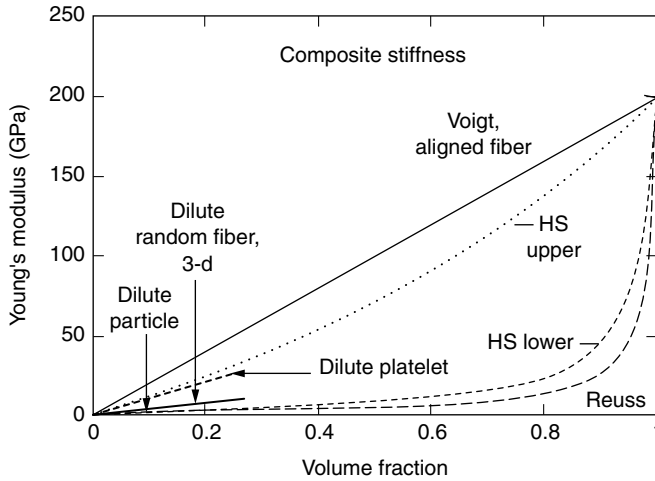
$$E = E_i V_i + E_m[1 - V_i] \tag{41.1}$$
FIGURE 41.1   Morphology of basic composite inclusions. (a) Particle, (b) fiber, and (c) platelet.
FIGURE 41.2   Voigt (a, laminar; b, fibrous) and Reuss (c) composite models, subjected to tension force indicated by arrows.


FIGURE 41.3 Stiffness vs. volume fraction for Voigt and Reuss models, as well as for dilute isotropic suspensions of platelets, fibers, and spherical particles embedded in a matrix. Phase moduli are 200 and 3 GPa.

in which E_i is the Young's modulus of the inclusions, and V_i is the volume fraction of inclusions, and E_m is the Young's modulus of the matrix. The Voigt relation for the stiffness is referred to as the rule of mixtures.

The Reuss stiffness E,

$$E = \left[\frac{V_i}{E_i} + \frac{1 - V_i}{E_m} \right]^{-1} \tag{41.2}$$

is less than that of the Voigt model. The Voigt and Reuss models provide upper and lower bounds respectively upon the stiffness of a composite of arbitrary phase geometry [Paul, 1960]. The bounds are far apart if, as is commonplace, the phase moduli differ a great deal, as shown in Figure 41.3. For composite materials which are isotropic, the more complex relations of Hashin and Shtrikman [1963] provide tighter bounds upon the moduli (Figure 41.3); both the Young's and shear moduli must be known for each constituent to calculate these bounds.

41.3 Anisotropy of Composites

Observe that the Reuss laminate is identical to the Voigt laminate, except for a rotation with respect to the direction of load. Therefore, the stiffness of the laminate is *anisotropic*, that is, dependent on direction [Lekhnitskii, 1963; Nye, 1976; Agarwal and Broutman, 1980]. Anisotropy is characteristic of composite materials. The relationship between stress σ_{ij} and strain ε_{kl} in anisotropic materials is given by the tensorial form of Hooke's law as follows:

$$\sigma_{ij} = \sum_{k=1}^{3} \sum_{l=1}^{3} C_{ijkl} \varepsilon_{kl} \tag{41.3}$$

Here C_{ijkl} is the elastic modulus tensor. It has $3^4 = 81$ elements, however since the stress and strain are represented by symmetric matrices with six independent elements each, the number of independent modulus tensor elements is reduced to 36. An additional reduction to 21 is achieved by considering elastic materials for which a strain energy function exists. Physically, C_{2323} represents a shear modulus since it couples a shear stress with a shear strain. C_{1111} couples axial stress and strain in the 1 or x direction,

but it is not the same as Young's modulus. The reason is that Young's modulus is measured with the lateral strains free to occur via the Poisson effect, while C_{1111} is the ratio of axial stress to strain when there is only one nonzero strain value; there is no lateral strain. A modulus tensor with 21 independent elements describes a *triclinic* crystal, which is the least symmetric crystal form. The unit cell has three different oblique angles and three different side lengths. A triclinic composite could be made with groups of fibers of three different spacings, oriented in three different oblique directions. Triclinic modulus elements such as C_{2311}, known as cross-coupling constants, have the effect of producing a shear stress in response to a uniaxial strain; this is undesirable in many applications. An *orthorhombic* crystal or an *orthotropic* composite has a unit cell with orthogonal angles. There are nine independent elastic moduli. The associated engineering constants are three Young's moduli, three Poisson's ratios, and three shear moduli; the cross-coupling constants are zero when stresses are aligned to the symmetry directions. An example of such a composite is a unidirectional fibrous material with a rectangular pattern of fibers in the cross-section. Bovine bone, which has a laminated structure, exhibits orthotropic symmetry, as does wood. In a material with *hexagonal* symmetry, out of the nine C elements, there are five independent elastic constants. For directions in the transverse plane the elastic constants are the same, hence the alternate name transverse isotropy. A unidirectional fiber composite with a hexagonal or random fiber pattern has this symmetry, as does human Haversian bone. In *cubic* symmetry, there are three independent elastic constants, a Young's modulus, E, a shear modulus, G, and an independent Poisson's ratio, ν. Cross-weave fabrics have cubic symmetry. Finally, an *isotropic* material has the same material properties in any direction. There are only two independent elastic constants, hence E, G, ν, and also the bulk modulus B are related in an isotropic material. Isotropic materials include amorphous solids, polycrystalline metals in which the grains are randomly oriented, and composite materials in which the constituents are randomly oriented.

Anisotropic composites offer superior strength and stiffness in comparison with isotropic ones. Material properties in one direction are gained at the expense of properties in other directions. It is sensible, therefore, to use anisotropic composite materials only if the direction of application of the stress is known in advance.

41.4 Particulate Composites

It is often convenient to stiffen or harden a material, commonly a polymer, by the incorporation of particulate inclusions. The shape of the particles is important [see Christensen, 1979]. In isotropic systems, stiff platelet (or flake) inclusions are the most effective in creating a stiff composite, followed by fibers; and the least effective geometry for stiff inclusions is the spherical particle, as shown in Figure 41.3. A dilute concentration of spherical particulate inclusions of stiffness E_i and volume fraction V_i, in a matrix (with Poisson's ratio assumed to be 0.5) denoted by the subscript m, gives rise to a composite with a stiffness E:

$$E = \frac{5(E_i - E_m)V_i}{3 + 2(E_i/E_m)} + E_m \tag{41.4}$$

The stiffness of such a composite is close to the Hashin–Shtrikman lower bound for isotropic composites. Even if the spherical particles are perfectly rigid compared with the matrix, their stiffening effect at low concentrations is modest. Conversely, when the inclusions are more compliant than the matrix, spherical ones reduce the stiffness the least and platelet ones reduce it the most. Indeed, soft platelets are suggestive of crack-like defects. Soft platelets, therefore result not only in a compliant composite, but also a weak one. Soft spherical inclusions are used intentionally as crack stoppers to enhance the toughness of polymers such as polystyrene (high impact polystyrene), with a small sacrifice in stiffness.

Particle reinforcement has been used to improve the properties of bone cement. For example, inclusion of bone particles in PMMA cement somewhat improves the stiffness and improves the fatigue life considerably [Park et al., 1986]. Moreover, the bone particles at the interface with the patient's bone are
FIGURE 41.4 Microstructure of a dental composite. Miradapt® [Johnson & Johnson] 50% by volume filler: barium glass and colloidal silica [Park and Lakes, 1992].

ultimately resorbed and are replaced by ingrown new bone tissue. This approach is in the experimental stages.

Rubber used in catheters, rubber gloves, etc. is usually reinforced with very fine particles of silica (SiO_2) to make the rubber stronger and tougher.

Teeth with decayed regions have traditionally been restored with metals such as silver amalgam. Metallic restorations are not considered desirable for anterior teeth for cosmetic reasons. Acrylic resins and silicate cements had been used for anterior teeth, but their poor material properties led to short service life and clinical failures. Dental composite resins have virtually replaced these materials and are very commonly used to restore posterior teeth as well as anterior teeth [Cannon, 1988].

The dental composite resins consist of a polymer matrix and stiff inorganic inclusions [Craig, 1981]. A representative structure is shown in Figure 41.4. The particles are very angular in shape. The inorganic inclusions confer a relatively high stiffness and high wear resistance on the material. Moreover, since they are translucent and their index of refraction is similar to that of dental enamel, they are cosmetically acceptable. Available dental composite resins use quartz, barium glass, and colloidal silica as fillers. Fillers have particle size from 0.04 to 13 μm, and concentrations from 33 to 78% by weight. In view of the greater density of the inorganic filler phase, a 77% weight percent of filler corresponds to a volume percent of about 55%. The matrix consists of a polymer, typically BIS-GMA. In restoring a cavity, the dentist mixes several constituents, then places them in the prepared cavity to polymerize. For this procedure to be successful the viscosity of the mixed paste must be sufficiently low and the polymerization must be controllable. Low viscosity liquids such as triethylene glycol dimethacrylate are used to lower the viscosity and inhibitors such as BHT (butylated trioxytoluene) are used to prevent premature polymerization. Polymerization can be initiated by a thermochemical initiator such as benzoyl peroxide, or by a photochemical initiator (benzoin alkyl ether) which generates free radicals when subjected to ultraviolet light from a lamp used by the dentist.

Dental composites have a Young's modulus in the range 10 to 16 GPa, and the compressive strength from 170 to 260 MPa [Cannon, 1988]. As shown in Table 41.1, these composites are still considerably less stiff than dental enamel, which contains about 99% mineral. Similar high concentrations of mineral particles in synthetic composites cannot easily be achieved, in part because the particles do not pack densely. Moreover, an excessive concentration of particles raises the viscosity of the unpolymerized paste. An excessively high viscosity is problematical since it prevents the dentist from adequately packing the paste into the prepared cavity; the material will then fill in crevices less effectively.

The thermal expansion of dental composites, as with other dental materials, exceeds that of tooth structure. Moreover, there is a contraction during polymerization of 1.2 to 1.6%. These effects are thought

TABLE 41.1   Properties of Bone, Teeth, and Biomaterials

to contribute to leakage of saliva, bacteria, etc., at the interface margins. Such leakage in some cases can cause further decay of the tooth.

Use of colloidal silica in the so-called "microfilled" composites allows these resins to be polished, so that less wear occurs and less plaque accumulates. It is more difficult, however, to make these with a high fraction of filler. All the dental composites exhibit creep. The stiffness changes by a factor of 2.5 to 4 (depending on the particular material) over a time period from 10 sec to 3 h under steady load [Papadogianis et al., 1985]. This creep may result in indentation of the restoration, but wear seems to be a greater problem.

Dental composite resins have become established as restorative materials for both anterior and posterior teeth. The use of these materials is likely to increase as improved compositions are developed and in response to concern over long term toxicity of silver-mercury amalgam fillings.

41.5   Fibrous Composites

Fibers incorporated in a polymer matrix increase the stiffness, strength, fatigue life, and other properties [Agarwal and Broutman, 1980; Schwartz, 1992]. Fibers are mechanically more effective in achieving a stiff, strong composite than are particles. Materials can be prepared in fiber form with very few defects which concentrate stress. Fibers such as graphite are stiff (Young's modulus is 200–800 GPa) and strong (the tensile strength is 2.7–5.5 GPa). Composites made from them can be as strong as steel but much lighter, as shown in Table 41.1. The stiffness of a composite with aligned fibers, if it is loaded along the fibers, is equivalent to the Voigt upper bound, Equation 41.1. Unidirectional fibrous composites, when

FIGURE 41.5 Knee prostheses with polyethylene tibial components reinforced with carbon fiber.

loaded along the fibers, can have strengths and stiffnesses comparable to that of steel, but with much less weight (Table 41.1). However if it is loaded transversly to the fibers, such a composite will be compliant, with a stiffness not much greater than that of the matrix alone. While unidirectional fiber composites can be made very strong in the longitudinal direction, they are weaker than the matrix alone when loaded transversely, as a result of stress concentration around the fibers. If stiffness and strength are needed in all directions, the fibers may be oriented randomly. For such a three-dimensional isotropic composite, for a low concentration of fibers,

$$E = \frac{E_i V_i}{6} + E_m \qquad (41.5)$$

so the stiffness is reduced by about a factor of six in comparison with an aligned composite as illustrated in Figure 41.3. However if the fibers are aligned randomly in a plane, the reduction in stiffness is only a factor of three. The degree of anisotropy in fibrous composites can be very well controlled by forming laminates consisting of layers of fibers embedded in a matrix. Each layer can have fibers oriented in a different direction. One can achieve quasi-isotropic behavior in the laminate plane; such a laminate is not as strong or as stiff as a unidirectional one, as illustrated in Table 41.1. Strength of composites depends on such particulars as the brittleness or ductility of the inclusions and the matrix. In fibrous composites failure may occur by (1) fiber breakage, buckling, or pullout, (2) matrix cracking, or (3) debonding of fiber from matrix.

Short fiber composites are used in many applications. They are not as stiff or as strong as composites with continuous fibers, but they can be formed economically by injection molding or by *in situ* polymerization. Choice of an optimal fiber length can result in improved toughness, due to the predominance of fiber pull-out as a fracture mechanism.

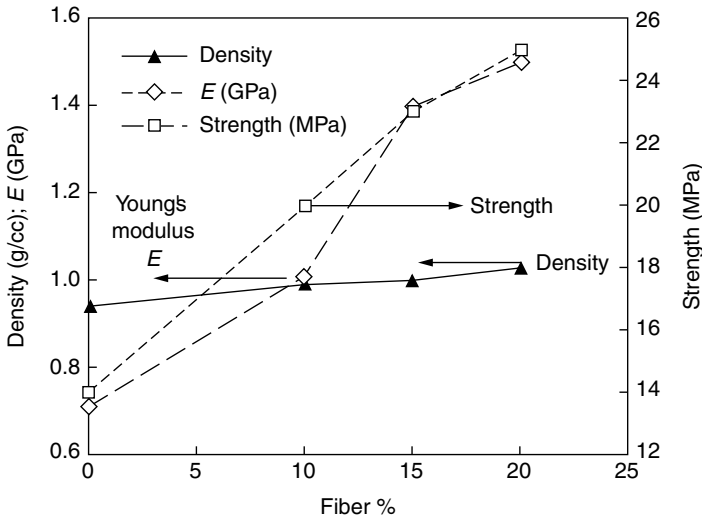
Carbon fibers have been incorporated in the high density polyethylene used in total knee replacements (Figure 41.5). The standard ultra high molecular weight polyethylene (UHMWPE) used in these implants


FIGURE 41.6 Properties of carbon fiber reinforced ultra high molecular weight polyethylene. (Replotted from Sclippa, E. and Piekarski, K. 1973. *J. Biomed. Mater. Res.*, **7**, 59–70. With permission.)

is considered adequate for most purposes for implantation in older patients. A longer wear-free implant lifetime is desirable for use in younger patients. It is considered desirable to improve the resistance to creep of the polymeric component, since excessive creep results in an indentation of that component after long term use. Representative properties of carbon reinforced ultra high molecular weight polyethylene are shown in Figure 41.6 [Sclippa and Piekarski, 1973]. Enhancements of various properties by a factor of two are feasible.

Polymethyl methacrylate (PMMA) used in bone cement is compliant and weak in comparison with bone. Therefore several reinforcement methods have been attempted. Metal wires have been used clinically as macroscopic "fibers" to reinforce PMMA cement used in spinal stabilization surgery [Fishbane and Pond, 1977]. The wires are made of a biocompatible alloy such as cobalt–chromium alloy or stainless steel. Such wires are not currently used in joint replacements owing to the limited space available. Graphite fibers have been incorporated in bone cement [Knoell et al., 1975] on an experimental basis. Significant improvements in the mechanical properties have been achieved. Moreover, the fibers have an added beneficial effect of reducing the rise in temperature which occurs during the polymerization of the PMMA in the body. Such high temperature can cause problems such as necrosis of a portion of the bone into which it is implanted. Thin, short titanium fibers have been embedded in PMMA cement [Topoleski et al., 1992]; a toughness increase of 51% was observed with a 5% volumetric fiber content. Fiber reinforcement of PMMA cement has not found much acceptance since the fibers also increase the viscosity of the unpolymerized material. It is consequently difficult for the surgeon to form and shape the polymerizing cement during the surgical procedure.

Metals are currently used in bone plates for immobilizing fractures and in the femoral component of total hip replacements. A problem with currently used implant metals is that they are much stiffer than bone, so they shield the nearby bone from mechanical stress. Stress-shielding results in a kind of disuse atrophy: the bone resorbs [Engh and Bobyn, 1988]. Therefore composite materials have been investigated as alternatives [Bradley et al., 1980; Skinner, 1988]. Fibrous composites can deform to higher strains (to about 0.01) than metals (0.001 for a mild steel) without damage. This resilience is an attractive characteristic for more flexible bone plates and femoral stems. Flexible composite bone plates are effective in promoting healing [Jockish, 1992]. Composite hip replacement prostheses have been made with carbon fibers in a matrix of polysulfone and polyetherether ketone (PEEK). These prostheses experience heavy load with a static component. Structural metals such as stainless steel and cobalt chromium alloys do not
FIGURE 41.7 Cellular solids structures, after Gibson and Ashby [1988]. Left: synthetic cellular solids: (a) open-cell polyurethane, (b) closed-cell polyethylene, (c) foamed nickel, (d) foamed copper, (e) foamed zirconia, (f) foamed mullite, (g) foamed glass, (h) polyester foam with both open and closed cells. Right: natural cellular solids: (a) cork, (b) balsa wood, (c) sponge, (d) cancellous bone, (e) coral, (f) cuttlefish bone, (g) iris leaf, (h) plant stalk.

creep significantly at room or body temperature. In composites which contain a polymer constituent, creep behavior is a matter of concern. The carbon fibers exhibit negligible creep, but polymer constituents tend to creep. Prototype composite femoral components were found to exhibit fiber dominated creep of small magnitude and are not expected to limit the life of the implant [Maharaj and Jamison, 1993].

Fibrous composites have also been used in external medical devices such as knee braces [Yeaple, 1989], in which biocompatibility is not a concern but light weight is crucial.

41.6 Porous Materials

The presence of voids in porous or cellular solids will reduce the stiffness of the material. For some purposes, that is both acceptable and desirable. Porous solids are used for many purposes: flexible structures such as (1) seat cushions, (2) thermal insulation, (3) filters, (4) cores for stiff and lightweight sandwich panels, (5) flotation devices, and (6) to protect objects from mechanical shock and vibration; and in biomaterials, as coatings to encourage tissue ingrowth. Representative cellular solid structures are shown in Figure 41.7.

The stiffness of an open-cell foam is given by [Gibson and Ashby, 1988]

$$E = E_s[V_s]^2 \tag{41.6}$$

in which E_s is the Young's modulus and V_s is the volume fraction of the solid phase of the foam; V_s is also called the relative density.
FIGURE 41.8   Representative stress-strain curve for a cellular solid. The plateau region for compression in the case of elastomeric foam (a rubbery polymer) represents elastic buckling; for an elastic-plastic foam (such as metallic foam), it represents plastic yield, and for an elastic-brittle foam (such as ceramic) it represents crushing. On the tension side, point 'A' represents the transition between cell wall bending and cell wall alignment. In elastomeric foam, the alignment occurs elastically, in elastic plastic foam it occurs plastically, and an elastic-brittle foam fractures at A.

The strength for crushing of a brittle foam and the elastic collapse of an elastomeric foam is given, respectively, by

$$\sigma_{\text{crush}} = 0.65\,\sigma_{\text{f,s}}[V_{\text{s}}]^{3/2} \tag{41.7}$$

$$\sigma_{\text{coll}} = 0.05\,E_{\text{s}}[V_{\text{s}}]^2 \tag{41.8}$$

Here $\sigma_{\text{f,s}}$ is the fracture strength of the solid phase. These strength relations are valid for relatively small density. Their derivation is based on the concept of *bending* of the cell ribs and is presented by Gibson and Ashby [1988]. Most man-made closed cell foams tend to have a concentration of material at the cell edges, so that they behave mechanically as open cell foams. The salient point in the relations for the mechanical properties of cellular solids is that the *relative density* dramatically influences the stiffness and the strength. As for the relationship between stress and strain, a representative stress strain curve is shown in Figure 41.8. The physical mechanism for the deformation mode beyond the elastic limit depends on the material from which the foam is made. Trabecular bone, for example, is a natural cellular solid, which tends to fail in compression by crushing. Many kinds of trabecular bone appear to behave mechanically as an open cell foam. For trabecular bone of unspecified orientation, the stiffness is proportional to the cube of the density and the strength as the square of the density [Gibson and Ashby, 1988], which indicates behavior dominated by bending of the trabeculae. For bone with oriented trabeculae, both stiffness and strength in the trabecular direction are proportional to the density, a fact which indicates behavior dominated by axial deformation of the trabeculae.

Porous materials have a high ratio of surface area to volume. When porous materials are used in biomaterial applications, the demands upon the inertness and biocompatibility are likely to be greater than for a homogeneous material.

Porous materials, when used in implants, allow tissue ingrowth [Spector et al., 1988a,b]. The ingrowth is considered desirable in many contexts, since it allows a relatively permanent anchorage of the implant to the surrounding tissues. There are actually two composites to be considered in porous implants (1) the implant prior to ingrowth, in which the pores are filled with tissue fluid which is ordinarily of no
FIGURE 41.9 Irregular pore structure of porous coating in Ti5Al4V alloy for bony ingrowth. The top scanning electron microscopic picture is a 5× magnification of the rectangular region of the bottom picture (200×). (From Park, J.B. and Lakes, R.S. 1992. *Biomaterials*, Plenum, New York.)

mechanical consequence; and (2) the implant filled with tissue. In the case of the implant prior to ingrowth, it must be recognized that the stiffness and strength of the porous solid are much less than in the case of the solid from which it is derived.

Porous layers are used on bone compatible implants to encourage bony ingrowth [Galante et al., 1971; Ducheyne, 1984]. The pore size of a cellular solid has no influence on its stiffness or strength (though it does influence the toughness), however pore size can be of considerable biological importance. Specifically, in orthopedic implants with pores larger than about 150 μm, bony ingrowth into the pores occurs and this is useful to anchor the implant. This minimum pore size is on the order of the diameter of osteons in normal Haversian bone. It was found experimentally that pores <75 μm in size did not permit the ingrowth of bone tissue. Moreover, it was difficult to maintain fully viable osteons within pores in the 75 to 150 μm size range. Representative structure of such a porous surface layer is shown in Figure 41.9. Porous coatings are also under study for application in anchoring the artificial roots of dental implants to the underlying jawbone. Porous hydroxyapatite has been studied for use in repairing large defects in bone [Meffert et al., 1985; Holmes et al., 1986]. Hydroxyapatite is the mineral constituent of bone, and it has the nominal composition $Ca_{10}(PO_4)_6(OH)_2$. Implanted hydroxyapatite is slowly resorbed by the body over several years and replaced by bone. Tricalcium phosphate is resorbed more quickly and has been considered as an implant constituent to speed healing.

When a porous material is implanted in bone, the pores become filled first with blood which clots, then with osteoprogenitor mesenchymal cells, then, after about 4 weeks, bony trabeculae. The ingrown bone then becomes remodeled in response to mechanical stress. The bony ingrowth process depends on a degree of mechanical stability in the early stages of healing. If too much motion occurs, the ingrown tissue will be collagenous scar tissue, not bone.

Porous materials used in soft tissue applications include polyurethane, polyamide, and polyester velours used in percutaneous devices. Porous reconstituted collagen has been used in artificial skin, and braided polypropylene has been used in artificial ligaments. As in the case of bone implants, the porosity encourages tissue ingrowth which anchors the device.

Blood vessel replacements are made with porous materials which encourage soft tissue to grow in, eventually forming a new lining, or neointima. The new lining consists of the patient's own cells. It is a natural nonthrombogenic surface resembling the lining of the original blood vessel. This is a further example of the biological role of porous materials as contrasted with the mechanical role.

Ingrowth of tissue into implant pores is not always desirable. For example, sponge (polyvinyl alcohol) implants used in early mammary augmentation surgery underwent ingrowth of fibrous tissue, and contracture and calcification of that tissue, resulting in hardened, calcified breasts. Current mammary implants make use of a balloon-like nonporous silicone rubber layer enclosing silicone oil or gel, or perhaps a saline solution in water. A porous layer of polyester felt or velour attached to the balloon is provided at the back surface of the implant so that limited tissue ingrowth will anchor it to the chest wall and prevent it from migrating.

Foams are also used externally to protect the human body from injury. Examples include knee pads, elbow pads, wrestling mats, and wheelchair cushions. Since these foams are only in contact with skin rather than any internal organs, they are not subject to rigorous biocompatibility requirements. They are therefore designed based on mechanical considerations. Foam used in sports equipment must have the correct compliance to limit impact force without bottoming out. Foam used in wheelchair cushions is intended to prevent pressure sores in people who suffer limited mobility. The properties of cushions are crucial in reducing illness and suffering in people who are confined to wheelchairs or hospital beds for long periods. Prolonged pressure on body parts can obstruct circulation in the capillaries. If this lasts too long it may cause a sore or ulcer called a pressure sore, also called a bed sore. In its most severe manifestation, a pressure sore can form a deep crater-like ulcer in which underlying muscle or bone is exposed [Dinsdale, 1974]. A variety of flexible cushion materials have been tried to minimize the incidence and severity of pressure sores [Garber, 1985]. Viscoelastic foam allows the cushion to progressively conform to the body shape. However, progressive densification of the foam due to creep results in a stiffer cushion which must be periodically replaced.

Porous materials are produced in a variety of ways. For example, in the case of bone compatible surfaces they are formed by sintering of beads or wires. Vascular and soft tissue implants are produced by weaving or braiding fibers as well as by nonwoven "felting" methods. Protective foams for use outside the body are usually produced by use of a "blowing agent" which is a chemical which evolves gas during the polymerization of the foam. An interesting approach to producing micro-porous materials is the replication of structures found in biological materials: the *replamineform* process [White et al., 1976]. The rationale is that the unique structure of communicating pores is thought to offer advantages in the induction of tissue ingrowth. The skeletal structure of coral or echinoderms (such as sea urchins) is replicated by a casting process in metals and polymers; these have been tried in vascular and tracheal prostheses as well as in bone substitutes.

41.7   Biocompatibility

Carbon itself has been successfully used as a biomaterial. Carbon based fibers used in composites are known to be inert in aqueous (even seawater) environments, however they do not have a track record in the biomaterials setting. *In vitro* studies by Kovacs [1993] disclose substantial electrochemical activity of carbon fiber composites in an aqueous environment. If such composites are placed near a metallic implant, galvanic corrosion is a possibility. Composite materials with a polymer matrix absorb water when placed in a hydrated environment such as the body. Moisture acts as a plasticizer of the matrix and shifts the glass transition temperature towards lower values [DeIasi and Whiteside, 1978], hence a reduction in stiffness and an increase in mechanical damping. Water immersion of a graphite epoxy

cross-ply composite [Gopalan et al., 1989] for 20 days reduced the strength by 13% and the stiffness by 9%. Moisture absorption by polymer constituents also causes swelling. Such swelling can be beneficial in dental composites since it offsets some of the shrinkage due to polymerization.

Flexible composite bone plates are effective in promoting healing [Jockish, 1992], but particulate debris from composite bone plates gives rise to a foreign body reaction similar to that caused by ultra high molecular weight polyethylene.

41.8 Summary

Composite materials are a relatively recent addition to the class of materials used in structural applications. In the biomaterials field, the ingress of composites has been even more recent. In view of their potential for high performance, composite materials are likely to find increasing use as biomaterials.

Biodegradable Polymeric Biomaterials: An Updated Overview

Chih-Chang Chu
Cornell University

42.1 Introduction

The term **biodegradation** is loosely associated with materials that could be broken down by nature either through hydrolytic mechanisms without the help of enzymes and/or enzymatic mechanism. Other terms like *absorbable, erodible, and resorbable* have also been used in the literature to indicate biodegradation.

42-1

TABLE 42.1   Properties of Commercially Important Synthetic Absorbable Polymers

Polymer	Crystallinity	T_m (°C)	T_g (°C)	T_{dec} (°C)	Fiber Strength MPa	Fiber Modulus GPa	Fiber Elongation (%)
PGA	High	230	36	260	890	8.4	30

The interests in biodegradable polymeric biomaterials for biomedical engineering use have increased dramatically during the past decade. This is because this class of biomaterials has two major advantages that non-biodegradable biomaterials do not have. First, they do not elicit permanent chronic foreign-body reactions due to the fact that they are gradually absorbed by the human body and do not permanently leave traces of residual in the implantation sites. Second, some of them have recently been found to be able to regenerate tissues, so called **tissue engineering**, through the interaction of their biodegradation with immunologic cells like macrophages. Hence, surgical implants made from biodegradable biomaterials could be used as a temporary scaffold for tissue regeneration. This approach toward the reconstruction of injured, diseased, or aged tissues is one of the most promising fields in the next century.

Although the earliest and most commercially significant biodegradable polymeric biomaterials were originated from linear aliphatic polyesters like polyglycolide and polylactide from poly(α-hydroxyacetic acids), recent introduction of several new synthetic and natural biodegradable polymeric biomaterials extends the domain beyond this family of simple polyesters. These new commercially significant biodegradable polymeric biomaterials include poly(orthoesters), polyanhydrides, polysaccharides, poly(ester-amides), tyrosine-based polyarylates or polyiminocarbonates or polycarbonates, poly(D,L-lactide-urethane), poly(β-hydroxybutyrate), poly(ε-caprolactone), poly[*bis*(carboxylatophenoxy) phosphazene], poly(amino acids), pseudo-poly(amino acids), and copolymers derived from amino acids and non-amino acids.

All the above biodegradable polymeric biomaterials could be generally divided into eight groups based on their chemical origin: (1) Biodegradable linear aliphatic polyesters (e.g., polyglycolide, polylactide, polycaprolactone, polyhydroxybutyrate) and their copolymers within the aliphatic polyester family like poly(glycolide-L-lactide) copolymer and poly(glycolide-ε-caprolactone) copolymer; (2) Biodegradable copolymers between linear aliphatic polyesters in (1) and monomers other than linear aliphatic polyesters like, poly(glycolide-trimethylene carbonate) copolymer, poly(L-lactic acid-L-lysine) copolymer, Tyrosine-based polyarylates or polyiminocarbonates or polycarbonates, poly(D,L-lactide-urethane), and poly(ester-amide); (3) Polyanhydrides; (4) Poly(orthoesters); (5) Poly(ester-ethers) like poly-p-dioxanone; (6) Biodegradable polysaccharides like hyaluronic acid, chitin, and chitson; (7) polyamino acids like poly-L-glutamic acid and poly-L-lysine; (8) Inorganic biodegradable polymers like polyphosphazene and poly[*bis*(carboxylatophenoxy)phosphazene] which have a nitrogen-phosphorus backbone instead of ester linkage. Recently, there is a new approach of making new biodegradable polymers through

melt-blending of highly accepted biodegradable polymers like those of glycolide and lactide base [Shalaby, 1994].

The earliest, most successful, and frequent biomedical applications of biodegradable polymeric biomaterials have been in wound closure [Chu et al., 1996]. All biodegradable wound closure biomaterials are based upon the glycolide and lactide families. For example, polyglycolide (Dexon from American Cyanamid), poly(glycolide-L-lactide) random copolymer with 90 to 10 — ratio (Vicryl from Ethicon), poly(ester-ether) (PDS from Ethicon), poly(glycolide-trimethylene carbonate) random block copolymer (Maxon from American Cyanamid), and poly(glycolide-ε-caprolactone) copolymer (Monocryl from Ethicon). This class of biodegradable polymeric biomaterials is also the one most studied for their chemical, physical, mechanical, morphological, and biological properties and their changes with degradation time and environment. Some of the above materials like Vicryl have been commercially used as surgical meshes for repair of a hernia or the body wall.

The next largest biomedical application of biodegradable polymeric biomaterials that are commercially satisfactory is drug control/release devices. Some well-known examples in this application are polyanhydrides and poly(ortho-ester). Biodegradable polymeric biomaterials, particularly totally resorbable composites, have also been experimentally used in the field of orthopedics, mainly as components for internal bone fracture fixation like PDS pins. However, their wide acceptance in other parts of orthopaedic implants may be limited due to their inherent mechanical properties and their biodegradation rate. Besides the commercial uses described above, biodegradable polymeric biomaterials have been experimented with as (1) vascular grafts, (2) vascular stents, (3) vascular couplers for vessel anastomosis, (4) nerve growth conduits, (5) augmentation of defected bone, (6) ligament/tendon prostheses, (7) intramedullary plug during total hip replacement, (8) anastomosis ring for intestinal surgery, and (9) stents in ureteroureterostomies for accurate suture placement.

Due to space limitation, the emphasis of this chapter will be on the commercially most significant and successful biomedical biodegradable polymers based on (1) linear aliphatic polyesters, (2) some very recent research and development of important classes of synthetic biodegradable polymers, (3) a new theoretical approach to modeling the hydrolytic degradation of glycolide/lactide based biodegradable polymers, (4) the effects of some new extrinsic factors on the degradation of the most commercially significant biodegradable polymers, and (5) the new biomedical applications of this class of synthetic biodegradable polymers in tissue engineering and regeneration. The details of the applications of this family and other biodegradable polymeric biomaterials and their chemical, physical, mechanical, biological, and biodegradation properties can be found in other recent reviews [Barrows, 1986; Vert et al., 1992; Kimura, 1993; Park et al., 1993; Shalaby, 1994; Hollinger, 1995; Chu et al., 1996].

42.2 Glycolide/Lactide Based Biodegradable Linear Aliphatic Polyesters

This class of biodegradable polymers is the most successful, important, and commercially widely used biodegradable biomaterials in surgery. It is also the class of biodegradable biomaterials that were most extensively studied in terms of degradation mechanisms and structure–property relationships. Among them, polyglycolide or polyglycolic acid (PGA) is the most important one because most other biodegradable polymers are derived from PGA either through copolymerization, for example, poly(glycolide-L-lactide) copolymer or modified glycolide monomer, for example, poly-*p*-dioxanone.

42.2.1 Glycolide Based Biodegradable Homopolymers Polyesters

PGA can be polymerized either directly or indirectly from glycolic acid. The direct polycondensation produces a polymer of M_n less than 10,000 because of the requirement of a very high degree of dehydration (99.28% up) and the absence of monofunctional impurities. For PGA of molecular weight higher than 10,000 it is necessary to proceed through the ring-opening polymerization of the cyclic dimers
FIGURE 42.1   FTIR spectra of polyglycolic acid disks as a function of *in vitro* hydrolysis time in phosphate buffer of pH 7.44 at 37°C. (a) 0 day; (b) 55 h; (c) 7 days; (d) 21 days.

of glycolic acid. Numerous catalysts are available for this ring-opening polymerization. They include organometallic compounds and Lewis acids [Chujo et al., 1967; Wise et al., 1979]. For biomedical applications, stannous chloride dihydrate or trialkyl aluminum are preferred. PGA was found to exhibit an orthorhombic unit cell with dimensions $a = 5.22$ Å, $b = 6.19$ Å, and c(fiber axis) $= 7.02$ Å. The planar zigzag-chain molecules form a sheet structure parallel to the ac plane and do not have the polyethylene type arrangement [Chatani et al., 1968]. The molecules between two adjacent sheets orient in opposite directions. The tight molecular packing and the close approach of the ester groups might stabilize the crystal lattice and contribute to the high melting point, T_m, of PGA (224 to 230°C). The glass transition temperature, T_g, ranges from 36 to 40°C. The specific gravities of PGA are 1.707 for a perfect crystal and 1.50 in a completely amorphous state [Chujo et al., 1967a]. The heat of fusion of 100% crystallized PGA is reported to be 12 kJ/mol (45.7 cal/g) [Brandrup et al., 1975]. A recent study of injection molded PGA disks reveals their IR spectroscopic characteristics [Chu et al., 1995]. As shown in Figure 42.1, the four bands at 850, 753, 713, and 560 cm^{-1} are associated with the amorphous regions of the PGA disks and could be used to assess the extends of hydrolysis. Peaks associated with the crystalline phase included those at 972, 901, 806, 627, and 590 cm^{-1}. Two broad, intense peaks at 1142 and 1077 cm^{-1} can be assigned to C—O stretching modes in the ester and oxymethylene groups, respectively. These two peaks are associated mainly with ester and oxymethylene groups originating in the amorphous domains. Hydrolysis could cause both of these C—O stretching modes to substantially decrease in intensity.

42.2.2 Glycolide-Based Biodegradable Copolyesters Having Aliphatic Polyester Based Co-Monomers

Other commercially successful glycolide-based biodegradable polymeric biomaterials are the copolymers of glycolide with other monomers within linear aliphatic polyesters like lactides, carbonates, and ε-caprolactone. The glycolide-lactide random copolymers are the most studied and have a wide range of properties and applications, depending on the composition ratio of glycolide to lactide. Figure 42.2 illustrates the dependence of biodegradation rate on the composition of glycolide to lactide in the copolymer. For wound closure purposes, a high concentration of glycolide monomer is required for achieving proper mechanical and degradation properties. Vicryl sutures, sometime called polyglactin 910,
FIGURE 42.2 The effect of poly(L-lactide) composition in polyglycolide on the time required for 50% mass loss implanted under the dorsal skin of rat. (From Miller, R.A., Brady, J.M., and Cutright, D.E., 1977. *J. Biomed. Mater. Res.*, 11:711. With permission.)

contain a 90/10 molar ratio of glycolic to L-lactide and this molar ratio is important for the Vicryl suture to retain crystalline characteristics. For biomedical use, Lewis acid catalysts are preferred for the copolymers [Wise et al., 1979]. If D,L-instead of L-lactide is used as the co-monomer, the U-shape relationship between the level of crystallinity and glycolide composition disappears. This is because polylactide from 100% D,L-lactide composition is totally amorphous. IR bands associated with Vicryl molecules in the amorphous domains are 560, 710, 850, and 888 cm^{-1}, while 590, 626, 808, 900, and 972 cm^{-1} are associated with the crystalline domains [Frederick et al., 1984]. Like PGA, these IR bands could be used to assess the extent of hydrolysis.

A relatively new block copolymer of glycolide and carbonates, such as trimethylene carbonate, has been commercialized. Maxon is made from a block copolymer of glycolide and 1,3-dioxan-2-one (trimethylene carbonate or GTMC) and consists of 32.5% by weight (or 36 mol%) of trimethylene carbonate [Casey et al., 1984; Katz et al., 1985]. Maxon is a poly(ester-carbonate). The polymerization process of Maxon is divided into two stages. The first stage is the formation of a middle block which is a random copolymer of glycolide and 1,3-dioxan-2-one. Diethylene glycol is used as an initiator and stannous chloride dihydrate (SnCl$_2 \cdot$ 2H$_2$O) serves as the catalyst. The polymerization is conducted at about 180°C. The weight ratio of glycolide to trimethylene carbonate in the middle block is 15 : 85. After the synthesis of the middle block, the temperature of the reactive bath is raised to about 220°C to prevent the crystallization of the copolymer and additional glycolide monomers as the end blocks are added into the reaction bath to form the final triblock copolymer.

The latest glycolide-based copolymer that has become commercially successful is Monocryl suture. It is a segmented block copolymer consisting of both soft and hard segments. The purpose of having soft segments in the copolymer is to provide good handling properties like pliability, while the hard segments are used to provide adequate strength. The generic copolymerization process between glycolic acid and ε-caprolactone was recently reported by Fukuzaki et al. in Japan [1989, 1991]. The resulting copolymers were low molecular weight biodegradable copolymers of glycolic acid and various lactones for potential drug delivery purposes. The composition of lactone ranged from as low as 15 to as high as 50 mol% and the weight average for molecular weight ranged from 4,510 to 16,500. The glass transition temperature ranged from 18 to −43°C, depending on the copolymer composition and molecular weight.

Monocryl is made from two stages of the polymerization process [Bezwada et al., 1995]. In the first stage, soft segments of prepolymer of glycolide and ε-caprolactone are made. This soft segmented

prepolymer is further polymerized with glycolides to provide hard segments of polyglycolide. Monocryl has a composition of 75% glycolide and 25% ε-caprolactone and should have a higher molecular weight than those glycolide/ε-caprolactone copolymers reported by Fukuzaki et al., for adequate mechanical properties required by sutures. The most unique aspect of Monocryl monofilament suture is its pliability as claimed by Ethicon [Bezwada et al., 1995]. The force required to bend a 2/0 suture is only about 2.8×10^4 lb-in^2 for Monocryl, while the same size PDSII and Maxon monofilament sutures require about 3.9 and 11.6×10^4 lb-in^2 force, respectively. This inherent pliability of Monocryl is due to the presence of soft segments and T_g resulting from the ε-caprolactone co-monomer unit. Its T_g is expected to be between 15 and $-36°C$.

42.2.3 Glycolide-Based Biodegradable Copolyesters with Non-Aliphatic Polyester-Based Co-Monomers

In this category, the most important one is the glycolide copolymer consisting of poly(ethylene 1,4-phenylene-bis-oxyacetate) (PEPBO) (Jamiokowski and Shalaby, 1991). The development of this type of glycolide-based copolymer was initiated because of the adverse effect of γ irradiation on the mechanical properties of glycolide-based synthetic absorbable sutures. There is a great desire to develop γ-irradiation sterilizable, synthetic, absorbable polymers to take advantage of the highly convenient and reliable method of sterilization. Shalaby et al. recently reported that the incorporation of about 10 mol% of a polymeric radiostabilizer like PEPBO into PGA backbone chains would make the copolymer sterilizable by γ irradiation without a significant accelerated loss of mechanical properties upon hydrolysis when compared with the unirradiated copolymer control (MPG) [Jamiokowski et al., 1991]. The changes in tensile breaking force of both MPG and PGA sutures implanted intramuscularly and subcutaneously in rats for various periods show the great advantage of such copolymers. MPG fibers γ-irradiated at 2.89 Mrads did not show any loss in tensile breaking force during the first 14 days postimplantation when compared with unimplanted samples. On the contrary, PGA sutures γ-irradiated at 2.75 Mrads lost 62% of the tensile breaking force of their unimplanted samples. There was no tensile breaking force remaining for the irradiated PGA at the end of 21 days, while both 2.89 and 5 Mrads irradiated MPG retained 72 and 55% of their corresponding 0 day controls, respectively. The inherent more hydrolytic resistance of MPG must be attributed to the presence of an aromatic group in the backbone chains. This aromatic polyester component is also responsible for the observed γ-irradiation stability. It is not known at this time whether the new γ-irradiation-resistant MPG is biocompatible with biologic tissues due to the lack of published histologic data.

42.2.4 Glycolide-Derived Biodegradable Polymers Having Ether Linkage

Poly-p-dioxanone (PDS) is derived from the glycolide family with better flexibility. It is polymerized from ether-containing lactones, 1,4-dioxane-2,5-dione (i.e., p-dioxanone) monomers with a hydroxylic initiator and tin catalyst [Shalaby, 1994]. The resulting polymer is semi-crystalline with T_m about 106–115°C and T_g -10–0°C. The improved flexibility of PDS relative to PGA as evidenced in its lower T_g is due to the incorporation of an ether segment in the repeating unit which reduces the density of ester linkages for intermolecular hydrogen bonds. Because of the less dense ester linkages in PDS when compared with PGA or glycolide-L-lactide copolymers, PDS is expected and has been shown to degrade at a slower rate *in vitro* and *in vivo*. PDS having an inherent viscosity of 2.0 dl/g in hexafluoroisopropanol is adequate for making monofilament sutures. Recently, an advanced version of PDS, PDSII, was introduced. PDSII was achieved by subjecting the melt-spun fibers to a high temperature (128°C) for a short period of time. This additional treatment partially melts the outermost surface layer of PDS fibers and leads to a distinctive skin-core morphology. The heat employed also results in larger crystallites in the core of the fiber than the untreated PDS fiber. The tensile strength-loss profile of PDSII sutures is better than that of PDS sutures.

A variety of copolymers having high molar ratios of PDS compared to other monomers within the same linear aliphatic polyester family have been reported for the purpose of improving the mechanical and biodegradation properties [Shalaby, 1994]. For example, copolymer of PDS (80%) and PGA (up to 20%) has an absorption profile similar to Dexon and Vicryl sutures but it has compliance similar to PDS. Copolymer of PDS (85%) and PLLA (up to 15%) results in a more compliant (low modulus) suture than homopolymer PDS but with absorption profiles similar to PDS [Bezwada et al., 1990].

Copolymer fibers made from PDS and monomers other than linear aliphatic polyester like morpholine-2,5-dione (MD) exhibit rather interesting biodegradation properties. This copolymer fiber was absorbed 10 to 25% earlier than PDS. The copolymer, however, retained a tensile breaking strength profile similar to PDS with a slightly faster strength loss during the earlier stage, that is, the first 14 days [Shalaby, 1994]. This ability to break the inherent fiber structure–property relationship through copolymerization is a major improvement in biodegradation properties of absorbable sutures. It is interesting to recognize that a small % (3%) of MD in the copolymer suture is sufficient to result in a faster mass loss profile without the expense of its tensile strength-loss profile. The ability to achieve this ideal biodegradation property might be attributed to both an increasing hydrophilicity of the copolymer and the disruption of crystalline domains due to MD moiety. As described later, the loss of suture mass is mainly due to the destruction of crystalline domains, while the loss of tensile breaking strength is chiefly due to the scission of tie-chain segments located in the amorphous domains. The question is why MD–PDS copolymeric suture retains its strength-loss similar to PDS. The possible explanation is that the amide functional groups in MD could form stronger intermolecular hydrogen bonds than ester functional groups. This stronger hydrogen bond contributes to the strength retention of the copolymer of PDS and MD during *in vivo* biodegradation. The incorporation of MD moiety into PDS also lowers the unknot and knot strength of unhydrolyzed specimens, but increases elongation at break. This suggests that the copolymer of PDS and MD should have a lower level of crystallinity than PDS which is consistent with its observed faster mass loss *in vivo*.

To improve γ-irradiation stability of PDS, radiostabilizers like PEPBO have been copolymerized with PDS to form segmented copolymers the same way as PEPBO with glycolide described above [Koelmel et al., 1991; Shabaly, 1994]. The incorporation of 5 to 10% of such stabilizer in PDS has been shown not only to improve γ-irradiation resistance considerably but to also increase the compliance of the material. For example, PEPBO-PDS copolymer retained 79, 72, and 57% of its original tensile breaking strength at 2, 3, and 4 weeks in *in vivo* implantation, while PDS homopolymer retained only 43, 30, and 25% at the corresponding periods. It appears that an increasing (CH_2) group between the two ester functional groups of the radiation stabilizers improves the copolymer resistance toward γ-irradiation.

42.2.5 Lactide Biodegradable Homopolymers and Copolymers

Polylactides, particularly poly-L-lactide (PLLA), and copolymers having >50% L- or DL-lactide have been explored for medical use without much success mainly due to their much slower absorption and difficulty in melt processing. PLLAs are prepared in solid state through ring-opening polymerization due to their thermal instability and should be melt-processed at the lowest possible temperature [Shalaby, 1994]. Other methods like solution spinning, particularly for high molecular weight, and suspension polymerization have been reported as better alternatives. PLLA is a semi-crystalline polymer with $T_m = 170°C$ and $T_g = 56°C$. This high T_g is mainly responsible for the extremely slow biodegradation rate reported in the literature. The molecular weight of lactide-based biodegradable polymers suitable for medical use ranges from 1.5 to 5.0 dl/g inherent viscosity in chloroform. Ultra high molecular weight of polylactides have been reported [Tunc, 1983; Leenslag et al., 1984]. For example, an intrinsic viscosity as high as 13 dl/g was reported by Leenslag et al. High strength PLLA fibers from this ultra high molecular weight polylactide was made by hot-drawing fibers from solutions of good solvents. The resulting fibers had tensile breaking strength close to 1.2 GPa [Gogolewski et al., 1983]. Due to a dissymmetric nature of lactic acid, the polymer

made from the optically inactive racemic mixture of D and L enantiomers, poly-DL-lactide, however, is an amorphous polymer.

Lactide-based copolymers having a high percentage of lactide have recently been reported, particularly those copolymerized with aliphatic polycarbonates like trimethylene carbonate (TMC) or 3,3-dimethyltrimethylene carbonate (DMTMC) [Shieh et al., 1990]. The major advantage of incorporating TMC or DMTMC units into lactide is that the degradation products from TMC or DMTMC are largely neutral pH and hence are considered to be advantageous. Both *in vitro* toxicity and *in vivo* non-specific foreign body reactions like sterile sinuses have been reported in orthopaedic implants made from PGA and/or PLLA [Eitenmuller et al., 1989; Bostman et al., 1990; Daniels et al., 1992; Hofmann, 1992; Winet et al., 1993]. Several investigators indicated that the glycolic or lactic-acid rich-degradation products have the potential to significantly lower the local pH in a closed and less body-fluid buffered regions surrounded by bone [Sugnuma et al., 1992]. This is particularly true if the degradation process proceeds with a burst mode (i.e., a sudden and rapid release of degradation products). This acidity tends to cause abnormal bone resorption and/or demineralization. The resulting environment may be cytotoxic [Daniels et al., 1992]. Indeed, inflammatory foreign body reactions with a discharging sinus and osteolytic foci visible on x-ray have been encountered in clinical studies [Eitenmuller et al., 1989]. Hollinger et al. recently confirmed the problem associated with PGA and/or PLLA orthopaedic implants [Winet et al., 1993]. A rapid degradation of a 50 : 50 ratio of glycolide-lactide copolymer in bone chambers of rabbit tibias has been found to inhibit bone regeneration. However, emphasis has been placed on the fact that extrapolation of *in vitro* toxicity to *in vivo* biocompatibility must consider microcirculatory capacity. The increase in the local acidity due to a faster accumulation of the highly acidic degradation products is also known to lead to an accelerated acid-catalyzed hydrolysis in the immediate vicinity of the biodegradable device. This acceleration in hydrolysis could lead to a faster loss of mechanical property of the device than we expect. This finding suggests the need to use components in totally biodegradable composites so that degradation products with less acidity would be released into the surrounding area. A controlled slow release rather than a burst release of degradation products at a level that the surrounding tissue could timely metabolize them would also be helpful in dealing with the acidity problem. Copolymers of composition ratio of 10DMTMC/90LLA or 10TMC/90LLA appear to be a promising absorbable orthopaedic device. Other applications of this type of copolymers include nerve growth conduits, tendon prostheses, and coating materials for biodegradable devices.

Another unique example of Llactide copolymer is the copolymer of L-lactide and 3-(S)[(alkyloxycarbonyl) methyl]-1,4-dioxane-2,5-dione, a cyclic diester [Kimura, 1993]. The most unique aspect of this new biodegradable copolymer is the carboxyl acid pendant group which obviously would make the new polymer not only more hydrophilic and hence faster biodegradation but also more reactive toward future chemical modification through the pendant carboxyl group. The availability of these carboxyl reactive pendant sites could be used to chemically bond antimicrobial agents or other biochemicals like growth factors for making future wound closure biomaterials having new and important biological functions. Unfortunately, there are no reported data to evaluate the performance of this new absorbable polymer for biomedical engineering use up to the present time.

Block copolymers of PLLA with poly(amino acids) have also been reported as a potential controlled drug delivery system [Nathan et al., 1994]. This new class of copolymers consists of both ester and amide linkages in the backbone molecules and is sometimes referred as poly(depsipeptides) or poly(esters-amides). Poly(depsipeptides) could also be synthesized from ring-opening polymerization of morpholine-2,5-dione and its derivatives [Helder et al., 1986]. Barrows has also made a series of poly(ester-amides) from polyesterification of diols that contain preformed amide linkages, such as amidediols [Barrows, 1994]. Katsarava and Chu et al. just reported the synthesis of high-molecular-weight poly(ester-amides) of M_w from 24,000 to 167,000 with narrow polydispersity ($M_w/M_n = 1.20 - 1.81$) via solution polycondensation of di-*p*-toluenesulfonic acid salts of *bis*-(α-amino acid) α, ω-alkylene diesters and di-*p*-nitrophenyl esters of diacids [Katsarava et al., In press]. These poly(ester-amide)s consisted of naturally occurring and non-toxic building blocks and had excellent film forming properties. These polymers were mostly amorphous materials with T_g from 11 to 59°C. The rationale for making poly(ester-amides) is to combine the

well-known absorbability and biocompatibility of linear aliphatic polyesters with the high performance and the flexibility of potential chemical reactive sites of amide of polyamides. Poly(ester-amides) could be degraded either by enzyme and/or nonenzymatic mechanisms. There is no commercial use of this class of copolymers at the present time.

The introduction of poly(ethylene oxide) (PEO) into PLLA in order to modulate the hydrophilicity and degradability of PLLA for drug control/release biomaterials has been reported and an example is the triblock copolymer of PLA/PEO/PLA [Li et al., 1998a]. Biomaterials having an appropriate PLLA and PEO block length were found to have a hydrogel property that could deliver hydrophilic drugs as well as hydrophobic ones like steroids and hormones. Another unique biodegradable biomaterial consisting of a star-block copolymer of PLLA, PGA, and PEO was also reported for protein drug delivery devices [Li et al., 1998b]. This star-shaped copolymer has 4 or 8 arms made of PEO, PLLA, and PGA. The glass transition temperature and the crystallinity of this star-shaped block copolymer were significantly lower than the corresponding linear PLLA and PGA.

Because of the characteristic of very slow biodegradation rate of PLLA and the copolymers having a high composition ratio of PLLA, their biomedical applications have been mainly limited to (1) orthopaedic surgery, (2) drug control/release devices, (3) coating materials for suture, (4) vascular grafts, and (5) surgical meshes to facilitate wound healing after dental extraction.

42.3 Non-Glycolide/Lactide Based Linear Aliphatic Polyesters

All glycolide/lactide based linear aliphatic polyesters are based on poly(α-hydroxy acids). Recently, there are two unique groups of linear aliphatic polyesters based on poly(ω-hydroxy acids) and the most famous ones are poly(ε-caprolactone) [Kimura, 1993], poly(β-hydroxybutyrate) (PHB), poly(β-hydroxyvalerate) (PHV) and the copolymers of PHB/PHV (Gross, 1994). Poly(ε-caprolactone) has been used as a comonomer with a variety of glycolide/lactide based linear aliphatic polyesters described earlier. PHB and PHV belong to the family of poly(hydroxyalkanoates) and are mainly produced by prokaryotic types of microorganisms like *Pseudomonas olevorans* or *Alcaligenes eutrophus* through biotechnology. PHB and PHV are the principal energy and carbon storage compounds for these microorganisms and are produced when there are excessive nutrients in the environment. These naturally produced PHB and PHV are stereochemically pure and are isotactic. They could also be synthesized in labs, but the characteristics of steroregularity is lost.

This family of biodegradable polyesters is considered to be environmentally friendly because they are produced from propionic acid and glucose and could be completely degraded to water, biogas, biomass, and humic materials [Gross, 1994]. Their biodegradation requires enzymes. Hence, PHB, PHV, and their copolymers are probably the most important biodegradable polymers for environmental use. However, the biodegradability of this class of linear aliphatic polyesters in human or animal tissues has been questionable. For example, high molecular weight PHB or PHB/PHV fibers do not degrade in tissues or simulated environments over periods of up to six months [Williams, 1990]. The degradability of PHB could be accelerated by γ-irradiation or copolymerization with PHV.

An interesting derivative of PHB, poly(β-malic acid) (PMA), has been synthesized from β-benzyl malolactonate followed by catalytic hydrogenolysis. PMA differs from PHB in that the β-(CH_3) substituent is replaced by $-COOH$ [Kimura, 1993]. The introduction of pendant carboxylic acid group would make PMA more hydrophilic and easier to be absorbed.

42.4 Non-Aliphatic Polyesters Type Biodegradable Polymers

42.4.1 Aliphatic and Aromatic Polycarbonates

The most significant aliphatic polycarbonates are based upon DMTMC and TMC. They are made by the same ring-opening polymerization as glycolide-based biodegradable polyesters. The homopolymers

are biocompatible with a controllable rate of biodegradation. Pellets of poly(ethylene carbonate) were absorbed completely in two weeks in the peritoneal cavity of rats. A slight variation of this polycarbonate, that is, poly(propylene carbonate), however, did not show any sign of absorption after two months [Barrows, 1986]. Copolymers of DMTMC/ε-caprolactone and DMTMC/TMC have been reported to have adequate properties for wound closure, tendon prostheses, and vascular grafts. The most important advantage of aliphatic polycarbonates is the neutral pH of the degradation products.

Poly(BPA-carbonates) made from bisphenol A (BPA) and phosgene is non-biodegradable, but an analog of poly(BPA-carbonate) like poly(iminocarbonates) have been shown to degrade in about 200 days [Barrows, 1986]. In general, this class of aromatic polycarbonates takes an undesirably long period to degrade, presumably due to the presence of an aromatic ring which could protect adjacent ester bonds to be hydrolyzed by water or enzymes. Different types of degradation products of this polymer under different pH environments are produced. At pH >7.0, the degradation products of this polymer are BPA, and ammonia and CO_2, while insoluble poly(BPA-carbonate) oligomers were produced with pH <7.0 [Barrows, 1986]. The polymer had good mechanical properties and acceptable tissue biocompatibility. Unfortunately, there is currently no commercial use of this class of polymer in surgery.

42.4.2 Poly(alkylene oxalates) and Copolymers

This class of high crystalline biodegradable polymers was initially developed [Shalaby, 1994] for absorbable sutures and their coating. They consist of $[-ROOC-COO-]_n$ repeating unit where R is $(CH_2)_x$ with x ranging from 4 to 12. R could also be cyclic (1,4-*trans*-cyclohexanedimethanol) or aromatic (1,4-benzene, 1,3-benzene dimethanol) for achieving higher melting temperature. The biodegradation properties depend on the number of (CH_2) group, x, and the type of R group (i.e., acyclic vs. cyclic or aromatic). In general, a higher number of methylene group and/or the incorporation of cyclic or aromatic R group would retard the biodegradation rate and hence make the polymer absorbed slower. For example, there was no mass of the polymer with $x = 4$ remaining *in vivo* (rats) after 28 days, while the polymer with $x = 6$ retained 80% of its mass after 42 days *in vivo*. An isomorphic copolyoxalate consisting of 80% cyclic R group like 1,4-*trans*-cyclohexanedimethanol and 20% with acyclic R group like 1,6-hexanediol retained 56% of its original mass after 180 days *in vivo*. By varying the ratio of cyclic to acyclic monomers, copolymers with a wide range of melting temperatures could be made, for example, copolymer of 95/5 ratio of cyclic (i.e., 1,4-*trans*-cyclohexanedimethanol)/acyclic (i.e., 1,6-hexanediol) monomers had a $T_m = 210°C$, while the copolymer with 5/95 ratio had a $T_m = 69°C$. Poly(alkylene oxalates) with $x = 3$ or 6 had been experimented with as drug control/release devices. The tissue reaction to this class of biodegradable polymers has been minimal.

42.5 Biodegradation Properties of Synthetic Biodegradable Polymers

The reported biodegradation studies of a variety of biodegradable polymeric biomaterials have mainly focused on their tissue biocompatibility, the rate of drug release, or loss of strength and mass. Recently, the degradation mechanisms and the effects of intrinsic and extrinsic factors, such as pH [Chu, 1981, 1982], enzymes [Williams et al., 1977, 1984; Williams, 1979; Chu et al., 1983], γ-irradiation [Campbell et al., 1981; Chu et al., 1982, 1983; Williams et al., 1984; Zhang et al., 1993], electrolytes [Pratt et al., 1993a], cell medium [Chu et al., 1992], annealing treatment [Chu et al., 1988], plasma surface treatment [Loh et al., 1992], external stress [Miller et al., 1984; Chu, 1985a], and polymer morphology [Chu et al., 1989] and on a chemical means to examine the degradation of PGA fibers [Chu et al., 1985] have been systemically examined and the subject has been recently reviewed [Chu, 1985b, 1991, 1995a, b; Hollinger, 1995; Chu et al., 1996]. Table 42.2 is an illustration of structural factors of polymers that could control their degradation [Kimura, 1993]. Besides these series of experimental studies of a variety of factors that could

TABLE 42.2   Structural Factors to Control the Polymer Degradability

Factors	Methods of control
Chemical structure of main chain and side groups	Selection of chemical bonds and functional groups
Aggregation state	Processing, copolymerization
Crystalline state	Polymer blend
Hydrophilic/hydrophobic balance	Copolymerization, introduction of functional groups
Surface area	Micropores
Shape and morphology	Fiber, film, composite

affect the degradation of biodegradable polymeric biomaterials, there are two new areas that broaden the above traditional study of biodegradation properties of biodegradable polymers into the frontier of science. They are: theoretical modeling and the role of free radicals.

42.5.1   Theoretical Modeling of Degradation Properties

The most systematic theoretical modeling study of degradation properties of biodegradable biomaterials was reported by Pratt and Chu who used computational chemistry to theoretically model the effects of a variety of substituents which could exert either steric effect and/or inductive effect on the degradation properties of glycolide/lactide based biodegradable polymers [Pratt et al., 1993b, 1994a, b]. This new approach could provide scientists with a better understanding of the relationship between the chemical structure of biodegradable polymers and their degradation behavior at a molecular level. It also could help the future research and development of this class of polymers through the intelligent prediction of structure–property relationships. In those studies, Pratt and Chu examined the affect of various derivatives of linear aliphatic polyester (PGA) and a naturally occurring linear polysaccharide (hyaluronic acid) on their hydrolytic degradation phenomena and mechanisms.

The data showed a decrease in the rate of hydrolysis by about a factor of 106 with isopropyl α-substituents, but nearly a six-fold increase with *t*-butyl α-substituents [Pratt et al., 1993b]. The role of electron donating and electron withdrawing groups on the rate of hydrolytic degradation of linear aliphatic polyesters was also theoretically modeled by Pratt and Chu [Pratt et al., 1994a]. Electron withdrawing substituents a to the carbonyl group would be expected to stabilize the tetrahedral intermediate resulting from hydroxide attack, that is, favoring hydroxide attack but disfavoring alkoxide elimination. Electron releasing groups would be expected to show the opposite effect. Similarly, electronegative substituents on the alkyl portion of the ester would stabilize the forming alkoxide ion and favor the elimination step. Pratt and Chu found that the rate of ester hydrolysis is greatly affected by halogen substituents due primarily to charge delocalization. The data suggest that the magnitude of the inductive effect on the hydrolysis of glycolic esters decreases significantly as the location of the substituent is moved further away from the α-carbon because the inductive effect is very distance-sensitive. In all three locations of substitutions (α, β, and γ), Cl and Br substituents exhibited the largest inductive effect compared to other halogen elements.

Therefore, Pratt and Chu concluded that the rate of ester hydrolysis is greatly affected by both alkyl and halogen substituents due primarily to either steric hinderance or charge delocalization. In the steric effect, alkyl substituents on the glycolic esters cause an increase in activation enthalpies, and a corresponding decrease in reaction rate, up to about three carbon sizes, while bulkier alkyl substituents other than isopropyl make the rate-determining elimination step more facile. It appears that aliphatic polyesters containing a isopropyl groups, or slightly larger linear alkyl groups, such as n-butyl, n-pentyl, etc., would be expected to show a longer strength retention, given the same fiber morphology. In the inductive effect, α-substituents on the acyl portion of the ester favor the formation of the tetrahedral intermediate through charge delocalization, with the largest effect seen with Cl substitution, but retard the rate-determining

alkoxide elimination step by stabilizing the tetrahedral intermediate. The largest degree of stabilization is caused by the very electronegative F substituent.

42.5.2   The Role of Free Radicals in Degradation Properties

Salthouse et al. had demonstrated that the biodegradation of synthetic absorbable sutures is closely related to macrophage activity through the close adhesion of macrophage onto the surface of the absorbable sutures [Matlaga et al., 1980]. It is also known that inflammatory cells, particularly leukocytes and macrophages are able to produce highly reactive oxygen species like superoxide ($^{\cdot}O_2^-$) and hydrogen peroxide during inflammatory reactions toward foreign materials [Badwey et al., 1980; Devereux et al., 1991]. These highly reactive oxygen species participate in the biochemical reaction, frequently referred to as a respiratory burst, which is characterized by the one electron reduction of O_2 into superoxide via either NADPH or NADH oxidase as shown below. The reduction of O_2 results in an increase in O_2 uptake and the consumption of glucose.

$$2O_2 + \text{NADPH} \xrightarrow{\text{(NADPH Oxidase)}} 2\,^{\cdot}O_2^- + \text{NADP}^+ + \text{H}^+ \tag{42.1}$$
The resulting superoxide radicals are then neutralized to H_2O_2 via cytoplasmic enzyme superoxide dismutase (SOD).

$$2\,^{\cdot}O_2^- + 2\text{H}^+ \xrightarrow{\text{(SOD)}} \text{H}_2\text{O}_2 + \text{O}_2 \tag{42.2}$$
Very recently, Williams et al. suggested that these reactive oxygen species may be harmful to polymeric implant surfaces through their production of highly reactive, potent, and harmful hydroxyl radicals $^{\cdot}$OH in the presence of metals like iron as shown in the following series of redox reactions [Williams et al., 1991; Ali et al., 1993; Zhong et al., 1994].

$$^{\cdot}O_2 + M^{+n} \rightarrow O_2 + M^{+(n-1)} \tag{42.3}$$

$$\text{H}_2\text{O}_2 + M^{+(n-1)} \rightarrow {}^{\cdot}\text{OH} + \text{HO}^- + M^{+n} \tag{42.4}$$
The net reaction will be:

$$^{\cdot}O_2^- + \text{H}_2\text{O}_2 \rightarrow {}^{\cdot}\text{OH} + \text{HO}^- + \text{O}_2 \tag{42.5}$$
and is often referred to as the metal-catalyzed Haber–Weiss reaction [Haber et al., 1934].

Although the role of free radicals in the hydrolytic degradation of synthetic biodegradable polymers is largely unknown, a very recent study using absorbable sutures like Vicryl in the presence of an aqueous free radical solution prepared from H_2O_2 and ferrous sulfate, $FeSO_4$, raised the possibility of the role of free radicals in the biodegradation of synthetic absorbable sutures [Williams et al., 1991; Zhong et al., 1994]. As shown below, both $^{\cdot}$OH radicals and OH$^-$ are formed in the process of oxidation of Fe^{+2} by H_2O_2 and could exert some influence on the subsequent hydrolytic degradation of Vicryl sutures.

$$\text{Fe}^{+2} + \text{H}_2\text{O}_2 \rightarrow \text{Fe}^{+3} + {}^{\cdot}\text{OH} + \text{OH}^-$$
SEM results indicated that Vicryl sutures in the presence of free radical solutions exhibited many irregular surface cracks at both 7 and 14 days *in vitro*, while the same sutures in the two controls (H_2O_2 or $FeSO_4$ solutions) did not have these surface cracks. Surprisingly, the presence of surface cracks of Vicryl sutures treated in the free radical solutions did not accelerate the tensile breaking strength-loss as would be expected. Thermal properties of Vicryl sutures under the free radical and 3% H_2O_2 media showed

the classical well-known maximum pattern of the change of the level of crystallinity with hydrolysis time. The level of crystallinity of Vicryl sutures peaked at 7 days in both media (free radical and 3% H_2O_2). The time for peak appearance in these two media was considerably earlier than Vicryl sutures in conventional physiological buffer media. Based on the Chu's suggestion of using the time of the appearance of the crystallinity peak as an indicator of degradation rate, it appears that these two media accelerated the degradation of Vicryl sutures when compared with regular physiological buffer solution. Based on their findings, Williams et al. proposed the possible routes of the role of ˙OH radicals in the hydrolytic degradation of Vicryl sutures [Zhong et al., 1994]. Unfortunately, the possible role of OH^-, one of the byproducts of Fenton reagents ($H_2O_2/FeSO_4$), was not considered in the interpretation of their findings. OH^- species could be more potent than OH toward hydrolytic degradation of synthetic absorbable sutures. This is because hydroxyl anions are the sole species which attack carbonyl carbon of the ester linkages during alkaline hydrolysis. Since an equal amount of ˙OH and OH^- are generated in Fenton reagents, the observed changes in morphological, mechanical, and thermal properties could be partially attributed to OH^- ions as well as ˙OH radicals.

Besides hydroxyl radicals, the production of superoxide ions and singlet oxygen during phagocytosis has been well documented [Babior et al., 1973]. Although the role of superoxide in simple organic ester hydrolysis has been known since the 1970s [Forrester et al., 1984, 1987; Johnson, 1976; Mango et al., 1976; San Fillipo et al., 1976], its role in the hydrolytic degradation of synthetic biodegradable polyester-based biomaterials has remained largely unknown. Such an understanding of the superoxide ion role during the biodegradation of foreign materials has become increasing desirable because of the advanced understanding of how the human immune system reacts to foreign materials and the increasing use of synthetic biomaterials for human body repair.

Lee and Chu very recently examined the reactivity of the superoxide ion towards biodegradable biomaterials having an aliphatic polyester structure at different reaction conditions such as temperature, time, and superoxide ion concentration [Lee et al., 1996a]. Due to the extreme reactivity of the superoxide ion, it has been observed that the effect of superoxide ion-induced hydrolytic degradation of PDLLA and PLLA was significant in terms of changes in molecular weights and thermal properties. The superoxide ion-induced fragmentation of PDLLA would result in a mixture of various species with different chain lengths. A combined GPC method with a chemical tagging method revealed that the structure of oligomer species formed during the superoxide-induced degradation of PDLLA and PLLA was linear. The significant reduction in molecular weight of PDLLA by superoxide ion was also evident in the change of thermal properties like T_g. The linear low molecular species (oligomer, trimers, and dimers) in the reaction mixture could act as an internal plasticizer to provide the synergetic effects of lowering T_g by increasing free volume. The effect of the superoxide ion-induced hydrolytic degradation on molecular weight of PLLA was similar to PDLLA but with a much smaller magnitude. The mechanism of simple hydrolysis of ester by superoxide ion proposed by Forrester et al. was subsequently modified to interpret the data obtained from the synthetic biodegradable polymers.

In addition to the PDLLA and PLLA, superoxide ions also have a significant adverse effect on the hydrolytic degradation of synthetic absorbable sutures [Lee et al., 1996c]. A significant reduction in molecular weight has been found along with mechanical and thermal properties of these sutures over a wide range of superoxide ion concentrations, particularly during the first few hours of contact with superoxide ions. For example, the PGA suture lost almost all of its mass at the end of 24 h contact with superoxide ions at 25°C, while the same suture would take at least 50 days in an *in vitro* buffer for a complete mass loss. The surface morphology of these sutures was also altered drastically. The exact mechanism, however, is not fully known yet; Lee et al. suggested the possibility of simultaneous occurrence of several main-chain scissions by three different nucleophilic species.

Lee and Chu also reported that the addition of Fenton agent or hydrogen peroxide to the degradation medium would retard the well-known adverse effect of the conventional γ-irradiation sterilization of synthetic absorbable sutures [Lee et al., 1996a]. They found that these γ-irradiated sutures retained better tensile breaking strength in the Fenton medium than in the regular buffer media. Chu et al. postulated that the γ-irradiation induced α-carbon radicals in these sutures react with the hydroxyl radicals from

the Fenton agent medium and hence neutralize the adverse effect of α-carbon radicals on the backbone chain scission. This mechanism is supported by the observed gradual loss of ESR signal of the sutures in the presence of the Fenton agent in the medium.

Instead of the adverse effect of free radicals on the degradation properties of synthetic biodegradable polyesters, Lee and Chu described an innovative approach of covalent bonding nitroxyl radicals onto these biodegradable polymers so that the nitroxyl radical attached polymers would have biological functions similar to nitric oxide [Lee et al., 1996b, 1998]. A preliminary *in vitro* cell culture study of these new biologically active biodegradable polymers indicated that they could retard the proliferation of human smooth muscle cells as native nitric oxide. The full potential of this new class of biologically active biodegradable polymers is currently under investigation by Chu for a variety of therapeutic applications.

42.6   The Role of Linear Aliphatic Biodegradable Polyesters in Tissue Engineering and Regeneration

The use of biodegradable polymers as the temporary scaffolds either to grow cells/tissues *in vitro* for tissue engineering applications or to regenerate tissues *in vivo* has very recently become a highly important aspect of research and development that broadens this class of biodegradable polymers beyond their traditional use in wound closure and drug control/release biomaterials. The scaffolds used in either tissue engineering or regeneration are to provide support for cellular attachment and subsequent controlled proliferation into a predefined shape or form. Obviously, a biodegradable scaffold would be preferred because of the elimination of chronic foreign body reaction and the generation of additional volume for regenerated tissues.

Although many other biodegradable polymers of natural origin like alginate [Atala et al., 1994], hyaluronate [Benedetti et al., 1993; Larsen et al., 1993], collagen [Hirai et al., 1995] and laminin [Dixit, 1994] have been experimented with for such a purpose, synthetic biodegradable polymers of linear aliphatic polyesters like PGA, PLA, and their copolymers [Bowald et al., 1979, 1980; Greisler, 1982; Greisler et al., 1985, 1987a, b, 1988a, b, c, 1991a; Freed et al., 1993; Mikos et al., 1993; Yu et al., 1993, 1994; Mooney et al., 1994, 1995, 1996a, b, c; Kim et al., 1998a, b] have received more attention because of their consistent sources, reproducible properties, means to tailor their properties, and versatility in manufacturing processes.

Biodegradable polymers must be fabricated into stable textile structures before they can be used as the scaffold for tissue engineering or regeneration. The stability of the scaffold structure is important during tissue engineering and regeneration in order to maintain its proper size, shape, or form upon the shear force imposed by the circulating culture media in a bioreactor, the contractile force imposed by the growing cells on the scaffold surface, and other forces like the compression from surrounding tissues.

Kim et al. reported that, although ordinary non-woven PGA matrices have very good porosity (to facilitate diffusion of nutrients) with a high surface to volume ratio (to promote cell attachment and proliferation) and have been used to engineer dental pulp and smooth muscle tissues having comparable biological contents as the native tissues [Kim et al., 1998b; Mooney et al., 1996c], these non-woven PGA matrices could not maintain their original structure during tissue engineering due to the relatively weak non-woven textile structure and stronger contractile force exerted by the attached and proliferated cells/tissues [Kim et al., 1998a]. This led to deformed engineered tissues that may have undesirable properties; for example, the smooth muscle engineered on collagen gels exhibited significant contraction over time [Zeigler et al., 1994; Hirai et al., 1995].

Because of this shortcoming of the existing non-woven PGA matrices, Kim et al. very recently reported the use of PLLA to stabilize the PGA matrices [Kim et al., 1998a]. A 5% w/v PLLA solution in chloroform was sprayed onto PGA non-woven matrices (made of 12 μm diameter PGA fibers) of 97% porosity and either 3 mm or 0.5 mm thickness. The PLLA-impregnated PGA non-wovens could be subjected to additional heat treatment at 195°C to enhance their structural stability further. Figure 42.3 shows
FIGURE 42.3 Scanning electron micrograph of the exterior of PLLA-impregnated and annealed PGA matrix. (From Kim, B.S. and Mooney, D.J., 1998a. *J. Biomed. Mater. Res.*, 41: 322–332. With permission).

the morphology of such a heat annealed PLLA-impregnated PGA non-woven matrix [Kim et al., 1998]. The PLLA was deposited mainly on the crosspoints of PGA fibers and hence interlocked the possible sliding of PGA fibers upon external force. Depending on the amount of PLLA used and subsequent heat treatment, the resulting PLLA-impregnated PGA non-woven matrices had an increase in compressive modulus of 10- to 35-fold when compared with the original PGA non-woven. The PLLA-impregnated PGA non-woven matrices also retained their initial volume ($101 \pm 4\%$) and about same shape as the original during the seven weeks in culture, while the untreated PGA non-woven exhibited severe distortion in shape and contracted about 5% of its original volume. Since PLLA is well-known to degrade at a much slower rate than PGA, its presence on the PGA fibers surface would be expected to make the treated PGA non-woven matrices degrade at a much slower rate than the untreated PGA non-woven. For example, the PLLA treated PGA non-woven retained about 80% of its initial mass, while the untreated PGA control had only 10% at the end of the seven week culture.

Linear aliphatic polyesters like PGA, its lactide copolymer, and poly-p-dioxanone have also been fabricated into both woven and knitted forms for the *in vivo* regeneration of blood vessels in animals [Bowald et al., 1979, 1980; Greisler, 1982; Greisler et al., 1985, 1987a, 1988c, 1991b; Yu et al., 1993, 1994]. The published results from a variety of animals like dogs and rabbits indicate that full-wall healing with pseudo-endothelial lining was observed. This class of synthetic biodegradable polymers are promising candidates for the regeneration of vascular tissue.

These encouraging findings were believed to be associated with the intense macrophage/biomaterial interactions. [Greisler, 1988a; Greisler et al., 1989]. This interaction leads to a differential activation of the macrophage which, in turn, yields different macrophage products being released into the microenvironment [Greisler et al., 1991b]. Greisler et al. [1988b] have documented active stimulatory or inhibitory effects of various bioresorbable and non-resorbable materials on myofibroblast, vascular smooth muscle cell, and endothelial cell regeneration, and has shown a transinterstitial migration to be their source when lactide/glycolide copolymeric prostheses are used. The rate of tissue ingrowth parallels

the kinetics of macrophage mediated prosthetic resorption in all lactide/glycolides studied [Gresler, 1982; Greisler et al., 1985, 1987a, 1988a]. Macrophage phagocytosis of the prosthetic material is observed histologically as early as one week following implantation of a rapidly resorbed material, such as PGA or polyglactin 910 (PG910), and is followed by an extensive increase in the myofibroblast population and neovascularization of the inner capsules [Greisler, 1982; Greisler et al., 1985, 1986]. Autoradiographic analyses using tritiated thymidine demonstrated a significantly increased mitotic index within these inner capsular cells, that mitotic index paralleling the course of prosthetic resorption [Greisler et al., 1991a]. Polyglactin 910, for example, resulted in a mitotic index of $20.1 \pm 16.6\%$ three weeks following implantation, progressively decreasing to $1.2 \pm 1.3\%$ after 12 weeks. The more slowly resorbed polydioxanone prostheses demonstrated a persistently elevated mitotic index, $7.1 \pm 3.8\%$, 12 weeks after implantation, a time in which the prosthetic material was still being resorbed. By contrast Dacron never yielded greater than a $1.2 \pm 1.3\%$ mitotic index [Greisler et al., 1991a]. These mitotic indices correlated closely with the slopes of the inner capsule thickening curves suggesting that myofibroblast proliferation contributed heavily to this tissue deposition.

Therefore, the degradation property of synthetic biodegradable polymers somehow relates to macrophage activation which subsequently leads to the macrophage production of the required growth factors that initiate tissue regeneration. Different degradation properties of synthetic biodegradable polymers would thus be expected to result in different levels of macrophage activation, i.e., different degrees of tissue regeneration.

Defining Terms

Biodegradation: Materials that could be broken down by nature either through hydrolytic mechanisms without the help of enzymes and/or enzymatic mechanism. It is loosely associated with absorbable, erodable, resorbable.

Tissue Engineering: The ability to regenerate tissue through the help of artifical materials and devices.

Kimura, Y., 1993, Biodegradable polymers, In: *Biomedical Applications of Polymeric Materials*, T. Tsuruta, T. Hayashi, K. Kataoka, K. Ishihara, and Y. Kimura, Eds., pp. 164–190. CRC Press, Inc., Boca Raton, FL.

Park, K., Shalaby, W.S.W., and Park. H., 1993. *Biodegradable Hydrogels for Drug Delivery*, Technomic Publishing, Lancaster, PA.

Shalaby, S.W., 1994. *Biomedical Polymers: Designed-to-Degrade Systems*, Hanser Publishers, New York.

Vert, M., Feijen, J., Albertsson, A., Scott, G. and Chiellini, E., 1992. *Biodegradable Polymers and Plastics*, Royal Society of Chemistry, Cambridge, England.

The review by Barrows is brief with an emphasis on their applications with an extensive lists of patents. The book and chapter by Chu et al. focuses on the most successful use of biodegradable polymers in medicine, namely wound closure biomaterials like sutures. It is so far the most comprehensive review of all aspects of biodegradable wound closure biomaterials with very detailed chemical, physical, mechanical, biodegradable, and biological information. The chapter by Kimura is an overview of the subject with

some interesting new polymers. The chapter includes both enzymatically degradable natural polymers and non-enzymatically degradable synthetic polymers. The biodegradable hydrogel book by Park et al. is the only book available that focuses on hydrogel. Probably the most broad coverage of biodegradable polymeric biomaterials is the very recent book edited by Shalaby. It has 8 chapters and covers almost all commercially and experimentally available biodegradable polymers. The book edited by Vert et al. is based on the *Proceedings of the 2nd International Scientific Workshop on Biodegradable Polymers and Plastics* held in Montpellier, France in November 1991. The book covers both medical and non-medical applications of biodegradable polymers. It has broader coverage of biodegradable polymers with far more chapters than Shalaby's book, but its chapters are shorter and less comprehensive than Shalaby's book which is far more focused on biomedical use.

Topics of biodegradable polymeric biomaterials can also be found in *Journal of Biomedical Materials Research*, *Journal of Applied Biomaterials*, *Biomaterials*, *Journal of Biomaterials Science: Polymer Ed.*, *Journal of Applied Polymer Science*, *Journal of Materials Science*, and *Journal Polymer Science*.

Biologic Biomaterials: Tissue-Derived Biomaterials (Collagen)

Shu-Tung Li
Collagen Matrix, Inc.

43.1 Structure and Properties of Collagen and Collagen-Rich Tissues

43.1.1 Structure of Collagen

Collagen is a multifunctional family of proteins of unique structural characteristics. It is the most abundant and ubiquitous protein in the body, its functions ranging from serving crucial biomechanical functions in bone, skin, tendon, and ligament to controlling cellular gene expressions in development [Nimni and Harkness, 1988]. Collagen molecules like all proteins are formed *in vivo* by enzymatic regulated step-wise polymerization reaction between amino and carboxyl groups of amino acids, where R is a side group of

43-1

an amino acid residue.

$$
(-\underset{\underset{R}{|}}{\underset{\|}{C}} - \underset{\underset{|}{H}}{N} - \underset{\underset{|}{H}}{C} -)_n
$$

(43.1)

The simplest amino acid is **glycine** (Gly) (R=H), where a hypothetical flat sheet organization of polyglycine molecules can form and be stabilized by intermolecular hydrogen bonds (Figure 43.1a). However, when R is a large group as in most other amino acids, the stereochemical constraints frequently force the **polypeptide** chain to adapt a less constraining conformation by rotating the bulky R groups away from the crowded interactions, forming a helix, where the large R groups are directed toward the surface of the helix (Figure 43.1b). The hydrogen bonds are allowed to form within a helix between the hydrogen attached to nitrogen in one amino acid residue and the oxygen attached to a second amino acid residue. Thus, the final conformation of a protein, which is directly related to its function, is governed primarily by the amino acid sequence of the particular protein.

Collagen is a protein comprised of three polypeptides (α chains), each having a general amino acid sequence of $(-Gly-X-Y-)_n$, where X is any other amino acid and is frequently **proline** (Pro) and Y is any other amino acid and is frequently *hydroxyproline* (Hyp). A typical amino acid composition of collagen is shown in Table 43.1. The application of helical diffraction theory to high-angle collagen x-ray
FIGURE 43.1   (a) Hypothetical flat sheet structure of a protein. (b) Helical arrangement of a protein chain.

TABLE 43.1   Amino Acid Content of Collagen

Amino Acids	Content, residues/1000 residues[a]
Gly	334
Pro	122
Hyp	96
Acid polar (Asp, Glu, Asn)	124
Basic polar (Lys, Arg, His)	91
Other	233

[a]Reported values are average values of 10 different determinations for tendon tissue.

diffraction pattern [Rich and Crick, 1961] and the stereochemical constraints from the unusual amino acid composition [Eastoe, 1967] led to the initial triple-helical model and subsequent modified triple helix of the collagen molecule. Thus, collagen can be broadly defined as a protein which has a typical triple helix extending over the major part of the molecule. Within the triple helix, glycine must be present as every third amino acid, and proline and hydroxyproline are required to form and stabilize the triple helix.

To date, 19 proteins can be classified as collagen [Fukai et al., 1994]. Among the various collagens, type I collagen is the most abundant and is the major constituent of bone, skin, ligament, and tendon. Due to the abundance and ready accessibility of these tissues, they have been frequently used as a source for the preparation of collagen. This chapter will not review the details of the structure of the different collagens. The readers are referred to recent reviews for a more in-depth discussion of this subject [Nimni, 1988; van der Rest et al., 1990; Fukai et al., 1994; Brodsky and Ramshaw, 1997]. It is, however, of particular relevance to review some salient structural features of the type I collagen in order to facilitate the subsequent discussions of properties and its relation to biomedical applications.

A type I collagen molecule (also referred to as *tropocollagen*) isolated from various tissues has a molecular weight of about 283,000 daltons. It is comprised of three left-handed helical polypeptide chains (Figure 43.2a) which are intertwined forming a right-handed helix around a central molecular axis (Figure 43.2b). Two of the polypeptide chains are identical (α_1) having 1056 amino acid residues, and the third polypeptide chain (α_2) has 1029 amino acid residues [Miller, 1984]. The triple-helical structure has a rise per residue of 0.286 nm and a unit twist of 108°, with 10 residues in three turns and a **helical pitch** (repeating distance within a single chain) of 30-residues or 8.68 nm [Fraser et al., 1983]. Over 95% of the amino acids have the sequence of Gly–X–Y. The remaining 5% of the molecule does not have the sequence of Gly–X–Y and is therefore not triple-helical. These nonhelical portions of the molecule are located at the N- and C-terminal ends and are referred to as **telopeptides** (9 to 26 residues) [Miller, 1984]. The whole molecule has a length of about 280 nm and a diameter of about 1.5 nm and has a conformation similar to a rigid rod (Figure 43.2c).
FIGURE 43.2 Diagram depicting the formation of collagen, which can be visualized as taking place in several steps: (a) single chain left-handed helix; (b) three single chains intertwined into a triple stranded helix; (c) a collagen (tropocollagen) molecule; (d) collagen molecules aligned in D staggered fashion in a fibril producing overlap and hole regions.
FIGURE 43.3 A space-filling model of the collagen triple helix, showing all the atoms in a ten-residue segment of repeating triplet sequence (Gly–Pro–Hyp)$_n$. The arrow shows an interchain hydrogen bond. The arrow heads identify the hydroxy groups of hydroxyproline in one chain. The circle shows a hydrogen-bonded water molecule. The short white lines identify the ridge of amino acid chains. The short black lines indicate the supercoil of one chain [Piez, 1984].

The triple-helical structure of a collagen molecule is stabilized by several factors (Figure 43.3): (1) a tight fit of the amino acids within the triple-helix — this geometrical stabilization factor can be appreciated from a space-filling model constructed from a triple helix with (Gly–Pro–Hyp) sequence (Figure 43.3); (2) the interchain hydrogen bond formation between the backbone carbonyl and amino hydrogen interactions; and (3) the contribution of water molecules to the interchain hydrogen bond formation.

The telopeptides are regions where **intermolecular crosslinks** are formed *in vivo*. A common inter-molecular crosslinks is formed between an **allysine** (the ε-amino group of **lysine** or hydroxy-lysine has been converted to an aldehyde) of one telopeptide of one molecule and an ε-amino group of a lysine or **hydroxylysine** in the triple helix or a second molecule (43.2). Thus the method commonly used to solubil-ize the collagen molecules from crosslinked **fibrils** with **proteolytic enzymes** such as **pepsin** removes the telopeptides (cleaves the intermolecular crosslinks) from the collagen molecule. The pepsin solubilized collagen is occasionally referred to as **atelocollagen** [Stenzl, 1974].

$$\rightarrow \text{Pr} - \text{CH}_2 - \text{CH}_2 - \text{CH}_2 - \text{CH} = \text{N} - \text{CH}_2 - \text{CH} - \text{CH}_2 - \text{CH}_2 - \text{Pr}$$

$$\text{Dehydrohydroxylysinonorleucine}$$

(43.2)
Since the presence of hydroxyproline is unique in collagen **elastin** contains a small amount), the determ-ination of collagen content in a collagen-rich tissue is readily done by assaying the hydroxyproline content.

Collagen does not appear to exist as isolated molecules in the extracellular space in the body. Instead, collagen molecules aggregate into *fibrils*. Depending on the tissue and age, a collagen fibril varies from about 50 to 300 nm in diameter with indeterminate length and can be easily seen under electron microscopy (Figure 43.4). The fibrils are important structural building units for large **fibers** (Figure 43.5). Collagen molecules are arranged in specific orders both longitudinally and in cross-section, and the organization
FIGURE 43.4 (a) Scanning electron micrograph of the surface of an adult rabbit bone matrix, showing how the collagen fibrils branch and interconnect in an intricate, woven pattern ($\times 4800$) (Tifft, 1980). (b) Transmission electron micrographs of ($\times 24,000$) parallel collagen fibrils in tendon [Fung, 1992]. (c) Transmission electron micrographs of ($\times 24,000$) mesh work of fibrils in skin [Fung, 1993].
FIGURE 43.5 Diagram showing the collagen fibers of the connective tissue in general which are composed of unit collagen fibrils.

of collagen molecules in a fibril is tissue-specific [Katz and Li, 1972, 1973b]. The two-dimensional structure (the projection of a three-dimensional structure onto a two-dimensional plane) of a type I collagen fibril has been unequivocally defined both by an analysis of small-angle x-ray diffraction pattern along the meridian of a collagenous tissue [Bear, 1944] and by examination of the transmission electron micrographs of tissues stained with negative or positive stains [Hodge and Petruska, 1963]. In this structure (Figure 42.2d) the collagen molecules are staggered with respect to one another by a distance of D (64 to 67 nm) or multiple of D, where D is the fundamental repeat distance seen in the small-angle x-ray diffraction pattern, or the repeating distance seen in the electron micrographs. Since a collagen molecule has a length of about $4.4D$, this staggering of collagen molecules creates overlap regions of about $0.4D$ and hole or defect regions of about $0.6D$.

One interesting and important structural aspect of collagen is its approximate equal number of acidic (**aspartic** and **glutamic acids**) and basic (lysines and **arginines**) side groups. Since these groups are charged under physiological conditions, the collagen is essentially electrically neutral [Li and Katz, 1976]. The packing of collagen molecules with a D staggering results in clusters of regions where the charged groups are located [Hofmann and Kuhn, 1981]. These groups therefore are in close proximity to form intra- and intermolecular hydrogen-bonded **salt-linkages** of the form ($Pr - COO^{-+}H_3N - Pr$) [Li et al., 1975]. In addition, the side groups of many amino acids are nonpolar [**alanine (Ala)**, **valine** (Val), **leucine** (Leu), **isoleucine** (Ile), *proline* (Pro), and *phenolalanine* (Phe)] in character and hence *hydrophobic*; therefore, chains with these amino acids avoid contact with water molecules and seek interactions with the nonpolar chains of amino acids. In fact, the result of molecular packing of collagen in a fibril is such that the nonpolar groups are also clustered, forming hydrophobic regions within collagen fibrils [Hofmann and Kuhn, 1981]. Indeed, the packing of the collagen molecules in various tissues is believed to be a result of intermolecular interactions involving both the electrostatic and hydrophobic interactions [Hofmann and Kuhn, 1981; Katz and Li, 1981; Li et al., 1975].

The three-dimensional organization of type I collagen molecules within a fibril has been the subject of extensive research over the past 40 years [Fraser et al., 1983; Katz and Li, 1972, 1973a, b, 1981; Miller, 1976; Ramachandran, 1967; Yamuchi et al., 1986]. Many structural models have been proposed based on

an analysis of equatorial and off-equatorial x-ray diffraction patterns of rat-tail-tendon collagen [Miller, 1976; North et al., 1954], *intrafibrillar volume* determination of various collagenous tissues [Katz and Li, 1972, 1973a, b], intermolecular side chain interactions [Hofmann and Kuhn, 1981; Katz and Li, 1981; Li et al., 1981], and intermolecular crosslinking patterns studies [Yamuchi et al., 1986]. The general understanding of the three-dimensional molecular packing in type I collagen fibrils is that the collagen molecules are arranged in hexagonal or near hexagonal arrays [Katz and Li, 1972, 1981; Miller, 1976]. Depending on the tissue, the intermolecular distance varies from about 0.15 nm in rat tail tendon to as large as 0.18 nm in bone and dentin [Katz and Li, 1973b]. The axial staggering of the molecules by $1\sim 4D$ with respect to one another is tissue-specific and has not yet been fully elucidated.

There are very few interspecies differences in the structure of type I collagen molecule. The extensive homology of the structure of type I collagen may explain why this collagen obtained from animal species is acceptable as a material for human implantation.

43.1.2 Properties of Collagen-Rich Tissue

The function of collagenous tissue is related to its structure and properties. This section reviews some important properties of collagen-rich tissues.

43.1.2.1 Physical and Biomechanical Properties

The physical properties of tissues vary according to the amount and structural variations of the collagen fibers. In general, a collagen-rich tissue contains about 75 to 90% of collagen on a dry weight basis. Table 43.2 is a typical composition of a collagen-rich soft tissue such as skin. Collagen fibers (bundles of collagen fibrils) are arranged in different configurations in different tissues for their respective functions at specific anatomic sites. For example, collagen fibers are arranged in parallel in tendon (Figure 43.4b) and ligament for their high-tensile strength requirements, whereas collagen fibers in skin are arranged in random arrays (Figure 43.4c) to provide the resiliency of the tissue under stress. Other structure-supporting functions of collagen such as transparency for the lens of the eye and shaping of the ear or tip of the nose can also be provided by the collagen fiber. Thus, an important physical property of collagen is the three-dimensional organization of the collagen fibers.

The collagen-rich tissues can be thought of as a composite polymeric material in which the highly oriented crystalline collagen fibrils are embedded in the amorphous ground substance of noncollagenous **polysaccharides**, **glycoproteins**, and elastin. When the tissue is heated, its specific volume increases, exhibiting a glass transition at about 40°C and a melting of the crystalline collagen fibrils at about 56°C. The melting temperature of crystalline collagen fibrils is referred to as the *denaturation temperature* of collagenous tissues.

The stress–strain curves of a collagenous tissue such as tendon exhibit nonlinear behavior (Figure 43.6). This nonlinear behavior of stress–strain of tendon collagen is similar to that observed in synthetic fibers. The initial toe region represents alignment of fibers in the direction of stress. The steep rise in slope represents the majority of fibers stretched along their long axes. The decrease in slope following the steep rise may represent the breaking of individual fibers prior to the final catastrophic failure. Table 43.3 summarizes some mechanical properties of collagen and elastic fibers. The difference in biomechanical

properties between collagen and elastin is a good example of the requirements for these proteins to serve their specific functions in the body.

Unlike tendon or ligament, skin consists of collagen fibers randomly arranged in layers or lamellae. Thus skin tissues show mechanics anisotropy (Figure 43.7). Another feature of the stress-strain curve of the skin is its extensibility under small load as compared to tendon. At small load the fibers are straightened and aligned rather than stretched. Upon further stretching the fibrous lamellae align with respect to each other and resist further extension. When the skin is highly stretched the modulus of elasticity approaches that of tendon as expected of the aligned collagen fibers.

Cartilage is another collagen-rich tissue which has two main physiological functions. One is the maintenance of shape (ear, tip of nose, and rings around the trachea), and the other is to provide bearing surfaces at joints. It contains very large and diffuse proteoglycan (protein-polysaccharide) molecules which form a gel in which the collagen-rich molecules entangled. They can affect the mechanical properties of the collagen by hindering the movements through the interstices of the collagenous matrix network.

The joint cartilage has a very low coefficient of friction (<0.01). This is largely attributed to the squeeze-film effect between cartilage and synovial fluid. The synovial fluid can be squeezed out through highly fenestrated cartilage upon compressive loading, and the reverse action will take place in tension. The lubricating function is carried out in conjunction with **glycosaminoglycans** (GAG), especially **chondroitin sulfates.** The modulus of elasticity (10.3 to 20.7 MPa) and tensile strength (3.4 MPa) are quite low. However, wherever high stress is required the cartilage is replaced by purely collagenous tissue. Mechanical properties of some collagen-rich tissues are given in Table 43.4 as a reference.

43.1.2.2 Physiochemical Properties

Electrostatic properties: A collagen molecule has a total of approximately 240 ε-amino and guanidino groups of lysines, hydroxylysines, and arginines and 230 carboxyl groups of aspartic and glutamic acids.
FIGURE 43.7   Stress–strain curves of human abdominal skin [Daly, 1966].

Longitudinal	0.07	81.0

Source: Park, J.B. and Lakes, R.S. 1992. Structure-
property relationships of biological materials. In *Bioma-
terials: An Introduction*, 2nd ed., pp. 185–222, Plenum
Press, New York.

These groups are charged under physiological conditions. In a native fibril, most of these groups interact
either intra- or intermolecularly forming salt-linkages providing significant stabilization energy to the
collagen fibril [Li et al., 1975]. Only a small number of charged groups are free. However, the electrostatic
state within a collagen fibril can be altered by changing the pH of the environment. Since the pK for an
amino group is about 10 and about 4 for a carboxyl group, the electrostatic interactions are significantly
perturbed at a pH below 4 and above 10. The net result of the pH change is a weakening of the intra- and
intermolecular electrostatic interactions, resulting in a swelling of the fibrils. The fibril swelling can be
prevented by chemically introducing covalent intermolecular crosslinks. Any bifunctional reagent which
reacts with amino, carboxyl, and hydroxyl groups can serve as a crosslinking agent. The introduction of
covalent intermolecular crosslinks fixes the physical state of the fibrillar structure and balances the swelling
pressures obtained from any pH changes.

   Another way of altering the electrostatic state of a collagen fibril is by chemically modifying the electro-
static side groups. For example, the positively charged ε-amino groups of lysine and hydroxylysine can be
chemically modified with acetic anhydride, which converts the ε-amino groups to a neutral acetyl group
[Green et al., 1954]. The result of this modification increases the number of the net negative charges of the
fibril. Conversely, the negatively charged carboxyl groups of aspartic and glutamic acid can be chemically

modified to a neutral group by methylation [Fraenkel-Conrat, 1944]. Thus, by adjusting the pH of the solution and applying chemical modification methods, a range of electrostatic properties of collagen can be obtained.

Ion and macromolecular binding properties: In the native state and under physiological conditions, a collagen molecule has only about 60 free carboxyl groups [Li et al., 1975]. These groups have the capability of binding cations such as calcium with a free energy of formation for the protein-COO–Ca^{++} of about 1.2 kcal/mol. This energy is not large enough to compete for the hydrogen bonded salt-linkage interactions, which have a free energy of formation of about −1.6 kcal/mol. The extent of ion binding, however, can be enhanced in the presence of lyotropic salts such as KCNS, which breaks the salt-linkages, or by shifting the pH away from the ***isoelectric point*** of collagen. Macromolecules can bind to collagen via covalent bonding, cooperative ionic binding, entrapment, entanglement, and a combination of the above. In addition, binding of charged ions and macromolecules can be significantly increased by modifying the charge profile of collagen as described previously. For example, a complete *N*-acetylation of collagen will eliminate all the positively charged ε-amino groups and, thus, will increase the free negatively charged groups. The resulting acetylated collagen enhances the binding of positively charged ions and macromolecules. On the other hand, the methylation of collagen will eliminate the negatively charged carboxyl groups and, thus, will increase the free positively charge moieties. The methylated collagen, therefore, enhances the binding of negatively charged ions and macromolecules [Li and Katz, 1976].

Fiber-forming properties: Native collagen molecules are organized in tissues in specific orders. *Polymorphic* forms of collagen can be reconstituted from the collagen molecules, obtained either from enzymatic digestion of collagenous tissues or by extracting the tissues with salt solutions. The formation of polymorphic aggregates of collagen depends on the environment for reconstitution [Piez, 1984]. Native arrangement of the collagen molecules is formed under physiological conditions. Various polymorphic molecular aggregates may be formed by changing the state of intermolecular interactions. For example, when collagen molecules are aggregated under high concentrations of a neutral salt or under nonaqueous conditions, the collagen molecules associate into random arrays having no specific regularities detectable by electron microscopy. The collagen molecules can be induced to aggregate into other polymorphic forms such as the **segment-long-spacing** (SLS) form where all heads are aligned in parallel and the **fibrous-long-spacing** (FLS) form where the molecules are randomly aligned in either a head-to-tail, tail-to-tail, or head-to-head orientation.

43.1.2.3 Biologic Properties

Hemostatic properties: Native collagen aggregates are intrinsically hemostatic. The mechanism of collagen-induced hemostasis has been the subject of numerous investigations [Wilner et al., 1968; Jaffe and Deykin, 1974; Wang et al., 1978]. The general conclusion from these studies is that **platelets** first adhere to a collagen surface. This induces the release of platelet contents, followed by platelet aggregation, leading to the eventual hemostatic plug. The hemostatic activity of collagen is dependent on the size of the collagen aggregate and the native organization of the molecules [Wang et al., 1978]. Denatured collagen (**gelatin**) is not effective in inducing hemostasis [Jonas et al., 1988].

Cell interaction properties: Collagen forms the essential framework of the tissues and organs. Many cells, such as epithelial and endothelial cells, are found resting on the collagenous surfaces or within a collagenous matrix such as that of many connective tissue cells. Collagen-cell interactions are essential features during the development stage and during wound healing and tissue remodeling in adults [Kleinman et al., 1981; Linbold and Kormos, 1991]. Studying collagen-cell interactions is useful in developing simulated tissue and organ structures and in investigating cell behavior in the *in vivo* simulated systems. Numerous studies have aimed at developing viable tissues and organs ***in vitro*** for transplantation applications [Bell et al., 1981; Montesano et al., 1983; Silbermann, 1990; Bellamkonda and Aebischer, 1994; Hubbel, 1995; Moghe et al., 1996; Sittinger et al., 1996].

Immunologic properties: **Soluble collagen** has long been known to be a poor immunogen [Timpl, 1982]. A significant level of antibodies cannot be raised without the use of Freund's complete adjuvant (a mixture of mineral oil and heat-killed *mycobacteria*) which augments antibody response. It is known that insoluble

collagen is even less immunogenic [Stenzel et al., 1974]. Thus, xenogeneic collagenous tissue devices such as porcine and bovine pericardial heart valves are acceptable for long-term implantation in humans. The reasons for the low antibody response against collagen are not known. It may be related to the homology of the collagen structure from different species (low level of foreignness) or to certain structural features associated with collagen [Timpl, 1982].

43.2 Biotechnology of Collagen

43.2.1 Isolation and Purification of Collagen

There are two distinct ways of isolating and purifying collagen material. One is the molecular technology and the other is the fibrillar technology. These two technologies are briefly reviewed here.

43.2.1.1 Isolation and Purification of Soluble Collagen Molecules

The isolation and purification of soluble collagen molecules from a collagenous tissue is achieved by using a proteolytic enzyme such as pepsin to cleave the telopeptides [Miller and Rhodes, 1982]. Since telopeptides are the natural crosslinking sites of collagen, the removal of telopeptides renders the collagen molecules and small collagen aggregates soluble in an aqueous solution. The pepsin-solubilized collagen can be purified by repetitive precipitation with a neutral salt. Pepsin-solubilized collagen in monomeric form is generally soluble in a buffer solution at low temperature. The collagen molecules may be reconstituted into fibrils of various **polymorphisms**. However, the reconstitution of the pepsin-solubilized collagen into fibrils of native molecular packing is not as efficient as the intact molecules, since the telopeptides facilitate fibril formation [Comper and Veis, 1977].

43.2.1.2 Isolation and Purification of Fibrillar Collagen

The isolation and purification of collagen fibers relies on the removal of noncollagenous materials from the collagenous tissue. Salt extraction removes the newly synthesized collagen molecules that have not been covalently incorporated into the collagen fibrils. Salt also removes the noncollagenous materials that are soluble in aqueous conditions and are bound to collagen fibrils by nonspecific interactions. **Lipids** are removed by low-molecular-weight organic solvents such as low-molecular-weight ethers and alcohols. Acid extraction facilities the removal of acidic proteins and glycosaminoglycans due to weakening of the interactions between the acidic proteins and collagen fibrils. Alkaline extraction weakens the interaction between the basic proteins and collagen fibrils and thus facilitates the removal of basic proteins. In addition, various enzymes other than **collagenase** can be used to facilitate the removal of the small amounts of glycoproteins, proteoglycans, and elastins from the tissue. Purified collagen fibers can be obtained through these sequential extractions and enzymatic digestions from the collagen-rich tissues.

43.2.2 Matrix Fabrication Technology

The purified collagen materials obtained from either the molecular technology or from the fibrillar technology are subjected to additional processing to fabricate the materials into useful devices for specific medical applications. The different matrices and their medical applications are summarized in Table 43.5. The technology in fabricating these matrices are briefly outlined below.

43.2.2.1 Membranous Matrix

Collagen membranes can be produced by drying a collagen solution or a fibrillar collagen dispersion cast on a nonadhesive surface. The thickness of the membrane is governed by the concentration and the initial thickness of the cast solution or dispersion. In general, membrane thickness of up to 0.5 mm can be easily obtained by air drying a cast collagen material. Additional chemical crosslinking is required to stabilize the membrane from dissolution or dissociation. The membrane produced by casting and air drying does not permit manipulation of the pore structure. Generally, the structure of a cast membrane is dense and amorphous with minimal **permeability** to macromolecules [Li et al., 1991]. Porous membranes

TABLE 43.5   Summary of Different Collagen Matrices and Their Medical Applications

Matrix form	Medical application
Membrane (film, sheet)	Oral tissue repair; wound dressings; dura repair; patches
Porous (sponge, felt, fibers)	Hemostats; wound dressings; cartilage repair; soft-tissue augmentation
Gel	Drug and biologically active macromolecule delivery; soft- and hard-tissue augmentation
Solution	Soft-tissue augmentation; drug delivery
Filament	Tendon and ligament repair; sutures
Tubular (membrane, sponge) Composite	Nerve repair; vascular repair
Collagen/synthetic polymer	Vascular repair; skin repair; wound dressings
Collagen/biological polymer	Soft-tissue augmentation; skin repair
Collagen/ceramic	Hard-tissue repair

may be obtained by freeze-drying a cast solution or dispersion of a predetermined density or by partially compressing a preformed porous matrix to a predetermined density and pore structure.

43.2.2.2   Porous Matrix

Porous collagen matrices are generally obtained by freeze-drying an aqueous volume of collagen solution or dispersion. The freeze-dried porous matrix requires chemical crosslinking to stabilize the structure. A convenient way to stabilize the porous matrix is to crosslink the matrix by vapor using a volatile crosslinking agent such as formaldehyde or glutaraldehyde. The pore structure of the matrix depends, to a large extent, on the concentration of the collagen in the solution or dispersion. Other factors that contribute to the pore structure include the rate of freezing, the size of fibers in the dispersion, and the presence and absence of other macromolecules. **Apparent densities** from 0.05 to 0.3 g matrix per cubic centimeter matrix volume can be obtained. These porous matrices generally have pores from about 50 μm to as large as 1500 μm.

43.2.2.3   Gel Matrix

A *gel matrix* may be defined as a homogeneous phase between a liquid and a solid. As such, a gel may vary from a simple viscous fluid to a highly concentrated putty-like material. Collagen gels may be formed by shifting the pH of a dispersion away from its isoelectric point. Alternatively, the collagen material may be subjected to a chemical modification procedure to change its charge profile to a net positively charged or a net negatively charged protein before hydrating the material to form a gel matrix. For example, native fibers dispersed in water at pH 7 will be in the form of two phases. The dispersed fibers become gel when the pH changes from 7 to 3. Succinylating the primary amino groups of collagen, which converts the positively charged amino groups to negatively charged carboxyl groups, changes the isoelectric point of collagen from about 7 to about 4.5. Such a collagen material swells to a gel at a pH of 7.

43.2.2.4   Solution Matrix

A collagen solution is obtained by dissolving the collagen molecules in an aqueous solution. Collagen molecules are obtained by digesting the insoluble tissue with pepsin to cleave the crosslinking sites of collagen (telopeptides) as previously described. The solubility of collagen depends on the pH, the temperature, the ionic strength of the solution, and the molecular weight. Generally, collagen is more soluble in the cold. Collagen molecules aggregate into fibrils when the temperature of the solution increases to the body temperature. pH plays an important role in solubilizing collagen. Collagen is more soluble at a pH away from the isoelectric point of the protein. Collagen is less soluble at higher ionic strength of a solution. The solubility of collagen decreases with increasing the size of molecular aggregates. Thus, collagen becomes increasingly less soluble with increasing the extent of crosslinking [Bailey et al., 1970].

43.2.2.5 Filamentous Matrix

Collagen filaments can be produced by extrusion techniques [Kemp et al., 1995; Li and Stone, 1993; Schimpf and Rodriquez, 1976]. A collagen solution or dispersion having a concentration in the range of 0.5 to 1.5% (w/v) is first prepared. Collagen is extruded into a coacervation bath containing a high concentration of a salt or into an aqueous solution at a pH of the isoelectric point of the collagen. Tensile strength of 30 MPa has been obtained for the reconstituted filaments.

43.2.2.6 Tubular Matrix

Tubular matrices may be formed by extrusion through a coaxial cylinder [Stenzl et al., 1974], or by coating collagen onto a mandrel [Li, 1990]. Different properties of the tubular membranes can be obtained by controlling the drying properties.

43.2.2.7 Composite Matrix

Collagen can form a variety of homogeneous composites with other water-soluble materials. Ions, peptides, proteins, and polysaccharides can all be uniformly incorporated into a collagen matrix. The methods of homogeneous composite formation include ionic and covalent bonding, entrapment, entanglement, and coprecipitation. A heterogeneous composite can be formed between collagen, ceramics, and synthetic polymers that have distinct properties for medical applications [Li, 1988].

43.3 Design of a Resorbable Collagen-Based Medical Implant

Designing a medical implant for tissue or organ repair requires a thorough understanding of the structure and function of the tissue and organ to be repaired, the structure and properties of the materials used for repair, and the design requirements. There are at present two schools of thought regarding the design of an implant, namely the permanent implant and the *resorbable implant.* The permanent implants are intended to permanently replace the damaged tissues or organs are fabricated from various materials including metals and natural or synthetic polymers. For example, most of the weight-bearing orthopedic and oral implants are made of metals or alloys. Non-weight-bearing tissues and organs are generally replaced with implants that are fabricated either from synthetic or natural materials. Implants for blood vessel, heart valve, and most soft tissue repair fall into this class. Permanent implants, particularly those made of synthetic and biological materials, frequently suffer from the long-term effects of material degradation. Material degradation can result from biological processes such as enzymatic degradation or environmentally induced degradation from mechanical, metal-catalyzed oxidation, and from the permeation of body fluids into the polymeric devices [Bruck, 1991]. The material degradation is particularly manifested in applications where there is repetitive stress-strain on the implant, such as artificial blood vessels and heart valves.

As a result of the lack of suitable materials for long-term implantation, the concept of using a resorbable template to guide host tissue regeneration (guided tissue regeneration) has received vigorous attention in recent years. This area of research can be categorized into synthetic and biological templates. **Polyglycolic acid** (PGA), **polylactic acid** (PLA), polyglycolic-polylactic acid copolymers, and **polydioxanone** are among the polymers most selected for resorbable medical implant development. Among the biological materials used for resorbable medical implant development, *collagen* has been one of the most popular materials in this category. Collagen-based templates have been developed for skin [Yannas and Burke, 1981], peripheral nerve [Li et al., 1990; Yannas et al., 1985], oral tissue [Altman and Li, 1990; Blumenthal, 1988], and meniscal regeneration [Li et al., 1994; Stone et al., 1997]. A variety of other collagen based templates are being developed for tissue repair and regeneration applications [Goldstein et al., 1989; Ma et al., 1990; Li, et al., 1997].

The following discussion is useful in designing a template for tissue repair and regeneration applications. By way of an example, the design parameters listed below are specifically applied to the development of a **resorbable collagen** based template for guiding meniscal tissue repair and regeneration in the knee joint.

Menisci are semilunar fibrocartilages that are anatomically located between the femoral condyles and tibial plateau, providing stability, weight bearing, shock absorption and assisting in lubrication of the knee joint. A major portion of the meniscal tissue is avascular except the peripheral rim, which comprises about 10 to 30% of the total width of the structure and which is nourished by the peripheral vasculature [Arnoczky and Warren, 1982]. Collagen is the major matrix material of the **meniscus**, and the fibers are oriented primarily in the circumferential direction in the line of stress for mechanical function. Repair of damaged meniscal tissue in the peripheral vascular rim can be accomplished with sutures. However, in cases where the injured site is in the avascular region, partial or total removal of the meniscal tissue is often indicated. This is primarily due to the inadequacy of the *fibrochondrocytes* alone to self-repair the damaged meniscal tissue. Studies in animals and humans have shown that removal of the meniscus is a prelude to degenerative knees manifested by the development of **osteoarthritis** [Hede and Sarberg, 1992; Shapiro and Glimcher, 1980]. At present there is no suitable permanent substitute for meniscal tissue.

43.3.1 Biocompatibility

Biocompatibility of the materials and their degraded products is a prerequisite for resorbable implant development. Purified collagen materials have been used either as implants or have been extensively tested in clinical studies as implants without adverse effects. The meniscus template can be fabricated from purified type I collagen fibers that are further crosslinked chemically to increase the stability and reduce the immunogenicity *in vivo*. In addition, small amounts of noncollagenous materials such as glycosaminoglycans and growth factors can be incorporated into the collagen matrix to improve the osmotic properties as well as the rate of tissue ingrowth.

Since the primary structure of a collagen molecule from bovine is homologous to human collagen [Miller, 1984], the *in vivo* degradation of bovine collagen implant should be similar to the normal host tissue remodeling process during wound healing. For a resorbable collagen template, the matrix is slowly degraded by the host over time. It is known that a number of cell types such as **polymorphonuclear leukocytes**, **fibroblasts**, and **macrophages**, during the wound healing period, are capable of secreting enzyme collagenases which cleave a collagen molecule at 1/4 position from the C-terminal end of the molecule [Woolley, 1984]. The enzyme first reduces a collagen molecule to two smaller triple helices which are not stable at body temperature and are subsequently denatured to random coiled polypeptides. These polypeptides are further degraded by proteases into amino acids and short peptides that are metabolized through normal metabolic pathways [Nimni and Harkness, 1988].

Despite the safety record of collagen materials for implantation, during the process of preparing the collagen template, small amounts of unwanted noncollagenous materials could be incorporated into the device such as salts and crosslinking agents. Therefore, a series of biocompatibility testing must be conducted to ensure the residuals of these materials do not cause any safety issues. The FDA has published a new guideline for biocompatibility testing of implantable devices (Biological Evaluation of Medical Devices, 1995).

43.3.2 Physical Dimension

The physical dimension of a template defines the boundary of regeneration. Thus, the size of the collagen template should match the tissue defect to be repaired. A properly sized meniscal substitute has been found to function better than a substitute which mismatches the physical dimension of the host meniscus [Rodkey et al., 1998; Sommerlath et al., 1991]. For a porous, elastic matrix such as the one designed from collagen for meniscal tissue repair, the shape of the meniscus is further defined *in vivo* by the space available between the femoral condyles and tibial plateau within the synovial joint.

43.3.3 Apparent Density

The apparent density as defined as the weight of the dry matrix in a unit volume of matrix. Thus, the apparent density is a direct measure of the empty space which is not occupied by the matrix material

per se in the dry state. For example, for a collagen matrix of an apparent density 0.2 g/cm^3, the empty space would be 0.86 cm^3 for a 1 cm^3 total space occupied by the matrix, taking the density of collagen to be 1.41 g/cm^3 [Noda, 1992]. The apparent density is also directly related to the mechanical strength of a matrix. In weight-bearing applications, the apparent density has to be optimized such that the mechanical properties are not compromised for the intended function of the resorbable implant as described in the mechanical properties section.

43.3.4 Pore Structure

The dimension of a mammalian fibrogenic cell body is on the order of 10 to 50 μm, depending on the substrate to which the cell adheres [Folkman et al., 1978]. In order for cells to infiltrate into the interstitial space of a matrix, the majority of the pores must be significantly larger than the dimension of a cell such that both the cell and its cellular processes can easily enter the interstitial space. In a number of studies using collagen-based matrices for tissue regeneration, it has been found that pore size plays an important role in the effectiveness of the collagen matrix to induce host tissue regeneration [Chvapil, 1982; Dagalailis et al., 1980; Yannas, 1996]. It was suggested that pore size in the range of 100 to 400 μm was optimal for tissue regeneration. Similar observations were also found to be true for porous metal implants in total hip replacement [Cook et al., 1991]. The question of interconnecting pores may not be a critical issue in a collagen template as collagenases are synthesized by most **inflammatory cells** during wound healing and remodeling processes. The interporous membranes which exist in the noninterconnecting pores should be digested as part of resorption and wound healing processes.

43.3.5 Mechanical Property

In designing a resorbable collagen implant for weight-bearing applications, not only the initial mechanical strength is important, but the gradual strength reduction of the partially resorbed template has to be compensated by the strength increase from the regenerated tissue such that at any given time point, the total mechanical properties of the template are maintained. In order to accomplish this goal, one must first be certain that the initial mechanical properties are adequate for supporting the weight-bearing application. For example, compressing the implant with multiple body weights should not cause fraying of the collagen matrix material. It is also of particular importance to design an implant having an adequate and consistent suture pullout strength in order to reduce the incidence of detachment of the implant from the host tissue. The suture pullout strength is also important during surgical procedures as the lack of suture pull strength may result in retrieval and reimplantation of the template. In meniscal tissue repair the suture pullout strength of 1 kg has been found to be adequate for arthroscopically assisted surgery in simulated placement procedures in human cadaver knees, and this suture pullout strength should be maintained as the minimal strength required for this particular application.

43.3.6 Hydrophilicity

Hydration of an implant facilitates nutrient diffusion. The extent of hydration would also provide information on the space available for tissue ingrowth. The porous collagen matrix is highly hydrophilic and therefore facilitates cellular ingrowth. The biomechanical properties of the hydrophilic collagen matrix such as fluid outflow under stress, fluid inflow in the absence of stress, and the resiliency for shock absorption are the properties also found in the weight-bearing cartilagenous tissues.

43.3.7 Permeability

The permeability of ions and macromolecules is of primary importance in tissues that do not rely on vascular transport of nutrients to the end organs. The diffusion of nutrients into the interstitial space ensures the survival of the cells and their continued ability of growth and synthesis of tissue specific extracellular matrix. Generally, the permeability of a macromolecule the size of the bovine serum albumin

(MW 67,000) can be used as a guideline for probing accessibility of the interstitial space of a collagen template [Li et al., 1994].

43.3.7.1 *In Vivo* Stability

As stated above, the rate of template resorption and the rate of new tissue regeneration have to be balanced so that the adequate mechanical properties are maintained at all times. The rate of *in vivo* resorption of a collagen-based implant can be controlled by controlling the density of the implant and the extent of intermolecular crosslinking. The lower the density, the greater the interstitial space and generally the larger the pores for cell infiltration, leading to a higher rate of matrix degradation. The control of the extent of intermolecular crosslinking can be accomplished by using bifunctional crosslinking agents under conditions that do not denature the collagen. Glutaraldehyde, formaldehyde, adipyl chloride, hexamethylene diisocyanate, and carbodiimides are among the many agents used in crosslinking the collagen-based implants. Crosslinking can also be achieved through vapor phase of a crosslinking agent. The vapor phase crosslinking is effective using crosslinking agents of high vapor pressures such as formaldehyde and glutaraldehyde. The vapor crosslinking is particularly useful for thick implants of vapor permeable dense fibers where crosslinking in solution produces nonuniform crosslinking. In addition, intermolecular crosslinking can be achieved by heat treatment under high vacuum. This treatment causes the formation of an amide bond between an amino group of one molecule and the carboxyl group of an adjacent molecule and has often been referred to in the literature as dehydrothermal crosslinking.

The shrinkage temperature of the crosslinked matrix has been used as a guide for *in vivo* stability of a collagen implant [Li, 1988]. The temperature of shrinkage of collagen fibers measures the transition of the collagen molecules from the triple helix to a random coil conformation. This temperature depends on the number of intermolecular crosslinks formed by chemical means. Generally, the higher the number of intermolecular crosslinks, the higher the thermal shrinkage temperature and more stable the material *in vivo*.

A second method of assessing the *in vivo* stability is to determine the crosslinking density by applying the theory of rubber elasticity to denatured collagen [Wiederhorn and Beardon, 1952]. Thus, the *in vivo* stability can be directly correlated with the number of intermolecular crosslinks introduced by a given crosslinking agent.

Another method that has been frequently used in assessing the *in vivo* stability of a collagen-based implant is to conduct an *in vitro* collagenase digestion of a collagen implant. Bacterial collagenase is generally used in this application. The action of bacterial collagenase on collagen is different from that of mammalian collagenase [Woolley, 1984]. In addition, the enzymatic activity used in *in vitro* studies is arbitrarily defined. Thus, the data generated from the bacterial collagenase should be viewed with caution. The bacterial collagenase digestion studies, however, are useful in comparing a prototype with a collagen material of known rate of *in vivo* resorption.

Each of the above parameters should be considered in designing a resorbable implant. The interdependency of the parameters must also be balanced for maximal efficacy of the implant.

43.4 Tissue Engineering for Tissue and Organ Regeneration

Biomedical applications of collagen have entered a new era in the past decade. The potential use of collagen materials in medicine has increasingly been appreciated as the science and technology advances.

One major emerging field of biomedical research which has received rigorous attention in recent years is tissue engineering. Tissue engineering is an interdisciplinary science of biochemistry, cell and molecular biology, genetics, materials science, biomedical engineering, and medicine to produce innovative three-dimensional composites having structure/function properties that can be used either to replace or correct poorly functioning components in humans and animals or to introduce better functional components into these living systems. Thus, the field of tissue engineering requires a close collaboration among various disciplines for success.

TABLE 43.6   Survey of Collagen-Based Medical Products, and Research and Development Activities

Applications	Comments
Hemostasis	Commercial Products: Sponge, fiber, and felt forms are used in cardiovascular [Abbott and Austin, 1975]; neurosurgical [Rybock and Long, 1977]; dermatological [Larson, 1988]; ob/gyn [Cornell et al., 1985]; orthopaedic [Blanche and Chaux, 1988]; oral surgical applications [Stein et al., 1985]
Dermatology	Commercial Products: Injectable collagen for soft tissue augmentation [Webster et al., 1984]; collagen based artificial skins [Bell et al., 1981; Yannas and Burke, 1981]. Research and Development: Collagen based wound dressings [Armstrong et al., 1986]
Cardiovascular Surgery and Cardiology	Commercial Products: Collagen coated and gelatin coated vascular grafts [Jonas et al., 1988, Li, 1988]; chemically processed human vein graft [Dardik et al., 1974]; bovine arterial grafts [Sawyer et al., 1977]; porcine heart valves [Angell et al., 1982]; bovine pericardial heart valves [Walker et al., 1983]; vascular puncture hole seal device [Merino et al., 1992]
Neurosurgery	Research and Development: Guiding peripheral nerve regeneration [Archibald et al., 1991; Yannas et al., 1985]; dura replacement material [Collins et al., 1991]
Periodontal and Oral Surgery	Research and Development: Collagen membranes for periodontal ligament regeneration [Blumenthal, 1988]; resorbable oral tissue wound dressings [Ceravalo and Li, 1988]; collagen/hydroxyapatite for augmentation of alveolar ridge [Gongloff and Montgomery, 1985]
Ophthalmology	Commercial Products: Collagen corneal shield to facilitate epithelial healing [Ruffini et al., 1989]. Research and Development: Collagen shield for drug delivery to the eye [Reidy et al., 1990]
Orthopaedic Surgery	Commercial Products: Collagen with hydroxyapatite and autogenous bone marrow for bone repair [Hollinger et al., 1989]. Research and Development: Collagen matrix for meniscus regeneration [Li et al., 1994]; collagenous material for replacement and regeneration of Achilles tendon [Kato et al., 1991]; reconstituted collagen template for ACL reconstruction [Li et al., 1997]
Other Applications	Research and Development: Drug delivery support [Sorensen et al., 1990]; delivery vehicles for growth factors and bioactive macromolecules [Deatherage and Miller, 1987; Li et al., 1996]; collagenous matrix for delivery of cells for tissue and organ regeneration [Bell et al., 1981]

Tissue engineering consists primarily of three components: (1) extracellular matrix, (2) cells, and (3) regulatory signals (e.g., tissue specific growth factors). One of the key elements in tissue engineering is the extracellular matrix which either provides a scaffolding for cells or acts as a delivery vehicle for regulatory signals such as growth factors.

Type I collagen is the major component of the extracellular matrix and is intimately associated with development, wound healing, and regeneration. The development of the type I collagen based matrices described in this review article will greatly facilitate the future development of tissue engineering products for tissue and organ repair and regeneration applications.

To date, collagen-based implants have been attempted for many tissue and organ repair and regeneration applications. A complete historical survey of all potential medical applications of collagen is a formidable task but a selected survey of collagen-based medical products and the research and development activities are summarized in Table 43.6 as a reference.

Defining Terms

Alanine (Ala):   One of the amino acids in collagen molecules.

Allysine: The ε-amino group of lysine has been enzymatically modified to an aldehyde group.

Apparent density: Calculated as the weight of the dry collagen matrix per unit volume of matrix.

Arginine (Arg):   One of the amino acids in collagen molecules.

Aspartic acid (Asp):   One of the amino acids in collagen molecules.

Atelocollagen: A collagen molecule without the telopeptides.

Chondroitin sulfate: Sulfated polysaccharide commonly found in cartilages,bone, corea, tendon, and skin.

Collagen: A family fibrous insoluble proteins having a triple helical conformation extending over a major part of the molecule. Glycine is present at every third amino acid in the triple helix and proline and hydroxyproline are required in the triple helix.

Collagenase: A proteolytic enzyme that specifically catalyzes the degradation of collagen molecules.

Dehydrohydroxylysinonorleucine (deH-HLNL):   A covalently crosslinked product between an allysine and a hydroxylysine residues in collagen fibrils.

D spacing: The repeat distance observed in collagen fibrils by electron microscopic and x-ray diffraction methods.

Elastin: One of the proteins in connective tissue. It is highly stable at high temperatures and in chemicals. It also has rubberlike properties.

Fiber: A bundled group of collagen fibrils.

Fibril: A self-assembled group of collagen molecules.

Fibroblast: Any cell from which connective tissue is developed.

Fibrochondrocyte: Type of cells that are associated with special types of cartilage tissues such as meniscus of the knee and intervertebral disc of the spine.

Fibrous long spacing (FLS):   One of the polymorphic forms of collagen where the collagen molecules are randomly aligned in either head-to-tail, tail-to-tail, or head-to-head orientation.

Gelatin: A random coiled form (denatured form) of collagen molecules.

Glutamic acid (Glu):   One of the amino acids in collagen molecules.

Glycine (Gly):   One of the amino acids in collagen molecules having the simplest structure.

Glycoprotein: A compound consisting of a carbohydrate protein. The carbohydrate is generally hexosamine, an amino sugar.

Glycosaminoglycan (GAG):   A polymerized sugar (see polysaccharide) commonly found in various connective tissues.

Helical pitch: Repeating distance within a single polypeptide chain in a collagen molecule.

Hemostat: Device or medicine which arrests the flow of blood.

Hydrophilicity: The tendency to attract and hold water.

Hydrophobicity: The tendency to repel or avoid contact with water. Substances generally are nonpolar in character, such as lipids and nonpolar amino acids.

Hydroxylysine (Hyl):   One of the amino acids in collagen molecules.

Hydroxyproline (Hyp):   One of the amino acids uniquely present in collagen molecules.

Inflammatory cell: Cells associated with the succession of changes which occur in living tissue when it is injured. These include macrophages, polymorphonuclear leukocytes, and lymphocytes.

Intermolecular crosslink: Covalent bonds formed *in vivo* between a side group of one molecule and a side group of another molecule; covalent bonds formed between a side group of one molecule and one end of a bifunctional agent and between a side group of a second molecule and the other end of a bifunctional agent.

Intrafibrillar volume: The volume of a fibril excluding the volume occupied by the collagen molecule.

In vitro: In glass, as in a test tube. An *in vitro* test is one done in the laboratory, usually involving isolated tissues, organs, or cells.

In vivo: In the living body or organism. A test performed in a living organism.

Isoelectric point: Generally used to refer to a particular pH of a protein solution. At this pH, there is no net electric charge on the molecule.

Isoleucine (Ile):   One of the amino acids in collagen molecules.

Leucine (Leu):   One of the amino acids in collagen molecules.

Lipid: Any one of a group of fats or fat-like substances, characterized by their insolubility in water and solubility in fat solvents such as alcohol, ether, and chloroform.

Lysine (Lys):   One of the amino acids in collagen molecules.

Meniscus: A C-shaped fibrocartilage anatomically located between the femoral condyles and tibial plateau providing stability and shock absorption and assisting in lubrication of the knee joint.

Macrophage: Cells of the reticuloendothelial system having the ability to phagocytose particulate substances and to store vital dyes and other colloidal substances. They are found in loose connective tissues and various organs of the body.

Mycobacterium: A genus of acid-fast organisms belonging to the Mycobacteriaceae which includes the causative organisms of tuberculosis and leprosy. They are slender, nonmotile, gram-positive rods and do not produce spores or capsules.

Osteoarthritis: A chronic disease involving the joint, especially those bearing the weight, characterized by destruction of articular cartilage, overgrown of bone with impaired function.

Permeability: The space within a collagen matrix, excluding the space occupied by collagen molecules, which is accessible to a given size of molecule.

Pepsin: A proteolytic enzyme commonly found in the gastric juice. It is formed by the chief cells of gastric glands and produces maximum activity at a pH of 1.5 to 2.0.

Phenolalanine (Phe):   One of the amino acids in collagen molecules.

Platelet: A round or oval disk, 2 to 4 μm in diameter, found in the blood of vertebrates. Platelets contain no hemoglobin.

Polydioxanone: A synthetic polymer formed from dioxanone monomers which degrades by hydrolysis.

Polyglycolic acid (PGA):   A synthetic polymer formed from glycolic acid monomers which degrades by hydrolysis.

Polylactic acid (PLA):   A synthetic polymer formed from lactic acid monomers which degrades by hydrolysis.

Polymorphism: Different types of aggregated states of the collagen molecules.

Polymorphonuclear leukocyte: A white blood cell which possesses a nucleus composed of two or more lobes or parts; a granulocyte (neutrophil, eosinophil, basophil).

Polypeptide: Polymerized amino acid molecules formed by enzymatically regulated stepwise polymerization *in vivo* between the carboxyl group of one amino acid and the amino group of a second amino acid.

Polysaccharide: Polymerized sugar molecules found in tissues as lubricant (synovial fluid) or cement (between osteons, tooth root attachment) or complexed with proteins such as glycoproteins or proteoglycans.

Proline (Pro):   One of the amino acids commonly occurring in collagen molecules.

Proteolytic enzyme: Enzymes which catalyze the breakdown of native proteins.

Resorbable collagen: Collagen which can be biodegraded *in vivo*.

Salt-linkage: An electrostatic bond formed between a negative charge group and a positive charge group in collagen molecules and fibrils.

Segment-long-spacing (SLS):   One of the polymorphic forms of collagen where all heads of collagen molecules are aligned in parallel.

Soluble collagen: Collagen molecules that can be extracted with salts and dilute acids. Soluble collagen molecules contain the telopeptides.

Telopeptide: The two short nontriple helical peptide segments located at the ends of collagen molecules.

Valine (Val):   One of the amino acids in collagen molecules.

44.1 Blood Interfacing Implants

K.B. Chandran

44.1.1 Introduction

Blood comes in contact with foreign materials for a short term in extracorporeal devices such as **dialysers**, **blood oxygenators**, ventricular assist devices, and **catheters**. Long-term vascular implants include heart valve prostheses, **vascular grafts**, and **cardiac pacemakers** among others. In this section, we will be concerned with development of biomaterials for long-term implants, specifically for heart valve prostheses, total artificial heart (**TAH**), and vascular grafts. The primary requirements for biomaterials for long-term implants are biocompatibility, nontoxicity, and durability. Furthermore, the material should be nonirritating to the tissue, resistant to **platelet** and **thrombus** deposition, nondegradable in the physiological environment, and neither absorb blood constituents nor release foreign substances into the blood stream [Shim and Lenker, 1988]. In addition, design considerations include that the implant should mimic the function of the organ that it replaces without interfering with the surrounding anatomical structures and must be of suitable size and weight. The biomaterials chosen must be easily available, inexpensive, easily machinable, sterilizable, and have a long storage life. The selection of material will also be dictated by the strength requirement for the implant being made. As an example, an artificial heart valve prosthesis is required to open and close on an average once every second. The biomaterial chosen must be such that

the valve is durable and will not fail under **fatigue stress** after implantation in a patient. As sophisticated measurement techniques and detailed computational analyses become available with the advent of super computers, our knowledge on the complex dynamics of the functioning of the implants is increasing. Improvements in design based on such knowledge and improvements in selection and manufacture of biomaterials will minimize problems associated with blood interfacing implants and significantly improve the quality of life for patients with implants. We will discuss the development of biomaterials for the blood interfacing implants, problems associated with the same, and future directions in the development of such implants.

44.1.2   Heart Valve Prostheses

Attempts at replacing diseased natural human valves with prostheses began about four decades ago. The details of the development of heart valve prostheses, design considerations, *in vitro* functional testing, and durability testing of valve prototypes can be found in several monographs [Shim and Lenker, 1988; Chandran, 1992]. The heart valve prostheses can be broadly classified into **mechanical prostheses** (made of non-biological material) and **bioprostheses** (made of biological tissue). Currently available mechanical and tissue heart valve prostheses in the United States are listed in Table 44.1.

44.1.2.1   Mechanical Heart Valves

Lefrak and Starr [1970] describe the early history of mechanical valve development. The initial designs of mechanical valves were of centrally occluding caged ball or caged disc type. The Starr–Edwards caged ball prostheses, commercially available at the present time, was successfully implanted in the mitral position in 1961. The caged ball prostheses is made of a polished Co–Cr alloy (**Stellite 21®**) cage and a silicone rubber ball (Silastic®) which contains 2% by weight barium sulfate for **radiopacity** (Figure 44.1). The valve **sewing rings** use a silicone rubber insert under a knitted composite polytetrafluorethylene (PTFE-**Teflon®**) and **polypropylene** cloth. Even though these valves have proven to be durable, the centrally occluding design of the valve results in a larger pressure drop in flow across the valve and higher **turbulent stresses** distal to the valve compared to other designs of mechanical valve prostheses [Yoganathan et al., 1979a, b; 1986; Chandran et al., 1983]. The relatively large profile design of caged ball or disc construction also increases the possibility of interference with anatomical structures after implantation. The **tilting disc valves**, with improved hemodynamic characteristics, were introduced in the late 1960s. The initial design consisted of a polyacetal (**Delrin®**) disc with a Teflon® sewing ring. Delrin acetal resins are thermoplastic
FIGURE 44.1   A caged-ball heart valve prosthesis. (Courtesy of Baxter Health Care, Irvine, CA.)

polymers manufactured by the polymerization of **formaldehyde** [Shim and Lenker, 1988]. Even though Delrin exhibited excellent wear resistance and mechanical strength with satisfactory performance after more than 20 years of implantation, it was also found to swell when exposed to humid environments such as **autoclaving** and blood contact. To avoid design and manufacturing difficulties due to the swelling phenomenon, the Delrin disc was soon replaced by the **pyrolytic carbon** disc and has become the preferred material for mechanical valve prostheses occluders to date. Pyrolytic carbons are formed in a fluidized bed by pyrolysis of a gaseous hydrocarbon in the range of 1000 to 2400°C. For biomedical applications, carbon is deposited onto a preformed polycrystalline graphite substrate at temperatures below 1500°C (low temperature isotropic pyrolytic carbon, **LTI** Pyrolite®). Increase in strength and wear resistance is obtained by codepositing silicone (up to 10% by weight) with carbon in applications for heart valve prostheses. The pyrolytic carbon discs exhibit excellent blood compatibility, as well as wear and fatigue resistance. The guiding **struts** of tilting disc valves are made of **titanium** or Co–Cr alloys (**Haynes 25®** and Stellite 21®). The Co–Cr based alloys, along with pure titanium and its alloy (Ti6A14V) exhibit excellent mechanical properties as well as resistance to corrosion and thrombus deposition. A typical commercially available tilting disc valve with a pyrolytic carbon disk is shown in Figure 44.2a. A tilting disc valve with the leaflet made of **ultra high molecular weight polyethylene** (Chitra valve — Figure 44.2b) is currently marketed in India. The advantages of **leaflets** with relatively more flexibility compared to pyrolytic carbon leaflets are discussed in Chandran et al. [1994a]. Another new concept in a tilting disc valve design introduced by Reul et al. [1995] has an S-shaped leaflet with leading and trailing edges being parallel to the direction of blood flow. The housing for the valve is nozzle-shaped to minimize flow separation at the inlet and energy loss in flow across the valve. Results from *in vitro* evaluation and animal implantation have been encouraging.

In the late 1970s, a bileaflet design was introduced for mechanical valve prostheses and several different bileaflet models are being introduced into the market today. The leaflets as well as the housing of the bileaflet valves are made of pyrolytic carbon and the bileaflet valves show improved hemodynamic characteristics especially in smaller sizes compared to tilting disc valves. A typical bileaflet valve is shown in Figure 44.3. Design features to improve the hydrodynamic characteristics of the mechanical valves include the opening angle of the leaflets [Baldwin et al., 1997] as well as having an open-pivot design in which the pivot area protrudes into the orifice and is exposed to the washing action of flowing blood [Drogue and Villafana, 1997]. Other design modifications to improve the mechanical valve function include: the use of double polyester (Dacron®) velour material for the suture ring to encourage rapid and controlled tissue ingrowth, and mounting the cuff on a rotation ring which surrounds the orifice ring to protect the cuff mounting mechanism from deeply placed annulus sutures. A PTFE (Teflon®) insert in the cuff provides pliability without excessive drag on the sutures. Tungsten (20% by weight) is incorporated into the leaflet substrate in order to visualize the leaflet motion *in vivo*.

FIGURE 44.4 A tri-leaflet heart valve prosthesis under development. (Courtesy of Triflo Medical, Inc., Costa Mesa, CA.)

Another attempt to design a mechanical valve which mimics the geometry and function of the tri-leaflet aortic valve is that of Lapeyre et al. (1994) (Figure 44.4a, b). The geometry of the valve affords true central flow characteristics with reduced backflow. Accelerated fatigue tests have also shown good wear characteristics for this design and the valve is undergoing further evaluation including animal studies. Other improvements in the mechanical valves which augment performance include: machining of the valve housing to fit a disk so as to produce optimal washing and minimal regurgitation [McKenna, 1997]; a supra-annular design so that a larger-sized valve can be inserted in the aortic position in the case of patients with small aortic annulus [Bell, 1997]; and coating of a titanium alloy ring with a thin, uniform, and strongly adherent film of high-density turbostratic carbon (Carbofilm™) [Bona et al., 1997] in order to integrate the structural stability of the metal alloy to the non-thrombogenecity of pyrolytic carbon. Details of contemporary design efforts in mechanical valve design and potential future biomaterials such as Boralyn® (boron carbide) are discussed in Wieting [1997].

In spite of the desirable characteristics of the biomaterials used in the heart valve prostheses, problems with **thrombo-embolic complications** are significant with implanted valves and patients with mechanical valves are under long-term anticoagulant therapy. The mechanical stresses induced by the flow of blood across the valve prostheses have been linked to the lysis and activation of **formed elements of blood** (red blood cells, white blood cells, and platelets) resulting in the deposition of thrombi in regions with

relative stasis in the vicinity of the prostheses. Numerous *in vitro* studies with mechanical valves in pulse duplicators simulating physiological flow have been reported in the literature and have been reviewed by Chandran [1988] and Dellsperger and Chandran [1991]. Such studies have included measurement of velocity profiles and turbulent stresses distal to the valve due to flow across the valve. The aim of these studies has been the correlation of regions prone to thrombus deposition and tissue overgrowth with explanted valves and the experimentally measured bulk turbulent shear stresses as well as regions of relative stasis. In spite of improvements in design of the prostheses to afford a centralized flow with minimal flow disturbances and fluid mechanical stresses, the problems with thrombus deposition remain significant.

Reports of strut failure, material **erosion** and leaflet escapes, as well as **pitting** and erosion of valve leaflets and housing, have resulted in numerous investigations of the **closing dynamics** of mechanical valves. The dynamics of the leaflet motion and its impact with the valve housing or seat stop is very complex and a number of experimental and numerical studies have appeared recently in the literature. As the leaflet impacts against the seat stop and comes to rest instantaneously, high positive and **negative pressure** transients are present on the outflow and inflow side of the occluder, respectively, at the instant when the leaflet impacts against the seat stop or the guiding strut [Leuer, 1986; Chandran et al., 1994a]. The *negative pressure transients* have been shown to reach magnitudes below the **liquid vapor pressure** and have been demonstrated to be a function of the loading rate on the leaflet inducing the valve closure. As the magnitudes of negative pressure transients go below the liquid vapor pressure, **cavitation bubbles** are initiated and the subsequent collapse of the cavitation bubbles may also be a factor in the lysis of red blood cells, platelets, and **valvular structures** [Chandran et al., 1994a; Lee et al., 1994]. Typical cavitation bubbles visualized in an *in vitro* study with tilting disc and bileaflet valves are shown in Figure 44.5. A correlation is also observed between the region where cavitation bubbles are present, even though for a period of time less than a millisecond after valve closure, and sites of pitting and erosion reported in the pyrolytic carbon material in the valve housing and on the leaflets with explanted valves [Kafesjian, 1994] as well as those used in total artificial hearts [Leuer, 1987]. An electron micrograph of pitting and erosion observed in the pyrolytic carbon valve housing of an explanted bileaflet mechanical valve is shown in Figure 44.6. The pressure transients at valve closure are substantially smaller in mechanical valves with a flexible occluder and leaflets made of ultra high molecular weight polyethylene (Figure 44.2b) may prove to be advantageous based on the closing dynamic analysis [Chandran et al., 1994a]. A correlation between the average velocity of the leaflet edge and the negative pressure transients in the same region at the instant of valve closure, as well as the presence of cavitation bubbles has been reported recently [Chandran et al., 1997]. This study demonstrated that for the valves of the same geometry (e.g., tilting disk) and size, the leaflet edge velocity as well as the negative pressure transients were similar. However, the presence of cavitation bubbles depended on the local interaction between the leaflet and the seat stop. Hence, it was pointed out that magnitudes of leaflet velocity or presence of pressure transients below the liquid vapor pressure might not necessarily indicate cavitation inception with mechanical valve closure. Chandran et al. [1998] have also demonstrated the presence of negative pressure transients in the atrial chamber with implanted mechanical valves in the mitral position in animals, demonstrating that potential for cavitation exists with implanted mechanical valves. Similar to the *in vitro* results, the transients were of smaller magnitudes with the Chitra valve made of flexible leaflets, and no pressure transients were observed with tissue valve implanted in the mitral position *in vivo*. The demonstration of the negative pressure transients with mechanical valve closure also shows that this phenomenon is localized and the flow chamber or valve holder rigidity with the *in vitro* experiments will not affect the valve closing dynamics.

The pressure distribution on the leaflets and impact forces between the leaflets and guiding struts have also been experimentally measured in order to understand the causes for strut failure [Chandran et al., 1994b]. The flow through the clearance between the leaflet and the housing at the instant of valve closure [Lee and Chandran, 1994a, b] and in the fully closed position [Reif, 1991] and the resulting wall shear stresses within the clearance are also being suggested as responsible for clinically significant hemolysis and thrombus initiation. Detailed analysis of the complex closing dynamics of the leaflets may also be exploited in improving the design of the mechanical valves to minimize problems with structural failure

[Cheon and Chandran, 1994]. Further improvements in the design of the valves based on the closing dynamics as well as improvements in material may result in minimizing thrombo-embolic complications with implanted mechanical valves.

44.1.2.2 Biological Heart Valves

The first biological valves implanted were **homografts** with valves explanted from cadavers within 48 h after death. Preservation of the valves included various techniques of sterilization, freeze drying, and immersing in antibiotic solution. The use of homografts is not popular due to problems with long term durability and due to limited availability except in a few centers [Shim and Lenker, 1988; Lee and Boughner, 1991]. Attempts were also made in the early 1960s in the use of **xenografts** (valves made from animal tissue) and porcine bioprostheses became commercially available after the introduction of the gluteraldehyde (rather than formaldehyde which was initially used) fixation technique. Gluteraldehyde reacts with tissue proteins to form crosslinks and results in improved durability [Carpentier et al., 1969]. The valves are harvested from 7 to 12 month old pigs and attached to supporting **stents** and preserved. The stent provided support to preserve the valve in the natural shape and to achieve normal opening and closing. Initial supports were made of metal and subsequently flexible polypropylene stents were introduced. The flexible stents provided the advantage of ease of assembling the valve and **finite element analyses** have demonstrated reduction in stresses at the juncture between the stent and tissue leaflets resulting in increased durability and increased leaflet coaptation area [Reis et al., 1971; Hamid et al., 1985]. A typical porcine bioprosthesis is included in Figure 44.7a.

Fixed bovine pericardial tissue is also used to construct heart valves in which design characteristics such as orifice area, valve height, and degree of coaptation can be specified and controlled. Thus, the geometry and flow dynamics past **pericardial prostheses** mimic those of the natural human aortic valves more closely. Due to the low profile design of pericardial prostheses and increased orifice area, these valves are less stenotic compared to porcine bioprostheses, especially in smaller sizes [Chandran et al., 1984]. In the currently available bioprostheses, the stents are constructed from polypropylene, **Acetol®** homopolymer or copolymer, Elgiloy wire, or titanium. A stainless steel radiopaque marker is also introduced to visualize the valve *in vivo*. Other biomaterials, which have been employed in making the bioprostheses, include **fascia lata** tissue as well as human **duramater** tissue. The former was prone to deterioration and hence unsuitable for bioprosthetic application, while the latter lacked commercial availability.

The advantage with bioprostheses is the freedom from thrombo-embolism and hence not requiring long term anticoagulant therapy in general. These prostheses are preferable in patients who do not tolerate anticoagulants. On the other hand, bioprosthetic valves are prone to **calcification** and leaflet tear with an average lifetime of about 10 years before replacement is necessary, and is generally attributed to the tissue fixation process. Numerous attempts are being made to improve the design as well as fixation in bioprostheses in order to minimize problems with calcification and increase duration of the function of the implant. As an example, a bovine pericardial trileaflet valve (Figure 44.7[b]) treated with a non-aldehyde fixation resulting in collagen crosslink formation without a new "foreign" chemical process [Phillips and Printz, 1997] has been introduced in the European market. A non-aldehyde iodine-based sterilization process also sterilizes the valve.

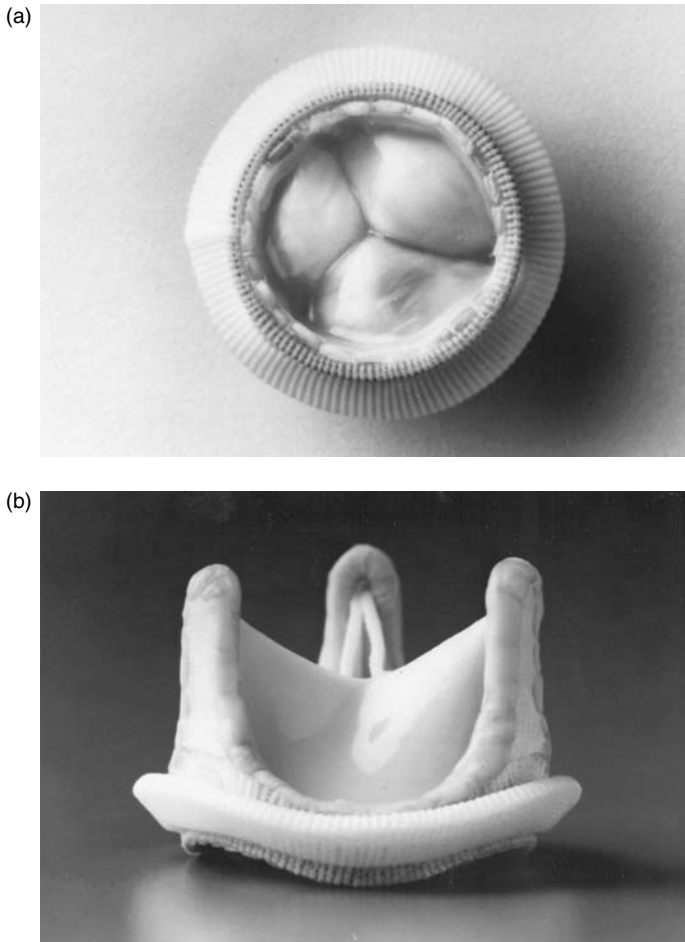
Numerous studies linking the mechanical stresses on the leaflets with calcification, focal thinning, and leaflet failure [Thubrikar et al., 1982a; Sabbah et al., 1985], and design improvements to minimize the stresses on the leaflets [Thubrikar et al., 1982b] have been reported in the literature. Further details on the effects of tissue fixation and mechanical effects of fixation on the leaflets are reported elsewhere [Lee and Boughner, 1991]. Improvements in fixation techniques as well as in design of the bioprostheses are continually being made in order to minimize problems with calcification of the leaflets and improve the durability and functional characteristics of bioprosthetic heart valves [Piwnica and Westaby, 1998]. The biomaterials used in commercially available mechanical and bioprosthetic heart valves are included in Table 44.2. Table 44.3 includes a summary of the problems associated with implanted artificial heart valves.


FIGURE 44.7 Typical bioprostheses: (a) Hancock porcine bioprosthesis (courtesy of Medtronic Heart Valves, Minneapolis, MN); (b) PhotoFix™ α pericardial prosthesis. (Courtesy of Sulzer-CarboMedics, Inc., Austin, TX.)

44.1.2.3 Synthetic Heart Valves

Concurrently, efforts have also been made in the development of valve prostheses made of synthetic material. Several attempts to make bileaflet [Braunwald et al., 1960] and trileaflet valves [Roe et al., 1958; Hufnagel, 1977; Gerring et al., 1974; Ghista and Reul, 1977] made of polyurethanes, polyester fabrics, and silicone rubber were not successful due to problems with durability of relatively thin leaflets made of synthetic material. With the advent of the total artificial hearts (TAH) and **left ventricular assist devices** (LVAD) in the 1980s, an additional impetus on the development of synthetic valves is present. Due to problems with thrombus deposition in the vicinity of the mechanical valves used in the TAH and subsequent stroke episodes in patients with permanent implants, the use of the device is currently restricted as a bridge to transplantation. In such temporary use before a donor heart becomes available (on an average of several weeks), the four mechanical prostheses used in the TAH results in substantial cost. Hence, efforts are being made to replace the mechanical valves with those made with synthetic material. With **vacuum forming** or **solution casting** techniques, synthetic valves can be made at a fraction of the cost of mechanical valves, provided their function in a TAH environment for several weeks will be satisfactory. Implantation of synthetic trileaflet valves [Russel et al., 1980; Harold et al., 1987], even more recently, have resulted in limited success due to leaflet failure and calcification. Hemodynamic comparison

TABLE 44.2 Biomaterial Used in Heart Valve Prostheses [Shim and Lenker, 1988; Dellsperger and Chandran, 1988]

Type	Component	Biomaterial
Caged ball	Ball/occluder	Silastic
	Cage	Stellite 21®/Titanium
	Suture ring	Silicone rubber insert under knitted composite Teflon®/polypropylene cloth
Tilting disc	Leaflet	Delrin®; Pyrolytic carbon (carbon deposited on graphite substrate); ultra high molecular polyethylene (UHMPE)
	Housing/strut	Haynes 25®/Titanium
	Suture ring	Teflon®/Dacron®
Bileaflet	Leaflets	Pyrolytic carbon
	Housing	Pyrolytic carbon
	Suture ring	Double velour Dacron® tricot knit polyester
Porcine bioprostheses	Leaflets	Porcine aortic valve fixed by stabilized gluteraldehyde
	Stents	Polypropylene stent covered with Dacron®; lightweight Elgiloy wire covered with porous knitted Teflon® cloth
	Suture ring	Dacron®; soft silicone rubber insert covered with porous, seamless Teflon® cloth
Pericardial bioprostheses	Leaflets	Porcine pericardial tissue fixed by stabilized gluteraldehyde before leaflets are sewn to the valve stents
	Stents	Polypropylene stent covered with Dacron®; Elgiloy wire and nylon support band covered with polyester and Teflon® cloth
	Suture ring	PTFE fabric over silicone rubber filter

(d) Infection

of vacuum formed and solution cast trileaflet valves to currently available bioprostheses have produced satisfactory results [Chandran et al., 1989a, b]. *Finite element analysis* of synthetic valves can be exploited in design improvements similar to those reported for bioprostheses [Chandran et al., 1991a].

44.1.3 Total Artificial Hearts (TAH) or Ventricular Assist Devices (VAD)

Artificial circulatory support can be broadly classified into two categories. The first category is for those patients who undergo open heart surgery to correct **valvular disorders**, ventricular *aneurysm*, or coronary **artery** disease. In several cases, the heart may not recover sufficiently after surgery to take over the pumping action. In such patients ventricular assist devices are used as extracorporeal devices to maintain circulation until the heart recovers. Other ventricular assist devices include **intra-aortic balloon pumps** as well as

cardiopulmonary bypass. Within several days or weeks, when the natural heart recovers, these devices will be removed. In the second category are patients with advanced stages of cardiomyopathy and are subjects for heart transplantation. Due to problems in the availability of suitable donor hearts, not all patients with a failed heart are candidates for heart transplantation. For those patients not selected for transplantation, the concept of replacing the natural heart with a total artificial heart has gained attention in recent years [Akutsu and Kolff, 1958; Jarvick, 1981; DeVries and Joyce, 1983; Unger, 1989; Kambic and Nose, 1991]. A number of attempts in the permanent implantation of TAH with pneumatically powered units were made in the 1980s. However, due to neurological complications as a result of thrombo-embolism, infection, and hematological and renal complications, permanent implantations are currently suspended. If a suitable donor heart is not readily available, TAHs can be used as "bridge to transplantation" for several weeks until a donor heart becomes available. Until recently, most of the circulatory assist devices were pneumatically driven and a typical pneumatic heart is shown in Figure 44.8a. It has two chambers for the left and right ventricle with inlet and outlet valves for each of the chambers. A line coming from the external pneumatic driver passes through the skin and is attached to the diaphragm housing through the connector shown in the photograph. Thus, the patient is tethered to an external pneumatic drive. He can move around for a short period of time by attaching the pneumatic line to a portable driver that he can carry.

Electrically driven blood pumps, which can afford tether-free operation within the body, unlike those of the pneumatically powered pumps, are currently at various stages of development for long-term use (of more than 2 years). The components of such devices include the blood pump in direct contact with blood, energy converter (from electrical to mechanical energy), variable column compensator, implantable batteries, transcutaneous energy transmission system, and external batteries. The blood pump configuration in these devices includes sac, diaphragm, and **pusher plate devices**. Materials used in blood contacting surfaces in these devices are synthetic polymers (polyurethanes, segmented polyurethanes, **Biomer®**, and others). Segmented polyurethane elastomer used in prosthetic ventricles with a thromboresistant additive modifying the polymeric surface have resulted in improved blood compatibility and reduced thrombo-embolic risk in animal trials [Farrar et al., 1988]. Design considerations include reduction of regions of stagnation of blood within the blood chamber and minimizing the mechanical stresses induced on the formed elements in blood. Apart from the characteristics of these materials to withstand repetitive high mechanical stresses and minimize failure due to fatigue, surface interaction with blood is also another crucial factor. An electrically powered total artificial heart intended for long term implantation is shown in Figure 44.8b. The details of the design considerations for the circulatory assist devices are included in Rosenberg [1995a] and details of the evaluation of the electrically powered heart is included in Rosenberg et al. [1995b].

Due to significant problems with thrombo-embolic complications and subsequent neurological problems with long-term implantation of TAH in humans, attention has been focused on minimizing factors responsible for thrombus deposition. In order to eliminate crevices formed with the quick connect system, valves sutured in place at the inflow and outflow orifices were offered as an alternative in the Philadelphia Heart [Wurzel et al., 1988]. An alternative quick connect system using precision machined components has been demonstrated to reduce valve- and connector-associated thrombus formation substantially [Holfert et al., 1987]. Several *in vitro* studies have been reported in the literature in order to assess the effect of fluid dynamic stresses on thrombus deposition [Phillips et al., 1979; Tarbell et al., 1986; Baldwin et al., 1990; Jarvis et al., 1991]. These have included flow visualization and **laser Doppler anemometry** velocity and turbulence measurements within the ventricular chamber as well as in the vicinity of the inflow and outflow orifices. The results of such studies indicate that the flow within the chamber generally has a smooth washout of blood in each pulsatile flow cycle with relatively large turbulent stresses and regions of stasis found near the valves. The thrombus deposition found with implanted TAH in the vicinity of the inflow valves also indicates that the major problem with the working of these devices are still with the flow dynamics across the mechanical valves. Computational flow dynamic analysis within the ventricular chamber may also be exploited to improve the design of the valve chambers and the mechanical valves in order to reduce the turbulent stresses near the vicinity of the inflow and outflow orifices [Kim et al., 1992]. Structural failure of the mechanical valves, initially reported with the TAH may have been the result of

TABLE 44.4   Classification of Vascular Prostheses

Prosthesis	Comments
Surgically-implanted biological grafts	
Autograft	Graft transplanted from part of a patient's body to another
	Example: saphenous vein graft for peripheral bypass
Allograft	Homograft. Transplanted vascular graft tissues derived from the
	same species as recipient. Example: glutaraldehyde treated umbilical cord vein graft
Xenograft	Heterograft. Surgical graft of vascular tissues derived from one
	species to a recipient of another species. Example: modified bovine heterograft
Surgically-implanted synthetic grafts	
Dacron (polyethylene terephthalate)	Woven, knitted
PTFE (polytetrafluoroethylene)	Expanded, knitted
Other	Nylon, polyurethane

increased load on the valves during closure due to the relatively large dp/dt (p is pressure, t is time) at which the TAH was operated. Attempts at reducing the dp/dt during closure of the inflow valves have also been reported with modified designs of the artificial heart driver [Wurzel et al., 1988]. Due to the relatively large dp/dt at which TAHs are operated, there is increased possibility of cavitation bubble initiation and subsequent collapse of the bubbles may also be another important reason for thrombus deposition near the mechanical valve at the inflow orifice. Introducing synthetic valves to replace the mechanical valves [Chandran et al., 1991b] may prove to be advantageous with respect to cavitation initiation and may minimize thrombus formation.

44.1.4   Vascular Prostheses

In advanced stages of vascular diseases such as obstructive **atherosclerosis** and aneurysmal dilatation, when other treatment modalities fail, replacement of diseased segments with vascular prostheses is a common practice. Vascular prostheses can be classified as given in Table 44.4.

44.1.4.1   Surgically Implanted Biological Grafts

Arterial homografts, even though initially used in large scale, resulted in aneurysm formation especially in the proximal suture line [Strandness and Sumner, 1975]. Still, a viable alternative is to use the saphenous vein graft from the same patient. Vein grafts have a failure rate of about 20% in one year and up to 30% in five years after implantation. Vein grafts from the same patients are also unavailable or unsuitable in about 10 to 30% of the patients [Abbott and Bouchier-Hayes, 1978]. Modified **bovine heterograft** and gluteraldehyde treated **umbilical cord vein grafts** have also been employed as vascular prostheses with less success compared to autologous vein grafts.

44.1.4.2   Surgically Implanted Synthetic Grafts

Prostheses made of synthetic material for vascular replacement have been used for over 40 years. Polymeric material currently used as implants include **nylon**, polyester, **polytetrafluoroethylene** (**PTFE**), polypropylene, polyacrylonitrile, and silicone rubber [Park and Lakes, 1992]. However, Dacron® (polyethylene terephthalate) and PTFE are the more common vascular prostheses materials currently available. These materials exhibit the essential qualities for implants — they are biocompatible, resilient, flexible, durable, and resistant to sterilization and biodegradation. Detailed discussion on the properties, manufacturing techniques, and testing of Dacron® prostheses is included in Guidoin and Couture [1992]. Figure 44.9a depicts a Dacron vascular graft having a bifurcated configuration. Figure 44.9b shows expanded PTFE vascular grafts having a variety of configurations and sizes: straight, straight with external reinforcement rings (to resist external compression), and bifurcated.

(a)

(b)
FIGURE 44.9   (a) Photograph of a Dacron vascular graft having a bifurcated configuration. (Courtesy of W.L. Gore and Associates, Inc., Flagstaff, AZ.) (b) Photographs of expanded PTFE vascular grafts with straight, straight with external reinforcement rings to resist compression, and bifurcated configurations. (Courtesy of W.L. Gore and Associates, Inc., Flagstaff, AZ.)

Synthetic vascular grafts implanted as large-vessel replacements have resulted in reasonable degrees of success. However, in medium- and small-diameter prostheses (less than 6 mm in diameter), loss of **patency** within several months after implantation is more acute. Graft failure due to thrombosis or intimal hyperplasia with thrombosis is primarily responsible in failures within 30 days after implantation, and intimal hyperplasia formation is the reason for failure within 6 months after surgery. Soon after implantation, a layer of **fibrin** and fibrous tissue covers the intimal and outer surface of the prosthesis, respectively. A layer of **fibroblasts** replaces the fibrin and is referred to as **neointima**. In the later stages, **neointimal hyperplasia** formation occurs and ultimately results in the occlusion of the vessels in small-diameter vascular grafts. Attempts are being made currently in suitably modifying the surface characteristics of the prostheses in order to reduce the problems with loss of patency. Studies are also being performed in order to understand the mechanical stresses induced at the anastomotic region, which may result in deposits on the intimal surface and occlusion of the vessels [Chandran and Kim, 1994]. The alterations

in mechanical stresses with the implantation of vascular prostheses in the arterial circulation may include changes in the deformation and stress concentrations at the anastomotic site. Altered fluid shear stresses at the intimal surface in the vicinity of the anastomosis has also been suggested as important particularly since the loss of patency is present more often at the distal anastomosis. The vascular prostheses should have the same dynamic response after implantation as the host artery in order to reduce the effect of abnormal mechanical stresses at the junction. For a replacement graft of the same size as the host artery, mismatch in **compliance** may be the most important factor resulting in graft failure [Abbott and Bouchier-Hayes, 1978]. In implanting the prostheses, **end-to-end configuration** is common in the reconstruction of peripheral arteries. **End-to-side configuration** is common in coronary artery bypass where blood will flow from the host artery (aorta) to the prosthesis branching out at the anastomotic site. At the other end, the graft is attached distal to the occlusion in the host (coronary) vessel to enable perfusion of the vascular bed downstream from the occlusion. Numerous studies analyzing the abnormal flow dynamics within the anastomotic geometry and stress distribution within the vascular material at the junction to the prostheses have been reported in delineating the causes for intimal hyperplasia formation and loss of patency [Kim and Chandran, 1993; Kim et al., 1993; Ojha et al., 1990; Keynton et al., 1991; Chandran et al., 1992; Rodgers et al., 1987; Rhee and Tarbell, 1994] and a detailed discussion on the mechanical aspects of vascular prostheses can be found in Chandran and Kim [1994]. Improvements in the blood–surface interactions are also being attempted in order to improve the functioning capability of vascular grafts. Attempts at seeding the grafts with **endothelial cells** [Hunter et al., 1983], and modifying the graft material properties by removing the **crimping** and heat fusing a coil of bendable and dimensionally stable polypropylene at the outer surface to make it kink resistant [Guidoin et al., 1983], and employing a compliant and biodegradable graft which will promote regeneration of arterial wall in small caliber vessels [Van der Lei et al., 1985, 1986] are a few examples of such improvements.

44.1.4.3 Transluminally Placed Endovascular Prostheses (Stent-Grafts)

Endoluminal approaches to treating vascular disease involve the insertion of a prosthetic device into the vasculature through a small, often percutaneous, access site created in a remote vessel, followed by the intraluminal delivery and deployment of a prosthesis via transcatheter techniques [Veith et al., 1995]. In contrast to conventional surgical therapies for vascular disease, the use of transluminally placed endovascular prostheses are distinguished by their "minimally invasive" nature. Because these techniques do not require extensive surgical intervention, they have the potential to simplify the delivery of vascular therapy, improve procedural outcomes, decrease procedural costs, reduce morbidity, and broaden the patient population that may benefit from treatment. Not surprisingly, endoluminal therapies have generated intense interest within the vascular surgery, interventional radiology, and cardiology communities over recent years.

The feasibility of using transluminally placed endovascular prostheses, or stent-grafts, for the treatment of traumatic vascular injury [Marin et al., 1994], atherosclerotic obstructions [Cragg and Dake, 1993], and aneurysmal vascular disease [Parodi et al., 1991; Yusuf et al., 1994; Dake et al., 1994] has been demonstrated in human beings. Endoluminal stent-grafts continue to evolve to address a number of cardiovascular pathologies at all levels of the arterial tree. Figure 44.10a depicts endoluminal stent-grafts having a variety of configurations (straight, bifurcated) and functional diameters (peripheral, aortic) that are currently under clinical investigation.

Endoluminal stent-grafts are catheter-deliverable endoluminal prostheses comprised of an intravascular stent component and a biocompatible graft component. The function of these devices is to provide an intraluminal conduit that enables blood flow through pathologic vascular segments without the need for open surgery. The stent component functions as an arterial attachment mechanism and provides structural support to both the graft and the treated vascular segment. By design, stents are delivered to the vasculature in a low profile, small diameter delivery configuration, and can be elastically or plastically expanded to a secondary, large diameter configuration upon deployment. Vascular attachment is achieved by the interference fit created when a stent is deployed within the lumen of a vessel having a diameter smaller than that of the stent. The graft component, on the other hand, is generally constructed from a biocompatible material such as expanded polytetrafluoroethylene (ePTFE), woven polyester (Dacron), or polyurethane. The graft

(a)

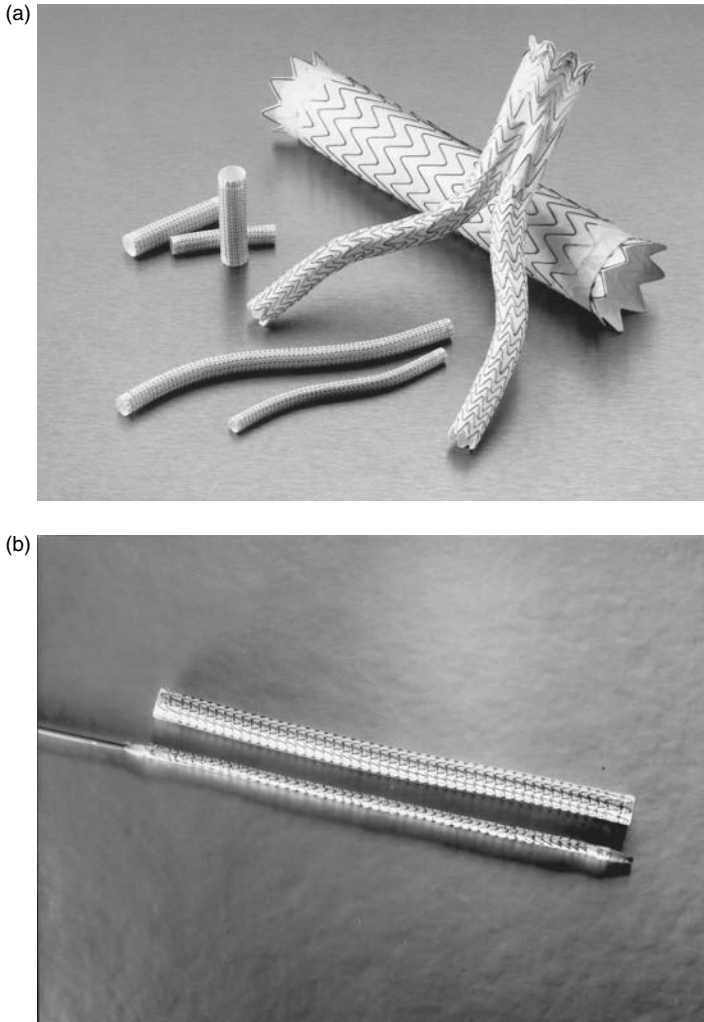
(b)


FIGURE 44.10 (a) Endoluminal stent-grafts of straight and bifurcated configurations and sizes currently under clinical investigation. (Courtesy of W.L. Gore and Associates, Inc., Flagstaff, AZ.) (b) A stent-graft implant consisting of an expanded PTFE graft that is externally supported by a self-expanding nitinol stent. (Courtesy of W.L. Gore and Associates, Inc., Flagstaff, AZ.)

component has a number of real and theoretical functions, including: segregating potential thromboemboli or atheroemboli from the bloodstream, presenting a physical barrier to mass transport between the bloodstream and arterial wall, and mitigating cellular infiltration and the host inflammatory response. Figure 44.10b shows a stent-graft implant consisting of an expanded polytetrafluoroethylene (ePTFE) graft that is externally supported along its entire length by a self-expanding nitinol stent. The implant is radially constrained and attached to the leading end of a dual lumen polyethylene delivery catheter that allows transluminal delivery and deployment. Following introduction into the vascular system, the implant is positioned fluoroscopically within the diseased segment and released from the delivery system.

   Mechanical properties play an important role in determining the *in vivo* performance of an endoluminal stent-graft. Since the graft component typically lacks significant structural integrity, the mechanical behavior of the stent-graft predominantly depends upon the mechanical properties of its stent component. The type of mechanism required to induce dilatation from the delivery (small diameter) configuration, to the deployed (large diameter) configuration typically classifies stents. Self-expanding stents are designed to

spontaneously dilate (i.e., elastically recover) from the delivery diameter up to a maximal, pre-determined deployed diameter; whereas balloon-expandable stents are designed to be plastically enlarged over a range of values with the use of appropriately sized and pressurized dilatation balloons. Consequently, self-expanding stents exert a continuous, radially outward directed force on periluminal tissues, while balloon-expandable stents assume a fixed diameter that resists recoil of the surrounding periluminal tissues. Both types of stents exhibit utilitarian features. For example, in comparison to balloon-expandable devices, self-expanding stents can be rapidly deployed without the use of dilatation balloons, are elastic and therefore less prone to external compression, can radially adapt to post-deployment vascular remodeling, and retain some of the natural compliance of the vascular tissues. In contrast, balloon-expandable stents are much more versatile when it comes to conforming to irregular vascular morphologies because their diameter can be radially adjusted via balloon dilatation. Since the luminal diameter of self-expanding stents cannot be adjusted (i.e., enlarged) to any appreciable degree, accurate sizing of the host vessel is critical. A sizing mismatch resulting in oversizing can cause overcompression of the self-expanding stent and obstructive invagination of the stent into the lumen. Undersizing, in turn, can result in a poor interference fit, inadequate anchoring, device migration, and/or leakage of blood into the abluminal compartment. In either case, the stent provides a scaffold that structurally supports the graft material. Ongoing work in the field of biomedical engineering is directed at optimizing the biomechanical and biological performance of these devices.

44.1.5 Conclusions

In the last four decades, we have observed significant advances in the development of biocompatible materials to be used in blood interfacing implants. In the case of mechanical heart valve prostheses, pyrolytic carbon has become the material of choice for the occluder and the housing. The pyrolytic carbon is chemically inert and exhibits very little wear even after more than 20 years of use. However, thrombo-embolic complications still remain significant with mechanical valve implantation. The complex dynamics of valve function and the resulting mechanical stresses on the formed elements of blood appear to be the main cause for initiation of thrombus. More recent reports of structural failure with implanted mechanical valves and pitting and erosion observed on the pyrolytic carbon surfaces have resulted in investigations on cavitation bubble formation during valve closure. Along with further improvements in biomaterials for heart valves, detailed analysis of the closing dynamics and design improvements to minimize the adverse effects of mechanical stresses may be the key to reducing thrombus deposition. Improvements on mechanical heart valves or further developments in durable synthetic leaflet valves may also be vital for the development of TAHs for long-term implantation without neurologic complications.

In the case of vascular grafts, the mismatch of material properties (compliance) between the host artery and the graft, as well as geometric considerations in end-to-side anastomoses, appear to be important for the loss of patency within several months after implantation particularly with medium and small diameter arterial replacement. Most of the vascular grafts are stiffer compared to the host artery and it has been suggested that the mechanical stresses resulting from the discontinuity at the junction is the major cause for neointimal hyperplasia formation and subsequent occlusion of the conduit. Developments with more compliant grafts and in modifying the surface interaction of the graft with blood (endothelialization or other treatment of the graft material) may result in reducing the problems with loss of patency. Recent advances in the use of minimally invasive stent-grafts also show promise in improving the quality of life of patients with vascular disease.

Defining Terms

Acetol: Product of the addition of two moles of alcohol to one of an aldehyde.
Aneurysms: Abnormal bulging or dilatation of a segment of a blood vessel or myocardium.
Artery: Blood vessel transporting blood in a direction away from the heart.
Atherosclerosis: Lipid deposits in the intima of arteries.

ATS valve: A bileaflet mechanical valve made by ATS (Advancing The Standard) Inc.

Autoclaving: Sterilizing by steam under pressure.

Biomer®:   Segmented polyurethane elastomer.

Bioprostheses: Prosthetic heart valves made of biological tissue.

Blood oxygenators: Extracorporeal devices to oxygenate blood during heart bypass surgery.

Bovine heterograft: Graft material (arterial) transplanted from bovine species.

Calcification: Deposition of insoluble salts of calcium.

Cardiac pacemakers: Prosthesis implanted to stimulate cardiac muscles to contract.

Cardiopulmonary bypass: Connectors bypassing circulation to the heart and the lungs.

Catheters: Hollow cylindrical tubing to be passed through the blood vessels or other canals.

Cavitation bubbles (vapor cavitation):   Formation of vapor bubbles due to transient reduction in pressure to below the liquid vapor pressure.

Closing dynamics: Dynamics during the closing phase of heart valves.

Compliance: A measure of ease with which a structure can be deformed; ratio of volumetric strain to increase in unit pressure.

Crimping: Creasing of the synthetic vascular grafts in the longitudinal direction to accommodate the large intermittent flow of blood.

Delrin®:   Polyacetal made by Union Carbide.

Dialysers: Devices to filter the blood of waste products taking over the function of the kidney.

dp/dt: Slope of the pressure vs. time curve of the ventricles.

Duramater: A tough fibrous membrane forming the outer cover of the brain and the spinal cord.

Electrohydraulic blood pump: Blood pumps energized by the conversion of electrical to hydraulic energy.

End-to-end configuration: End of the vascular graft anastamosed to the end of the host artery.

End-to-side configuration: End of the vascular graft anastamosed to the side of the host.

Endothelial cells: A layer of flat cells lining the intimal surface of blood vessels.

Erosion: A state of being worn away.

Fascia lata: A sheet of fibrous tissue enveloping the muscles of the thigh.

Fatigue stress: Level of stress below which the material would not undergo fatigue failure (107 cycles is used as the normal limit).

Fibrin: An elastic filamentous protein derived from fibrinogen in coagulation of the blood.

Fibroblasts: An elongated cell with cytoplasmic processes present in connective tissue capable of forming collagen fibers.

Finite element analysis: Structural analysis with the aid of a computer which divides the structure into finite elements and applies the laws of mechanics on each element.

Formaldehyde: Formic aldehyde, methyl aldehyde, a pungent gas used as antiseptic.

Formed elements in blood: Red blood cells, white blood cells, platelets, and other cells in whole blood.

Haynes 25®:   Co–Cr alloy.

Homografts: Transplants (heart valves, arterial segments, etc.) from the same species.

Intra-aortic balloon pumps: A balloon catheter inserted in the descending aorta and alternately inflated and deflated timed to the EKG in order to assist the ventricular pumping.

Laser Doppler anemometry: A velocity measurement device using the principle of Doppler shifted frequency of laser light by particles moving with the fluid.

Leaflets: Occluders on valves which open and close to aid blood flow in one direction.

Left ventricular assist devices: Prosthetic devices to assist the left ventricle in pumping blood.

Liquid vapor pressure: Pressure at which liquid vaporizes.

LTI: Low temperature (below 1500°C) isotropic pyrolytic carbon.

Mechanical prostheses: Prostheses made of non-biological material.

Negative pressure transients: Reduction in pressure for a short duration.

Neointima: Newly formed intimal surface.

Neointimal hyperplasia: Growth of new intimal surface formed by fibroblasts.

Nylon: Synthetic polymer with condensation polymerization.

Patency: State of being freely open.

Pericardial prostheses: Heart valve prosthesis made with fixed bovine pericardial tissue.

Pitting: Depression or indent on a surface.

Platelet: One of the formed elements of blood responsible for blood coagulation.

Polypropylene: One of the vinyl polymers with good flex life and good environmental stress crack resistance.

Polytetrafluoroethylene (PTFE): A fluorocarbon polymer known as Teflon®.

Pusher plate devices: Artificial heart devices working with pusher plates moving the blood.

Pyrolytic carbon: Carbon deposited onto preformed polycrystalline graphite substrate.

Radiopacity: Being opaque to x-ray.

Sewing rings: Rings surrounding the housing of artificial heart valves used to sew the valve to the tissue orifice with suture.

Solution casting: Casting by pouring molten material on dyes to form a structure.

Stellite 21®: Co–Cr alloy.

Stent: A device used to maintain the bodily orifice or cavity.

Strut: A projection in the structure such as guiding struts in heart valves used to guide the leaflets during opening and closing.

TAH: Total artificial heart replacing a failed natural heart.

Teflon®: See PTFE.

Thrombo-embolic complications: Complications due to breaking away (emboli) of thrombus blocking the distal blood vessels.

Thrombus: A clot in the blood vessels or in the cavities of the heart formed from the constituents of blood.

Tilting disc valves: Valves with a single leaflet tilting open and shut.

Titanium: Highly reactive metal having low density, good mechanical properties, and biocompatibility due to tenacious oxide layer formation.

Turbulent stresses: Stresses generated in the fluid due to agitated random motion of particles.

Ultra high molecular weight polyethylene: Linear thermoplastics with very high molecular weight ($>2 \times 10^6$ g/mol) used for orthopedic devices such as acetabular cup for hip joint replacement.

Umbilical cord vein grafts: Vascular graft made from umbilical cord veins.

Vacuum forming: A manufacturing technique for thermoplastic polymer in which a sheet is heated and formed over a mold while a vacuum is present under the sheet.

Valvular disorders: Diseased states of valves such as stenosis.

Valvular structures: Components of valves such as leaflets, struts, etc.

Vascular grafts: Grafts to replace segments of diseased vessels.

Xenografts: Grafts obtained from species other than that of the recipient.

44.2   Non-Blood-Interfacing Implants for Soft Tissues

K.J.L. Burg and S.W. Shalaby

Most tissues other than bone and cartilage are of the soft category. Implants do not generally interface directly with blood; the exceptions are located primarily in the cardiovascular systems. Non-blood-interfacing soft tissue implants are used to augment or replace natural tissues or to redirect specific biological functions. The implants can be transient; that is, of short-term function and thus made of absorbable materials, or they can be long-term implants which are expected to have prolonged functions and are made of nonabsorbable materials.

Toward the successful development of a new biomedical device or implant, including those used for soft tissues, the following milestones must be achieved: (1) acquire certain biologic and biomechanic data about the implant site and its function to aid in the selection of materials and engineering design of such an implant, to meet carefully developed product requirements; (2) construct a prototype and evaluate its physical and biologic properties both *in vitro* and *in vivo*, using the appropriate animal model; and (3) conduct a clinical study following a successful battery of animal safety studies depending on intended application and availability of historical safety and clinical data on the material or design. Extent of the studies associated with any specific milestone can vary considerably. Although different applications require different materials with specific properties, minimum requirements for soft-tissue implants should be met. The implant must (1) exhibit physical properties (e.g., flexibility and texture) which are equivalent

or comparable to those called for in the product profile; (2) maintain the expected physical properties after implantation for a specific period; (3) elicit no adverse tissue reaction; (4) display no carcinogenic, toxic, allergenic, and/or immunogenic effect; and (5) achieve assured sterility without compromising the physicochemical properties. In addition to these criteria, a product of potentially broad applications is expected to (1) be easily mass produced at a reasonable cost; (2) have acceptable aesthetic quality; (3) be enclosed in durable, properly labeled, easy-access packaging; and (4) have adequate shelf stability.

The most common types of soft-tissue implants are (1) sutures and allied augmentation devices; (2) percutaneous and cutaneous systems; (3) maxillofacial devices; (4) ear and eye prostheses; (5) space-filling articles; and (6) fluid transfer devices.

44.2.1 Sutures and Allied Augmentation Devices

Sutures and staples are the most common types of augmentation devices. In recent years, interest in using tapes and adhesives has increased and may continue to do so, should new efficacious systems be developed.

44.2.1.1 Sutures and Suture Anchors

Sutures are usually packaged as a thread attached to a metallic needle. Although most needles are made of stainless steel alloys, the thread component can be made of various materials, and the type used determines the class of the entire suture. In fact, it is common to refer to the thread as the suture. Presently, most needles are drilled (mechanically or by laser) at one end for thread insertion. Securing the thread in the needle hole can be achieved by crimping or adhesive attachment. Among the critical physical properties of sutures are their diameter, *in vitro* knot strength, needle-holding strength, needle penetration force, ease of knotting, knot security, and *in vitro* strength retention profile.

Two types of threads are used in suture manufacturing and are distinguished according to the retention of their properties in the biologic environment, namely, absorbable and nonabsorbable. These may also be classified according to their source of raw materials, that is, natural (catgut, silk, and cotton), synthetic (nylon, polypropylene, polyethylene terephthalate, and polyglycolide and its copolymers), and metallic sutures (stainless steel and tantalum). Sutures may also be classified according to their physical form, that is, monofilament and twisted or braided multifilament (or simply braids).

The first known suture, the absorbable catgut, is made primarily of collagen derived from sheep intestinal submucosa. It is usually treated with a chromic salt to increase its *in vivo* strength retention and through imparted crosslinking that retards absorption. Such treatment extends the functional performance of catgut suture from 1 to 2 weeks up to about 3 weeks. The catgut sutures are packaged in a specially formulated fluid to prevent drying and maintain necessary compliance for surgical handling and knot formation.

The use of synthetic absorbable sutures exceeded that of catgut over the past two decades. This is attributed to many factors including (1) higher initial breaking strength and superior handling characteristics; (2) availability of sutures with a broad range of *in vivo* strength retention profiles; (3) considerably milder tissue reactions and no immunogenic response; and (4) reproducible properties and highly predictable *in vivo* performance. Polyglycolide (PG) was the first synthetic absorbable suture to be introduced, about three decades ago. Because of the high modulus of oriented fibers, PG is made mostly in the braided form. A typical PG suture braid absorbs in about 4 months and retains partial *in vivo* strength after 3 weeks. However, braids made of the 90/10 glycolide/l-lactide copolymer have a comparable or improved strength retention profile and faster absorption rate relative to PG. The copolymeric sutures absorb in about 3 months and have gained wide acceptance by the surgical community.

As with other types of braided sutures, an absorbable coating which improves suture handling and knot formation has been added to the absorbable braids. To minimize the risk of infection and tissue drag that are sometimes associated with braided sutures, four types of monofilament sutures have been commercialized. The absorbable monofilaments were designed specifically to approach the engineering compliance of braided sutures, by combining appropriate materials to achieve low moduli, for example, polydioxanone and copolymers of glycolide with caprolactone or trimethylene carbonate.

Members of the nonabsorbable family of sutures include braided silk (a natural protein), nylon, and polyethylene terephthalate (PET). These braids are used as coated sutures. Although silk sutures have retained wide acceptance by surgeons, nylon and particularly PET sutures are used for critical procedures where high strength and predictable long-term performance are required. Meanwhile, the use of cotton sutures is decreasing constantly because of their low strength and occasional tissue reactivity due to contaminants. Monofilaments are important forms of nonabsorbable sutures and are made primarily of polypropylene, nylon, and stainless steel. An interesting application of monofilament sutures is illustrated in the use of polypropylene loops (or haptics) for intraocular lenses. The polypropylene sutures exhibit not only the desirable properties of monofilaments but also the biologic inertness reflected in the minimal tissue reactions associated with their use in almost all surgical sites. With the exception of its natural tendency to undergo hydrolytic degradation and, hence, continued loss of mechanical strength postoperatively, nylon monofilament has similar attributes to those of polypropylene. Because of their exceptionally high modulus, stainless steel sutures are not used in soft-tissue repair because they can tear these tissues. All sutures can be sterilized by gamma radiation except those made of synthetic absorbable polymers, polypropylene, or cotton, which are sterilized by ethylene oxide.

Related to the suture is the tissue suture anchor, used to attach soft tissue to bone. The anchor is embedded into bone and the suture can be used to reattach the soft tissue. The most common anchor is polylactide-based and is used in shoulder repair.

44.2.1.2 Nonsuture Fibrous and Microporous Implants

Woven PET and polypropylene fabrics are commonly used as surgical meshes for abdominal wall repair and similar surgical procedures where surgical "patching" is required. Braid forms and similar construction made of multifilament PET yarns have been used for repairing tendons and ligaments. Microporous foams of polytetrafluoroethylene (PTFE) are used as pledgets (to aid in anchoring sutures to soft tissues) and in repair of tendons and ligaments. Microporous collagen-based foams are used in wound repair to accelerate healing.

44.2.1.3 Clips, Staples, and Pins

Ligating clips are most commonly used for temporary or long-term management of the flow in tubular tissues. Titanium clips are among the oldest and still-versatile types of clips. Thermoplastic polymers such as nylon can be injection-molded into different forms of ligating clips. These are normally designed to have a latch and living hinge. Absorbable polymers made of lactide/glycolide copolymers and polydioxanone have been successfully converted to ligating clips with different design features for a broad range of applications.

Metallic staples were introduced about three decades ago as strong competitors to sutures for wound augmentation; their use has grown considerably over the past 10 years for everything from skin closure procedures to a multiplicity of internal surgical applications. Major advantages associated with the use of staples are ease of application and minimized tissue trauma. Metallic staples can be made of tantalum, stainless steel, or titanium–nickel alloys. Staples are widely used to facilitate closure of large incisions produced in procedures such as Caesarean sections and intestinal surgery. Many interesting applications of small staples have been discovered for ophthalmic and endoscopic use, a fast-growing area of minimally invasive surgery.

Thermoplastic materials based on lactide/glycolide copolymers have been used to produce absorbable staples for skin and internal wound closures. These staples consist primarily of two interlocking components, a fastener and receiver. They are advantageous in that they provide a quick means of closure with comparable infection resistance. They are limited to locations which do not have large tensile loads and/or thicker or more sensitive tissue.

A new form of ligating device is the subcutaneous pin. This is designed with a unique applicator to introduce the pin parallel to the axis of the wound. During its application, the linear pin acquires a zig-zag-like configuration for stabilized tissue anchoring. The pins are made of lactide/glycolide polymers.

44.2.1.4 Surgical Tapes

Surgical tapes are intended to minimize necrosis, scar tissue formation, problems of stitch abscesses, and weakened tissues. The problems with surgical tapes are similar to those experienced with traditional skin tapes. These include (1) misaligned wound edges, (2) poor adhesion due to moisture or dirty wounds, and (3) late separation of tapes when hematoma or wound drainage occur.

Wound strength and scar formation in skin may depend on the type of incision made. If the subcutaneous muscles in the fatty tissue are cut and the overlying skin is closed with tape, then the muscles retract. This, in turn, increases the scar area, causing poor cosmetic appearance when compared to a suture closure. Tapes also have been used successfully for assembling scraps of donor skin for skin graft.

44.2.1.5 Tissue Adhesives

The constant call for tissue adhesives is particularly justified when dealing with the repair of exceptionally soft tissues. Such tissues cannot be easily approximated by sutures, because sutures inflict substantial mechanical damage following the traditional knotting scheme and associated shear stresses. However, the variable biological environments of soft tissues and their regenerative capacity make the development of an ideal tissue adhesive a difficult task. Experience indicates that an ideal tissue adhesive should (1) be able to wet and bond to tissues; (2) be capable of onsite formation by the rapid polymerization of a liquid monomer without producing excessive heat or toxic byproducts; (3) be absorbable; (4) not interfere with the normal healing process; and (5) be easily applied during surgery. The two common types of tissue adhesives currently used are based on alkyl-*o*-cyanoacrylates and fibrin. The latter is a natural adhesive derived from fibrinogen, which is one of the clotting components of blood. Although fibrin is used in Europe, its use in the United States has not been approved because of the risk of its contamination with hepatitis and/or immune disease viruses. Due to its limited mechanical strength (tensile strength and elastic modulus of 0.1 and 0.15 MPa, respectively), fibrin is used mostly as a sealant and for adjoining delicate tissues as in nerve anastomoses. Meanwhile, two members of the cyanoacrylate family of adhesives, n-butyl- and iso-butyl-cyano-acrylates, are used in a number of countries as sealants, adhesives, and blocking agents. They are yet to be approved for use in the United States because of the lack of sufficient safety data. Due to a fast rate of polymerization and some limited manageability in localizing the adhesive to the specific surgical site, the *in vivo* performance of cyanoacrylates can be unpredictable. Because of the low strength of the adhesive joints or sealant films produced on *in vivo* polymerization of these cyanoacrylates, their applications generally are limited to use in traumatized fragile tissues (such as spleen, liver, and kidney) and after extensive surgery on soft lung tissues. A major safety concern of these alkyl cyanoacrylates is related to their nonabsorbable nature. Hence, a number of investigators have directed their attention to certain alkoxy-alkyl cyanoacrylates which can be converted to polymeric adhesives with acceptable absorbable profiles and rheological properties. Methoxypropyl cyanoacrylate, for example, has demonstrated both the absorbability and high compliance that is advantageous to soft tissue repair.

44.2.2 Percutaneous and Skin Implants

The need for percutaneous (*trans* or through the skin) implants has been accelerated by the advent of artificial kidneys and hearts and the need for prolonged injection of drugs and nutrients. Artificial skin is urgently needed to maintain the body temperature and prevent infection in severely burned patients. Actual permanent replacement of skin by biomaterials is still a great clinical challenge.

44.2.2.1 Percutaneous Devices

The problem of obtaining a functional and viable interface between the tissue (skin) and an implant (percutaneous device) is primarily due to the following factors. First, although initial attachment of the tissue into the interstices of the implant surface occurs, attachment cannot be maintained for a sustained time since the dermal tissue cells turn over continuously. Downgrowth of epithelium around the implant or overgrowth on the implant leads to extrusion or invagination, respectively. Second, any opening near

the implant that is large enough for bacteria to penetrate may result in infection, even though initially there may be a tight seal between skin and implant. Several factors are involved in the development of percutaneous devices:

1. Type of end use — this may deal with transmission of information (biopotentials, temperature, pressure, blood flow rate), energy (electrical stimulation, power for heart-assist devices), transfer of matter (cannula for blood), and load (attachment of a prosthesis);
2. Engineering factors — these may address materials selection (polymers, ceramics, metals, and composites), design variation (button, tube with and without skirt, porous or smooth surface), and mechanical stresses (soft and hard interface, porous or smooth interface);
3. Biologic factors — these are determined by the implant host (human, dog, hog, rabbit, sheep), and implant location (abdominal, dorsal, forearm);
4. Human factors — these can pertain to postsurgical care, implantation technique, and esthetic look.

No percutaneous devices are completely satisfactory. Nevertheless, some researchers believe that hydroxyapatite may be part of a successful approach. In one experimental trial, a hydroxyapatite-based percutaneous device was associated with less epidermal downgrowth (1 mm after 17 months vs. 4.6 mm after 3 months) when compared with a silicone rubber control specimen in the dorsal skin of canines. Researchers have also investigated coatings such as laminin-5 which has been shown to enhance epithelial attachment.

44.2.2.2 Artificial Skins

Artificial skin is another example of a percutaneous implant, and the problems are similar to those described above. Important for this application is a material which can adhere to a large (burned) surface and thus prevent the loss of fluids, electrolytes, and other biomolecules until the wound has healed.

In one study on wound-covering materials with controlled physicochemical properties, an artificial skin was designed with a crosslinked collagen-polysaccharide (chondroitin 6-sulfate) composite membrane. This was specifically chosen to have controlled porosity (5 to 150 μm in diameter), flexibility (by varying crosslink density), and moisture flux rate.

Several polymeric materials and reconstituted collagen have also been examined as burn dressings. Among the synthetic ones are the copolymers of vinyl chloride and vinyl acetate as well as polymethyl cyanoacrylate (applied as a fast-polymerizing monomer). The latter polymer and/or its monomer were found to be too brittle and histotoxic for use as a burn dressing. The ingrowth of tissue into the pores of polyvinyl alcohol sponges and woven fabric (nylon and silicone rubber velour) was also attempted without much success. Nylon mesh bonded to a silicone rubber membrane, another design attempt, prevented water evaporation but has not been found to induce fibrovascular growth.

Rapid epithelial layer growth by culturing cells *in vitro* from the skin of the burn patient for covering the wound area may offer a practical solution for less severely burned patients. Implantation of an allogenic fibroblast/polymer construct has proven useful for providing long-term skin replacement. Related to this, temporary tissue engineered replacements are possible alternatives for burns requiring larger area coverage. These can be similar to the synthetic dressing, a nylon mesh and silicone rubber component, but incorporates allogeneic fibroblasts. This temporary covering hopefully will stimulate or allow fibrovascular growth into the wound bed by providing the appropriate matrix proteins and growth factors.

44.2.3 Maxillofacial Implants

There are two types of maxillofacial implants: extraoral and intraoral. The former deals with the use of artificial substitutes for reconstructing defective regions in the maxilla, mandible, and face. Useful polymeric materials for extraoral implants require (1) match of color and texture with those of the patient; (2) mechanical and chemical stability (i.e., material should not creep or change color or irritate skin); and (3) ease of fabrication. Copolymers of vinyl chloride and vinyl acetate (with 5 to 20% acetate), polymethyl methacrylate, silicones, and polyurethane rubbers are currently used. Intraoral implants are used for repairing maxilla, mandibular, and facial bone defects. Material requirements for the intraoral

implants are similar to those of the extraoral ones. For the latter group of implants, metallic materials such as tantalum, titanium, and CoCr alloys are commonly used. For soft tissues, such as gum and chin, polymers such as silicone rubber and polymethylmethacrylate are used for augmentation.

44.2.4 Ear and Eye Implants

Implants can be used to restore conductive hearing loss from otosclerosis (a hereditary defect which involves a change in the bony tissue of the ear) and chronic otitis media (the inflammation of the middle ear which can cause partial or complete impairment of the ossicular chain). A number of prostheses are available for correcting these defects. The porous polyethylene total ossicular implant is used to achieve a firm fixation by tissue ingrowth. The tilt-top implant is designed to retard tissue ingrowth into the section of the shaft which may diminish sound conduction. Materials used in fabricating these implants include polymethyl methacrylate, polytetrafluoroethylene, polyethylene, silicone rubber, stainless steel, and tantalum. More recently, polytetrafluoroethylene–carbon composites, porous polyethylene, and pyrolytic carbon have been described as suitable materials for cochlear (inner ear) implants.

Artificial ear implants capable of processing speech have been developed with electrodes to stimulate cochlear nerve cells. Cochlear implants also have a speech processor that transforms sound waves into electrical impulses that can be conducted through coupled external and internal coils. The electrical impulses can be transmitted directly by means of a percutaneous device.

Eye implants are used to restore the functionality of damaged or diseased corneas and lenses. Usually the cornea is transplanted from a suitable donor. In cataracts, eye lenses become cloudy and can be removed surgically. Intraocular lenses (IOL) are implanted surgically to replace the original eye lens and to restore function. IOL are made from transparent acrylics, particularly polymethyl methacrylate, which has excellent optical properties. Infection and fixation of the lens to the tissues are frequent concerns, and a number of measures are being used to address them. Transplantation of retinal pigmented epithelium can be used in the treatment of adult onset blindness; the challenge is developing readily detachable or absorbable materials on which to culture sheets of these cells.

44.2.5 Space-Filling Implants

Breast implants are common space-filling implants. At one time, the enlargement of breasts was done with various materials such as paraffin wax and silicone fluids, by direct injection or by enclosure in a rubber balloon. Several problems have been associated with directly injected implants, including progressive instability and ultimate loss of original shape and texture as well as infection and pain. One of the early efforts in breast augmentation was to implant a sponge made of polyvinyl alcohol. However, soft tissues grew into the pores and then calcified with time, and the so-called marble breast resulted. Although the enlargement or replacement of breasts for cosmetic reasons alone is not recommended, prostheses have been developed for patients who have undergone radical mastectomy or who have nonsymmetrical deformities. The development of the tissue-engineered breast is ongoing, where fat or normal breast tissue may be derived from the patient and combined with an absorbable scaffold for transplantation. A silicone rubber bag filled with silicone gel and backed with polyester mesh to permit tissue ingrowth for fixation is a widely used prosthesis, primarily for psychological reasons. The artificial penis, testicles, and vagina fall into the same category as breast implants, in that they make use of silicones and are implanted for psychological reasons rather than to improve physical health.

44.2.6 Fluid Transfer Implants

Fluid transfer implants are required for cases such as hydrocephalus, urinary incontinence, glaucoma-related elevated intraocular pressure, and chronic ear infection. Hydrocephalus, caused by abnormally high pressure of the cerebrospinal fluid in the brain, can be treated by draining the fluid (essentially an ultrafiltrate of blood) through a cannula. Earlier shunts had two one-way valves at either end. However, the more recent Ames shunt has simple slits at the discharging end, which opens when enough fluid

pressure is exerted. The Ames shunt empties the fluid in the peritoneum while others drain into the blood stream through the right internal jugular vein or right atrium of the heart. The simpler peritoneal shunt shows less incidence of infection.

The use of implants for correcting the urinary system has not been successful because of the difficulty of adjoining a prosthesis to the living system for achieving fluid tightness. In addition, blockage of the passage by deposits from urine, salt for example, and constant danger of infection are major concerns. Several materials have been used for producing these implants, with limited long-term success; these include Dacron™, glass, polyvinyl alcohol, polyethylene, rubber, silver, tantalum, Teflon™, and Vitallium™. Tissue engineered devices also have application in urinary repair; for example, an alginate-chondrocyte system has been used clinically to treat vesicoureteral reflux. Preliminary results suggest that by transplanting the hydrogel system as a bulking agent below a refluxing ureter, neocartilage gradually develops to correct the reflux. Uroepithelial cells, combined with porous, absorbable polyester matrices show promise in the replacement of urologic tissues.

Drainage tubes, which are impermanent implants for chronic ear infection, can be made from polytetra-fluoroethylene (Teflon™). Glaucoma-related elevated intraocular pressure may be relieved by implanting a tube connecting the anterior eye chamber to the external subconjunctival space in order to direct aqueous humor. Complications can arise with occlusion of the tube due to wound healing processes; however, researchers are investigating combining this device with an absorbable drug delivery plug to regulate flow and deliver drugs to regulate the wound healing process.

44.2.7 Technologies of Emerging Interest

A new process for uniaxial solid-state orientation, using a range of compressive forces and temperatures, has been developed to produce stock sheets of polyether-ether ketone (PEEK) for machining dental implants with substantially increased strength and modulus as compared to their unoriented counterparts.

Surface treatment of materials is another emerging interest, a process potentially influencing both surface charge, topography, and conductivity. The former has obvious effects on cell adhesion and integration of traditional implants with surrounding tissues, and it has a profound effect on the success or failure of a tissue-engineered device.

Pertinent to the effect of surface chemistry and texture on tissue regeneration/ingrowth, recent studies on surface-phosphonylation to create hydroxyapatite-like substrates show that (1) surface-microtextured polypropylene and polyethylene transcortical implants in goat tibia having phosphonate functionalities (with or without immobilized calcium ions) do induce bone ingrowth, and (2) microtexture and surface phosphonylated (with and without immobilized calcium ions) rods made of PEEK and similarly treated rods of carbon fiber-reinforced PEEK induce bone ingrowth when implanted in the toothless region of the lower jaw of goats. The use of surface-phosphonylated and post-treated (with a bridging agent) UHMW-PE fibers and fabric do produce high strength and modulus composites at exceptionally low filler loading. Among these composites are those based on methyl methacrylate matrices, similar to those used in bone cement.

Conductivity manipulation may be extremely useful in such areas as biosensor design. Surface-conducting phosphonylated, ultra-high molecular weight polyethylene may be formed by exposure to aqueous pyrole solution. Preliminary results suggest that this is a stable process, yielding no apparent cytotoxic effects due to the material or leachables. New surface treatments will be instrumental in the development of the two rapidly expanding areas of biosensor design and tissue engineering, both areas which encompass non-blood-interfacing soft tissue implants.

45.1 Bone Repair and Joint Implants

S.-H. Park, A. Llinás, and V.K. Goel

The use of biomaterials to restore the function of traumatized or degenerated connective tissues and thus improve the quality of life of a patient has become widespread. In the past, implants were designed with insufficient cognizance of biomechanics. Accordingly, the clinical results were not very encouraging. An upsurge of research activities into the mechanics of joints and biomaterials has resulted in better designs with better *in vivo* performance. The improving long-term success of total joint replacements for the lower limb is testimony to this. As a result, researchers and surgeons have developed and used fixation devices for the joints, including artificial spine discs. A large number of devices are also available for the repair of the bone tissue. This chapter provides an overview of the contemporary scientific work related to the use of biomaterials for the repair of bone (e.g., fracture) and joint replacements ranging from a hip joint to a spine.

45.1.1 Long Bone Repair

The principal functions of the skeleton are to provide a frame to support the organ-systems, and to determine the direction and range of body movements. Bone provides an anchoring point (insertion), for most skeletal muscles and ligaments. When the muscles contract, long bones act as levers, with the joints functioning as pivots, to cause body movement.

Bone is the only tissue able to undergo spontaneous regeneration and to remodel its micro- and macro-structure. This is accomplished through a delicate balance between an *osteogenic* (bone forming) and *osteoclastic* (bone removing) process [Brighton, 1984]. Bone can adapt to a new mechanical environment by changing the equilibrium between osteogenesis and osteoclasis. These processes will respond to changes in the static and dynamic stress applied to bone; that is, if more stress than the physiological is applied, the equilibrium tilts toward more osteogenic activity. Conversely, if less stress is applied the equilibrium tilts toward osteoclastic activity (this is known as **Wolff's Law** of bone remodeling) [Wolff, 1986].

Nature provides different types of mechanisms to repair fractures in order to be able to cope with different mechanical environments about a fracture [Hulth, 1989; Schenk, 1992]. For example, incomplete fractures (cracks), which only allow micromotion between the fracture fragments, heal with a small amount of fracture-line *callus*, known as **primary healing**. In contrast, complete fractures which are unstable, and therefore generate macromotion, heal with a voluminous callus stemming from the sides of the bone, known as **secondary healing** [Brighton, 1984; Hulth, 1989].

The goals of fracture treatment are obtaining rapid healing, restoring function, and preserving cosmesis without general or local complications. Implicit in the selection of the treatment method is the need to avoid potentially deleterious conditions, for example, the presence of excessive motion between bone fragments which may delay or prevent fracture healing [Brighton, 1984; Brand and Rubin, 1987].

Each fracture pattern and location results in a unique combination of characteristics ("fracture personality") that require specific treatment methods. The treatments can be non-surgical or surgical. Examples of non-surgical treatments are immobilization with casting (plaster or resin) and bracing with a plastic apparatus. The surgical treatments are divided into external fracture fixation, which does not require opening the fracture site, or internal fracture fixation, which requires opening the fracture.

With external fracture fixation, the bone fragments are held in alignment by pins placed through the skin onto the skeleton, structurally supported by external bars. With internal fracture fixation, the bone fragments are held by wires, screws, plates, and/or intramedullary devices. Figure 45.1a,b show radiographs of externally and internally fixed fractures.

All the internal fixation devices should meet the general requirement of biomaterials, that is, biocompatability, sufficient strength within dimensional constraints, and corrosion resistance. In addition, the device should also provide a suitable mechanical environment for fracture healing. From this perspective, stainless steel, cobalt–chrome alloys, and titanium alloys are most suitable for internal fixation. Detailed mechanical properties of the metallic alloys are discussed in the chapter on metallic biomaterials. Most internal fixation devices persist in the body after the fracture has healed, often causing discomfort and requiring removal. Recently, biodegradable polymers, for example, polylactic acid (PLA) and polyglycolic acid (PGA), have been used to treat minimally loaded fractures, thereby eliminating the need for a second surgery for implant removal. A summary of the basic application of biomaterials in internal fixation is presented in Table 45.1. A description of the principal failure modes of internal fixation devices is presented in Table 45.2.

45.1.1.1 Wires

Surgical wires are used to reattach large fragments of bone, like the greater trochanter, which is often detached during total hip replacement. They are also used to provide additional stability in long-oblique or spiral fractures of long bones which have already been stabilized by other means (Figure 45.1b). Similar approaches, based on the use of wires, have been employed to restore stability in the lower cervical spine region and in the lumbar segment as well (Figure 45.1c).

Twisting and knotting is unavoidable when fastening wires to bone; however, by doing so, the strength of the wire can be reduced by 25% or more due to stress concentration [Tencer et al., 1993]. This can be partially overcome by using a thicker wire, since its strength increases directly proportional to its diameter. The deformed regions of the wire are more prone to corrosion than the un-deformed because of the higher strain energy. To decrease this problem and ease handling, most wires are annealed to increase the ductility.
FIGURE 45.1 Radiographs of (a) tibial fracture fixed with four pins and an external bar; (b) a total hip joint replacement in a patient who sustained a femoral fracture and was treated with double bone plates, screws, and surgical wire (arrows); (c) application of wires, screws, and plates in the spine.

Braided multistrain (multifilament) wire is an attractive alternative because it has a similar tensile strength than a monofilament wire of equal diameter, but more flexibility and higher fatigue strength [Taitsman and Saha, 1977]. However, bone often grows into the grooves of the braided multistrain wire, making it exceedingly difficult to remove, since it prevents the wire from sliding when pulled. When a wire is used with other metallic implants, the metal alloys should be matched to prevent galvanic corrosion [Park and Lakes, 1992].

45.1.1.2 Pins

Straight wires are called Steinmann pins; however if the pin diameter is less than 2.38 mm, it is called Kirschner wire. They are widely used primarily to hold fragments of bones together provisionally or permanently and to guide large screws during insertion. To facilitate implantation, the pins have different tip designs which have been optimized for different types of bone (Figure 45.2). The trochar tip is the most efficient in cutting; hence, it is often used for cortical bone.

The holding power of the pin comes from elastic deformation of surrounding bone. In order to increase the holding power to bone, threaded pins are used. Most pins are made of 316L stainless steel; however, recently, biodegradable pins made of polylactic or polyglycolic acid have been employed for the treatment of minimally loaded fractures.

FIGURE 45.1   Continued.

The pins can be used as part of elaborate frames designed for external fracture fixation (Figure 45.1a). In this application, several pins are placed above and below the fracture, but away from it. After the fracture fragments are manually approximated (reduced) to resemble the intact bone, the pins are attached to various bars, which upon assembly will provide stability to the fracture.

45.1.1.3 Screws

Screws are the most widely used devices for fixation of bone fragments. There are two types of bone screws: (1) cortical bone screws, which have small threads, and (2) cancellous screws, which have large threads to get more thread-to-bone contact. They may have either V or buttress threads (Figure 45.3). The cortical screws are subclassified further according to their ability to penetrate, into self-tapping and non-self-tapping (Figure 45.3). The self-tapping screws have cutting flutes which thread the pilot drill-hole during insertion. In contrast, the non-self-tapping screws require a tapped pilot drill-hole for insertion.

The holding power of screws can be affected by the size of the pilot drill-hole, the depth of screw engagement, the outside diameter of the screw, and quality of the bone [Cochran, 1982; DeCoster et al., 1990]. Therefore, the selection of the screw type should be based on the assessment of the quality of the bone at the time of insertion. Under identical conditions, self-tapping screws provide a slightly greater holding power than non-self-tapping screws [Tencer et al., 1993].

Screw pullout strength varies with time after insertion *in vivo*, and it depends on the growth of bone into the screw threads and/or resorption of the surrounding bone [Schatzker et al., 1975]. The bone immediately adjacent to the screw often undergoes *necrosis* initially, but if the screw is firmly fixed, when
FIGURE 45.1   Continued.

the bone revascularizes, permanent secure fixation may be achieved. This is particularly true for titanium alloy screws or screws with a roughened thread surface, with which bone ongrowth results in an increase in removal torque [Hutzschenreuter and Brümmer, 1980]. When the screw is subject to micro- or macro-movement, the contacting bone is replaced by a membrane of fibrous tissue, the purchase is diminished, and the screw loosens.

The two principal applications of bone screws are (1) as interfragmentary fixation devices to "lag" or fasten bone fragments together, or (2) to attach a metallic plate to bone. Interfragmentary fixation is used in most fractures involving cancellous bone and in those oblique fractures in cortical bone. In order to lag the fracture fragments, the head of the screw must engage the cortex on the side of insertion without gripping the bone, while the threads engage cancellous bone and/or the cortex on the opposing side. When screws are employed for bone plate fixation, the bone screw threads must engage both cortices. Screws are also used for the fixation of spine fractures (for plate fixation or compression of bone fragment; Figure 45.1c).

45.1.1.4   Plates

Plates are available in a wide variety of shapes and are intended to facilitate fixation of bone fragments. They range from the very rigid, intended to produce primary bone healing, to the relatively flexible, intended to facilitate physiological loading of bone.

TABLE 45.1   Biomaterials Applications in Internal Fixation

Materials	Properties	Application
Stainless steel	Low cost, easy fabrication	Surgical wire (annealed)
		Pin, plate, screw
		IM nail
Ti alloy	High cost	Surgical wire
	Low density and modulus	Plate, screws, IM nails
	Excellent bony contact	
Co–Cr alloys (wrought)	High cost	Surgical wire
	High density and modulus	IM nails
	Difficult fabrication	
Poly lactic acid	Resorbable	Pin, screw
Poly glycolic acid	Weak strength	
Nylon	Non-resorbable plastic	Cerclage band

TABLE 45.2   Failure Modes of Internal Fixation Devices

Failure mode	Failure location	Reasons for failure
Overload	Bone fracture site	Small size implant
	Implant screw hole	Unstable reduction
	Screw thread	Early weight bearing
Fatigue	Bone fracture site	Early weight bearing
	Implant screw hole	Small size implant
	Screw thread	Unstable reduction
		Fracture non-union
Corrosion	Screw head-plate hole	Different alloy implants
	Bent area	Over-tightening screw
		Misalignment of screw
		Over-bent
Loosening	Screw	Motion
		Wrong choice of screw type
		Osteoporotic bone

The rigidity and strength of a plate in bending depend on the cross-sectional shape (mostly thickness) and material of which it is made. Consequently, the weakest region in the plate is the screw hole, especially if the screw hole is left empty, due to a reduction of the cross-sectional area in this region. The effect of the material on the rigidity of the plate is defined by the elastic modulus of the material for bending, and by the shear modulus for twisting [Cochran, 1982]. Thus, given the same dimensions, a titanium alloy plate will be less rigid than a stainless steel plate, since the elastic modulus of each alloy is 110 and 200 GPa, respectively.

Stiff plates often shield the underlying bone from the physiological loads necessary for its healthful existence [Perren et al., 1988; O'Slullivan et al., 1989]. Similarly, flat plates closely applied to the bone prevent blood vessels from nourishing the outer layers of the bone [Perren, 1988]. For these reasons, the current clinical trend is to use more flexible plates (titanium alloy) to allow micromotion, and low-contact plates (only a small surface of the plate contacts the bone, LCP), to allow restoration of vascularity to the bone [Uhthoff and Finnegan, 1984; Claes, 1989]. The underlying goals of this philosophical change are to increase the fracture healing rate, to decrease the loss of bone mass in the region shielded by the plate, and consequently, to decrease the incidence of re-fractures which occur following plate removal.

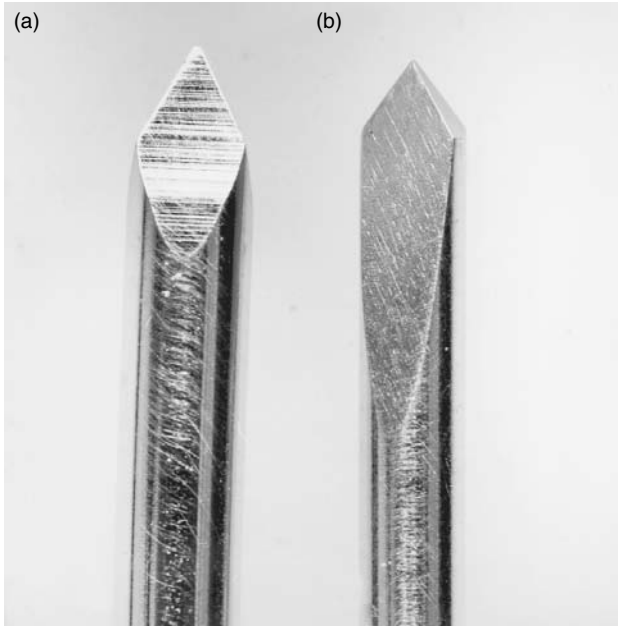
The interaction between bone and plate is extremely important since the two are combined into a composite structure. The stability of the plate-bone composite and the service life of the plate depends upon accurate fracture reduction. The plate is most resistant in tension; therefore, in fractures of long bones, the plate is placed along the side of the bone which is typically loaded in tension. Having excellent


FIGURE 45.2 Types of metallic pin tip: (a) trochar end and (b) diamond end.
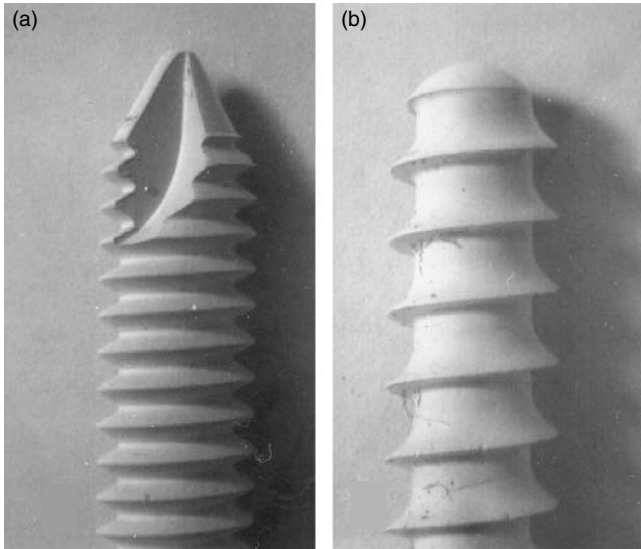

FIGURE 45.3 Bone screws: (a) a self-tapping V-threaded (has a cutting flute), and (b) a non-self-tapping, buttress threaded screw.

apposition of the bone fragments, as well as developing adequate compression between them, is critical in maintaining the stability of the fixation and preventing the plate from repetitive bending and fatigue failure. Interfragmentary compression also creates friction at the fracture surface, increasing resistance to torsional loads [Perren, 1991; Tencer et al., 1993]. On the contrary, too much compression causes micro fractures and necrosis of contacting bone due to the collapse of vesicular canals.

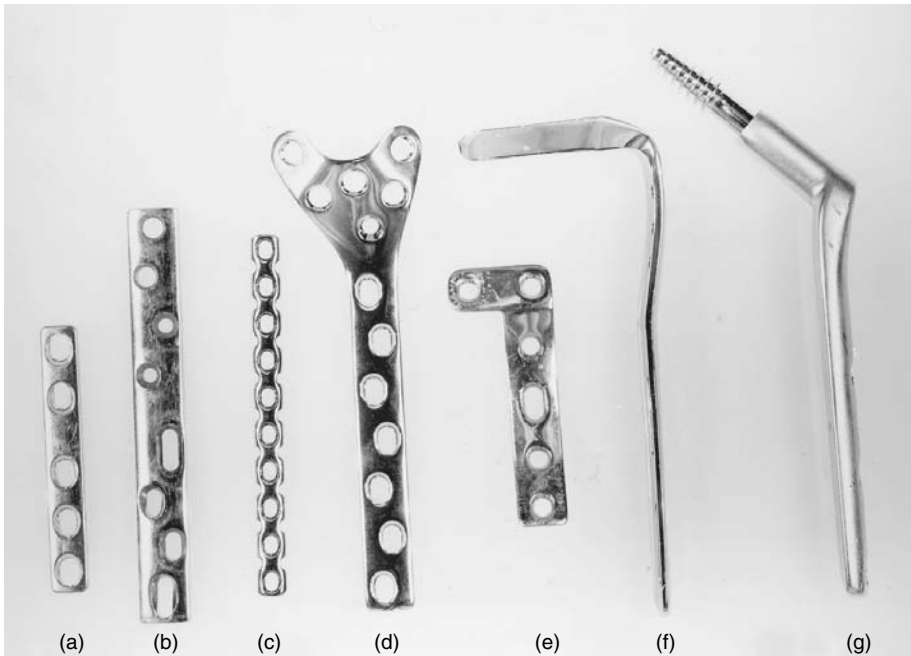
Compression between the fracture fragments can be achieved with a special type of plate called a *dynamic compression plate* (DCP). The dynamic compression plate has elliptic shape screw holes with its
FIGURE 45.4 Principle of a dynamic compression plate for fracture fixation. During tightening a screw, the screw head slides down on a ramp in a plate screw hole which results in pushing the plate away from a fracture end and compressing the bone fragments together.


FIGURE 45.5 Bone plates: (a) dynamic compression plate, (b) hybrid compression plate (lower part has dynamic compression screw holes), (c) reconstruction bone plate (easy contouring), (d) buttress bone plate, (e) L shaped buttress plate, (f) nail plate (for condylar fracture), and (g) dynamic compression hip screw.

long axis oriented parallel to that of the plate. The screw hole has a sliding ramp to the long axis of the plate. Figure 45.4 explains the principle of the dynamic compression plate.

Bone plates are often contoured in the operating room in order to conform to an irregular bone shape to achieve maximum contact of the fracture fragments. However, excessive bending decreases the service life of the plate. The most common failure modes of a bone plate-screw fixation are screw loosening and plate failure. The latter typically occurs through a screw hole due to fatigue and/or crevice corrosion [Weinstein et al., 1979].

In the vicinity of the joints, where the diameter of long bones is wider, the cortex thinner, and cancellous bone abundant, plates are often used as a buttress or retaining wall. A buttress plate applies force to the bone perpendicular to the surface of the plate, and prevents shearing or sliding at the fracture site. Buttress plates are designed to fit specific anatomic locations and often incorporate other methods of fixation besides cortical or cancellous screws, for example, a large lag screw or an I-beam. For the fusion of vertebral bodies following diskectomy, spinal plates are used along with bone grafts. These plates are secured to the vertebral bodies using screws (Figure 45.1c). Similar approaches have been employed to restore stability in the thoracolumbar and cervical spine region as well. Figure 45.5 illustrates a variety of types of bone plates.
FIGURE 45.6 Intramedullary devices: (a) Gross-Kempf (slotted), (b) Uniflex (Ti alloy, slotted), (c) Kuntscher, (d) Samson, (e) Harris, (f) Brooker-Wills distal locking pin, and (g) Enders pins.

45.1.1.5 Intramedullary Nails

Intramedullary devices (IM nails) are used as internal struts to stabilize long bone fractures. IM nails are also used for fixation of femoral neck or intertrochanteric bone fractures; however, this application requires the addition of long screws. A gamut of designs are available, going from solid to cylindrical, with shapes such as cloverleaf, diamond, and "C" (slotted cylinders). Figure 45.6 shows a variety of intramedullary devices.

Compared to plates, IM nails are better positioned to resist multi-directional bending than a plate or an external fixator, since they are located in the center of the bone. However, their torsional resistance is less than that of the plate [Cochran, 1982]. Therefore, when designing or selecting an IM nail, a high polar moment of inertia is desirable to improve torsional rigidity and strength. The torsional rigidity is proportional to the elastic modulus and the moment of inertia. For nails with a circular cross-section, torsional stiffness is proportional to the fourth power of the nail's radius. The wall thickness of the nail also affects the stiffness. A slotted, open section nail is more flexible in torsion and bending, and it allows easy insertion into a curved medullary canal for example, that of the femur [Tencer, 1993]. However, in bending, a slot is asymmetrical with respect to rigidity and strength. For example, a slotted nail is strongest when bending is applied so that the slot is near the neutral plane; the nail is weakest when oriented so that the slot is under tension.

In addition to the need to resist bending and torsion, it is vital for an IM nail to have a large contact area with the internal cortex of the bone to permit torsional loads to be transmitted and resisted by shear stress. Two different concepts are used to develop shear stress: (1) a three-point, high pressure contact, achieved with the insertion of curved pins, and (2) a positive interlocking between the nail and intramedullary canal, to produce a unified structure. Positive interlocking can be enhanced by reaming the intramedullary canal. Reaming permits a larger, longer, nail-bone contact area and allows the use of a larger nail, with increased rigidity and strength [Kessler et al., 1986].

The addition of screws through the bone and nail, proximal and distal to the fracture, known as interlocking, increases torsional stability and prevents shortening of the bone, especially in unstable fractures

[Perren, 1989]. The IM nail which has not been interlocked allows interfragmentary compressive force due to its low resistance to axial load. Another advantage of IM nails is that they do not require opening the fracture site, since they can be inserted through a small skin incision, typically located in one extreme of the bone. The insertion of an intramedullary nail, especially those that require reaming of the medullary canal, destroys the intramedullary vessels which supply two thirds of the cortex. However, this is not of clinical significance because revascularization occurs rapidly [Kessler et al., 1986; O'Slullivan et al., 1989].

45.1.2 Joint Replacements

Our ability to replace damaged joints with prosthetic implants has brought relief to millions of patients who would otherwise have been severely limited in their most basic activities and doomed to a life in pain. It is estimated that about 16 million people in the United States are affected by osteoarthritis, one of the various conditions that may cause joint degeneration and may lead a patient to a total joint replacement.

Joint degeneration is the end-stage of a process of destruction of the articular cartilage, which results in severe pain, loss of motion, and occasionally, an angular deformity of the extremity [Buckwalter et al., 1993]. Unlike bone, cartilage has a very limited capacity for repair [Salter, 1989]. Therefore, when exposed to a severe mechanical, chemical, or metabolic injury, the damage is permanent and often progressive.

Under normal conditions, the functions of cartilage are to provide a congruent articulation between bones, to transmit load across the joint, and to allow low-friction movements between opposing joint surfaces. The sophisticated way in which these functions are performed becomes evident from some of the mechanical characteristics of normal cartilage. For example, due to the leverage geometry of the muscles and the dynamic nature of human activity, the cartilage of the hip is exposed to about eight times body weight during fast walking [Paul, 1976]. Over a period of 10 years, an active person may subject the cartilage of the hip to more than 17 million weight bearing cycles [Jeffery, 1994]. From the point of view of the optimal lubrication provided by synovial fluid, cartilage's extremely low frictional resistance makes it 15 times easier to move opposing joint surfaces than to move an ice-skate on ice [Mow and Hayes, 1991; Jeffery, 1994].

Cartilage functions as a unit with subchondral bone, which contributes to shock absorption by undergoing viscoelastic deformation of its fine trabecular structure. Although some joints, like the hip, are intrinsically stable by virtue of their shape, the majority require an elaborate combination of ligaments, meniscus, tendons, and muscles for stability. Because of the large multidirectional forces that pass through the joint, its stability is a dynamic process. Receptors within the ligaments fire when stretched during motion, producing an integrated muscular contraction that provides stability for that specific displacement. Therefore, the ligaments are not passive joint restraints as once believed. The extreme complexity and high level of performance of biologic joints determine the standard to be met by artificial implants.

Total joint replacements are permanent implants, unlike those used to treat fractures, and the extensive bone and cartilage removed during implantation makes this procedure irreversible. Therefore, when faced with prosthesis failure and the impossibility to reimplant, the patient will face severe shortening of the extremity, instability or total rigidity of the joint, difficulty in ambulation, and often will be confined to a wheel chair.

The design of an implant for joint replacement should be based on the kinematics and dynamic load transfer characteristic of the joint. The material properties, shape, and methods used for fixation of the implant to the patient determines the load transfer characteristics. This is one of the most important elements that determines long-term survival of the implant, since bone responds to changes in load transfer with a remodeling process, mentioned earlier as Wollff's law. Overloading the implant-bone interface or shielding it from load transfer may result in *bone resorption* and subsequent loosening of the implant [Sarmiento et al., 1990]. The articulating surfaces of the joint should function with minimum friction and produce the least amount of wear products [Charnley, 1973]. The implant should be securely fixed to the body as early as possible (ideally immediately after implantation); however, removal of the implant should not require destruction of a large amount of surrounding tissues. Loss of tissue, especially

TABLE 45.3 Biomaterials for Total Joint Replacements

Materials	Properties	Application
Co–Cr alloy	Stem, head (ball)	Heavy, hard, stiff
(casted or wrought)	Cup, porous coating	High wear resistance
	Metal backing	
Ti alloy	Stem, porous coating	Low stiffness
	Metal backing	Low wear resistance
Pure titanium	Porous coating	Excellent osseousintegration
Tantalum	Porous structure	Excellent osseousintegration
	Good mechanical strength	
Alumina	Ball, cup	Hard, brittle
		High wear resistance
Zirconia	Ball	Heavy and high toughness
		High wear resistance
UHMWPE	Cup	Low friction, wear debris
		Low creep resistance
PMMA	Bone cement fixation	Brittle, weak in tension
		Low fatigue strength

Note: Stem: femoral hip stem/chondylar knee stem; head: femoral head of the hip stem; cup: acetabular cup of the hip.

TABLE 45.4 Types of Total Joint Replacements

Joint	Types
Hip	Ball and socket
Knee	Hinged, semiconstrained, surface replacement
	Unicompartment or bicompartment
Shoulder	Ball and socket
Ankle	Surface replacement
Elbow	Hinged, semiconstrained, surface replacement
Wrist	Ball and socket, space filler
Finger	Hinged, space filler

of bone, makes re-implantation difficult and often shortens the life span of the second joint replacement [Dupont and Charnley, 1972].

Decades of basic and clinical experimentation have resulted in a vast number of prosthetic designs and material combinations (Table 45.3 and Table 45.4) [Griss, 1984]. In the following section, the most relevant achievements in fixation methods and prosthetic design for different joints will be discussed at a conceptual level. Most joints can undergo partial replacement (hemiarthroplasty), that is, reconstruction of only one side of the joint while retaining the other. This is indicated in selected conditions when global joint degeneration has not taken place. This section will focus on total joint replacement, since this allows for a broader discussion of the biomaterials used.

45.1.2.1 Implant Fixation Method

The development of a permanent fixation mechanism of implants to bone has been one of the most formidable challenges in the evolution of joint replacement. There are three types of methods of fixation: (1) mechanical interlock, which is achieved by press-fitting the implant [Cameron, 1994a], by using polymethylmethacrylate, which is called bone cement, as a grouting agent [Charnley, 1979], or by using threaded components [Albrektsson et al., 1994]; (2) biological fixation, which is achieved by using textured or porous surfaces, which allow bone to grow into the interstices [Cameron, 1994b]; and (3) direct chemical bonding between implant and bone, for example, by coating the implant with calcium hydroxyapatite, which has a similar mineral composition to bone [Morscher, 1992]. Recently,

direct bonding with bone was observed with Bioglass, a glass-ceramic, through selective dissolution of the surface film [Hench, 1994]; however, the likelihood of its clinical application is still under investigation.

Each of the fixation mechanisms has an idiosyncratic behavior, and their load transfer characteristics as well as the failure mechanisms are different. Further complexity arises from prostheses which combine two or more of the fixation mechanisms in different regions of the implant. Multiple mechanisms of fixation are used in an effort to customize load transfer to requirements of different regions of bone in an effort to preserve bone mass. Loosening, unlocking, or de-bonding between implant and bone constitute some of the most important mechanisms of prosthetic failure.

45.1.2.2 Bone Cement Fixation

Fixation of implants with polymethylmethacrylate (PMMA, bone cement) provides immediate stability, allowing patients to bare all of their weight on the extremity at once. In contrast, implants which depend on bone ingrowth require the patient to wait about 12 weeks to bear full weight.

Bone cement functions as a grouting material; consequently, its anchoring power depends on its ability to penetrate between bone trabeculae during the insertion of the prosthesis [Charnley, 1979]. Being a viscoelastic polymer, it has the ability to function as a shock absorber. It allows loads to be transmitted uniformly between the implant and bone, reducing localized high-contact stress.

Fixation with bone cement creates bone-cement and cement-implant interfaces, and loosening may occur at either one. The mechanisms to enhance the stability of the metal-cement interface constitute an area of controversy in joint replacement. Some investigators have focused their efforts on increasing the bond between metal and cement by roughening the implant, or pre-coating it with PMMA to prevent sinking of the prosthesis within the cement mantle, and circulation of debris within the interface [Park et al., 1978; Barb et al., 1982; Harris, 1988]. In contrast, others polish the implant surfaces and favor wedge-shaped designs which encourage sinking of the prosthesis within the cement, to profit from the viscoelastic deformation of the mantle by loading the cement in compression [Ling, 1992].

The problems with bone-cement interface may arise from intrinsic factors, such as the properties of the PMMA and bone, as well as extrinsic factors such as the cementing technique. Refinements in the cementing technique, such as pulsatile lavage of the medullary canal, optimal hemostasis of the cancellous bone, as well as drying of the medullary canal and pressurized insertion of the prosthesis, can result in a cement-bone interface free of gaps, with maximal interdigitation with cancellous bone [Harris and Davies, 1988]. Despite optimal cementing technique, a thin *fibrous membrane* may appear in various regions of the interface, due to various factors such as the toxic effect of free methylmethacrylate monomer, necrosis of the bone resulting from high polymerization temperatures, or devascularization during preparation of the canal [Goldring et al., 1983]. Although a fibrous membrane in the bone cement interface may be present in a well-functioning implant, it may also increase in width over time (most probably as a result of the accumulation of polyethylene wear debris from the bearing couple), and may result in macromotion, bone loss, and eventual loosening [Ebramzadeh et al., 1994]. Finally, the cement strength itself may be improved by removing air bubbles by mixing monomer and polymer under vacuum and/or centrifuging it [Harris, 1988]. During implantation, various devices are used to guarantee uniform thickness of the mantle to minimize risk of fatigue failure of the cement [Oh et al., 1978].

45.1.2.3 Porous Ingrowth Fixation

Bone ingrowth can occur with inert implants which provide pores larger than 25 μm in diameter, which is the size required to accommodate an osteon. For the best ingrowth in clinical practice, pore size range should be 100 to 350 μm and pores should be interconnected with each other with similar size of opening [Cameron, 1994b]. Implant motion inhibits bony ingrowth and large bone-metal gaps prolong or prevent the **osseointegration** [Curtis et al., 1992]. Therefore, precise surgical implantation and prevention of post-operative weight bearing for about 12 weeks are required for implant fixation.

The porous coated implants require active participation of the bone in the fixation of the implant, in contrast to cementation where the bone has a passive role. Therefore, porous coated implants are best indicated in conditions where the bone mass is near-normal. The implant design should allow ingrown
FIGURE 45.7 Scanning electron micrographs of four different types of porous structures: (a) plasma sprayed coating (7×), (b) sintered wire mesh coating (7×), (c) sintered beads coating (20×), and (d) Hedrocell porous tantalum (50×).

bone to be subjected to continuous loading within a physiologic range in order to prevent loss of bone mass due to **stress shielding**. Porous ingrowth prostheses are notoriously difficult to remove, and substantial bone damage often results from the removal process. For this reason, they should be optimized to provide predictable ingrowth with a minimal area of surgically accessible porous coated surface.

Commercially pure titanium, titanium alloy, tantalum, and calcium hydroxyapatite (HA) are currently used as porous coating materials. With pure titanium, three different types of porosity can be achieved: (1) plasma spray coating, (2) sintering of wire mesh, or (3) sintering of beads on an implant surface (Figure 45.7) [Morscher, 1992]. Thermal processing of the porous coating may weaken the underlying metal (implant). Additional problems may result from flaking of the porous coating materials, since loosened metal particles may cause severe wear when they migrate into the articulation (bearing couple) [Agins et al., 1988]. A thin calcium hydroxyapatite coating over the porous titanium surface has been used in an effort to enhance osseointegration; however, it improves only early-stage interfacial strength [Friedman, 1992; Capello and Bauer, 1994]. The long-term degradation and/or resorption of hydroxyapatite is still under investigation.

Recently, a cellular, structural biomaterial comprised of 15 to 25% tantalum (75 to 85% porous) has been developed. The average pore size is about 550 μm, and the pores are fully interconnected. The porous tantalum is a bulk material (i.e., not a coating) and is fabricated via a proprietary chemical vapor infiltration process in which pure tantalum is uniformly precipitated onto a reticulated vitreous carbon skeleton. The porous tantalum possesses sufficient compressive strength for most physiological loads, and tantalum exhibits excellent biocompatibility [Black, 1994]. This porous tantalum can be mechanically attached or diffusion bonded to substrate materials such as Ti alloy. Current commercial applications included polyethylene-porous tantalum acetabular components for total hip joint replacement and repair of defects in the acetabulum.

45.1.3 Total Joint Replacements

45.1.3.1 Hip Joint Replacement

The prosthesis for total hip replacement consists of a femoral component and an acetabular component (Figure 45.8a). The femoral stem is divided into head, neck, and shaft. The femoral stem is made of Ti

(a)

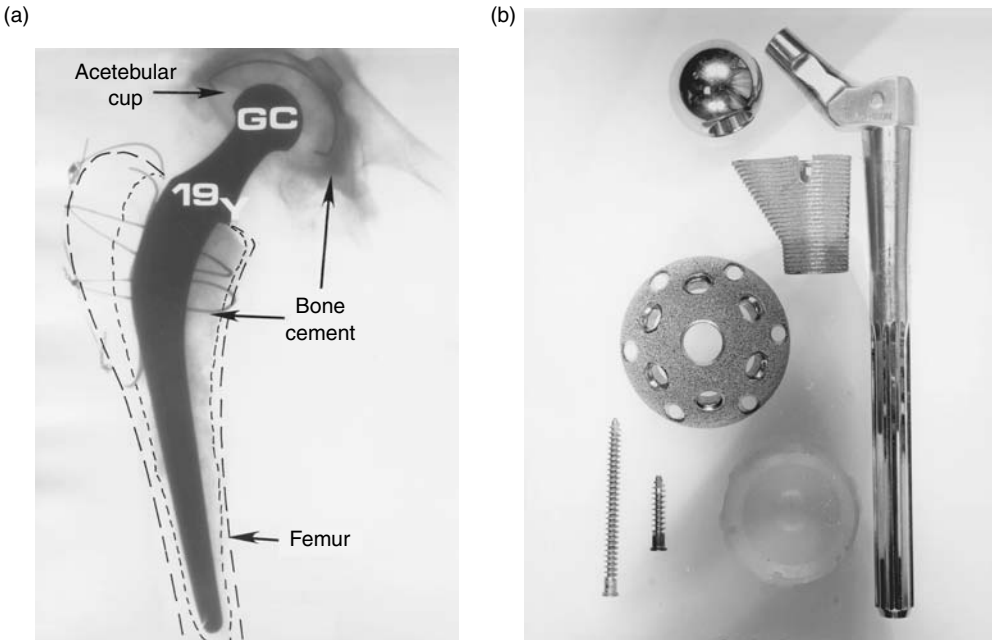
(b)


FIGURE 45.8   (a) Radiograph of bone cement fixed Charnley hip joint (monolithic femoral and acetabular component, 15-year follow-up). (b) Modular total hip system: head, femoral stem, porous coated proximal wedge, porous coated metal backing for cup, UHMWPE cup, and fixation screws.

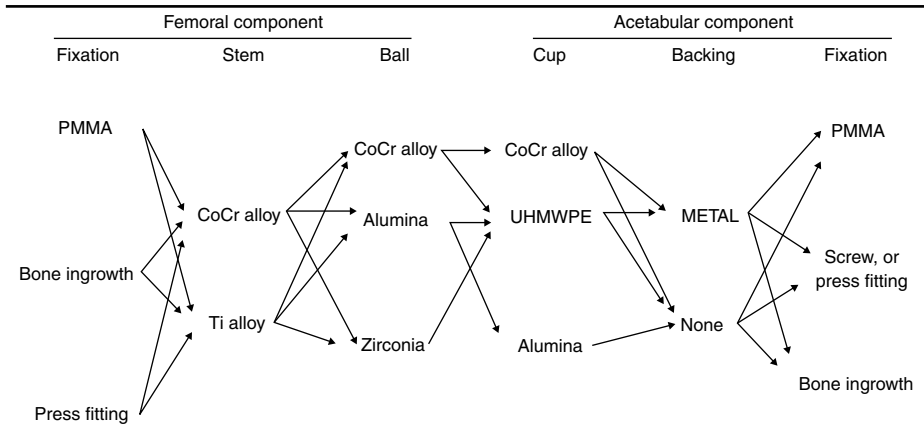
alloy or CoCr alloy (316L stainless steel was used earlier) and is fixed into a reamed medullary canal by cementation or press fitting. The femoral head is made of CoCr alloy, alumina, or zirconia. Although Ti alloy heads function well under clean articulating conditions, they have fallen into disuse because of their low wear resistance to third bodies, for example, bone or cement particles. The acetabular component is generally made of ultra-high molecular weight polyethylene (UHMWPE).

The prostheses can be monolithic when they consist of one part, or modular when they consist of two or more parts and require assembly during surgery. Monolithic components are often less expensive, and less prone to corrosion or disassembly. However, modular components allow customizing of the implant intraoperatively, and during future revision surgeries, for example, modifying the length of an extremity by using a different femoral neck length after the stem has been cemented in place, or exchanging a worn polyethylene bearing surface for a new one without removing the well-functioning part of the prosthesis from the bone. In modular implants (Figure 45.8b), the femoral head is fitted to the femoral neck with a Morse taper, which allows changes in head material and size, and neck length. Table 45.5 illustrates the most frequently used combinations of material in total hip replacement.

When the acetabular component is monolithic, it is made of UHMWPE; when it is modular, it consists of a metallic shell and a UHMWPE insert. The metallic shell seeks to decrease the microdeformation of the UHMWPE and to provide a porous surface for fixation of the cup [Skinner, 1992]. The metallic shell allows worn polyethylene liners to be exchanged. In cases of repetitive dislocation of the hip after surgery, the metallic shell allows replacing the old liner with a more constrained one, to provide additional stability. Great effort has been placed on developing an effective retaining system for the insert, as well as on maximizing the congruity between insert and metallic shell (Figure 45.8[b]). Dislodgment of the insert results in dislocation of the hip and damage of the femoral head, since it contacts the metallic shell directly. Micromotion between insert and shell produces additional polyethylene debris which can eventually contribute to bone loss [Friedman, 1994].

The hip joint is a ball-and-socket joint, which derives its stability from congruity of the implants, pelvic muscles, and capsule. The prosthetic hip components are optimized to provide a wide range of motion

TABLE 45.5   Possible Combination of Total Hip Replacements


without impingement of the neck of the prosthesis on the rim of the acetabular cup to prevent dislocation. The design characteristics must enable implants to support loads that may reach more than eight times body weight [Paul, 1976]. Proper femoral neck length and correct restoration of the center of motion and femoral offset decrease the bending stress on the prosthesis–bone interface. High-stress concentration or stress shielding may result in bone resorption around the implant. For example, if the femoral stem is designed with sharp corners (diamond shaped in a cross-section), the bone in contact with the corners of the implant may necrose and resorb.

Load bearing and motion of the prosthesis produces wear debris from the articulating surface, and from the interfaces were there is micromotion, for example, stem–cement interface. Bone chip, cement chip, or broken porous coating are often entrapped in the articulating space and cause severe polyethylene wear (third-body wear). The principal source of wear under normal conditions is the UHMWPE bearing surface in the cup. Approximately 150,000 particles are generated with each step and a large proportion of these particles are smaller than 1 μm. Cells from the immune system of the host, for example, *macrophages*, are able to identify the polyethylene particles as foreign and initiate a complex inflammatory response. This response may lead to rapid focal bone loss (**osteolysis**), bone resorption, loosening, and/or fracture of the bone. Recently, low-wear UHMWPE has been developed using a cross-linking of polyethylene molecular chains. There are several effective methods of cross-linking polyethylene, including irradiation of cross-linking, peroxide cross-linking, and silane cross-linking [Shen et al., 1996]. However, none of the cross-linked polyethylene has been clinically tested yet. Numerous efforts are underway to modify the material properties of articulating materials to harden and improve the surface finish of the femoral head [Friedman, 1994]. There is growing interest in metal–metal and ceramic–ceramic hip prostheses as a potential solution to the problem of osteolysis induced by polyethylene wear debris.

45.1.3.2 Knee Joint Replacements

The prosthesis for total knee joint replacement consists of femoral, tibial, and patellar components. Compared to the hip joint, the knee joint has a more complicated geometry and movement biomechanics, and it is not intrinsically stable. In a normal knee, the center of movement is controlled by the geometry of the ligaments. As the knee moves, the ligaments rotate on their bony attachments and the center of movement also moves. The eccentric movement of the knee helps distribute the load throughout the entire joint surface [Burstein and Wright, 1993].

The prostheses for total knee replacement (Figure 45.9) can be divided according to the extent to which they rely on the ligaments for stability: (1) *Constrained*: these implants have a hinge articulation, with a fixed axis of rotation, and are indicated when all of the ligaments are absent, for example in reconstructive procedures for tumoral surgery. (2) *Semi-constrained*: these implants control posterior
FIGURE 45.9 Various types of knee joints: (a) metal hinged, (b) hinged with plastic liner, (c) intramedullary fixed semiconstrained, (d) surface replacement, (e) uni-compartmental replacement, and (f) bi-compartmental replacement.

displacement of the tibia on the femur and medial-lateral angulation of the knee, but rely on the remaining ligaments and joint capsule to provide the rest of the constraint. Semi-constrained prostheses are often used in patients with severe angular deformities of the extremities, or in those that require revision surgery, when moderate ligamentous instability has developed. (3) *Non-constrained*: these implants provide minimal or no constraint. The prosthesis that provides minimal constraint requires resection of the posterior cruciate ligament during implantation, and the prosthetic constraint reproduces that normally provided by this ligament. The ones that provide no constraint spare the posterior cruciate ligament. These implants are indicated in patients who have joint degeneration with minimal or no ligamentous instability. As the degree of constraint increases with knee replacements, the need for the use of femoral and tibial intramedullary extensions of the prosthesis is greater, since the loads normally shared with the ligaments are then transferred to the prosthesis–bone interface.

Total knee replacements can be implanted with or without cement, the latter relying on porous coating for fixation. The femoral components are typically made of CoCr alloy and the monolithic tibial components are made of UHMWPE. In modular components, the tibial polyethylene component assembles onto a titanium alloy tibial tray. The patellar component is made of UHMWPE, and a titanium alloy back is added to components designed for uncemented use. The relatively small size of the patellar component compared to the forces that travel through the extensor mechanism, and the small area of bone available for anchorage of the prosthesis, make the patella vulnerable.

The wear characteristic of the surface of tibial polyethylene is different from that of acetabular components. The point contact stress and sliding motion of the components result in delamination and fatigue wear of the UHMWPE [Walker, 1993]. Presumably because of the relatively larger particle size of polyethylene debris, osteolysis around a total knee joint is less frequent than in a total hip replacement.

45.1.3.3 Ankle Joint Replacement

Total ankle replacements have not met with as much success as total hip and knee replacements, and typically loosen within a few years of service [Claridge et al., 1991]. This is mainly due to the high load
FIGURE 45.10 Miscellaneous examples of prostheses for total joint replacement: (a) ankle, (b) socket-ball shoulder joint, (c) hinged elbow joint, and (d) encapsulated finger joint.

transfer demand over the relatively small ankle surface area, and the need to replace three articulating surfaces (tibial, talar, and fibular). The joint configurations that have been used are cylindrical, reverse cylindrical, and spherical. The materials used to construct ankle joints are usually CoCr alloy and UHMWPE. Degeneration of the ankle joint is currently treated with fusion of the joint, since prostheses for total ankle replacement are still considered to be under initial development. Figure 45.10 shows ankle and other total joint replacements.

45.1.3.4 Shoulder Joint Replacements

The prostheses for total shoulder replacement consist of a humeral and a glenoid component. Like the femoral stem, the humeral component can be divided into head, neck, and shaft. Variations in the length of the neck result in changes in the length of the extremity. Even though the patient's perception of length of the upper extremity is not as accurate as that of the lower extremity, the various lengths of the neck are used to fine-tune the tension of the soft tissues to obtain maximal stability and range of motion.

The shoulder has the largest range of motion in the body, which results from a shallow ball and socket joint, which allows a combination of rotation and sliding motions between the joint surfaces. To compensate for the compromise in congruity, the shoulder has an elaborate capsular and ligamentous structure, which provides the basic stabilization. In addition, the muscle girdle of the shoulder provides additional dynamic stability. A decrease in the radius of curvature of the implant to compensate for soft tissue instability will result in a decrease in the range of motion [Neer, 1990].

45.1.3.5 Elbow Joint Replacements

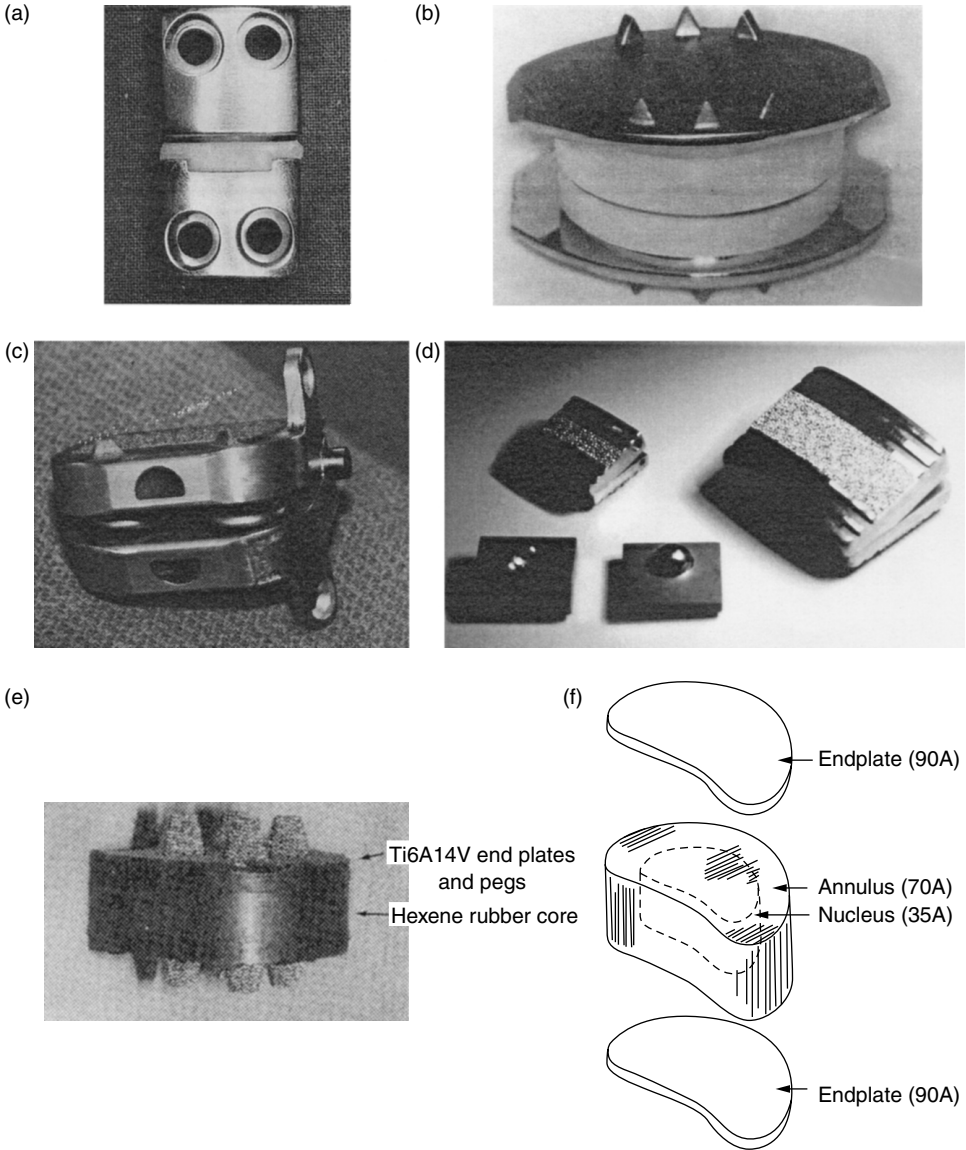
The elbow joint is a hinge-type joint allowing mostly flexion and extension, but having a polycentric motion [Goel and Blair, 1985]. The elbow joint implants are either hinged, semi-constrained, or unconstrained. These implants, like those of the ankle, have a high failure rate and are not used commonly. The high loosening rate is the result of high rotational moments, limited bone stock for fixation, and minimal


FIGURE 45.11   Experimental artificial discs "used" to restore function of the degenerated spine disc.

ligamentous support [Morrey, 1993]. In contrast to fusions of the ankle which function well, fusions of the elbow result in a moderate degree of incapacitation.

45.1.3.6 Finger Joint Replacements

Finger joint replacements are divided into three types: (1) hinge, (2) polycentric, and (c) space-filler. The most widely used are the space-filler type. These are made of high performance silicone rubber (polydimethylsiloxane) and are stabilized with a passive fixation method. This method depends on the development of a thin, fibrous membrane between implant and bone, which allows pistoning of the prosthesis. This fixation can provide only minimal rigidity of the joint [Swanson, 1973]. Implant wear and cold flow associated with erosive cystic changes of adjacent bone have been reported with silicone implants [Carter et al., 1986; Maistrelli, 1994].

45.1.3.7 Prosthetic Intervertebral Disk

Because of adjacent-level degeneration and other complications, such as non-fusion, alternatives to fusions have been proposed. One of the most recent developments for non-fusion treatment alternatives is replacement of the intervertebral discs [Hedman et al., 1991]. The goal of this treatment alternative is to restore the original mechanical function of the disc. One of the stipulations of artificial disc replacement is that remaining osseous spinal and paraspinal soft tissue components are not compromised by pathologic changes. Several artificial disk prostheses have been developed to achieve these goals (Figure 45.11).

45.1.3.8 Prostheses for Limb Salvage

Prosthetic implant technology has brought new lifestyles to thousands of patients who would lose their limbs due to bone cancer. In the past, the treatment for primary malignant bone cancer of the extremities was amputation. Significant advances in bone tumor treatment have taken place during the last two decades. The major treatment methods for limb reconstruction following bone tumor resection are resection arthrodesis (fusion of two bones), allograft-endoprosthetic composite, and endoprosthetic reconstruction. Endoprosthetic reconstruction is an extension of a total joint replacement(s) component to the resected bone area, and is the most popular option due to an advantage of fast postoperative recovery (Figure 45.12). Therefore, material and fixation methods for limb salvage endoprostheses are exactly the same as for total joint replacements. Femur, tibia, humerus, pelvis, and scapular are often resected and replaced endoprostheses. Similar to total joint replacements, disadvantages of the endoprosthetic
FIGURE 45.12 Radiographic appearance (montage) of a modular endoprosthetic replacement. Entire femur, hip joint, and knee joint of the bone tumor patient were replaced with prostheses for a limb salvage.

reconstruction are prosthesis loosening due to polyethylene wear and cement failure, and mechanical failure of the prostheses.

Most of the endoprostheses for limb salvage are of the expandable type [Ward et al., 1996]. Expandable endoprostheses are required for children who have a potential for skeletal growth. Several expandable prostheses require an open surgical procedure to be lengthened, whereas others have been developed that can be lengthened by servomechanisims within the endoprosthesis. The modular segmental system is a new option for expandable endoprosthesis. They can be revised easily to elongate modular components to gain length over time. The modular segmental system has several advantages over the mechanically expandable one. The use of the modular system allows intraoperative customization of the endoprosthesis during surgery. It minimizes discrepancies between custom implants and actual skeletal defects due to the radiographic magnification and uncertainty of margin of tumor resection. It allows the surgeon to assemble the prosthesis intraoperatively. The cost of the modular system is less than the cost of an expandable custom endoprosthesis. The modular system allows for simpler and less expensive revision when failures occur, obviating the need for an entirely new prosthesis when only one part needs to be replaced. On the other hand, the modular system has a high chance of corrosion failure at the Morse tapers and dislodgment at the Morse taper fittings. It can be lengthened only in certain increments. The modular component system has additional applications: metastatic bone disease, failure of internal fixation, severe acute fractures with poor bone quality, and failure of total joints with insufficient bone stock.

Defining Terms

Bone resorption: A type of bone loss due to the greater osteoclastic activity than the osteogenic activity.
Callus: Unorganized meshwork of woven bone which is formed following fracture of bone to achieve early stability of the fracture.
Fibrous membrane: Thin layer of soft tissue which covers an implant to isolate it from the body.
Necrosis: Cell death caused by enzymes or heat.
Osseointegration: Direct contact of bone tissues to an implant surface without fibrous membrane.
Osteolysis: Dissolution of bone mineral from the bone matrix.
Primary Healing: Bone healing in which union occurs directly without forming callus.
Secondary Healing: Bone union with a callus formation.
Stress shielding: Bone is protected from stress by the stiff implant.
Wolff's Law: Bone develops or adapts its structure to that most suited to resist the forces acting upon it.

45.2 Dental Implants: The Relationship of Materials Characteristic to Biologic Properties

J.C. Keller

As dental implants have become an acceptable treatment modality for partially and fully edentulous patients, it has become increasingly apparent that the interaction of the host tissue with the underlying implant surface is of critical importance for long-term prognosis [Young, 1988; Smith, 1993]. From the anatomical viewpoint, it is generally accepted that dental implants must contact and become integrated with several types of host tissues. Due largely to the work of Branemark and his colleagues [Albrektsson et al., 1983; Branemark, 1983], the importance of developing and maintaining a substantial bone-implant interface for mechanical retention and transmission of occlusal forces was realized. Despite documented long-term success of dental implants, longer-term implant failures are noted due to poor integration of connective and epithelial tissues and subsequent failure to develop a permucosal seal akin to that with natural tooth structures. From a biologic point of view, the characteristics of the implant substrate which permit hard and soft tissue integration and prevent adhesion of bacteria and plaque need to be further understood. It is likely that as a more complete understanding of the basic biologic responses of host tissues becomes known, refinements in the currently employed materials as well as new and improved materials will become available for use in the dental implant field.

It is important to realize that the overall biologic response of host tissue to dental implants can be divided into two distinct but interrelated phases (as given in Table 45.6). Phase I consists of the tissue responses which occur during the clinical healing phase immediately following implantation of dental implants. During this healing phase, the initial biologic processes of protein and molecular deposition on the implant surface are followed by cellular attachment, migration, and differentiation [Stanford and Keller, 1991]. It is therefore important to understand the characteristics of the implant material which affect the initial formation of the host tissue–implant interface. The characteristics include materials selection and the physical and chemical properties of the implant surface. These initial tissue responses lead to the cellular expression and maturation of extracellular matrix and ultimately to the development of bony interfaces with the implant material. After the initial healing phase is complete, usually between 3 and 6 months according to the two-stage Branemark implant design, the bone interface remodels under the occlusal forces placed on the implant during the Phase II functional period [Skalak, 1985; Brunski, 1992]. The overall bioresponses including bone remodeling during the functional phase of implant service life are then strongly influenced by the characteristics of loading and distribution of stress at the interface [Brunski, 1992]. The ability of the maturing interface to "remodel" as stresses are placed on the implant thus depend in large part on the original degree of tissue–implant surface interaction.

TABLE 45.6 Correlation Between the Clinical Phases of Implant Service Life with Biologic Events and Important Implant Materials Characteristics

Clinical phase	Biological events	Influential materials characteristics

This chapter will focus on the factors concerning dental implants which affect biologic properties of currently available dental implant materials. As pertains to each major topic, the influence of the materials properties on biologic responses will be emphasized.

45.2.1   Effects of Materials Selection

45.2.1.1   Metals and Alloys

Previously, dental implants have been fabricated from several metallic systems, including stainless steel and cobalt–chrome alloys as well as from the titanium family of metals. Several studies have reported on the ability of host bone tissues to "integrate" with various metal implant surfaces [Albrektsson et al., 1983; Katsikeris et al., 1987; Johansson et al., 1989]. In current paradigms, the term osseointegration refers to the ability of host tissues to form a functional interface with implant surfaces without an intervening layer of connective tissue akin to a foreign body tissue capsule observable at the light microscopic level [Albrektsson et al., 1983; Branemark, 1983]. By this definition, it becomes apparent that several biomedical materials including Ti and Ti alloy fulfill this general criterion. Ultrastructural investigations using transmission electron microscopy (TEM) approaches have further refined descriptions of the tissue implant interface, and the early work by Albrektsson and colleagues [1983] has become the descriptive standard by which other materials interfaces are compared. When bone was allowed to grow on Ti, a partially calcified amorphous ground substance was deposited in immediate contact with the implant, followed by a collagenous fibril-based extracellular matrix, osteoblast cell processes, and a more highly calcified matrix generally 200 to 300 Å from the implant surface.

However, other metallic materials have fallen from favor for use as dental implants due to widely differing mechanical properties compared to bone (Table 45.7), which can result in a phenomenon termed stress shielding [Slalak, 1985; Brunski, 1992], and the propensity for formation of potentially toxic corrosion products due to insufficient corrosion resistance properties [Van Orden, 1985; Lucas et al., 1987]. Ultrastructurally, the interface between bone and 316L stainless steel was described as consisting of a multiple-cell layer separating the bone from metal. Inflammatory cells were prominent in this layer, and a thick proteoglycan noncollagenous coating was present. This histologic appearance resembled that of a typical foreign body reaction and typifies a nonosseointegration-type response. The poor biologic response to stainless steel alloys has been reconfirmed by recently conducted *in vitro* studies which related the inability of host tissue to attach to the metal surface to the toxicity associated with metal ion release [Vrouwenvelder et al., 1993].

Due in large measure to the introduction and overall clinical success of the Branemark system, the range of metallic materials utilized for dental implants has become limited largely to commercially pure titanium (cpTi > 99.5%) and its major alloy, Ti–6A1–4V [De Porter et al., 1986; Keller et al., 1987]. Controversy remains, largely due to commercial advertising interests, as to which material provides a more suitable

surface for tissue integration. Early work by Johansson and coworkers [1989] reported that sputtercoated Ti alloy surfaces resulted in wide (5000 Å) **amorphous zones** devoid of collagen filaments, compared to the thinner 200 to 400 Å collagen-free amorphous zone surrounding cpTi surfaces. Subsequent studies revealed differences in the oxide characteristics between these sputtercoated cpTi and Ti alloy surfaces used for histologic and ultrastructural interfacial analyses. Significant surface contamination and the presence of *V* was observed in the Ti alloy surface, which led to an overall woven bone interface compared to the cpTi surface which had a more compact bone interface. Orr and colleagues [1992] demonstrated a similar ultrastructural morphology for interfaces of bone to Ti and Ti alloy, respectively. In each case an afibrillar matrix with calcified globular accretions, similar in appearance to cement lines in haversian systems, were observed in intimate contact with the oxide surface. Any slight differences in morphology were attributed to minor differences in surface topography or microtexture rather than chemical differences between the two surface oxides.

This is an area that is still under investigation, although recent research indicates that the stable oxide of cpTi and Ti alloy provide suitable surfaces for biologic integration [Keller et al., 1994]. Studies involving comprehensive surface analyses of prepared bulk cpTi and Ti alloy indicated that although the oxide on Ti alloy is somewhat thicker following standard surface preparations (polishing, cleaning, and acid passivation), the overall topography, the chemical characteristics, including presence and concentration of contaminants, and surface energetics were virtually identical for both materials as given in Table 45.8. *In vitro* experiments confirmed that the inherently clean condition of these oxides supports significant osteoblast cell attachment and migration and provides a hospitable surface to allow *in vitro* mineralization processes to occur [Orr et al., 1992].

In vitro experiments designed to study the ultrastructural details of bone-implant interfaces made from cpTi and Ti alloy may provide additional clues as to the histologic and ultrastructural differences which have been observed with these materials. Since clinical implants made from both materials appear to be successful [Branemark, 1983; De Porter et al., 1986], it is possible that because of the difference in mechanical properties between unalloyed and Ti alloy material, the longer-term tissue interface results from differences in bone remodeling due to the local biomechanical environment surrounding these materials [Brunski, 1992]. This hypothesis requires continued investigation for more definitive answers.

45.2.1.2 Ceramics and Ceramic Coatings

The use of single crystal sapphire or Al_2O_3 ceramic implants has remained an important component in the dental implant field [Driskell et al., 1973]. Although this material demonstrates excellent biologic compatibility, implants fabricated from Al_2O_3 have not reached a high degree of popularity in the United

States. Morphologic analyses of the soft tissue interface with Al_2O_3 revealed a hemidesmosomal external lamina attachment adjacent to the **junctional epithelium** — implant interface [Steflik et al., 1984]. This ultrastructural description is often used for comparison purposes when determining the extent of soft-tissue interaction with dental implants. Similarly, *in vivo* studies of the bone — Al_2O_3 implant interface reveal high levels of bone-to-implant contact, with areas of intervening fibrous connective tissue. Although fibrous tissue was present at the interface, the implant remained immobile, and the interface was consistent with a dynamic support system. More recent ultrastructural studies have demonstrated a mineralized matrix in immediate apposition to the Al_2O_3 implants similar to that described for Ti implants [Steflik et al., 1993].

An approach to enhancing tissue responses at dental implant interfaces has been the introduction of ceramics like, *calcium-phosphate-containing (CP) materials* as implant devices. The use of calcium-phosphate materials, in bulk or particulate form or as coatings on metal substrates has taken a predominant position in the biomedical implant area and has been the focus of several recent reviews [Koeneman et al., 1990; Kay, 1992]. One of the most important uses of CP materials has been as a coating on metallic (cpTi and Ti alloy) substrates. This approach has taken advantage of thin-film-coating technology to apply thin coatings of hydroxyapatite (HA) and tricalcium phosphate (TCP) materials to the substrate in order to enhance bone responses at implant sites. The most popular method of coating has been the plasma spray process [Herman, 1988]; although this process has some advantages, there are reports of nonuniform coatings, interfacial porosity, and vaporization of elements in the powder [Cook et al., 1991; Kay, 1992].

The use of this class of materials is based on the premise that a more natural hydroxyapatite (HA-like) could act as a scaffold for enhanced bone response — osseointegration — and thereby minimize the long-term healing periods currently required for uncoated metal implants.

Numerous *in vivo* investigations have clearly demonstrated that HA-like coatings can enhance bone responses at implant interfaces [Cook et al., 1991; Jarcho et al., 1997], although the mechanisms responsible for the development of the interface between hard tissue and these ceramic coatings are not well understood [Jansen et al., 1993]. Histologically, the overall bone-coating interface is similar in appearance and chronologic development to that reported for uncoated implant surfaces. Initially, an immature, trabecular, woven bone interface is formed followed by more dense, compact lamellar supporting bone structure. Ultrastructurally, the interface is reported to consist of a globular, afibrillar matrix directly on the HA surface, an electron-dense, proteoglycan rich layer (20 to 60 nm thick) and the presence of a mineralized collagenous matrix [De Bruijn et al., 1993]. Although the morphologic descriptions of the HA and Ti interfaces are similar, numerous studies have shown that the bone response to HA coatings is more rapid than with uncoated Ti surfaces, requiring approximately one-third to one-half the time to establish a firm osseous bed as uncoated Ti. Likewise, the extent of the bone response to HA coatings is superior and, according to some studies, leads to a several-fold increase in interfacial strength compared to uncoated Ti [Cook et al., 1991].

The cellular events which take place and lead to the interfacial ultrastructure with bone tissue and ceramic surfaces are under current investigation. Based upon preliminary findings, the advantageous biologic properties of HA coatings do not appear to be related to recruitment of additional cells during the early attachment phase of healing. Although recent work indicated that bone cells and tissue form normal cellular focal contacts during attachment to HA coatings, the level of initial *in vitro* attachment generally only approximates that observed with Ti [Puleo et al., 1991; Keller et al., 1992]. Rather, the mechanisms for the enhanced *in vitro* cell responses appear to be related, to a certain degree, to the degradation properties and release of Ca^{+2} and PO_4^{-3} ions into the biologic milieu. This surface corrosion is associated with highly degradable amorphous components of the coating and leads to surface irregularities which may enhance the quality of cell adhesion to these roughened materials [Bowers et al., 1992; Chehroudi et al., 1992]. Cellular events which occur following attachment may be influenced by the nature of the ceramic surface. Emerging evidence from a number of laboratories suggests that cellular-mediated events, including proliferation, matrix expression, and bone formation are enhanced following attachment to HA coatings and appear to be related to the gene expression of osteoblasts when cultured on different ceramic materials. These early cellular events lead to histologic and ultrastructural descriptions of bone healing

which take place on these surfaces and are very similar to those reported from *in vivo* studies [Orr et al., 1992; Steflik et al., 1993].

As determined from *in vitro* dissolution studies, there is general agreement that the biodegradation properties of the pertinent CP materials can be summarized as α-TCP > β-TCP >>> HA, whereas amorphous HA is more prone to biodegradation than crystalline HA [Koeneman et al., 1990]. Considerable attempts to investigate the effects of coating composition (relative percentages of HA, TCP) on bone integration have been undertaken. Using an orthopedic canine total hip model, Jasty and coworkers [1992] reported that by 3 weeks, a TCP/HA mixed coating resulted in significantly more woven bone apposition to the implants than uncoated implants. As determined by x-ray diffraction, the mixed coating consisted of 60% TCP, 20% crystalline HA, and 20% unknown Ca-PO$_4$ materials. Jansen and colleagues [1993] reported that, using HA-coated implants (90% HA, 10% amorphous CP), bony apposition was extensive in a rabbit tibia model by 12 weeks. However, significant loss of the coating occurred as early as 6 weeks after implantation. Most recently, Maxian and coworkers [1993] reported that poorly crystallized HA (60% crystalline) coatings demonstrated significant degradation and poor bone apposition *in vivo* compared to amorphous coatings. Both these reports suggest that although considerable bioresorption of the coating occurred in the cortical bone, there was significant bone apposition ($81 \pm 2\%$ for amorphous HA at 12 weeks, 77% for crystalline HA, respectively) which was not significantly affected by bioresorption.

From these *in vivo* reports, it is clear that HA coatings with relatively low levels of crystallinity are capable of significant bone apposition. However, as reported in a 1990 workshop report, the FDA is strongly urging commercial implant manufacturers to use techniques to increase the postdeposition crystallinity and to provide adequate adhesion of the coating to the implant substrate [Filiaggi et al., 1993]. Although the biologic responses to HA coatings are encouraging, other factors regarding HA coatings continue to lead to clinical questions regarding their efficacy. Although the overall bone response to HA-coated implants occurs more rapidly than with uncoated devices, with time an equivalent bone contact area is formed for both materials [Jasty et al., 1992]. These results have questioned the true need for HA-coated implants, especially when there are a number of disadvantages associated with the coating concept. Clinical difficulties have arisen due to failures within the coating itself and with continued dissolution of the coating, and to catastrophic failure at the coating–substrate interface [Koeneman et al., 1988].

Recent progress is reported in terms of the improvements in coating technology. Postdeposition heat treatments are often utilized to control the crystallinity (and therefore the dissolution characteristics) of the coatings, although there is still debate as to the relationship between compositional variations associated with differing crystallinity and optimization of biologic responses. Additional coating-related properties are also under investigation in regard to their effects on bone. These include coating thickness, level of acceptable porosity in the coating, and adherence of the coating to the underlying substrate. However, until answers concerning these variables have been more firmly established, HA coatings used for dental implants will remain an area of controversy and interest.

45.2.2 Effects of Surface Properties

45.2.2.1 Surface Topography

The effects of surface topography are different than the overall three-dimensional design or geometry of the implant, which is related to the interaction of the host tissues with the implant on a macroscopic scale as shown in Figure 45.13. This important consideration in overall biologic response to implants is discussed later in this chapter. In this discussion the concept of surface topography refers to the surface texture on a microlevel. It is on this microscopic level that the intimate cell and tissue interactions leading to osseointegration are based as shown in Figure 45.14.

The effects of surface topography on *in vitro* and *in vivo* cell and tissue responses have been a field of intense study in recent years. The overall goal of these studies is to identify surface topographies which
FIGURE 45.13 Examples of current dental implant designs, illustrating the variety of macroscopic topographies which are used to encourage tissue ingrowth. Left to right: Microvent, Corevent, Screw-vent, Swede-vent, Branemark, IMZ implant.

mimic the natural substrata in order to permit tissue integration and improve clinical performance of the implant. In terms of cell attachment, the *in vitro* work by Bowers and colleagues [1992] established that levels of short-term osteoblast cell attachment were higher on rough compared to smooth surfaces and cell morphology was directly related to the nature of the underlying substrate. After initial attachment, in many cases, cells of various origin often take on the morphology of the substrate as shown in Figure 45.15. Increased surface roughness, produced by such techniques as sand or grit blasting or by rough polishing, provided the rugosity necessary for optimum cell behavior.

Work in progress in several laboratories is attempting to relate the nature of the implant surface to cell morphology, intracellular cytoskeletal organization, and extracellular matrix development. Pioneering work by Chehroudi and coworkers [1992] suggests that microtextured surfaces (via micromachining or other techniques) could help orchestrate cellular activity and osteoblast mineralization by several mechanisms including proper orientation of collagen bundles and cell shape and polarity. This concept is related to the theory of **contact guidance** and the belief that cell shape will dictate cell differentiation through gene expression. In Chehroudi's work, both tapered pitted and grooved surfaces (with specific orientation and sequence patterns) supported mineralization with ultrastructural morphology similar in appearance to that observed by Davies and colleagues [1990]. However, mineralization was not observed on smooth surfaces in which osteoblastlike cells did not have a preferred growth orientation. Thus the control of surface microtopography by such procedures as micromachining may prove to be a valuable technology for the control and perhaps optimization of bone formation on implant surfaces.

It is apparent that macroscopic as well as microscopic topography may affect osteoblast differentiation and mineralization. In a recent study by Groessner-Schrieber and Tuan [1992], osteoblast growth, differentiation, and synthesis of matrix and mineralized nodules were observed on rough, textured, or porous coated titanium surfaces. It may be possible therefore, not only to optimize the interactions of host tissues with implant surfaces during the Phase I tissue responses but also to influence the overall bone responses to biomechanical forces during the remodeling phase (Phase II) of tissue responses.

Based on these concepts, current implant designs employ microtopographically roughened surfaces with macroscopic grooves, threads, or porous surfaces to provide sufficient bone ingrowth for mechanical
FIGURE 45.14   Laboratory-prepared cpTi surfaces with (a–c, top to bottom) smooth (1 μm polish), grooved (600 grit polish), and rough (sandblasted) surfaces.

stabilization and the prevention of detrimental micromotion as shown in Figure 45.16 and Figure 45.17 [De Porter et al., 1986; Keller et al., 1987; Pilliar et al., 1991; Brunski, 1992].

45.2.3 Surface Chemistry

Considerable attention has focused on the properties of the oxide found on titanium implant surfaces following surface preparation. Sterilization procedures are especially important and are known to affect not only the oxide condition but also the subsequent *in vitro* [Swart et al., 1992; Stanford et al., 1994] and *in vivo* [Hartman et al., 1989] biologic responses. Interfacial surface analyses and determinations of surface energetics strongly suggest that steam autoclaving is especially damaging to titanium oxide surfaces. Depending upon the purity of the autoclave water, contaminants have been observed on the metal oxide and are correlated with poor tissue responses on a cellular [Keller et al., 1990, 1994] and tissue [Meenaghan et al., 1979; Baier et al., 1984; Hartman et al., 1989] level.
FIGURE 45.15   Osteoblastlike cell morphology after 2 h attachment on (a–c, top to bottom) smooth, grooved, and rough cpTi surfaces.

The role of multiple sterilization regimens on the practice of implant utilization is also under scrutiny. Many implants and especially bone plate systems are designed for repackaging if the kit is not exhausted. However, early evidence indicates that this practice is faulty and, depending on the method of sterilization, may affect the integrity of the metal oxide surface chemistry [Vezeau et al., 1991]. *In vitro* experiments have verified that multiple-steam-autoclaved and ethylene-oxide-treated implant surfaces adversely affected cellular and morphologic integration. However, the effects of these treatments on long-term biological responses including *in vivo* situations remain to be clarified.

Other more recently introduced techniques such as radiofrequency argon plasma cleaning treatments have succeeded in altering metal oxide chemistry and structure [Baier et al., 1984; Swart et al., 1992]. Numerous studies have demonstrated that PC treatments produce a relatively contaminant-free surface with improved surface energy (wettability), but conflicting biologic results have been reported with these surfaces. Recent *in vitro* studies have demonstrated that these highly energetic surfaces do not necessarily improve cellular responses such as attachment and cell expression. This has been confirmed by *in vivo*
FIGURE 45.16 Light microscopic photomicrograph of a bone–smooth cpTi interface with intervening layer of soft connective tissue. This implant was mobile in the surgical site due to lack of tissue ingrowth. (Original magnification = 50×.)

studies which indicate that the overall histologic and ultrastructural morphology of the bone-implant interface is similar for plasma-cleaned and dry-heat-sterilized implant surfaces [Albrektsson et al., 1983]. Another promising technique for the sterilization of implant materials is the exposure of the implant surface to ultraviolet light [Singh and Schaff, 1989] or gamma irradiation [Keller et al., 1994]. Both these methods of sterilization produce a relatively contaminant-free thin oxide layer which fosters high levels of

cell attachment [Keller et al., 1994] and inflammatory-free long-term *in vivo* responses [Hartman et al., 1989]. Currently, gamma irradiation procedures are widely used for the sterilization of metallic dental implant devices.

45.2.3.1 Metallic Corrosion

Throughout the history of the use of metals for biomedical implant applications, electrochemical corrosion with subsequent metal release has been problematic [Galante et al., 1991]. Of the biomedical metal systems available today, Ti and its major medical alloy, Ti–6A1–4V, are thought to be the most corrosion resistant; however, Ti metals are not totally inert *in vivo* [Woodman et al., 1984]. Release of Ti ions from Ti oxides can occur under relatively passive conditions [Ducheyne, 1988]. Whereas other factors such as positioning of the implant and subsequent biomechanical forces may play important roles in the overall tissue response to implants, it is not unreasonable to predict that electrochemical interactions between the implant surface and host tissue may affect the overall response of host bone [Blumenthal and Cosma, 1989]. For example, it has been shown by several groups [De Porter et al., 1986; Keller et al., 1987] that the percentages of intimate bony contact with the implant is inconsistent, at best, and generally averages approximately 50% over a 5-year period. Continued studies involving the effects of dissolution products on both local and systemic host responses are required in order to more fully understand the consequences of biologic interaction with metal implants.

45.2.3.2 Future Considerations for Implant Surfaces

It is clear that future efforts to improve the host tissue responses to implant materials will focus, in large part, on controlling cell and tissue responses at implant interfaces. This goal will require continued acquisition of fundamental knowledge of cell behavior and cell response to specific materials' characteristics. It is likely that a better understanding of the cellular-derived extracellular matrix-implant interface will offer a mechanism by which biologic response modifiers such as growth and attachment factors or hormones may be incorporated. Advancements of this type will likely shift the focus of future research from implant surfaces which as osseoconductive (permissive) to those which are osseoinductive (bioactive).

Defining Terms

Amorphous zone: A region of the tissue-implant interface immediately adjacent to the implant substrate. This zone is of variable thickness (usually <1000 Å), is free of collagen, and is comprised of proteoglycans of unknown composition.

Calcium phosphate: A family of calcium- and phosphate-containing materials of synthetic or natural origin which are utilized for implants and bone augmentation purposes. The most prominent materials are the tricalcium-phosphate- and hydroxyapatite-based materials, although most synthetic implants are a mixture of the various compositions.

Contact guidance: The theory by which cells attach to and migrate on substrates of specific microstructure and topographic orientation. The ability of the cell to attach and migrate on a substrate is related to the cytoskeletal and attachment molecules present on the cell membrane.

Junctional epithelium: The epithelial attachment mechanism which occurs with teeth, and has been observed infrequently with implants by some researchers. Less than 10 cell layers thick, the hemidesmosomal attachments of the basal cells to the implant surface provide a mechanical attachment for epithelium and prevent bacterial penetration into the sulcular area.

Osseointegration: A term developed by P.I. Branemark and his colleagues indicating the ability of host bone tissues to form a functional, mechanically immobile interface with the implant. Originally described for titanium only, several other materials are capable of forming this interface, which presumes a lack of connective tissue (foreign body) layer.

Plasma spray: A high-temperature process by which calcium-phosphate-containing materials are coated onto a suitable implant substrate. Although the target material may be of high purity, the high-temperature softening process can dramatically affect and alter the resultant composition of the coating.

Controlling and Assessing Cell–Biomaterial Interactions at the Micro- and Nanoscale: Applications in Tissue Engineering

Jessica Kaufman

Catherine Klapperich
Boston University

46.1 A Need for Understanding Cell–Biomaterial Interactions at the Micro- and Nanoscale

A long-standing goal of tissue engineering has been to create functional tissues, ideally by promoting the regenerative capacity of a patient's autologous cells by controlling cellular response. Regardless of whether this is achieved by using artificial scaffolds or naturally derived extracellular matrices, the engineered tissue must be able to support the necessary physiological loads during the remodeling processes that ultimately lead to generation of the functional tissue. While there has been tremendous progress in engineering a number of tissue systems, namely skin replacements [1–3], an incomplete understanding of the underlying mechanisms that control cell behavior has led to limited clinical success. Specifically, there are many open questions as to how cell–biomaterial interactions impact cellular and ultimately tissue phenotype [4,5].

In order to gain a mechanistic understanding of factors that control cell behavior, molecular and cell biologists have numerous methodologies to systematically unravel specific cell-signaling pathways involved in regulating cell behavior. It has been more difficult to control properties of biomaterials with analogous precision, but this is rapidly changing with recent enabling micro- and nanotechnologies that create scaffolds characterized by features that can now be controlled at length-scales that range from cellular dimensions all the way down to the molecular scale.

A solid base of research in both engineering and the biomedical sciences has demonstrated that tissue regeneration in synthetic environments is possible and often successful, but is difficult to predict and control. Design of these scaffolds has been conducted largely by trial and error, and little is known about how the chemical and mechanical properties of the scaffold affect the biological response of the seeded cells. Due to this lack of understanding, it has proven significantly more difficult to engineer complex tissues like cartilage, bone, nerves, and muscle [6,7] By considering the biological response of cells to scaffolds a material property that can be controlled by altering processing variables, we can begin to build the framework necessary for intelligent de novo design of new scaffold materials. However, in order for biological response to be a useful design variable, it must be quantifiable. Several of the approaches reviewed in this chapter are aimed at quantifying biological responses.

In most tissue engineering applications, a positive result is more likely if the scaffold material can provide the environmental stimuli necessary for healthy tissue regeneration. In most tissues, the molecular nature of these factors is unknown, but is likely some combination of mechanical, chemical, and biological stimuli take place on the micro- and nanoscale. It is largely unknown how mechanical forces and surface chemistry affect the physiology of cells, but this is a very active area of research [8–10]. Recently, many researchers have begun to focus on precisely how cells are responding to chemical and topological features at the micro- and nanoscale. Covered in this chapter are current issues involved in probing cell–biomaterials interactions on the molecular level and their implications for tissue engineering research. Discussed are methods to quantify cell response, engineer cell-surface molecules for targeted cell–biomaterials interactions, gain geometric and surface chemical control of cell fate, and directed movement of cells on substrates with mechanical gradients. We also discuss recent enabling technologies in materials processing that have yielded nanoscale biomaterials as tissue engineering scaffolds for various organ systems. Finally, we discuss the need for determining potential undesirable immunogenic responses to nano- and microsystems.

This review is by no means complete, and we apologize in advance to our colleagues for not including all of the excellent work in this area.

46.2 Genomic and Proteomic Data as a Measure of Cell–Biomaterials Interactions

By combining our ever increasing control over fabricating nanoscale features and the increased standardization of biochemical assays afforded by access to information about the human genome, we can now embark on intelligent tissue engineering scaffold design. Cell adhesion, migration, growth, and

FIGURE 46.1 (See color insert following page 32-14.) Schematic of the combinatorial approach using cell responses as variables in synthetic biomaterials design for tissue engineering applications. Libraries of chemically well-defined materials are generated combinatorially. The materials are characterized both chemically and mechanically at the nano- and microscale. *In vitro* cell-based assays are used to assess gene and protein expression. Cell–biomaterial interactions are visualized in 3-D culture using confocal microscopy. Finally, data is stored in an organized database for use in de novo materials design.

extracellular matrix synthesis are four major areas of cell responses that are relevant to tissue engineering applications. These responses can be probed on many levels including mRNA levels (gene expression) and protein levels (proteomics). A schematic of the general approach taken in one of our laboratories is included in Figure 46.1.

We have used the collagen–glycosaminoglycan (collagen–GAG) mesh scaffold to probe molecular level cell–biomaterials interactions [11]. We seeded IMR-90 human fibroblasts onto three-dimensional (3-D) collagen–GAG meshes and control surfaces of tissue culture polystyrene (TCPS). Nucleic acids (mRNA) from cells from each culture were isolated, amplified, and hybridized to human genome microarrays (U133A Gene Chip, Affymetrix, Santa Clara, CA).

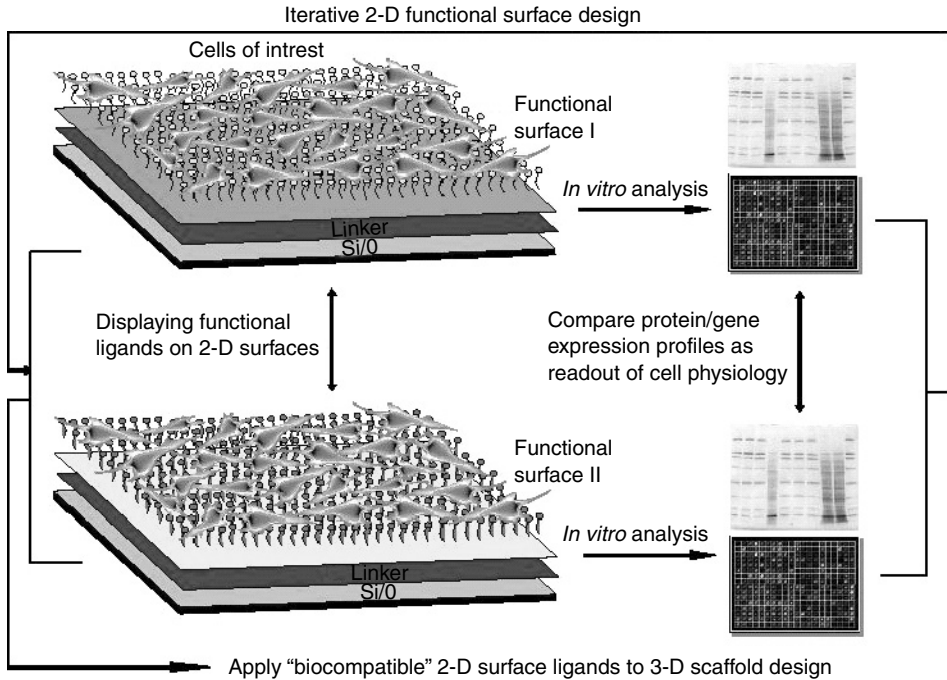
Connective tissue growth factor (CTGF) and tissue inhibitor metalloproteinase 3 (TIMP3) were down regulated in 3-D collagen exposed fibroblasts compared to the tissue culture polystyrene grown cells. CTGF, which plays a role in the induction of collagen, has known involvement in matrix accumulation in fibrosis, as well as the development of excess fibrous connective tissue. TIMP3 inactivates metalloproteinases, which degrade components of the extracellular matrix thereby remodeling the tissue. By underexpressing TIMP3, it is suspected that collagen–GAG interaction encourages the reorganization of the fibroblasts extracellular matrix. The 3-D arrangement stimulated the expression of proangiogenic genes including vascular endothelial growth factor (VEGF) and angiopoietin (ANGPTL2). The 3-D mesh environment also yielded high expression levels of the mRNA for proteins involved in matrix remodeling such as type III collagen (COL3A1).


FIGURE 46.2   (See color insert following page **32**-14.) A functional surface-based strategy to probe cell–ligand interactions — an iterative tissue engineering scaffold design approach. (Reproduced from Song, J. et al., *J. Mater. Chem.*, 2004, **14**: 2643–8. With permission.)

These studies and complementary proteomic work are beginning to more precisely define material biocompatibility for tissue regeneration. We extended this approach to look at how surfaces conjugated with anionic peptides affected gene and protein expression in osteosarcoma cells (Figure 46.2) [12]. Other researchers have taken similar approaches to study the migration and spreading behavior of endothelial cells on small-gauge vascular prostheses [13]. Ku et al. [14] looked at global gene expression of osteoblasts grown on different Ti–6Al–4V surface treatments. They were able to detect differences in inflammatory response of cells on three different surface treatments. Once a more complete understanding of the molecular nature of biocompatibility is achieved, the cell-surface molecule modifications and advanced materials design techniques described later will become much more powerful tools.

46.3   Engineering the Cell Surface to Control Cell-Adhesion Events

Another approach to controlling cell–biomaterials interactions is to modify the cell surface. The surfaces of cells are decorated with polysaccharides, glycolipids, and glycoproteins. These cell-surface molecules are the handles through which cells communicate with their surroundings. Cell-adhesion events can trigger signaling events inside of the cell and lead to changes in gene expression and eventually cell fate. These properties make cell-surface molecules ideal engineering targets. By modifying the molecules presented on a cell surface, it may be possible to control a cell's phenotype and eventual fate.

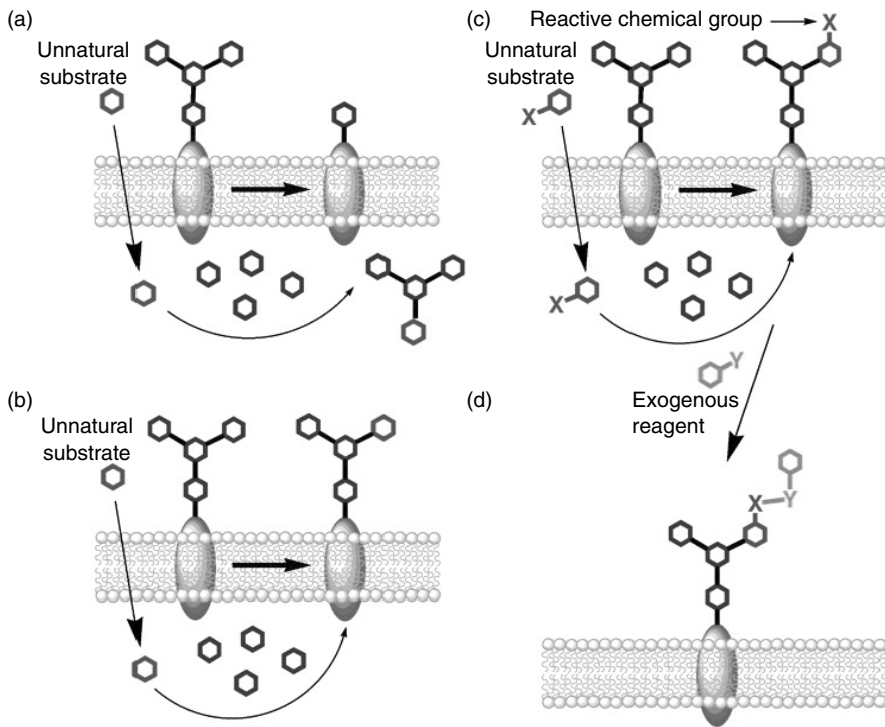
One way to modify the cell-surface molecules is by introducing nonnatural monosugars into the biosynthetic pathways that build up polysaccharides (Figure 46.3) [15,16]. By introducing monosaccharides with synthetic ketone groups, Bertozzi et al. were able to engineer previously nonadherent Jurkat cells to adhere to lipid bilayers decorated with azides [17]. These researchers have also demonstrated that a


FIGURE 46.3 (See color insert following page **32**-14.) (Right) Modulating cell-surface glycosylation by metabolic interference. (a) Unnatural substrates fed to cells can divert oligosaccharide biosynthesis away from endogenous scaffolds, reducing the expression of specific carbohydrate structures. (b) Unnatural substrates can be used in biosynthetic pathways and incorporated into cell-surface glycoconjugates. (c) If the unnatural substrates possess unique functional groups, their metabolic products on the cell-surface can be chemically elaborated with exogenous reagents (d). (Reproduced from Bertozzi, C.R. and L.L. Kiessling, *Science*, 2001, **291**: 2357–64. With permission.)

modification of a cell-surface molecule, polysialic acid (PSA), in substrata cells supporting the growth of chick dorsal root ganglion sensory neurons were able to differentially affect the outgrowth and plasticity of those cells [18]. In this case a cell-surface molecule that inhibits adhesion and outgrowth of neurons was modified, but it is easy to imagine that engineering cell-surface molecules that encourage such outgrowth would benefit work in nerve tissue regeneration. Since these artificial sugars can be installed through metabolic pathways, the cell culture needs only to be fed the engineered sugar through the media. It has also been demonstrated that feeding these sugars to small animals orally leads to the desired cell-surface modifications in cells of the animal, indicating that these substances may be able to be administered as drugs to patients or injected directly into the site of artificial tissue repair.

Other methods of cell-surface engineering also look promising. Genetic methods have been used to transfect cells with genes that express unique or unnatural cell-surface protein [19,20]. Kato and Mrksich [21] describe a method to modify both the cell and the biomaterial surface in a complimentary manner to encourage specific cell adhesion. They transfected Chinese hamster ovary (CHO) cells to express a chimeric receptor with a carbonic anhydrase IV (CAIV) domain at its terminus. This domain binds selectively to benzenesulfonamide groups that were installed on self-assembled monolayers designed for the study. The study demonstrates the ability to control both sides of the receptor–ligand interaction, which suggests a potentially powerful tool for tissue engineering.

Since cell-adhesion events are almost always the first step in the regeneration of injured or destroyed tissues, the ability to control these events should lead to the generation of better artificial tissues. Complementary modifications of the cell and biomaterial surfaces could allow cells to be directed to a

specific location for tissue regeneration. Current problems with cell seeding of artificial scaffolds could be ameliorated in this way. Of course it is essential to remain mindful that at this time only a patient's own cells can provide a preseeded tissue engineering scaffold that will not elicit an immune response. The advent of stem cell use in regenerative medicine and tissue engineering may solve some of these problems, but much research is left to be done [22,23].

46.4 Design of Model Micro- and Nanoenvironments to Probe and Direct Cell–Biomaterials Interactions

46.4.1 Geometric and Surface Chemical Control of Cell Fate

In order to sort out what cues cells are receiving from their three-dimensional extracellular environments, many groups have begun to make model environments with well-defined chemical and topological features. By maintaining control over the feature size and chemical character of the model system, changes in these variables can be made and the resulting cell responses can be measured using microbiological techniques. Most often, these features are made using photolithographic methods developed for the microelectronic industry [24]. Features approaching 1 μm in size are easily fabricated using these methods. In recent work, Dike et al. [25] demonstrated specific control over cell fate in vascular endothelial cells, showing that micropatterned surfaces can determine whether the cells would follow an angiogenic, apoptotic, or differentiation pathway.

Early work by Chen et al. [26] demonstrated that cells grown on subsequently smaller areas of microcontact printed extracellular matrix experienced different fates. In these experiments, changing the substrate extracellular matrix components and cell source, bovine or human, did not override the geometric effects. This work was expanded to three dimensions by examining how capillary endothelial cells grow in solution with fibronectin-coated beads [27]. Cells attached to single 10 μm beads did not improve viability whereas attaching cells to 25 μm beads did. The capillary epithelial cells undergo apoptosis unless the substrate is designed to allow them to adopt a relatively flat conformation by making multiple connections on a relatively planar surface.

Recently, Chen has used microneedle-like posts made of polydimethylsiloxane (PDMS) to measure the mechanical forces that smooth muscle cells exert on each other at cell adhesions (Figure 46.4) [28]. The researchers were also able to control the type of cell-adhesion molecules present on the tip of each elastomeric post. Using this approach of geometric control combined with precisely defined surface chemistries, they were able to demonstrate correlations between mechanical and chemical signals in these cells.

Just as Chen showed that cell fate can be determined by geometry of individual cells, Bhatia et al. [29] showed that the geometry of individual populations within a micropatterned coculture can also affect cell behavior. Cocultures were constructed by culturing hepatocytes on collagen-patterned wafers and then culturing fibroblasts directly on the substrate surrounding the wafers. In the experiment, the contact area between hepatocytes and fibroblasts and the contact area between individual hepatocytes were held constant. As the contact area between fibroblasts was increased, liver-specific functions in hepatocytes also increased. Work by Tang et al. [30] was a first step at using micropatterning techniques to create three-dimensional cocultures in collagen gels (Figure 46.5). Building up three-dimensional cultures with controlled geometries is a critical step toward multicellular tissue engineering constructs. Control of the local or microscale arrangement of cells in a tissue engineering scaffold will be a key to creating functional organs.

Cells do react to changes in their microscale environment, but cell–cell and cell–matrix adhesions are often nanoscale phenomena. Recently, techniques that yield nanoscale topography have emerged. As we are able to probe cells with smaller and smaller changes in surface topography and local surface chemistry, the closer we will come to mimicking the *in vivo* microenvironment. Andersson et al. [31] demonstrated that uroepithelial cells seeded onto substrates with nanoscale pillars expressed smaller amounts of the cytokines
FIGURE 46.4   (See color insert following page 32-14.) Cell culture on arrays of posts. (a) Scanning electron micrograph of a representative smooth muscle cell attached to an array of posts that was uniformly coated with fibronectin. Cells attached at multiple points along the posts as well as the base of the substrates. (b) Schematic of microcontact printing of protein (red), precoated on a PDMS stamp, onto the tips of the posts (gray). (c) Differential interference contrast (Upper) and immunofluorescence (Lower) micrographs of the same region of posts where a 2×2 array of posts has been printed with fibronectin. (d and e) Scanning electron micrograph (d) and phase-contrast micrograph (e) of representative smooth muscle cells attached to posts where only the tips of the posts have been printed with fibronectin by using a flat PDMS stamp. Cells deflected posts maximally during the 1 to 2-h period after plating, were fully spread after 2 h, and were fixed and critical point dried 4 h after plating. (Scale bars indicate 10 μm.) (Reproduced from Tan, J.L. et al., *Proc. Natl Acad. Sci. USA*, 2003, **100**: 1484–9. With permission.)

IL-6 and IL-8 than cells cultured on flat substrates of the same material. They saw no difference in cytokine production between cells grown on the flat substrate and one with parallel microscale grooves. Corneal epithelial cells were shown to exhibit significantly different phenotypes when seeded onto substrates with nanoscale features [32]. Focal adhesions and cytoskeleton proteins were found to align in the direction of the nanoscale features, a common result when cells are seeded on microscale surface topographies. This result was expected, since the surface of the corneal basal lamina is known to have features in the range of 20 to 200 nm.

46.4.2   Directed Movement of Cells on Mechanical Gradients

In addition to surface chemical micropatterning to control cell positioning, recently one of our laboratories has used micropatterning techniques to create mechanical gradient gels [33,34] (Figure 46.6). This phenomenon was first reported by Wang's and Dembo's groups [35] for 3T3 fibroblasts cultured on a substrate characterized with a step-gradient in mechanical properties. However, the method used to produce these substrates lacked precise control at the microscale, so we developed two methods based on photopolymerization to control substrate mechanical properties at the microscale. In one approach, mask patterns are used to control the degree of polymerization in polyacrylamide gels by controlling the UV light exposure time. Using this system, cell motility of bovine vascular smooth muscle cells were compared on mechanically patterned collagen-coated gels vs. uniformly compliant gels. The cells exhibited a clear migration from soft regions to stiff regions, durotaxis, when compared with cells grown on uniform hydrogels. Furthermore, the vascular smooth muscle cells accumulated in stiff regions of the gel, suggesting that mechanical patterning could be a powerful tool for creating complex cultures with multiple cell types that are stable over long periods of time.

The second approach involves the integration of a microfluidic gradient generator and photopolymerization to create substrate with well-defined compliance gradients [34]. An advantage of this approach is that more complex gradients can be achieved. In addition, variations in steepness of the gradient can be easily tuned in this system in order to quantify the range in which cells respond.

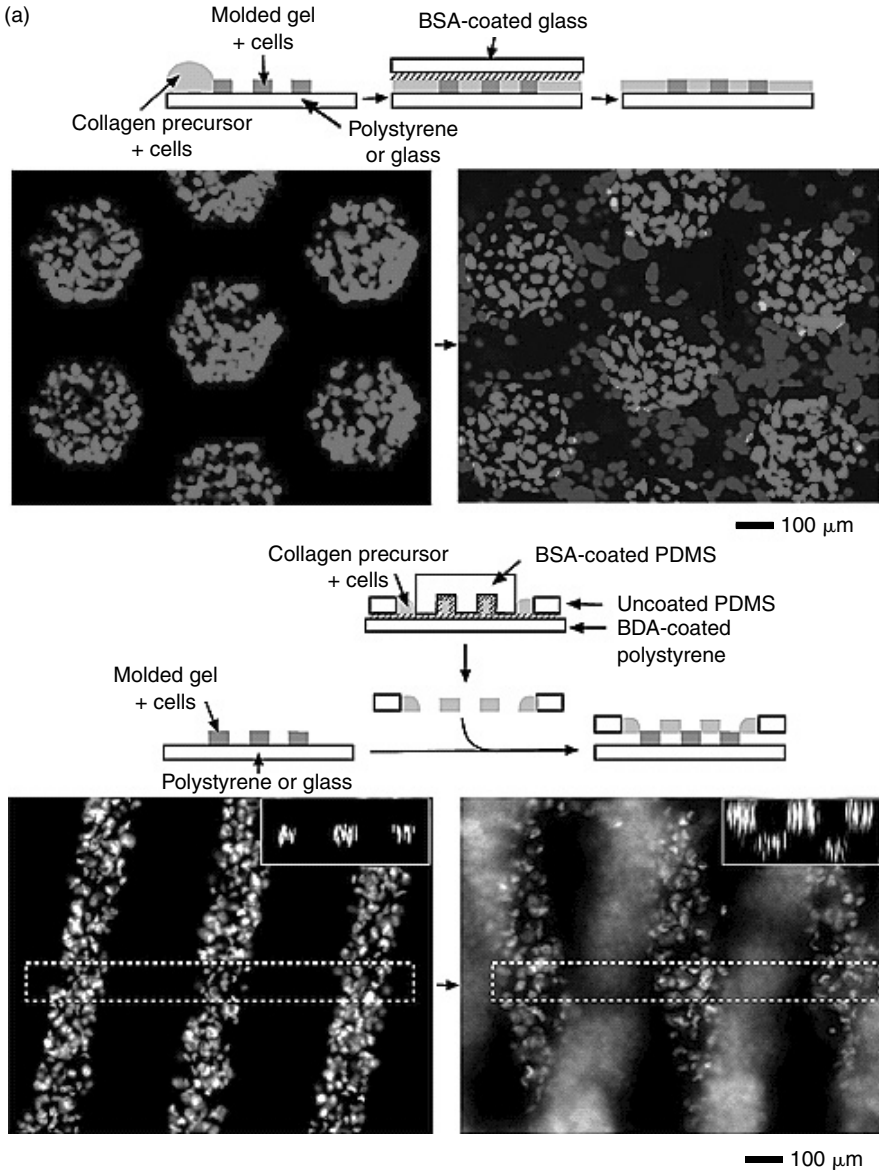
At this point, it is worth noting that there is limited data regarding the actual *local* mechanical properties of native and diseased tissues. Rather, our knowledge of tissue mechanical properties is largely based on *macroscopic* mechanical measurements. The lack of mechanical property characterization at the microscale


FIGURE 46.5 (See color insert following page **32**-14.) Schematic diagrams of the microfabrication of composite gels, and fluorescence images of cells in these gels. The shaded regions represent collagen gels in which fibroblasts are embedded. (a) (Left) An array of hexagonal gels (100 m on a side, 100 m thick) and cells on a glass coverslip. (Right) A composite structure that consists of an array of isolated hexagonal gels and a separate gel filling the spaces between the isolated gels on a glass coverslip. Fibroblasts in and between the hexagonal gels were prelabeled with green and red fluorescent dyes, respectively. (b) (Left) Lines (100 m wide, 100 m thick) of gel and cells formed by MIMIC on a glass coverslip. Nuclei of fibroblasts were labeled with the fluorescent dye Hoechst 33342 (1 g/ml; Molecular Probes). (Right) A bilayered structure that is composed of two layers of lines at a relative angle of ∼30 on a glass coverslip. The top layer is in focus, and the layer below is out-of-focus. (Insets) Cross-sectional views (corresponding to the regions outlined by dashed boxes) of deconvolved images. (Reproduced from Tang, M.D., A.P. Golden, and J. Tien, *J. Am. Chem. Soc.*, 2003, **125**: 12988-9. With permission.)
FIGURE 46.6 Methods for generating elastic substrata with gradients in mechanical properties. (a) Acrylamide is photopolymerized under transparency masks with varying degrees of opacity [33]. The radial gradient pattern boxed on the left can be used to create a substrate shown on the right with the 'map' of its mechanical properties (Young's modulus). (b) Acrylamide is photopolymerized using a combination of microfluidics and photopolymerization [34]. The gradient generator is used to create a gradient in the cross-linker (bis-acrylamide). The width of the gel is ~ 3 mm, and the gradient in the Young's modulus (as determined from atomic force microscopy) is approximately 12 Pa/μm. (Reproduced from Wong, J.Y., J.B. Leach, and Z.Q. Brown, *Surf. Sci.*, 2004, **570**: 119–33. With permission.)

is in part due to the limited number of techniques (e.g., modified atomic force microscopy [36]) that are able to measure the mechanical properties of hydrated tissues at this length-scale. Recently, we have developed a simple, inexpensive microindentation technique that is able to measure the local mechanical properties of hydrated biomaterials and tissue samples at the microscale [37]. While it is interesting that a number of different cell types have recently been shown to respond to changes in the mechanical properties of the substrate (see Reference 9), the measurement of the *local* mechanical properties of native and diseased tissues will be critical to establish clinical relevance when developing model *in vitro* biomaterial systems with physiologically matched mechanical properties.

46.4.3 Studies of Tissue Engineering Scaffolds with Nanoscale Features

Recently studies have been published that demonstrate enhanced cell growth, adhesion, and differentiation in the presence of nanoparticles or nanostructured coatings. In orthopedics, the fabrication of nanostructured ceramic coatings for total joint replacements has resulted in enhanced cell growth and bone remodeling *in vitro* [38]. Modified plasma spray processes have produced nanoscale hydroxyapatite coatings [39] for the same application. Hydrogel materials that either incorporate [40] or stimulate the nucleation of nanometer sized hydroxyapatite particles [41] have been demonstrated to form reasonable bone mimics. Tan and Saltzman [42] created a hierarchical bone-culture system employing microscale features coated with a nanoscale mineral phase. They were able to control both cell orientation and shape by modulating their surfaces. Further study will show if these materials will be successful as tissue engineering implants.

Several researchers focused on engineering soft tissues have also begun to employ nanostructured materials in the laboratory. Hydrogel materials with specific ligands for cell adhesion have been designed to affect desired cell-signaling events in native or implanted cells. A good review is provided by Boontheekul and Mooney [43]. Nerve tissue regeneration has been driven by the idea that if you can form a sheath of material of the appropriate size, then severed nerve endings will grow toward each other through it. Tubes have been made of silicone, collagen, and other synthetic and natural polymer materials. One common conclusion of much of this research is that not only do the regenerating axons need the mechanical cues provided by the artificial tube, but also most likely require the appropriate chemical signals at

the nanoscale to drive complete and functional regeneration. Some researchers have begun to incorporate peptide sequences known to be neurotrophic in their tube-filling materials [44].

Hepatocytes, which are difficult to culture *in vitro* were cultured on gold nanoparticles to create a gold/hepatocyte colloidal solution [45]. The researchers were able to demonstrate increased proliferation and activity of the cells in culture.

Nanostructured poly(lactic-co-glycolic acid) (PGLA) created through chemical etching techniques was shown to increase the number and function of bladder smooth muscle cells in tissue engineering scaffolds intended for the regeneration of the bladder [46,47]. The authors attribute this result to the nanoscale surface topography, which they say more closely mimics the *in vitro* environment of soft tissue cells. Operating under similar assumptions, Zhang and Ma [48] developed a tissue engineering scaffold in poly(L-lactic acid) (PLLA) having micrometer scale pores with walls exhibiting nanofibrous features using a phase separation technique. These scaffolds were compared with scaffolds made from the same material with micropores that had smooth walls. Differences in adsorption of extracellular proteins into the scaffolds were studied using Western blot analysis [49]. The nanofibrous materials adsorbed more proteins than the smooth-walled scaffolds. Specifically, more fibronectin and vitronectin was adsorbed onto the nanostructured materials. The nanofibrous materials also enhanced adhesion of MC3T3-E1 osteoblasts when compared to the smooth-walled scaffolds.

Modified electrospray techniques have been used to produce polymer meshes for tissue scaffolds that have nanometer-scale fibers. This process involves injecting a polymer solution through a charged needle onto a substrate some distance away from the injection point. A mat of material can be made in varying thicknesses, and this mat can be cut or molded into the desired shape. Scaffolds of nanoscale fibers have been formed from poly(D,L-lactide-co-glycolide [50], collagen and elastin [51], and poly(D,L-lactide)-poly(ethylene glycol) (PLA-PEG) [52].

Nanoscale surface roughness can also affect cell differentiation. A recently developed technique for growing bone-like minerals on a hydrolyzed poly(lactide-co-glycolide) substrate by incubating in a salt-rich simulated body fluid was used to create bone mimics by Mooney et al. [53]. The resulting mineral layer displays a plate-like nanostructure similar to natural bone. Mesenchymal stem cells cultured under osteoblast inducing conditions were grown on both smooth substrate and mineralized substrate. Surprisingly, the mineralized substrate inhibited differentiation of the stem cells. In a similar work by Jansen et al. [54], surfaces roughness at the micron scale showed no effect on the differentiation of rat bone marrow cells under osteogenic conditions. Understanding both the chemical and nanoscale topographical signals necessary for differentiation will thus be essential for the development of stem-cell-based tissue-engineered constructs.

46.5   Impact of Nanoscale Processing on Biomaterial Properties

Recently there have been a number of reports of biomaterials that exploit molecular self-assembly processes. For example, repeating peptide sequences and synthetic polymers that form gels at neutral pH and body temperature are attractive materials for injectable scaffold materials [55]. A good review of these materials is found in Zhang et al. [56]. These materials will probably not be able to replace structural tissues in the near term, but are promising as materials for filling defects in these and other soft tissues. While these materials in general do not have nanoscale features, they are products of nanotechnology in that they are designed from the bottom up using solid-phase peptide synthesis. Stupp and coworkers [57] describe the formation of peptide amphiphiles that self-assemble to form nanostructures similar to extracellular matrix. They also demonstrated the ability of these nanostructures to nucleate hydroxyapatite nanocrystals from solution. Deming and coworkers [58] describe hydrogel formation from repeating polypeptide amphiphiles. By using these engineered materials in lieu of naturally occurring proteins, they describe enhanced control over the mechanical properties and processing of these biocompatible gels.

Some of the processing techniques described here require the application of either harsh chemicals or high temperatures. Before these materials can be exposed to cells or implanted into the body,

they need to undergo extensive washing and in some cases sterilization. If nanostructured or micro/nanostructured materials prove to be advantageous for tissue engineering applications, more biocompatible manufacturing techniques will need to be developed.

46.6 Issues with Immune Response to Nanoparticles and Tissue Engineering Biomaterials

It has long been known in the orthopedic community that particles formed during the wear of total joint replacements will elicit an immune response in the body that can become chronic and systemic over the lifetime of an implant [59]. These particles are particularly troublesome when they are submicron in size and often lead to osteolysis, or pathological bone resorption [60–62] The cells responsible for digestion of these foreign particles, macrophages, initiate a more aggressive immune response to particles that are submicron in size [63,64] Total joint replacements are made of both polymer and metal components, and wear particles of both classes of materials have been found in tissues and organs throughout the bodies of patients wearing these devices [65].

Studies in the total joint replacement field should be a warning to those researchers attempting to use nanoparticles in imaging, detection, and tissue engineering applications. In fact, a recent study on polymer-based colloidal drug delivery systems found that nanoparticles from these injections are recognized and engulfed by the macrophages of the reticuloendothelial system [66] In addition, Akerman et al. [67] demonstrated that quantum dots (3–5 nm in size) used as fluorescent probes *in vivo* accumulated in the liver and the spleen of mice. This effect was eliminated by coating the quantum dots with polyethylene glycol. Given what we know about how submicron particle stimulate the immune system, it will be very important to consider what side effects nanoparticles of all types might have on all of the systems in the body.

One method of circumventing immune response is to encapsulate tissue-engineered constructs within immunoisolation membranes. By creating pores on the nanoscale, Desai et al. [68] have been able to prevent immune cells, antibodies, and complement from reaching the cells and biomaterials within the capsule, while allowing nutrients and products, such as insulin, to diffuse in and out of the capsule. Although, the cells and scaffold are not subject to an immune response, encapsulation devices, as with all implanted devices, will still have strong immune reactions at the biomaterial surface. To mitigate negative immune reactions, Desai et al. [69] have modified the outer surface of their biocapsule with PEG. *In vivo* studies suggest that the modified biocapsule elicits minimal fibrotic tissue development and no significant host response.

46.7 Summary

Recent advances in biomaterials science have allowed for greater control over materials chemistry and mechanical properties at smaller and smaller size scales. In addition to these advances, it is becoming more straightforward to test the molecular level response of cells to biomaterials. Only through the implementation of highly controlled biomaterials processing and characterization combined with a deeper understanding of cell response to synthetic microenvironments will the regeneration of more complicated tissues be possible.

VI

Biomechanics

Donald R. Peterson
University of Connecticut Health Center

BIOMECHANICS IS DEEPLY ROOTED THROUGHOUT scientific history and has been influenced by the research work of early mathematicians, engineers, physicists, biologists, and physicians. Not one of these disciplines can claim sole responsibility for maturing biomechanics to its current state; rather, it has been a conglomeration and integration of these disciplines, involving the application of mathematics, physical principles, and engineering methodologies, that have been responsible for its advancement. Several examinations exist that offer a historical perspective on biomechanics in dedicated chapters within a variety of biomechanics textbooks. For this reason, a historical perspective is not presented within this brief introduction and it is left to the reader to discover the material within one of these textbooks. As an example, Fung (1993) provides a reasonably detailed synopsis of those who were influential to the progress of biomechanical understanding. A review of this material and similar material from other authors commonly shows that biomechanics has occupied the thoughts of some of the most conscientious minds involved in a variety of sciences.

The study of biomechanics, or biological mechanics, employs the principles of mechanics, which is a branch of the physical sciences that investigates the effects of energy and forces on matter or material systems. Biomechanics often embraces a broad range of subject matter that may include aspects of classical mechanics, material science, fluid mechanics, heat transfer, and thermodynamics, in an attempt to model and predict the mechanical behaviors of living systems. As such, it may be called the "liberal arts" of the biomedical engineering sciences.

The contemporary approach to solving problems in biomechanics typically follows a sequence of fundamental steps that are commonly defined as observation, experimentation, theorization, validation,

and application. These steps are the basis of the engineering methodologies and their significance is emphasized within a formal education of the engineering sciences, especially biomedical engineering. Each step is considered to be equally important and an iterative relationship between steps, with mathematics serving as the common link, is often necessary in order to converge on a practical understanding of the system in question. An engineering education that ignores these interrelated fundamentals may produce engineers who are ignorant of the ways in which real-world phenomena differs from mathematical models. Since most biomechanical systems are inherently complex and cannot be adequately defined using only theory and mathematics, biomechanics should be considered as a discipline whose progress relies heavily on research and the careful implementation of this approach. When a precise solution is not obtainable, utilizing this approach will assist in identifying critical physical phenomena and obtaining approximate solutions that may provide a deeper understanding as well as improvements to the investigative strategy. Not surprisingly, the need to identify critical phenomena and obtain approximate solutions seems to be more significant in biomedical engineering than any other engineering discipline, which is primarily due to the complex biological processes involved.

Applications of biomechanics have traditionally focused on modeling the system-level aspects of the human body, such as the musculoskeletal system, the respiratory system, and the cardiovascular and cardiopulmonary systems. Technologically, most progress has been made on system-level device development and implementation, with obvious implications on athletic performance, work environment interaction, clinical rehabilitation, orthotics, prosthetics, and orthopaedic surgery. However, more recent biomechanics initiatives are now focusing on the mechanical behaviors of the biological subsystems, such as tissues, cells, and molecules, in order to relate subsystem functions across all levels by showing how mechanical function is closely associated with certain cellular and molecular processes. These initiatives have a direct impact on the development of biological nano- and microtechnologies involving polymer dynamics, biomembranes, and molecular motors. The integration of system and subsystem models will enhance our overall understanding of human function and performance and advance the principles of biomechanics. Even still, our modern understanding about certain biomechanic processes is limited, but through ongoing biomechanics research, new information that influences the way we think about biomechanics is generated and important applications that are essential to the betterment of human existence are discovered. As a result, our limitations are reduced and our understanding becomes more refined. Recent advances in biomechanics can also be attributed to advances in experimental methods and instrumentation, such as computational and imaging capabilities, which are also subject to constant progress. Therefore, the need to revise and add to the current selections presented within this section becomes obvious, ensuring the presentation of modern viewpoints and developments.

The third edition of this section presents a total of 20 chapters, 12 of which have been substantially updated and revised to meet this criterion. It also includes a new chapter introducing the importance of mechanics on a cellular level. These 20 selections present material from respected scientists with diverse backgrounds in biomechanics research and application. The presentation of the chapters within this section has been organized in an attempt to present the material in a systematic manner. The first group of chapters is related to musculoskeletal mechanics and includes hard and soft tissue mechanics, joint mechanics, and applications related to human function. The next group of chapters covers several aspects of biofluid mechanics and includes a wide range of circulatory dynamics, such as blood vessel and blood cell mechanics, and transport. It is followed by the new addition to this section, which introduces current methods and strategies for modeling cellular mechanics. The next group consists of two chapters introducing the mechanical functions and significance of the human ear. Finally, the remaining two chapters introduce performance characteristics of the human body system during exercise and exertion. It is the overall intention of this section to serve as a reference to the skilled professional as well as an introduction to the novice or student of biomechanics. Throughout all the editions of the biomechanics section, an attempt was made to incorporate material that covers a bulk of the biomechanics field; however, as biomechanics continues to grow, some topics may be inadvertently omitted causing a disproportionate

presentation of the material. Suggestions and comments from readers are welcome on subject matter that may be considered for future editions.

Mechanics of Hard Tissue

J. Lawrence Katz
University of Missouri-Kansas City

Hard tissue, *mineralized tissue*, and *calcified tissue* are often used as synonyms for bone when describing the structure and properties of bone or tooth. The *hard* is self-evident in comparison with all other mammalian tissues, which often are referred to as *soft tissues*. Use of the terms mineralized and calcified arises from the fact that, in addition to the principle protein, collagen, and other proteins, glycoproteins, and protein-polysaccherides, comprising about 50% of the volume, the major constituent of bone is a calcium phosphate (thus the term *calcified*) in the form of a crystalline carbonate **apatite** (similar to naturally occurring minerals, thus the term *mineralized*). Irrespective of its biological function, bone is one of the most interesting materials known in terms of structure–property relationships. Bone is an anisotropic, heterogeneous, inhomogeneous, nonlinear, thermorheologically complex viscoelastic material. It exhibits electromechanical effects, presumed to be due to streaming potentials, both *in vivo* and *in vitro* when wet. In the dry state, bone exhibits piezoelectric properties. Because of the complexity of the structure–property relationships in bone, and the space limitation for this chapter, it is necessary to concentrate on one aspect of the mechanics. Currey [1984] states unequivocally that he thinks, "the most important feature of bone material is its stiffness." This is, of course, the premiere consideration for the weight-bearing long bones. Thus, this chapter will concentrate on the elastic and viscoelastic properties of compact **cortical bone** and the elastic properties of trabecular bone as exemplar of mineralized tissue mechanics.

47.1   Structure of Bone

The complexity of bone's properties arises from the complexity in its structure. Thus it is important to have an understanding of the structure of mammalian bone in order to appreciate the related properties. Figure 47.1 is a diagram showing the structure of a human femur at different levels [Park, 1979]. For convenience, the structures shown in Figure 47.1 will be grouped into four levels. A further subdivision of structural organization of mammalian bone is shown in Figure 47.2 [Wainwright et al., 1982]. The individual figures within this diagram can be sorted into one of the appropriate levels of structure shown on Figure 47.1 as described in the following. At the smallest unit of structure we have the *tropocollagen* molecule and the associated apatite crystallites (abbreviated Ap). The former is approximately 1.5 by 280 nm, made up of three individual left-handed helical polypeptide (alpha) chains coiled into a right-handed triple helix. Ap crystallites have been found to be carbonate-substituted hydroxyapatite, generally thought to be nonstoichiometric. The crystallites appear to be about $4 \times 20 \times 60$ nm in size. This level is denoted the *molecular*. The next level we denote the *ultrastructural*. Here, the collagen and Ap are intimately associated and assembled into a microfibrilar composite, several of which are then assembled into fibers from approximately 3 to 5 μm thick. At the next level, the *microstructural*, these fibers are either randomly arranged (woven bone) or organized into concentric lamellar groups (**osteons**) or linear lamellar groups (**plexiform bone**). This is the level of structure we usually mean when we talk about bone *tissue* properties. In addition to the differences in lamellar organization at this level, there are also two different types of architectural structure. The dense type of bone found, for example, in the shafts of long bone is known as compact or *cortical bone*. A more porous or spongy type of bone is found, for example, at the articulating ends of long bones. This is called **cancellous bone**. It is important to note that the material and structural organization of collagen–Ap making up osteonic or *haversian* bone and plexiform bone are the same as the material comprising cancellous bone.
FIGURE 47.2 Diagram showing the structure of mammalian bone at different levels. Bone at the same level is drawn at the same magnification. The arrows show what types may contribute to structures at higher levels [Wainwright et al., 1982]. (Courtesy Princeton University Press.) (a) Collagen fibril with associated mineral crystals. (b) Woven bone. The collagen fibrils are arranged more or less randomly. Osteocytes are not shown. (c) Lamellar bone. There are separate lamellae, and the collagen fibrils are arranged in "domains" of preferred fibrillar orientation in each lamella. Osteocytes are not shown. (d) Woven bone. Blood channels are shown as large black spots. At this level woven bone is indicated by light dotting. (e) Primary lamellar bone. At this level lamellar bone is indicated by fine dashes. (f) **Haversian bone**. A collection of Haversian systems, each with concentric lamellae round a central blood channel. The large black area represents the cavity formed as a cylinder of bone is eroded away. It will be filled in with concentric lamellae and form a new Haversian system. (g) Laminar bone. Two blood channel networks are exposed. Note how layers of woven and lamellar bone alternate. (h) Compact bone of the types shown at the lower levels. (i) Cancellous bone.

Finally, we have the whole bone itself constructed of osteons and portions of older, partially destroyed osteons (called **interstitial lamellae**) in the case of humans or of osteons and/or plexiform bone in the case of mammals. This we denote the *macrostructural level*. The elastic properties of the whole bone results from the hierarchical contribution of each of these levels.

TABLE 47.1   Composition of Adult Human and Bovine Cortical Bone

Species	% H_2O	Ap	% Dry weight collagen	GAG[a]	Reference
Bovine	9.1	76.4	21.5	N.D[b]	Herring, 1977
Human	7.3	67.2	21.2	0.34	Pellagrino and Blitz, 1965; Vejlens, 1971

[a] Glycosaminoglycan.
[b] Not determined.

47.2 Composition of Bone

The composition of bone depends on a large number of factors: the species, which bone, the location from which the sample is taken, and the age, sex, and type of bone tissue, for example, woven, cancellous, cortical. However, a rough estimate for overall composition by volume is one-third Ap, one-third collagen and other organic components, and one-third H_2O. Some data in the literature for the composition of adult human and bovine cortical bone are given in Table 47.1.

47.3 Elastic Properties

Although bone is a viscoelastic material, at the quasi-static strain rates in mechanical testing and even at the ultrasonic frequencies used experimentally, it is a reasonable first approximation to model cortical bone as an anisotropic, linear elastic solid with Hooke's law as the appropriate constitutive equation. Tensor notation for the equation is written as:

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl} \tag{47.1}$$

where σ_{ij} and ε_{kl} are the second-rank stress and infinitesimal second rank strain tensors, respectively, and C_{ijkl} is the fourth-rank elasticity tenor. Using the reduced notation, we can rewrite Equation 47.1 as

$$\sigma_i = C_{ij}\epsilon_j \quad i,j = 1 \text{ to } 6 \tag{47.2}$$

where C_{ij} are the stiffness coefficients (elastic constants). The inverse of the C_{ij}, the S_{ij}, are known as the *compliance coefficients.*

The anisotropy of cortical bone tissue has been described in two symmetry arrangements. Lang [1969], Katz and Ukraincik [1971], and Yoon and Katz [1976a,b] assumed bone to be transversely isotropic with the bone axis of symmetry (the 3 direction) as the unique axis of symmetry. Any small difference in elastic properties between the radial (1 direction) and transverse (2 direction) axes, due to the apparent gradient in porosity from the periosteal to the endosteal sides of bone, was deemed to be due essentially to the defect and did not alter the basic symmetry. For a transverse isotropic material, the stiffness matrix $[C_{ij}]$ is given by

$$[C_{ij}] = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{11} & C_{13} & 0 & 0 & 0 \\ C_{13} & C_{13} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{44} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \tag{47.3}$$

where $C_{66} = \frac{1}{2}(C_{11} - C_{12})$. Of the 12 nonzero coefficients, only 5 are independent.

However, Van Buskirk and Ashman [1981] used the small differences in elastic properties between the radial and tangential directions to postulate that bone is an **orthotropic** material; this requires that 9 of

the 12 nonzero elastic constants be independent, that is,

$$[C_{ij}] = \begin{bmatrix} C_{11} & C_{12} & C_{13} & 0 & 0 & 0 \\ C_{12} & C_{22} & C_{23} & 0 & 0 & 0 \\ C_{13} & C_{23} & C_{33} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & C_{66} \end{bmatrix} \tag{47.4}$$

Corresponding matrices can be written for the compliance coefficients, the S_{ij}, based on the inverse equation to Equation 47.2:

$$\varepsilon_i = S_{ij}\sigma_j \quad i, j = 1 \text{ to } 6 \tag{47.5}$$

where the S_{ij}th compliance is obtained by dividing the $[C_{ij}]$ stiffness matrix, minus the ith row and jth column, by the full $[C_{ij}]$ matrix and vice versa to obtain the C_{ij} in terms of the S_{ij}. Thus, although $S_{33} = 1/E_3$, where E_3 is Young's modulus in the bone axis direction, $E_3 \neq C_{33}$, since C_{33} and S_{33}, are not reciprocals of one another even for an isotropic material, let alone for **transverse isotropy** or orthotropic symmetry.

The relationship between the compliance matrix and the technical constants such as Young's modulus (Ei) shear modulus (Gi) and Poisson's ratio (v_{ij}) measured in mechanical tests such as uniaxial or pure shear is expressed in Equation 47.6.

$$[S_{ij}] = \begin{bmatrix} \dfrac{1}{E_1} & \dfrac{-v_{21}}{E_2} & \dfrac{-v_{31}}{E_3} & 0 & 0 & 0 \\ \dfrac{-v_{12}}{E_1} & \dfrac{1}{E_2} & \dfrac{-v_{32}}{E_3} & 0 & 0 & 0 \\ \dfrac{-v_{13}}{E_1} & \dfrac{-v_{23}}{E_2} & \dfrac{1}{E_3} & 0 & 0 & 0 \\ 0 & 0 & 0 & \dfrac{1}{G_{23}} & 0 & 0 \\ 0 & 0 & 0 & 0 & \dfrac{1}{G_{31}} & 0 \\ 0 & 0 & 0 & 0 & 0 & \dfrac{1}{G_{12}} \end{bmatrix} \tag{47.6}$$

Again, for an orthotropic material, only 9 of the above 12 nonzero terms are independent, due to the symmetry of the S_{ij} tensor:

$$\frac{v_{12}}{E_1} = \frac{v_{21}}{E_2} \quad \frac{v_{13}}{E_1} = \frac{v_{31}}{E_3} \quad \frac{v_{23}}{E_2} = \frac{v_{32}}{E_3} \tag{47.7}$$

For the transverse isotropic case, Equation 47.5 reduces to only 5 independent coefficients, since

$$E_1 = E_2 \quad v_{12} = v_{21} \quad v_{31} = v_{32} = v_{13} = v_{23}$$

$$G_{23} = G_{31} \quad G_{12} = \frac{E_1}{2(1 + v_{12})} \tag{47.8}$$

In addition to the mechanical tests cited above, ultrasonic wave propagation techniques have been used to measure the anisotropic elastic properties of bone [Lang, 1969; Yoon and Katz, 1976a, b; Van Buskirk and Ashman, 1981]. This is possible, since combining Hooke's law with Newton's second law results in a wave

equation which yields the following relationship involving the stiffness matrix:

$$\rho V^2 U_m = C_{mrns} N_r N_s U_n \tag{47.9}$$

where ρ is the density of the medium, V is the wave speed, and $\mathbf{U}$ and $\mathbf{N}$ are unit vectors along the particle displacement and wave propagation directions, respectively, so that U_m, N_r, etc. are direction cosines.

Thus to find the five transverse isotropic elastic constants, at least five independent measurements are required, for example, a dilatational longitudinal wave in the 2 and 1(2) directions, a transverse wave in the 13(23) and 12 planes, etc. The technical moduli must then be calculated from the full set of C_{ij}. For improved statistics, redundant measurements should be made. Correspondingly, for orthotropic symmetry, enough independent measurements must be made to obtain all 9 C_{ij}; again, redundancy in measurements is a suggested approach.

One major advantage of the ultrasonic measurements over mechanical testing is that the former can be done with specimens too small for the latter technique. Second, the reproducibility of measurements using the former technique is greater than for the latter. Still a third advantage is that the full set of either five or nine coefficients can be measured on one specimen, a procedure not possible with the latter techniques. Thus, at present, most of the studies of elastic anisotropy in both human and other mammalian bone are done using ultrasonic techniques. In addition to the bulk wave type measurements described above, it is possible to obtain Young's modulus directly. This is accomplished by using samples of small cross sections with transducers of low frequency so that the wavelength of the sound is much larger than the specimen size. In this case, an extensional longitudinal (bar) wave is propagated (which experimentally is analogous to a uniaxial mechanical test experiment), yielding

$$V^2 = \frac{E}{\rho} \tag{47.10}$$

This technique was used successfully to show that bovine plexiform bone was definitely orthotropic while bovine haversian bone could be treated as transversely isotropic [Lipson and Katz, 1984]. The results were subsequently confirmed using bulk wave propagation techniques with considerable redundancy [Maharidge, 1984].

Table 47.2 lists the C_{ij} (in GPa) for human (haversian) bone and bovine (both haversian and plexiform) bone. With the exception of Knet's [1978] measurements, which were made using quasi-static mechanical testing, all the other measurements were made using bulk ultrasonic wave propagation.

In Maharidge's study [1984], both types of tissue specimens, haversian and plexiform, were obtained from different aspects of the same level of an adult bovine femur. Thus the differences in C_{ij} reported between the two types of bone tissue are hypothesized to be due essentially to the differences in

TABLE 47.2 Elastic Stiffness Coefficients for Various Human and Bovine Bones

Experiments (bone type)	C_{11} (GPa)	C_{22} (GPa)	C_{33} (GPa)	C_{44} (GPa)	C_{55} (GPa)	C_{66} (GPa)	C_{12} (GPa)	C_{13} (GPa)	C_{23} (GPa)
Van Buskirk and Ashman [1981] (bovine femur)	14.1	18.4	25.0	7.00	6.30	5.28	6.34	4.84	6.94
Knets [1978] (human tibia)	11.6	14.4	22.5	4.91	3.56	2.41	7.95	6.10	6.92
Van Buskirk and Ashman [1981] (human femur)	20.0	21.7	30.0	6.56	5.85	4.74	10.9	11.5	11.5
Maharidge [1984] (bovine femur haversian)	21.2	21.0	29.0	6.30	6.30	5.40	11.7	12.7	11.1
Maharidge [1984] (bovine femur plexiform)	22.4	25.0	35.0	8.20	7.10	6.10	14.0	15.8	13.6

All measurements made with ultrasound except for Knets [1978] mechanical tests.
FIGURE 47.3 Diagram showing how laminar (plexiform) bone (a) differs more between radial and tangential directions (R and T) than does haversian bone (b). The arrows are vectors representing the various directions [Wainwright et al., 1982] (Courtesy Princeton University Press).

microstructural organization (Figure 47.3) [Wainwright et al., 1982]. The textural symmetry at this level of structure has dimensions comparable to those of the ultrasound wavelengths used in the experiment, and the molecular and ultrastructural levels of organization in both types of tissues are essentially identical. Note that while C_{11}, almost equals C_{22} and that C_{44} and C_{55} are equal for bovine haversian bone, C_{11} and C_{22} and C_{44} and C_{55} differ by 11.6 and 13.4%, respectively, for bovine plexiform bone. Similarly, although C_{66} and $\frac{1}{2}(C_{11} - C_{12})$ differ by 12.0% for the haversian bone, they differ by 31.1% for plexiform bone. Only the differences between C_{13} and C_{23} are somewhat comparable: 12.6% for haversian bone and 13.9% for plexiform. These results reinforce the importance of modeling bone as a hierarchical ensemble in order to understand the basis for bone's elastic properties as a composite material-structure system in which the collagen–Ap components define the material composite property. When this material property is entered into calculations based on the microtextural arrangement, the overall anisotropic elastic anisotropy can be modeled.

The human femur data [Van Buskirk and Ashman, 1981] support this description of bone tissue. Although they measured all nine individual C_{ij}, treating the femur as an orthotropic material, their results are consistent with a near transverse isotropic symmetry. However, their nine C_{ij} for bovine femoral bone clearly shows the influence of the orthotropic microtextural symmetry of the tissue's plexiform structure.

The data of Knets [1978] on human tibia are difficult to analyze. This could be due to the possibility of significant systematic errors due to mechanical testing on a large number of small specimens from a multitude of different positions in the tibia.

The variations in bone's elastic properties cited earlier above due to location is appropriately illustrated in Table 47.3, where the mean values and standard deviations (all in GPa) for all g orthotropic C_{ij} are given for bovine cortical bone at each aspect over the entire length of bone.

Since the C_{ij} are simply related to the "technical" elastic moduli, such as Young's modulus (E), shear modulus (G), bulk modulus (K), and others, it is possible to describe the moduli along any given direction. The full equations for the most general anisotropy are too long to present here. However, they can be found in Yoon and Katz [1976a]. Presented below are the simplified equations for the case of transverse isotropy. Young's modulus is

$$\frac{1}{E(\gamma_3)} = S'_{33} = (1 - \gamma_3^2)2S_{11} + \gamma_3^4 S_{33} + \gamma_3^2(1 - \gamma_3^2)(2S_{13} + S_{44}) \tag{47.11}$$

where $\gamma_3 = \cos\phi$, and ϕ is the angle made with respect to the bone (3) axis.

TABLE 47.3   Mean Values and Standard Deviations for the C_{ij} Measured by Van Buskirk and Ashman [1981] at Each Aspect Over the Entire Length of Bone (all Values in GPa)

	Anterior	Medial	Posterior	Lateral
C_{11}	18.7 ± 1.7	20.9 ± 0.8	20.1 ± 1.0	20.6 ± 1.6
C_{22}	20.4 ± 1.2	22.3 ± 1.0	22.2 ± 1.3	22.0 ± 1.0
C_{33}	28.6 ± 1.9	30.1 ± 2.3	30.8 ± 1.0	30.5 ± 1.1
C_{44}	6.73 ± 0.68	6.45 ± 0.35	6.78 ± 1.0	6.27 ± 0.28
C_{55}	5.55 ± 0.41	6.04 ± 0.51	5.93 ± 0.28	5.68 ± 0.29
C_{66}	4.34 ± 0.33	4.87 ± 0.35	5.10 ± 0.45	4.63 ± 0.36
C_{12}	11.2 ± 2.0	11.2 ± 1.1	10.4 ± 1.0	10.8 ± 1.7
C_{13}	11.2 ± 1.1	11.2 ± 2.4	11.6 ± 1.7	11.7 ± 1.8
C_{23}	10.4 ± 1.4	11.5 ± 1.0	12.5 ± 1.7	11.8 ± 1.1

The shear modulus (rigidity modulus or torsional modulus for a circular cylinder) is

$$\frac{1}{G(\gamma_3)} = \frac{1}{2}(S'_{44} + S'_{55}) = S_{44} + (S_{11} - S_{12}) - \frac{1}{2}S_{44}(1 - \gamma_3^2)$$
$$+ 2(S_{11} + S_{33} - 2S_{13} - S_{44})\gamma_3^2(1 - \gamma_3^2)$$

(47.12)

where, again $\gamma_3 = \cos\phi$.

The bulk modulus (reciprocal of the volume compressibility) is

$$\frac{1}{K} = S_{33} + 2(S_{11} + S_{12} + 2S_{13}) = \frac{C_{11} + C_{12} + 2C_{33} - 4C_{13}}{C_{33}(C_{11} + C_{12}) - 2C_{13}^2}$$

(47.13)

Conversion of Equation 47.11 and Equation 47.12 from S_{ij} to C_{ij} can be done by using the following transformation equations:

$$S_{11} = \frac{C_{22}C_{33} - C_{23}^2}{\Delta} \quad S_{22} = \frac{C_{33}C_{11} - C_{13}^2}{\Delta}$$
$$S_{33} = \frac{C_{11}C_{22} - C_{12}^2}{\Delta} \quad S_{12} = \frac{C_{13}C_{23} - C_{12}C_{33}}{\Delta}$$
$$S_{13} = \frac{C_{12}C_{23} - C_{13}C_{22}}{\Delta} \quad S_{23} = \frac{C_{12}C_{13} - C_{23}C_{11}}{\Delta}$$
$$S_{44} = \frac{1}{C_{44}} \quad S_{55} = \frac{1}{C_{55}} \quad S_{66} = \frac{1}{C_{66}}$$

(47.14)

where

$$\Delta = \begin{bmatrix} C_{11} & C_{12} & C_{13} \\ C_{12} & C_{22} & C_{23} \\ C_{13} & C_{23} & C_{33} \end{bmatrix} = C_{11}C_{22}C_{33} + 2C_{12}C_{23}C_{13} - (C_{11}C_{23}^2 + C_{22}C_{13}^2 + C_{33}C_{12}^2)$$

(47.15)

In addition to data on the elastic properties of cortical bone presented above, there is also available a considerable set of data on the mechanical properties of cancellous (trabecullar) bone including measurements of the elastic properties of single trabeculae. Indeed as early as 1993, Keaveny and Hayes [1993] presented an analysis of 20 years of studies on the mechanical properties of trabecular bone. Most of the earlier studies used mechanical testing of bulk specimens of a size reflecting a cellular solid, that is, of the order of cubic mm or larger. These studies showed that both the modulus and strength of trabecular bone are strongly correlated to the apparent density, where apparent density, ρ_a, is defined as the product of individual trabeculae density, ρ_t, and the volume fraction of bone in the bulk specimen, V_f, and is given by $\rho_a = \rho_t V_f$.

TABLE 47.4 Elastic Moduli of Trabecular Bone Material Measured by Different Experimental Methods

Study	Method	Average modulus	(GPa)
Townsend et al. [1975]	Buckling	11.4	(Wet)
	Buckling	14.1	(Dry)
Ryan and Williams [1989]	Uniaxial tension	0.760	
Choi et al. [1992]	4-point bending	5.72	
Ashman and Rho [1988]	Ultrasound	13.0	(Human)
	Ultrasound	10.9	(Bovine)
Rho et al. [1993]	Ultrasound	14.8	
	Tensile test	10.4	
Rho et al. [1999]	Nanoindentation	19.4	(Longitudinal)
	Nanoindentation	15.0	(Transverse)
Turner et al. [1999]	Acoustic microscopy	17.5	
	Nanoindentation	18.1	
Bumrerraj and Katz [2001]	Acoustic microscopy	17.4	

Elastic moduli, E, from these measurements generally ranged from approximately 10 MPa to the order of 1 GPa depending on the apparent density and could be correlated to the apparent density in g/cc by a power law relationship, $E = 6.13P_a^{144}$, calculated for 165 specimens with an $r^2 = 0.62$ [Keaveny and Hayes, 1993].

With the introduction of micromechanical modeling of bone, it became apparent that in addition to knowing the bulk properties of trabecular bone it was necessary to determine the elastic properties of the individual trabeculae. Several different experimental techniques have been used for these studies. Individual trabeculae have been machined and measured in buckling, yielding a modulus of 11.4 GPa (wet) and 14.1 GPa (dry) [Townsend et al., 1975], as well as by other mechanical testing methods providing average values of the elastic modulus ranging from less than 1 GPa to about 8 GPa (Table 47.4). Ultrasound measurements [Ashman and Rho, 1988; Rho et al., 1993] have yielded values commensurate with the measurements of Townsend et al. [1975] (Table 47.4). More recently, acoustic microscopy and nanoindentation have been used, yielding values significantly higher than those cited above. Rho et al. [1999] using nanoindentation obtained average values of modulus ranging from 15.0 to 19.4 GPa depending on orientation, as compared to 22.4 GPa for osteons and 25.7 GPa for the interstitial lamellae in cortical bone (Table 47.4). Turner et al. [1999] compared nanoindentation and acoustic microscopy at 50 MHz on the same specimens of trabecular and cortical bone from a common human donor. While the nanoindentation resulted in Young's moduli greater than those measured by acoustic microscopy by 4 to 14%, the anisotropy ratio of longitudinal modulus to transverse modulus for cortical bone was similar for both modes of measurement; the trabecular values are given in Table 47.4. Acoustic microscopy at 400 MHz has also been used to measure the moduli of both human trabecular and cortical bone [Bumrerraj and Katz, 2001], yielding results comparable to those of Turner et al. [1999] for both types of bone (Table 47.4).

These recent studies provide a framework for micromechanical analyses using material properties measured on the microstructural level. They also point to using nano-scale measurements, such as those provided by atomic force microscopy (AFM), to analyze the mechanics of bone on the smallest unit of structure shown in Figure 47.1.

47.4 Characterizing Elastic Anisotropy

Having a full set of five or nine C_{ij} does permit describing the anisotropy of that particular specimen of bone, but there is no simple way of comparing the relative anisotropy between different specimens of the same bone or between different species or between experimenters' measurements by trying to relate individual C_{ij} between sets of measurements. Adapting a method from crystal physics

[Chung and Buessem, 1968] Katz and Meunier [1987] presented a description for obtaining two scalar quantities defining the compressive and shear anisotropy for bone with transverse isotropic symmetry. Later, they developed a similar pair of scalar quantities for bone exhibiting orthotropic symmetry [Katz and Meunier, 1990]. For both cases, the percentage compressive (Ac^*) and shear (As^*) elastic anisotropy are given, respectively, by

$$
Ac^*(\%) = 100 \frac{K^V - K_R}{K^V + K_R}
$$
$$
As^*(\%) = 100 \frac{G_V - G_R}{G_V + G_R}
$$

(47.16)

where K^V and K_R are the Voigt (uniform strain across an interface) and Reuss (uniform stress across an interface) bulk moduli, respectively, and G^V and G_R are the Voigt and Reuss shear moduli, respectively. The equations for K^V, K_R, G^V, and G_R are provided for both transverse isotropy and orthotropic symmetry in Appendix.

Table 47.5 lists the values of $As^*(\%)$ and $Ac^*(\%)$ for various types of hard tissues and apatites. The graph of $As^*(\%)$ vs. $Ac^*(\%)$ is given in Figure 47.4.

$As^*(\%)$ and $Ac^*(\%)$ have been calculated for a human femur, having both transverse isotropic and orthotropic symmetry, from the full set of Van Buskirk and Ashman [1981] C_{ij} data at each of the four aspects around the periphery, anterior, medial, posterior, and lateral, as denoted in Table 47.3, at fractional proximal levels along the femur's length, $Z/L = 0.3$ to 0.7. The graph of $As^*(\%)$ vs. Z/L, assuming transverse isotropy, is given in Figure 47.5. Note that the Anterior aspect, that is in tension during loading, has values of $As^*(\%)$ in some positions considerably higher than those of the other aspects. Similarly, the graph of $Ac^*(\%)$ vs. Z/L is given in Figure 47.6. Note here it is the posterior aspect that is in compression during loading, which has values of $Ac^*(\%)$ in some positions considerably higher than those of the other aspects. Both graphs are based on the transverse isotropic symmetry calculations; however, the identical trends were obtained based on the orthotropic symmetry calculations. It is clear that in addition to the moduli varying along the length and over all four aspects of the femur, the anisotropy varies as well, reflecting the response of the femur to the manner of loading.

Recently, Kinney et al. [2004] used the technique of resonant ultrasound spectroscopy (RUS) to measure the elastic constants (C_{ij}) of human dentin from both wet and dry samples. $As^*(\%)$ and $Ac^*(\%)$ calculated from these data are included in both Table 47.5 and Figure 47.4. Their data showed that the samples exhibited transverse isotropic symmetry. However, the C_{ij} for dry dentin implied even higher symmetry. Indeed, the result of using the average value for C_{11} and $C_{12} = 36.6$ GPa and the value for $C_{44} = 14.7$ GPa for dry dentin in the calculations suggests that dry human dentin is very nearly elastically isotropic. This isotropic-like behavior of the dry dentin may have clinical significance. There is independent experimental evidence to support this calculation of isotropy based on the ultrasonic data. Small angle x-ray diffraction

TABLE 47.5 $Ac*(\%)$ vs. $As*\%$ for Various Types of Hard Tissues and Apatites

Experiments (specimen type)	$Ac^*(\%)$	$As^*(\%)$
Van Buskirk et al. [1981] (bovine femur)	1.522	2.075
Katz and Ukraincik [1971] (OHAp)	0.995	0.686
Yoon (redone) in Katz [1984] (FAp)	0.867	0.630
Lang [1969,1970] (bovine femur dried)	1.391	0.981
Reilly and Burstein [1975] (bovine femur)	2.627	5.554

of human dentin yielded results implying isotropy near the pulp and mild anisotropy in mid-dentin [Kinney et al., 2001].

It is interesting to note that haversian bones, whether human or bovine, have both their compressive and shear anisotropy factors considerably lower than the respective values for plexiform bone. Thus, not only is plexiform bone both stiffer and more rigid than haversian bone, it is also more anisotropic. These two scalar anisotropy quantities also provide a means of assessing whether there is the possibility either of systematic errors in the measurements or artifacts in the modeling of the elastic properties of hard tissues. This is determined when the values of $Ac^*(\%)$ and/or $As^*(\%)$ are much greater than the close range of lower values obtained by calculations on a variety of different ultrasonic measurements (Table 47.5). A possible example of this is the value of $As^*(\%) = 7.88$ calculated from the mechanical testing data of Knets [1978], Table 47.2.

47.5 Modeling Elastic Behavior

Currey [1964] first presented some preliminary ideas of modeling bone as a composite material composed of a simple linear superposition of collagen and Ap. He followed this later [1969] with an attempt to take into account the orientation of the Ap crystallites using a model proposed by Cox [1952] for fiber-reinforced composites. Katz [1971a] and Piekarski [1973] independently showed that the use of Voigt and Reuss or even Hashin–Shtrikman [1963] composite modeling showed the limitations of using linear combinations of either elastic moduli or elastic compliances. The failure of all these early models could be traced to the fact that they were based only on considerations of material properties. This is comparable to trying to determine the properties of an Eiffel Tower built using a composite material by simply modeling the composite material properties without considering void spaces and the interconnectivity of the structure [Lakes, 1993]. In neither case is the complexity of the structural organization involved. This consideration of hierarchical organization clearly must be introduced into the modeling.

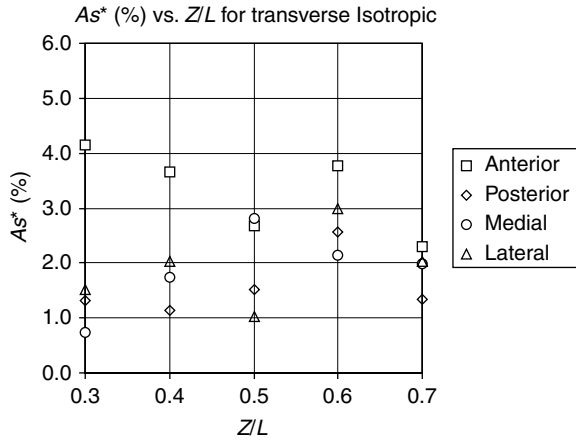
Katz in a number of papers [1971b, 1976] and meeting presentations put forth the hypothesis that haversian bone should be modeled as a hierarchical composite, eventually adapting a hollow fiber composite model by Hashin and Rosen [1964]. Bonfield and Grynpas [1977] used extensional (longitudinal) ultrasonic wave propagation in both wet and dry bovine femoral cortical bone specimens oriented at angles of 5, 10, 20, 40, 50, 70, 80, and 85° with respect to the long bone axis. They compared their experimental results for Young's moduli with the theoretical curve predicted by Currey's model [1969]; this is shown in Figure 47.7. The lack of agreement led them to "conclude, therefore that an alternative model is required to account for the dependence of Young's modulus on orientation" [Bonfield and Grynpas, 1977].


FIGURE 47.5   Values $As^*(\%)$ calculated from the data in Table 18.3 for human femoral bone, treated as having transverse isotropic symmetry, is plotted vs. Z/L for all four aspects, anterior, medial, posterior, lateral around the bone's periphery; Z/L is the fractional proximal distance along the femur's length.
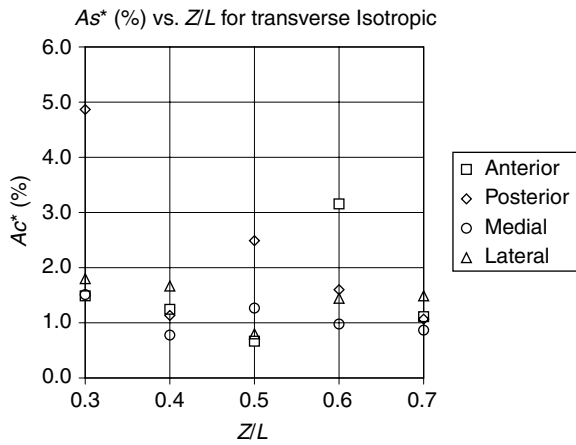

FIGURE 47.6   Values $Ac^*(\%)$ calculated from the data in Table 18.3 for human femoral bone, treated as having transverse isotropic symmetry, is plotted vs. Z/L for all four aspects, anterior, medial, posterior, lateral around the bone's periphery; Z/L is the fractional proximal distance along the femur's length.

Katz [1980, 1981], applying his hierarchical material-structure composite model, showed that the data in Figure 47.7 could be explained by considering different amounts of Ap crystallites aligned parallel to the long bone axis; this is shown in Figure 47.8. This early attempt at hierarchical micromechanical modeling is now being extended with more sophisticated modeling using either finite-element micromechanical computations [Hogan, 1992] or homogenization theory [Crolet et al., 1993]. Further improvements will come by including more definitive information on the structural organization of collagen and Ap at the molecular-ultrastructural level [Wagner and Weiner, 1992; Weiner and Traub, 1989].

47.6   Viscoelastic Properties

As stated earlier, bone (along with all other biologic tissues) is a viscoelastic material. Clearly, for such materials, Hooke's law for linear elastic materials must be replaced by a constitutive equation which
FIGURE 47.7 Variation in Young's modulus of bovine femur specimens (E) with the orientation of specimen axis to the long axis of the bone, for wet (o) and dry (x) conditions compared with the theoretical curve (———) predicted from a fiber-reinforced composite model [Bonfield and Grynpas, 1977] (Courtesy *Nature* 1977, 270: 453. ©Macmillan Magazines Ltd.).
FIGURE 47.8 Comparison of predictions of Katz two-level composite model with the experimental data of Bonfield and Grynpas. Each curve represents a different lamellar configuration within a single osteon, with longitudinal fibers; A, 64%; B, 57%; C, 50%; D, 37%; and the rest of the fibers assumed horizontal. (From Katz J.L., *Mechanical Properties of Bone, AMD*, vol. 45, New York, American Society of Mechanical Engineers, 1981. With permission.)

includes the time dependency of the material properties. The behavior of an anisotropic linear viscoelastic material may be described by using the *Boltzmann superposition integral* as a constitutive equation:

$$\sigma_{ij}(t) = \int_{-\infty}^{t} C_{ijkl}(t - \tau) \frac{d\epsilon_{kl}(\tau)}{d\tau} d\tau \tag{47.17}$$

where $\sigma_{ij}(t)$ and $\epsilon_{kl}(\tau)$ are the time-dependent second rank stress and strain tensors, respectively, and $C_{ijkl}(t - \tau)$ is the fourth-rank relaxation modulus tensor. This tensor has 36 independent elements for the lowest symmetry case and 12 nonzero independent elements for an orthotropic solid. Again, as for linear elasticity, a reduced notation is used, that is, $11 \rightarrow 1$, $22 \rightarrow 2$, $33 \rightarrow 3$, $23 \rightarrow 4$, $31 \rightarrow 5$, and $12 \rightarrow 6$. If we apply Equation 47.17 to the case of an orthotropic material, for example, plexiform bone, in uniaxial tension (compression) in the one direction [Lakes and Katz, 1974], in this case using the reduced notation, we obtain

$$\sigma_1(t) = \int_{-\infty}^{t} \left[C_{11}(t - \tau) \frac{d\epsilon_1(\tau)}{d\tau} + C_{12}(t - \tau) \frac{d\epsilon_2(\tau)}{d\tau} + C_{13}(t - \tau) \frac{d\epsilon_3(\tau)}{d\tau} \right] d\tau \tag{47.18}$$

$$\sigma_2(t) = \int_{-\infty}^{t} \left[C_{21}(t - \tau) \frac{d\epsilon_1(\tau)}{d\tau} + C_{22}(t - \tau) \frac{d\epsilon_2(\tau)}{d\tau} + C_{23}(t - \tau) \frac{d\epsilon_3(\tau)}{d\tau} \right] = 0 \tag{47.19}$$

for all t, and

$$\sigma_3(t) = \int_{-\infty}^{t} \left[C_{31}(t - \tau) \frac{d\epsilon_1(\tau)}{d\tau} + C_{32}(t - \tau) \frac{d\epsilon_2(\tau)}{d\tau} + C_{33}(t - \tau) \frac{d\epsilon_3(\tau)}{d\tau} \right] d\tau = 0 \tag{47.20}$$

for all t.

Having the integrands vanish provides an obvious solution to Equation 47.19 and Equation 47.20. Solving them simultaneously for $[d\epsilon_2^{(\tau)}]/d\tau$ and $[d\epsilon_3^{(\tau)}]/d\tau$ and and substituting these values in Equation 47.17 yields

$$\sigma_1(t) = \int_{-\infty}^{t} E_1(t - \tau) \frac{d\epsilon_1(\tau)}{d\tau} d\tau \tag{47.21}$$

where, if for convenience we adopt the notation $C_{ij} \equiv C_{ij}(t - \tau)$, then Young's modulus is given by

$$E_1(t - \tau) = C_{11} + C_{12} \frac{[C_{31} - (C_{21} C_{33}/C_{23})]}{[(C_{21} C_{33}/C_{23}) - C_{32}]} + C_{13} \frac{[C_{21} - (C_{31} C_{22}/C_{32})]}{[(C_{22} C_{33}/C_{32})/ - C_{23}]} \tag{47.22}$$

In this case of uniaxial tension (compression), only nine independent orthotropic tensor components are involved, the three shear components being equal to zero. Still, this time-dependent Young's modulus is a rather complex function. As in the linear elastic case, the inverse form of the Boltzmann integral can be used; this would constitute the compliance formulation.

If we consider the bone being driven by a strain at a frequency ω, with a corresponding sinusoidal stress lagging by an angle δ, then the complex Young's modulus $E^*(\omega)$ may be expressed as

$$E^*(\omega) = E'(\omega) + iE''(\omega) \tag{47.23}$$

where $E'(\omega)$, which represents the stress–strain ratio in phase with the strain, is known as the storage modulus, and $E''(\omega)$, which represents the stress–strain ratio 90 degrees out of phase with the strain, is known as the loss modulus. The ratio of the loss modulus to the storage modulus is then equal to $\tan\delta$. Usually, data are presented by a graph of the storage modulus along with a graph of $\tan\delta$, both against frequency. For a more complete development of the values of $E'(\omega)$ and $E''(\omega)$, as well as for the derivation of other viscoelastic technical moduli, see Lakes and Katz [1974]; for a similar development of the shear storage and loss moduli, see Cowin [1989].

Thus, for a more complete understanding of bone's response to applied loads, it is important to know its rheologic properties. There have been a number of early studies of the viscoelastic properties of various long bones [Sedlin, 1965; Smith and Keiper, 1965; Lugassy, 1968; Black and Korostoff, 1973; Laird and Kingsbury, 1973]. However, none of these was performed over a wide enough range of frequency (or time) to completely define the viscoelastic properties measured, for example, creep or stress relaxation. Thus it is not possible to mathematically transform one property into any other to compare results of three different experiments on different bones [Lakes and Katz, 1974].

In the first experiments over an extended frequency range, the biaxial viscoelastic as well as uniaxial viscoelastic properties of wet cortical human and bovine femoral bone were measured using both dynamic and stress relaxation techniques over eight decades of frequency (time) [Lakes et al., 1979]. The results of these experiments showed that bone was both nonlinear and thermorheologically complex, that is, time–temperature superposition could not be used to extend the range of viscoelastic measurements. A nonlinear constitutive equation was developed based on these measurements [Lakes and Katz, 1979a].

In addition, relaxation spectrums for both human and bovine cortical bone were obtained; Figure 47.9 shows the former [Lakes and Katz, 1979b]. The contributions of several mechanisms to the loss tangent of cortical bone is shown in Figure 47.10 [Lakes and Katz, 1979b]. It is interesting to note that almost all the major loss mechanisms occur at frequencies (times) at or close to those in which there are "bumps," indicating possible strain energy dissipation, on the relaxation spectra shown on Figure 47.9. An extensive review of the viscoelastic properties of bone can be found in the CRC publication *Natural and Living Biomaterials* [Lakes and Katz, 1984].

Following on Katz's [1976, 1980] adaptation of the Hashin–Rosen hollow fiber composite model [1964], Gottesman and Hashin [1979] presented a viscoelastic calculation using the same major assumptions.

47.7 Related Research

As stated earlier, this chapter has concentrated on the elastic and viscoelastic properties of compact cortical bone and the elastic properties of trabecular bone. At present there is considerable research activity on the fracture properties of the bone. Professor William Bonfield and his associates at Queen Mary and Westfield College, University of London and Professor Dwight Davy and his colleagues at Case Western Reserve University are among those who publish regularly in this area. Review of the literature is necessary in order to become acquainted with the state of bone fracture mechanics.

An excellent introductory monograph which provides a fascinating insight into the structure–property relationships in bones including aspects of the two areas discussed immediately above is Professor John D. Currey's Bones Structure and Mechanics [2002], the 2nd edition of the book, *The Mechanical Adaptations of Bones.* Princeton University Press [1984].

Defining Terms

Apatite: Calcium phosphate compound, stoichiometric chemical formula $Ca_5(PO_4)_3 \cdot X$, where X is OH^- (hydroxyapatite), F^- (fluorapatite), Cl^- (chlorapatite), etc. There are two molecules in the basic crystal unit cell.

Cancellous bone: Also known as porous, spongy, trabecular bone. Found in the regions of the articulating ends of tubular bones, in vertebrae, ribs, etc.

Cortical bone: The dense compact bone found throughout the shafts of long bones such as the femur, tibia, etc. also found in the outer portions of other bones in the body.

Haversian bone: Also called osteonic. The form of bone found in adult humans and mature mammals, consisting mainly of concentric lamellar structures, surrounding a central canal called the haversian canal, plus lamellar remnants of older haversian systems (osteons) called interstitial lamellae.

Interstitial lamellae: See *Haversian bone* above.

Orthotropic: The symmetrical arrangement of structure in which there are three distinct orthogonal axes of symmetry. In crystals this symmetry is called orthothombic.

Osteons: See *Haversian bone* above.

Plexiform: Also called laminar. The form of parallel lamellar bone found in younger, immature nonhuman mammals.

Transverse isotropy: The symmetry arrangement of structure in which there is a unique axis perpendicular to a plane in which the other two axes are equivalent. The long bone direction is chosen as the unique axis. In crystals this symmetry is called hexagonal.

Further Information

Several societies both in the United States and abroad hold annual meetings during which many presentations, both oral and poster, deal with hard tissue biomechanics. In the United States these societies include the Orthopaedic Research Society, the American Society of Mechanical Engineers, the Biomaterials Society, the American Society of Biomechanics, the Biomedical Engineering Society, and the Society for Bone and Mineral Research. In Europe there are alternate year meetings of the European Society of Biomechanics and the European Society of Biomaterials. Every four years there is a *World Congress of Biomechanics*; every three years there is a *World Congress of Biomaterials.* All of these meetings result in documented proceedings; some with extended papers in book form.

The two principal journals in which bone mechanics papers appear frequently are the *Journal of Biomechanics* published by Elsevier and the *Journal of Biomechanical Engineering* published by the American Society of Mechanical Engineers. Other society journals which periodically publish papers in the field are the *Journal of Orthopaedic Research* published for the Orthopaedic Research Society, the *Annals of Biomedical Engineering* published for the Biomedical Engineering Society, and the *Journal of Bone and Joint Surgery* (both American and English issues) for the American Academy of Orthopaedic Surgeons and the British Organization, respectively. Additional papers in the field may be found in the journal *Bone and Calcified Tissue International.*

The 1984 CRC volume, *Natural and Living Biomaterials* (Hastings G.W. and Ducheyne P., Eds.) provides a good historical introduction to the field. A recent more advanced book is *Bone Mechanics Handbook* (Cowin S.C., Ed. 2001), the 2nd ed. of *Bone Mechanics* (Cowin S.C., Ed. 1989).

Many of the biomaterials journals and society meetings will have occasional papers dealing with hard tissue mechanics, especially those dealing with implant–bone interactions.

Appendix

The Voigt and Reuss moduli for both transverse isotropic and orthotropic symmetry are given below:

Voigt transverse isotropic

$$K^{V} = \frac{2(C_{11} + C_{12}) + 4(C_{13} + C_{33})}{9}$$

$$G^{V} = \frac{(C_{11} + C_{12}) - 4C_{13} + 2C_{33} + 12(C_{44} + C_{66})}{30}$$

(47.A1)

Reuss transverse isotropic

$$K_{R} = \frac{C_{33}(C_{11} + C_{12}) - 2C_{13}^{2}}{(C_{11} + C_{12} - 4C_{13} + 2C_{33})}$$

$$G_{R} = \frac{5[C_{33}(C_{11} + C_{12}) - 2C_{13}^{2}]C_{44}C_{66}}{2\{[C_{33}(C_{11} + C_{12}) - 2C_{13}^{2}](C_{44} + C_{66}) + [C_{44}C_{66}(2C_{11} + C_{12}) + 4C_{13} + C_{33}]/3\}}$$

(47.A2)

Voigt orthotropic

$$K^{V} = \frac{C_{11} + C_{22} + C_{33} + 2(C_{12} + C_{13} + C_{23})}{9}$$

$$G^{V} = \frac{[C_{11} + C_{22} + C_{33} + 3(C_{44} + C_{55} + C_{66}) - (C_{12} + C_{13} + C_{23})]}{15}$$

(47.A3)

Reuss orthotropic

$$K_{R} = \frac{\Delta}{C_{11}C_{22} + C_{22}C_{33} + C_{33}C_{11}} - 2(C_{11}C_{23} + C_{22}C_{13} + C_{33}C_{12})$$

$$+ 2(C_{12}C_{23} + C_{23}C_{13} + C_{13}C_{12}) - (C_{12}^{2} + C_{13}^{2} + C_{23}^{2})$$

$$G_{R} = 15/(4\{(C_{11}C_{22} + C_{22}C_{33} + C_{33}C_{11} + C_{11}C_{23} + C_{22}C_{13} + C_{33}C_{22})$$

$$- [C_{12}(C_{12} + C_{23}) + C_{23}(C_{23} + C_{13}) + C_{13}(C_{13} + C_{12})]\}/\Delta$$

$$+ 3(1/C_{44} + 1/C_{55} + 1/C_{66}))$$

(47.A4)

where Δ is given in Equation 47.15.

Musculoskeletal Soft Tissue Mechanics

Richard L. Lieber
University of California

Thomas J. Burkholder
Georgia Institute of Technology

Biological soft tissues are nonlinear, anisotropic, fibrous composites, and detailed description of their behavior is the subject of active research. One can separate these tissues based on their mode of loading: cartilage is generally loaded in compression; tendons and ligaments are loaded in tension; and muscles generate active tension. The structure and material properties differ to accommodate the tissue function, and this chapter outlines those features. Practical models of each tissue are described, with particular focus on active force generation by skeletal muscle and application to segmental modeling.

48.1 Structure of Soft Tissues

48.1.1 Cartilage

Articular cartilage is found at the ends of bones, where it serves as a shock absorber and lubricant between bones. It is best described as a hydrated proteoglycan gel supported by a sparse population of chondrocytes, and its composition and properties vary dramatically over its 1- to 2-mm thickness. The bulk composition of articular cartilage consists of approximately 20% collagen, 5% proteoglycan, primarily aggrecan bound to hyaluronic acid, with most of the remaining 75% water [Ker, 1999]. At the articular surface, collagen fibrils are most dense and arranged primarily in parallel with the surface. Proteoglycan content is very low and chondrocytes are rare in this region. At the bony interface, collagen fibrils are oriented perpendicular to the articular surface, chondrocytes are more abundant, but proteoglycan content is low. Proteoglycans are most abundant in the middle zone, where collagen fibrils lack obvious orientation in association with the transition from parallel to perpendicular alignment.

Collagen itself is a fibrous protein composed of tropocollagen molecules. Tropocollagen is a triple-helical protein, which self-assembles into the long collagen fibrils observable at the ultrastructural level. These fibrils, in turn, aggregate and intertwine to form the ground substance of articular cartilage. When cross-linked into a dense network, as in the superficial zone of articular cartilage, collagen has a low permeability to water and helps to maintain the water cushion of the middle and deep zones. Collagen fibrils arranged in a random network, as in the middle zone, structurally immobilize the large proteoglycan (PG) aggregates, creating the solid phase of the composite material.

Proteoglycans consist of a number of negatively charged glycosaminoglycan chains bound to an aggrecan protein core. Aggrecan molecules, in turn, bind to a hyaluronic acid backbone, forming a PG of 50 to 100 MDa, which carries a dense negative charge. This negative charge attracts positively charged ions (Na^+) from the extracellular fluid, and the resulting Donnan equilibrium results in rich hydration of the tissue creating an osmotic pressure that enables the tissue to act as a shock absorber.

The overall structure of articular cartilage is analogous to a jelly-filled balloon. The PG-rich middle zone is osmotically pressurized, with fluid restrained from exiting the tissue by the dense collagen network of the superficial zone and the calcified structure of the deep bone. The interaction between the mechanical loading forces and osmotic forces yields the complex material properties of articular cartilage.

48.1.2 Tendon and Ligament

The passive tensile tissues, tendon and ligament, are also composed largely of water and collagen, but contain very little of the PGs that give cartilage its unique mechanical properties. In keeping with the functional role of these tissues, the collagen fibrils are organized primarily in long strands parallel to the axis of loading (Figure 48.1) [Kastelic, et al., 1978]. The collagen fibrils, which may be hollow tubes [Gutsmann et al., 2003], combine in a hierarchical structure, with the 20–40-nm fibrils being bundled into 0.2–12-μm fibers. These fibers are birefringent under polarized light, reflecting an underlying wave or crimp structure with a periodicity between 20 and 100 μm. The fibers are bundled into fascicles, supported by fibroblasts or tenocytes, and surrounded by a fascicular membrane. Finally, multiple fascicles are bundled into a complete tendon or ligament encased in a reticular membrane.

As the tendon is loaded, the bending angle of the crimp structure of the collagen fibers can be seen to reversibly decrease, indicating that deformation of this structure is one source of elasticity. Individual
FIGURE 48.1 Tendons are organized in progressively larger filaments, beginning with molecular tropocollagen, and building to a complete tendon encased in a reticular sheath.

collagen fibrils also display some inherent elasticity, and these two features are believed to determine the bulk properties of passive tensile tissues.

48.1.3 Muscle

48.1.3.1 Gross Morphology

Muscles are described as running from a proximal origin to a distal insertion. While these attachments are frequently discrete, distributed attachments, and distinctly bifurcated attachments, are also common. Description of the subdomains of a muscle is largely by analogy to the whole body. The mass of muscle fibers can be referred to as the belly. In a muscle with distinctly divided origins, the separate origins are often referred to as heads, and in a muscle with distinctly divided insertions, each mass of fibers terminating on distinct tendons is often referred to as a separate belly.

A muscle generally receives its blood supply from one main artery, which enters the muscle in a single, or sometimes two branches. Likewise, the major innervation is generally by a single nerve, which carries both motor efferents and sensory afferents.

Some muscles are functionally and structurally subdivided into compartments. A separate branch of the principle nerve generally innervates each compartment, and motor units of the compartments do not overlap. Generally, a dense connective tissue, or fascial, plane separates the compartments.

48.1.3.2 Fiber Architecture

Architecture, the arrangement of fibers within a muscle, determines the relationship between whole muscle length changes and force generation. The stereotypical muscle architecture is fusiform, with the muscle originating from a small tendonous attachment, inserting into a discrete tendon, and having fibers running generally parallel to the muscle axis (Figure 48.2). Fibers of unipennate muscles run parallel to each other but at an angle (pennation angle) to the muscle axis. Bipennate muscle fibers run in two distinct directions. Multipennate or fan-like muscles have one distinct attachment and one broad attachment, and pennation angle is different for every fiber. Strap-like muscles have parallel fibers that run from a broad bony origin to a broad insertion. As the length of each of these muscles is changed, the change in length of its fibers depends on fiber architecture. For example, fibers of a strap-like muscle undergo essentially the same length change as the muscle, where the length change of highly pennate fibers is reduced by their angle.

48.1.3.3 Sarcomere

Force generation in skeletal muscle results from the interaction between myosin and actin proteins. These molecules are arranged in antiparallel filaments, a 2- to 3-nm diameter thin filament composed mainly of actin, and a 20-nm diameter thick filament composed mainly of myosin. Myosin filaments are arranged in a hexagonal array, rigidly fixed at the M-line, and are the principal constituents of the A-band (anisotropic, light bending). Actin filaments are arranged in a complimentary hexagonal array and rigidly fixed at the Z-line, comprising the l-band (isotropic, light transmitting). The sarcomere is a nearly crystalline structure, composed of an A-band and two adjacent l-bands, and is the fundamental unit of muscle force generation. Sarcomeres are arranged into arrays of myofibrils, and one muscle cell or myofiber contains many myofibrils. Myofibers themselves are multinucleated syncitia, hundreds of microns in diameter, and may be tens of millimeters in length that are derived during development by the fusion of myoblasts.

The myosin protein occurs in several different isoforms, each with different force-generating characteristics, and each associated with expression of characteristic metabolic and calcium-handling proteins. Broadly, fibers can be characterized as either fast or slow, with slow fibers having a lower rate of actomyosin ATPase activity, slower velocity of shortening, slower calcium dynamics, and greater activity of oxidative metabolic enzymes. The lower ATPase activity makes these fibers more efficient for generating force, while the high oxidative capacity provides a rich energy source, making slow fibers ideal for extended periods of activity. Their relatively slow speed of shortening results in poor performance during fast or ballistic motions.

48.2 Material Properties

48.2.1 Cartilage

The behavior of cartilage is highly viscoelastic. A compressive load applied to articular cartilage drives the positively charged fluid phase through the densely intermeshed and negatively charged solid phase while deforming the elastic PG-collagen structure. The mobility of the fluid phase is relatively low, and, for rapid changes in load, cartilage responds nearly as a uniform linear elastic solid with a Young's modulus of approximately 6 MPa [Carter and Wong, 2003].

At lower loading rates, cartilage displays more nonlinear properties. Ker [1999] reports that human limb articular cartilage stiffness can be described as $E = E_0(1 + \sigma^{0.366})$, with $E_0 = 3.0$ MPa and σ expressed in MPa.

48.2.2 Tendon and Ligament

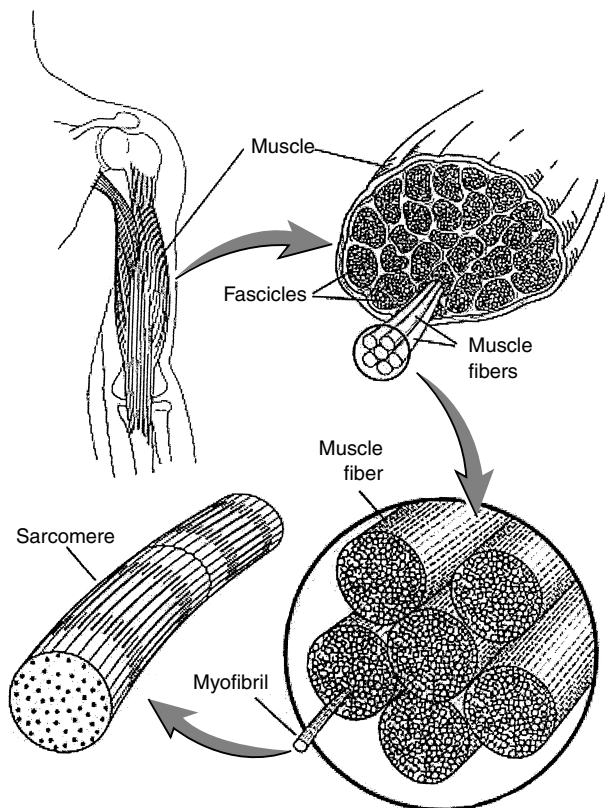
At rest, the collagen fibrils are significantly crimped or wavy so that initial loading acts primarily to straighten these fibrils. At higher strains, the straightened collagen fibrils must be lengthened. Thus, tendons are more compliant at low loads and less compliant at high loads. The highly nonlinear low load region has been referred to as the "toe" region and occurs up to approximately 3% strain and 5 MPa [Butler et al., 1979; Zajac, 1989]. Typically, tendons have nearly linear properties from about 3% strain until ultimate strain, which ranges from 9 to 10% (Table 48.1). The tangent modulus in this linear


FIGURE 48.2 Skeletal muscle is organized in progressively larger filaments, beginning with molecular actin and myosin, arranged as myofibrils. Myofibrils assemble into sarcomeres and myofilaments. Myofilaments are assembled into myofibers, which are organized into the fascicles that form a whole muscle.

region is approximately 1.5 GPa. Ultimate tensile stress reported for tendons is approximately 100 MPa [McElhaney et al., 1976]. However, under physiological conditions, tendons operate at stresses of only 5 to 10 MPa (Table 48.1) yielding a typical safety factor of 10.

48.2.3 Muscle

Tension generated by skeletal muscle depends on length, velocity, level of activation, and history. Performance characteristics of a muscle depend on both its intrinsic properties and the extrinsic organization of that tissue. Whole muscle maximum shortening velocity depends both upon the sliding velocity of its component sarcomeres and on the number of those sarcomeres arranged in series. Likewise, maximum isometric tension depends on both the intrinsic tension-generating capacity of the actomyosin crossbridges and on the number of sarcomeres arranged in parallel. The relationship between intrinsic properties and extrinsic function is further complicated by pennation of the fibers. Given the orthotropic nature of the muscle fiber, material properties should be considered relative to the fiber axis. That is, the relevant area for stress determination is not the geometric cross section, but the physiological cross section, perpendicular to the fiber axis. The common form for estimation of the physiological cross sectional area (PCSA) is:

$$\text{PCSA} = \frac{M \cdot \cos(\Theta)}{\rho \cdot \text{FL}}$$

where M is muscle mass, Θ is pennation angle, ρ is muscle density (1.06 g/cm^3), and FL is fiber length. Likewise, the relevant gage length for strain determination is not muscle length, but fiber length, or fascicle length in muscles composed of serial fibers.

Maximum muscle stress: Maximum active stress, or specific tension, varies somewhat among fiber types and species (Table 48.2) around a generally accepted average of 250 kPa. This specific tension can be determined in any system in which it is possible to measure force and estimate the area of contractile material. Given muscle PCSA, maximum force produced by a muscle can be predicted by multiplying this PCSA by specific tension (Table 48.2). Specific tension can also be calculated for isolated muscle fibers or motor units in which estimates of cross-sectional area have been made.

Maximum muscle contraction velocity: Muscle maximum contraction velocity is primarily dependent on the type and number of sarcomeres in series along the muscle fiber length [Gans, 1982]. The intrinsic

velocity of shortening has been experimentally determined for a number of muscle types (Table 48.3). Maximum contraction velocity of a given muscle can thus be calculated based on a knowledge of the number of serial sarcomeres within the muscle multiplied by the maximum contraction velocity of an individual sarcomere (Table 48.4 to Table 48.6). Sarcomere shortening velocity varies widely among species and fiber types (Table 48.3).

48.3 Modeling

48.3.1 Cartilage

Although cartilage can be modeled as a simple elastic element, more accurate results are obtained using a biphasic model [Mow et al., 1980], which describes the motion of the hydrating fluid relative to the charged organic matrix. The total stress acting on the cartilage is separated into independent solid and

These equations can be solved analytically for the special case of confined compression against a porous platen [Mow et al., 1980]. The surface displacement during creep under an applied load f_0 is

$$\frac{u}{h} = \frac{f_0}{H_A}\left(1 - \frac{2}{\pi^2}\sum_{n=0}^{2}\left(n + \frac{1}{2}\right)^{-2}\exp\left\{-\pi^2\left(n + \frac{1}{2}\right)^2\frac{H_A kf}{(1 + 2a_0)h^2}\right\}\right)$$

where h is the tissue thickness, and H_A is the aggregate modulus ($\lambda + 2\mu$). Those authors estimate k as $7.6 \pm 3.0 \times 10^{-13}$ m^4/Nsec and H_A as 0.70 ± 0.09 MPa for bovine articular cartilage. Chen et al. [2001] report strongly depth-dependent values for H_A ranging between 1.16 ± 0.20 MPa in the superficial zone to 7.75 ± 1.45 MPa in the deep zone in human articular cartilage. The biphasic approach has been extended to finite element modeling, resulting in the u–p class of models [Wayne et al., 1991].

48.3.2   Tendon and Ligament

The composition and structure of the tensile soft tissues is quite similar to that of cartilage, and the biphasic theory can be applied to them as well. Fluid pressure serves a smaller role in tissues loaded

in tension, and the complication of the biphasic model is generally unnecessary. For modeling of segmental mechanics, it is frequently sufficient to treat these structures according to a one-dimensional approximation.

While considering tendons and ligaments as simple nonlinear elastic elements (Table 48.6) are often sufficient, additional accuracy can be obtained by incorporating viscous damping. The quasi-linear viscoelastic approach [Fung, 1981] introduces a stress relaxation function, $G(t)$, that depends only on time, is convoluted with the elastic response, $T^e(\lambda)$, that depends only on the stretch ratio, to yield the complete stress response, $K(\lambda, t)$. To obtain the stress at any point in time requires that the contribution of all preceding deformations be assessed:

$$T(t) = \int_{-\infty}^{f} G(t - \tau) \frac{\partial T^e(\lambda)}{\partial \lambda} \frac{\partial \lambda}{\partial \tau} \, d\tau$$
FIGURE 48.3   The Hill model of muscle separates the active properties of muscle into a contractile element, in series with a purely elastic element. The properties of the passive muscle are represented by the parallel elastic element.

Both the elastic response and the relaxation function are empirically determined. The common form for the relaxation function is a sum of exponentials

$$G(t) = A + \sum_i B_i e^{-t/\tau_i}$$

The form of the elastic response varies, but usually includes a power or exponential term to accommodate the toe region.

48.3.3 Muscle

48.3.3.1 Types of Muscle Models

There are three general classes of models for predicting muscle force: biochemical, or crossbridge, models; constitutive models; and phenomenological, or Hill, models. Crossbridge models [Huxley, 1957; Huxley and Simmons, 1971] attempt to determine force from the chemical reactions of the crossbridge cycle. Though accurate at the cross-bridge cycle, it is generally computationally prohibitive to model a whole muscle in this manner. Constitutive models, such as that described by Zahalak and Ma [1990], generally attempt to determine muscle behavior by describing populations of cross-bridges. A potentially powerful approach, this technique has not yet been widely adopted. The vanguard of muscle modeling remains the phenomenological model first described by Hill [1939], that describes the viscoelastic behavior of skeletal muscle using a framework analogous to the standard linear solid (Figure 48.3). Although the series elastic element represents primarily tendon, some series elasticity is found even in muscles lacking any external tendon or in segments of single fibers. The parallel elastic element represents the passive properties of the muscle, currently thought to reside primarily in titin. The contractile component is described by independent isometric force–length (Figure 48.4) and isotonic force–velocity relations (Figure 48.5) and an activation function [Zajac, 1989].

48.3.3.2 Muscle Force–Length Relationship

Under conditions of constant length, muscle force generated is proportional to the magnitude of the interaction between the actin and myosin contractile filaments. Myosin filament length in all species is approximately 1.6 μm, but actin filament length varies (Table 48.7). Optimal sarcomere length and maximum sarcomere length can be calculated using these filament lengths. For optimal force generation, each half myosin filament must completely overlap an actin filament, without opposing actin filaments overlapping. No active force is produced at sarcomere spacings shorter than the myosin filament length or longer than
FIGURE 48.4 The force-generating capacity of a sarcomere depends strongly on the degree of overlap of myosin and actin filaments.
FIGURE 48.5 Active force generation depends strongly on shortening velocity.

the sum of the myosin and the pair of actin filament lengths. The range of operating sarcomere lengths varies among muscles, but generally covers a range of ±15% of optimal length [Burkholder and Lieber, 2003].

48.3.3.3 Muscle Force–Velocity Relationship

Under conditions of constant load the relationship between force and velocity is nearly hyperbolic [Hill, 1938]. The shortening force–velocity relation was can be described by:

$$(P + a)v = b(P_0 - P)$$

TABLE 48.7   Actin Filament Lengths

Species	Actin filament length (μm)	Optimal length (μm)	References
Cat	1.12	2.24	Herzog et al. [1992]

Carp	0.98	1.92	Sosnicki et al. [1991]

while the lengthening relation can be described by:

$$F = 1.8 - 0.8 \frac{v_{\max} + v}{V_{\max} - 7.6\ V}$$

The dynamic parameters (a, b, and $V_{\max}$) vary across species and fiber types (Table 48.3).

It should be noted that this formulation omits several potentially important force-generating phenomena. Notable among these are the persistent extra tension obtained following stretch [Edman et al., 1982], the exaggerated short range stiffness [Rack and Westbury, 1974], and changes in the force–length relation associated with activation level [Rack and Westbury, 1969]. Some of these features can be accommodated by considering series elasticity and sarcomere length inhomogeneity [Morgan, 1990], and each represents a nonlinearity that substantially complicates modeling and may not be necessary for first approximations of muscle function.

Common applications of muscle modeling include forward simulation to predict output forces or motions and inverse analysis to estimate the muscle forces that produced an observed motion. In neither of these cases is it necessarily practical to determine muscle contractile properties empirically, and it is frequently necessary to resort to estimation of the force–length and force–velocity relations from muscle structure. If a muscle is considered to be a composition of uniform sarcomeres in series and in parallel, then the deformation of single sarcomeres can be estimated from whole muscle length changes. A simplified view of a muscle is an array of identical fibers of uniform length arranged at a common pennation angle to the line of force. Peak isometric tension can be estimated from PCSA. Pennation angle determines the relationship between muscle and fiber length changes:

$$\frac{\Delta L_m}{L_m} = \frac{\Delta L_f}{L_f} \cos(\theta)$$

If sarcomere length is known at any muscle length, it is then possible to scale the sarcomere length–tension and velocity–tension relations to the whole muscle. When reporting architectural data (Tables), muscle and fiber lengths should be normalized to optimal sarcomere length.

Joint-Articulating Surface Motion

Kenton R. Kaufman
Kai-Nan An
Mayo Clinic

Knowledge of joint-articulating surface motion is essential for design of prosthetic devices to restore function; assessment of joint wear, stability, and degeneration; and determination of proper diagnosis and surgical treatment of joint disease. In general, kinematic analysis of human movement can be arranged into two separate categories (1) gross movement of the limb segments interconnected by joints, or (2) detailed analysis of joint articulating surface motion which is described in this chapter. Gross movement is the relative three-dimensional joint rotation as described by adopting the Eulerian angle system. Movement of this type is described in Chapter 51: Analysis of Gait. In general, the three-dimensional unconstrained rotation and translation of an articulating joint can be described utilizing the concept of the screw displacement axis. The most commonly used analytic method for the description of 6-degree-of-freedom

49-1
FIGURE 49.1   Three types of articulating surface motion in human joints.

displacement of a rigid body is the screw displacement axis [Kinzel et al., 1972; Spoor and Veldpaus, 1980; Woltring et al., 1985].

Various degrees of simplification have been used for kinematic modeling of joints. A hinged joint is the simplest and most common model used to simulate an anatomic joint in planar motion about a single axis embedded in the fixed segment. Experimental methods have been developed for determination of the instantaneous center of rotation for planar motion. The *instantaneous center of rotation* is defined as the point of zero velocity. For a true hinged motion, the instantaneous center of rotation will be a fixed point throughout the movement. Otherwise, loci of the instantaneous center of rotation or centrodes will exist. The center of curvature has also been used to define joint anatomy. The *center of curvature* is defined as the geometric center of coordinates of the articulating surface.

For more general planar motion of an articulating surface, the term *sliding, rolling,* and *spinning* are commonly used (Figure 49.1). Sliding (gliding) motion is defined as the pure translation of a moving segment against the surface of a fixed segment. The contact point of the moving segment does not change, while the contact point of the fixed segment has a constantly changing contact point. If the surface of the fixed segment is flat, the instantaneous center of rotation is located at infinity. Otherwise, it is located at the center of curvature of the fixed surface. Spinning motion (rotation) is the exact opposite of sliding motion. In this case, the moving segment rotates, and the contact points on the fixed surface does not change. The instantaneous center of rotation is located at the center of curvature of the spinning body that is undergoing pure rotation. Rolling motion occurs between moving and fixed segments where the contact points in each surface are constantly changing and the arc lengths of contact are equal on each segment. The instantaneous center of rolling motion is located at the contact point. Most planar motion of anatomic joints can be described by using any two of these three basic descriptions.

In this chapter, various aspects of joint-articulating motion are covered. Topics include the anatomical characteristics, joint contact, and axes of rotation. Joints of both the upper and lower extremity are discussed.

49.1   Ankle

The ankle joint is composed of two joints: the talocrural (ankle) joint and the talocalcaneal (subtalar joint). The talocrural joint is formed by the articulation of the distal tibia and fibula with the trochlea of the talus. The talocalcaneal joint is formed by the articulation of the talus with the calcaneus.

49.1.1   Geometry of the Articulating Surfaces

The upper articular surface of the talus is wedge-shaped, its width diminishing from front to back. The talus can be represented by a conical surface. The wedge shape of the talus is about 25% wider in front than behind with an average difference of 2.4 ± 1.3 mm and a maximal difference of 6 mm [Inman, 1976].

49.1.2   Joint Contact

The talocrural joint contact area varies with flexion of the ankle (Table 49.1). During plantarflexion, such as would occur during the early stance phase of gait, the contact area is limited and the joint is incongruous.

TABLE 49.1 Talocalcaneal (Ankle) Joint Contact Area

Pereira et al. [1996]	1.49 (20°)	1.67	1.47 (10°)
Rosenbaum et al. [2003]		2.11 ± 0.72	

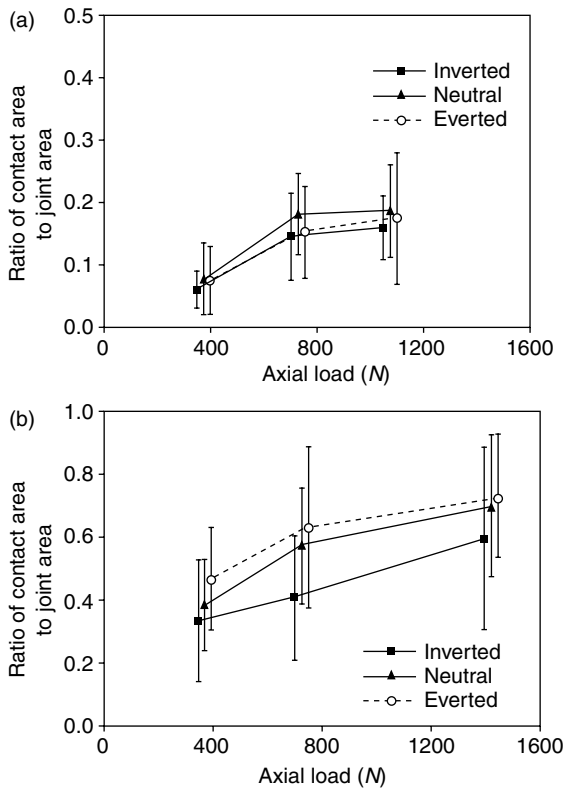
Note: The contact area is expressed in square centimeters.


FIGURE 49.2   Ratio of total contact area to joint area in the (a) anterior/middle facet and (b) posterior facet of the subtalar joint as a function of applied axial load for three different positions of the foot. (From Wagner U.A., Sangeorzan B.J., Harrington R.M., and Tencer A.F. 1992. *J. Orthop. Res.* 10: 535. With permission.)

As the position of the joint progresses from neutral to dorsiflexion, as would occur during the midstance of gait, the contact area increases and the joint becomes more stable. The area of the subtalar articulation is smaller than that of the talocrural joint. The contact area of the subtalar joint is 0.89 ± 0.21 cm^2 for the posterior facet and 0.28 ± 15 cm^2 for the anterior and middle facets [Wang et al., 1994]. The total contact area (1.18 ± 0.35 cm^2) is only 12.7% of the whole subtalar articulation area (9.31 ± 0.66 cm^2)

		Plantarflexion: 5 mm superior to tip of lateral malleolus to 15 mm anterior, 10 mm inferior to tip of medial malleolus

[a] Fix. = fixed axis of rotation; Ins. = instantaneous axis of rotation; Q-I = quasi-instantaneous axis of rotation.

[Wang et al., 1994]. The contact area/joint area ratio increases with increases in applied load (Figure 49.2).

49.1.3 Axes of Rotation

Joint motion of the talocrural joint has been studied to define the axes of rotation and their location with respect to specific anatomic landmarks (Table 49.2). The axis of motion of the talocrural joint essentially passes through the inferior tibia at the fibular and tibial malleoli (Figure 49.3). Three types of motion have been used to describe the axes of rotation: fixed, quasi-instantaneous, and instantaneous axes. The motion that occurs in the ankle joints consists of dorsiflexion and plantarflexion. Minimal or no transverse rotation takes place within the talocrural joint. The motion in the talocrural joint is intimately related to the motion in the talocalcaneal joint which is described next.

The motion axes of the talocalcaneal joint have been described by several authors (Table 49.3). The axis of motion in the talocalcaneal joint passes from the anterior medial superior aspect of the navicular bone to the posterior lateral inferior aspect of the calcaneus (Figure 49.4). The motion that occurs in the talocalcaneal joint consists of inversion and eversion.

49.2 Knee

The knee is the intermediate joint of the lower limb. It is composed of the distal femur and proximal tibia. It is the largest and most complex joint in the body. The knee joint is composed of the tibiofemoral articulation and the patellofemoral articulation.

49.2.1 Geometry of the Articulating Surfaces

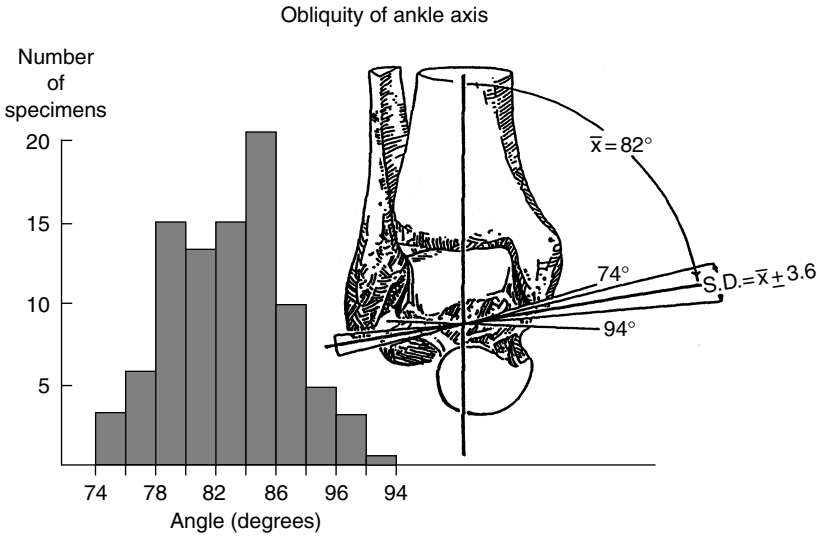
The shape of the articular surfaces of the proximal tibia and distal femur must fulfill the requirement that they move in contact with one another. The profile of the femoral condyles varies with the condyle


FIGURE 49.3 Variations in angle between middle of tibia and empirical axis of ankle. The histogram reveals a considerable spread of individual values. (From Inman V.T. 1976. *The Joints of the Ankle*, Baltimore, Williams and Wilkins. With permission.)

TABLE 49.3 Axis of Rotation for the Talocalcaneal (Subtalar) Joint

Investigators	Axis[a]	Position
Manter [1941]	Fix.	16° (8–24°) with respect to sagittal plane, and 42° (29–47°) with respect to transverse plane
Shephard [1951]	Fix.	Tuberosity of the calcaneus to the neck of the talus
Hicks [1953]	Fix.	Posterolateral corner of the heel to superomedial aspect of the neck of the talus
Root et al. [1966]	Fix.	17° (8–29°) with respect to sagittal plane, and 41° (22–55°) with respect to transverse plane
Isman and Inman [1969]	Fix.	23° ± 11° with respect to sagittal plane, and 41° ± 9° with respect to transverse plane

Rastegar et al. [1980]	Ins.	Instant centers of rotation pathways in posterolateral quadrant of the distal articulating tibial surface, varying with applied load
Van Langelaan [1983]	Ins.	A bundle of axes that make an acute angle with the longitudinal direction of the foot passing through the tarsal canal having a direction from anteromediosuperior to posterolateroinferior
Engsberg [1987]	Ins.	A bundle of axes with a direction from anteromediosuperior to posterolateroinferior

[a] Fix. = fixed axis of rotation; Ins. = instantaneous axis of rotation.

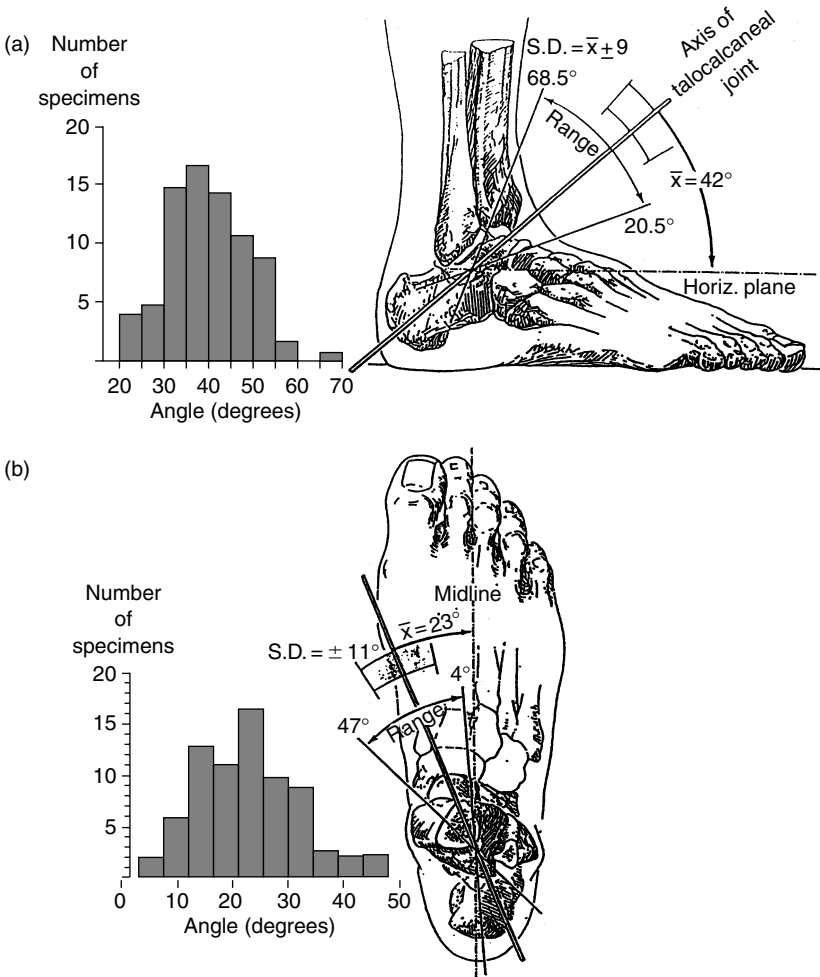
examined (Figure 49.5 and Table 49.4). The tibial plateau widths are greater than the corresponding widths of the femoral condyles (Figure 49.6 and Table 49.6). However, the tibial plateau depths are less than those of the femoral condyle distances. The medial condyle of the tibia is concave superiorly (the center of curvature lies above the tibial surface) with a radius of curvature of 80 mm [Kapandji, 1987]. The lateral condyle is convex superiorly (the center of curvature lies below the tibial surface) with a radius of curvature of 70 mm [Kapandji, 1987]. The shape of the femoral surfaces is complementary to the shape of the tibial plateaus. The shape of the posterior femoral condyles may be approximated by spherical surfaces (Table 49.4).


FIGURE 49.4   (a) Variations in inclination of axis of subtalar joint as projected upon the sagittal plane. The distribution of the measurements on the individual specimens is shown in the histogram. The single observation of an angle of almost 70° was present in a markedly cavus foot. (b) Variations in position of subtalar axis as projected onto the transverse plane. The angle was measured between the axis and the midline of the foot. The extent of individual variation is shown on the sketch and revealed in the histogram. (From Inman V.T. 1976. *The Joints of the Ankle*, Baltimore, Williams and Wilkins. With permission.)

The geometry of the patellofemoral articular surfaces remains relatively constant as the knee flexes. The knee sulcus angle changes only ±3.4° from 15 to 75° of knee flexion (Figure 49.7). The mean depth index varies by only ±4% over the same flexion range (Figure 49.7). Similarly, the medial and lateral patellar facet angles (Figure 49.8) change by less than a degree throughout the entire knee flexion range (Table 49.7). However, there is a significant difference between the magnitude of the medial and lateral patellar facet angles.

49.2.2 Joint Contact

The mechanism for movement between the femur and tibia is a combination of rolling and gliding. Backward movement of the femur on the tibia during flexion has long been observed in the human knee.

The magnitude of the rolling and gliding changes through the range of flexion. The tibial-femoral contact point has been shown to move posteriorly as the knee is flexed, reflecting the coupling of posterior motion with flexion (Figure 49.9). In the intact knee at full extension, the center of pressure is approximately 25 mm from the anterior edge of the tibial plateau [Andriacchi et al, 1986]. The medial femoral condyle rests

further anteriorly on the tibial plateau than the lateral plateau. The medial femoral condyle is positioned 35 ± 4 mm from the posterior edge while the lateral femoral condyle is positioned 25 ± 4 mm from the posterior edge (Figure 49.9). During knee flexion to 90°, the medial femoral condyle moves back 15 ± 2 mm and the lateral femoral condyle moves back 12 ± 2 mm. Thus, during flexion the femur moves posteriorly on the tibia (Table 49.9).

The patellofemoral contact area is smaller than the tibiofemoral contact area (Table 49.10). As the knee joint moves from extension to flexion, a band of contact moves upward over the patellar surface (Figure 49.10). As knee flexion increases, not only does the contact area move superiorly, but it also becomes larger. At 90° of knee flexion, the contact area has reached the upper level of the patella. As the knee continues to flex, the contact area is divided into separate medial and lateral zones.

49.2.3 Axes of Rotation

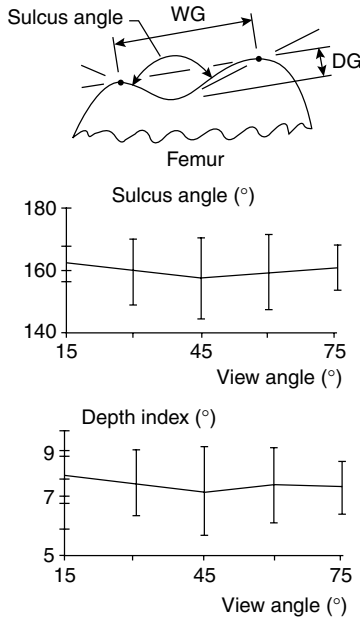
The tibiofemoral joint is mainly a joint with two degrees of freedom. The first degree of freedom allows movements of flexion and extension in the sagittal plane. The axis of rotation lies perpendicular to the


FIGURE 49.7 The trochlear geometry indices. The sulcus angle is the angle formed by the lines drawn from the top of the medial and lateral condyles to the deepest point of the sulcus. The depth index is the ratio of the width of the groove (WG) to the depth (DG). Mean and SD; $n = 12$. (From Farahmand et al. *J. Orthop. Res.* 16: 1, 140.)
FIGURE 49.8 Medial (γ_m) and lateral (γ_n) patellar facet angles. (From Ahmed A.M., Burke D.L., and Hyder A. 1987. *J. Orthop. Res.* 5: 69–85.)

sagittal plane and intersects the femoral condyles. Both fixed axes and screw axes have been calculated (Figure 49.11). In Figure 49.11, the optimal axes are fixed axes, whereas the screw axis is an instantaneous axis. The symmetric optimal axis is constrained such that the axis is the same for both the right and left knee. The screw axis may sometimes coincide with the optimal axis but not always, depending upon the motions of the knee joint. The second degree of freedom is the axial rotation around the long axis of the tibia. Rotation of the leg around its long axis can only be performed with the knee flexed. There is also an automatic axial rotation which is involuntarily linked to flexion and extension. When the knee is flexed, the tibia internally rotates. Conversely, when the knee is extended, the tibia externally rotates.

During knee flexion, the patella makes a rolling/gliding motion along the femoral articulating surface. Throughout the entire flexion range, the gliding motion is clockwise (Figure 49.12). In contrast, the direction of the rolling motion is counter-clockwise between 0 and 90° and clockwise between 90 and 120° (Figure 49.12). The mean amount of patellar gliding for all knees is approximately 6.5 mm per 10° of

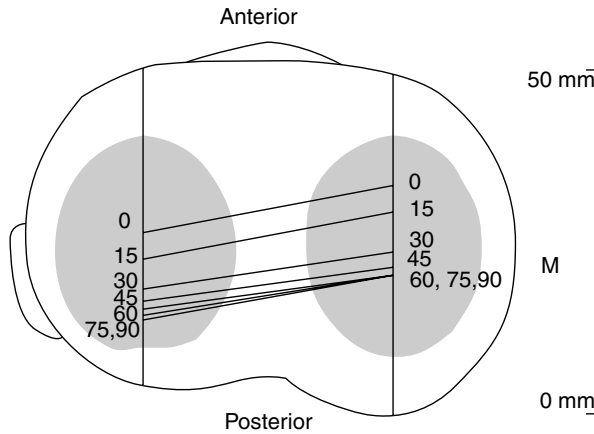

FIGURE 49.9   Diagram of the tibial plateau, showing the tibiofemoral contact pattern from 0° to 90° of knee flexion, in the loaded knee. In both medial and lateral compartments, the femoral condyle rolls back along the tibial plateau from 0° to 30°. Between 30° and 90° the lateral condyle continues to move posteriorly, while the medial condyle moves back little. (From Scarvell, J.M., Smith, P.N., Refshauge, K.M., Galloway, H.R., and Woods, K.R. Evaluation of a method to map tibiofemoral contact points in the normal knee using MRI. *J. Orthop. Res.* 22:788–793, 2004.)

flexion between 0 and 80° and 4.5 mm per 10° of flexion between 80 and 120°. The relationship between the angle of flexion and the mean rolling/gliding ratio for all knees is shown in Figure 49.13. Between 80 and 90° of knee flexion, the rolling motion of the articulating surface comes to a standstill and then changes direction. The reversal in movement occurs at the flexion angle where the quadriceps tendon first contacts the femoral groove.

49.3   Hip

The hip joint is composed of the head of the femur and the acetabulum of the pelvis. The hip joint is one of the most stable joints in the body. The stability is provided by the rigid ball-and-socket configuration.

49.3.1   Geometry of the Articulating Surfaces

The femoral head is spherical in its articular portion which forms twothirds of a sphere. The diameter of the femoral head is smaller for females than for males (Table 49.11). In the normal hip, the center of the femoral head coincides exactly with the center of the acetabulum. The rounded part of the femoral head is spheroidal rather than spherical because the uppermost part is flattened slightly. This causes

the load to be distributed in a ringlike pattern around the superior pole. The geometrical center of the femoral head is traversed by the three axes of the joint, the horizontal axis, the vertical axis, and the anterior/posterior axis. The head is supported by the neck of the femur, which joins the shaft. The axis of the femoral neck is obliquely set and runs superiorly, medially, and anteriorly. The angle of inclination of the femoral neck to the shaft in the frontal plane is the neck-shaft angle (Figure 49.14). In most adults, this angle is about 130° (Table 49.11). An angle exceeding 130° is known as *coxa valga*; an angle less than 130° is known as *coxa vara.* The femoral neck forms an acute angle with the transverse axis of the femoral condyles. This angle faces medially and anteriorly and is called the *angle of anteversion* (Figure 49.15). In the adult, this angle averages about 7.5° (Table 49.11).

The acetabulum receives the femoral head and lies on the lateral aspect of the hip. The acetabulum of the adult is a hemispherical socket. Its cartilage area is approximately 16 cm^2 [Von Lanz and Wauchsmuth, 1938]. Together with the labrum, the acetabulum covers slightly more than 50% of the femoral head

[Tönnis, 1987]. Only the sides of the acetabulum are lined by articular cartilage, which is interrupted inferiorly by the deep acetabular notch. The central part of the cavity is deeper than the articular cartilage and is nonarticular. This part is called the *acetabular fossae* and is separated from the interface of the pelvic bone by a thin plate of bone.

49.3.2 Joint Contact

Miyanaga et al. [1984] studied the deformation of the hip joint under loading, the contact area between the articular surfaces, and the contact pressures. They found that at loads up to 1000 N, pressure was distributed largely to the anterior and posterior parts of the lunate surface with very little pressure applied to the central portion of the roof itself. As the load increased, the contact area enlarged to include the outer and inner edges of the lunate surface (Figure 49.16). However, the highest pressures were still measured anteriorly and posteriorly. Of five hip joints studied, only one had a pressure maximum at the zenith or central part of the acetabulum.

Davy et al. [1989] utilized a telemetered total hip prosthesis to measure forces across the hip after total hip arthroplasty. The orientation of the resultant joint contact force varies over a relatively limited range during the weight-load-bearing portions of gait. Generally, the joint contact force on the ball of the hip prosthesis is located in the anterior/superior region. A three-dimensional plot of the resultant joint force during the gait cycle, with crutches, is shown in Figure 49.17.

49.3.3 Axes of Rotation

The human hip is a modified spherical (ball-and-socket) joint. Thus, the hip possesses three degrees of freedom of motion with three correspondingly arranged, mutually perpendicular axes that intersect at the geometric center of rotation of the spherical head. The transverse axis lies in the frontal plane and

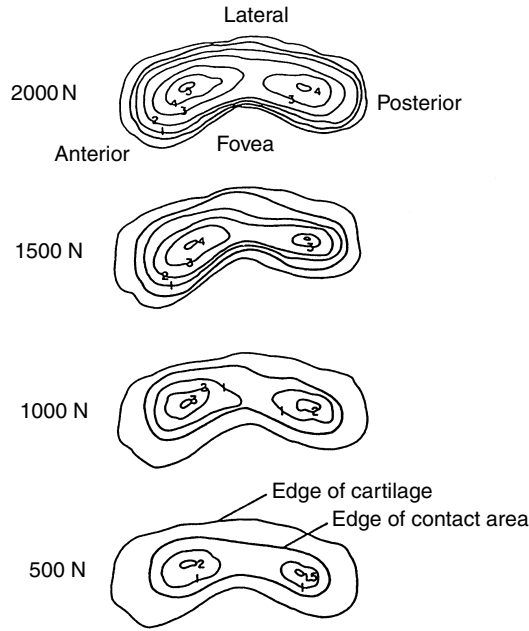
controls movements of flexion and extension. An anterior/posterior axis lies in the sagittal plane and controls movements of adduction and abduction. A vertical axis which coincides with the long axis of the limb when the hip joint is in the neutral position controls movements of internal and external rotation. Surface motion in the hip joint can be considered as spinning of the femoral head on the acetabulum. The


FIGURE 49.16 Pressure distribution and contact area of hip joint. The pressure is distributed largely to the anterior and posterior parts of the lunate surface. As the load increased, the contact area increased. (From Miyanaga Y., Fukubayashi T., and Kurosawa H. 1984. *Arch. Orth. Trauma Surg.* 103:13. With permission.)

pivoting of the bone socket in three planes around the center of rotation in the femoral head produces the spinning of the joint surfaces.

49.4   Shoulder

The shoulder represents the group of structures connecting the arm to the thorax. The combined movements of four distinct articulations — glenohumeral, acromioclavicular, sternoclavicular, and scapulothoracic — allow the arm to be positioned in space.

49.4.1   Geometry of the Articulating Surfaces

The articular surface of the humerus is approximately one-third of a sphere (Figure 49.18). The articular surface is oriented with an upward tilt of approximately 45° and is retroverted approximately 30° with respect to the condylar line of the distal humerus [Morrey and An, 1990]. The average radius of curvature of the humeral head in the coronal plane is 24.0 ± 2.1 mm [Iannotti et al., 1992]. The radius of curvature in the anteroposterior and axillary-lateral view is similar, measuring 13.1 ± 1.3 and 22.9 ± 2.9 mm, respectively [McPherson et al., 1997]. The humeral articulating surface is spherical in the center. However, the peripheral radius is 2 mm less in the axial plane than in the coronal plane. Thus the peripheral contour of the articular surface is elliptical with a ratio of 0.92 [Iannotti et al., 1992]. The major axis is superior to inferior and the minor axis is anterior to posterior [McPherson et al., 1997]. More recently, the three-dimensional geometry of the proximal humerus has been studied extensively. The articular surface, which is part of a sphere, varies individually in its orientation with respect to inclination and retroversion, and it has variable medial and posterior offsets [Boileau and Walch, 1997]. These findings have great impact in implant design and placement in order to restore soft-tissue function.
FIGURE 49.17   Scaled three-dimensional plot of resultant force during the gait cycle with crutches. The lengths of the lines indicate the magnitude of force. Radial line segments are drawn at equal increments of time, so the distance between the segments indicates the rate at which the orientation of the force was changing. For higher amplitudes of force during stance phase, line segments in close proximity indicate that the orientation of the force was changing relatively little with the cone angle between 30 and 40° and the polar angle between −25 and −15°. (From Davy D.T., Kotzar D.M., Brown R.H. et al. 1989. *J. Bone Joint Surg.* 70A: 45. With permission.)
FIGURE 49.18   The two-dimensional orientation of the articular surface of the humerus with respect to the bicondylar axis. By permission of Mayo Foundation.

The glenoid fossa consists of a small, pear-shaped, cartilage-covered bony depression that measures 39.0 ± 3.5 mm in the superior/inferior direction and 29.0 ± 3.2 mm in the anterior/posterior direction [Iannotti et al., 1992]. The anterior/posterior dimension of the glenoid is pear-shaped with the lower half being larger than the top half. The ratio of the lower half to the top half is $1 : 0.80 \pm 0.01$ [Iannotti et al.,
FIGURE 49.19 The glenoid faces slightly superior and posterior (retroverted) with respect to the body of the scapula. By permission of Mayo Foundation.

TABLE 49.12 Glenohumeral Contact Areas

Elevation angle (°)	Contact areas at SR (cm^2)	Contact areas at 20° internal to SR (cm^2)
0	0.87 ± 1.01	1.70 ± 1.68
30	2.09 ± 1.54	2.44 ± 2.15
60	3.48 ± 1.69	4.56 ± 1.84
90	4.95 ± 2.15	3.92 ± 2.10
120	5.07 ± 2.35	4.84 ± 1.84
150	3.52 ± 2.29	2.33 ± 1.47
180	2.59 ± 2.90	2.51 ± NA

SR = starting external rotation which allowed the shoulder to reach maximal elevation in the scapular plane ($\approx 40° \pm 8°$); NA = not applicable.

Source: Soslowsky L.J., Flatow E.L., Bigliani L.U., Pablak R.J., Mow V.C., and Athesian G.A. 1992. *J. Orthop. Res.* 10: 524.

1992]. The glenoid radius of curvature is 32.2 ± 7.6 mm in the anteroposterior view and 40.6 ± 14.0 mm in the axillary–lateral view [McPherson et al., 1997]. The glenoid is therefore more curved superior to inferior (coronal plane) and relatively flatter in an anterior to posterior direction (sagittal plane). Glenoid depth is 5.0 ± 1.1 mm in the anteroposterior view and 2.9 ± 1.0 mm in the axillary–lateral [McPherson et al., 1997], again confirming that the glenoid is more curved superior to inferior. In the coronal plane the articular surface of the glenoid comprises an arc of approximately 75° and in the transverse plane the arc of curvature of the glenoid is about 50° [Morrey and An, 1990]. The glenoid has a slight upward tilt of about 5° [Basmajian and Bazant, 1959] with respect to the medial border of the scapula (Figure 49.19) and is retroverted a mean of approximately 7° [Saha, 1971]. The relationship of the dimension of the humeral head to the glenoid head is approximately 0.8 in the coronal plane and 0.6 in the horizontal or transverse plane [Saha, 1971]. The surface area of the glenoid fossa is only one-third to one-fourth that of the humeral head [Kent, 1971]. The arcs of articular cartilage on the humeral head and glenoid in the frontal and axial planes were measured [Jobe and Iannotti, 1995]. In the coronal plane, the humeral heads had an arc of 159° covered by 96° of glenoid, leaving 63° of cartilage uncovered. In the transverse plane, the humeral arc of 160° is opposed by 74° of glenoid, leaving 86° uncovered.
FIGURE 49.20 Humeral contact positions as a function of glenohumeral motion and positions. (From Morrey B.F. and An K.N. 1990. C.A. Rockwood and F.A. Matsen (Eds.), *The Shoulder*, pp. 208–245, Philadelphia, Saunders. With permission.)

49.4.2 Joint Contact

The degree of conformity and constraint between the humeral head and glenoid has been represented by conformity index (radius of head/radius of glenoid) and constraint index (arc of enclosure/360) [McPherson, 1997]. Based on the study of 93 cadaveric specimens, the mean conformity index was 0.72 in the coronal and 0.63 in the sagittal plane. There was more constraint to the glenoid in the coronal vs. sagittal plane (0.18 vs. 0.13). These anatomic features help prevent superior–inferior translation of the humeral head but allow translation in the sagittal plane. Joint contact areas of the glenohumeral joint tend to be greater at mid-elevation positions than at either of the extremes of joint position (Table 49.12). These results suggest that the glenohumeral surface is maximum at these more functional positions, thus distributing joint load over a larger region in a more stable configuration. The contact point moves forward and inferior during internal rotation (Figure 49.20). With external rotation, the contact is posterior/inferior. With elevation, the contact area moves superiorly. Lippitt and associates [1998] calculated the stability ratio, which is defined as a force necessary to translate the humeral head from the glenoid fossa divided by the compressive load times 100. The stability ratios were in the range of 50–60% in the superior–inferior direction and 30–40% in the anterior–posterior direction. After the labrum was removed, the ratio decreased by approximately 20%. Joint conformity was found to have significant influence on translations of humeral head during active positioning by muscles [Karduna et al., 1996].

49.4.3 Axes of Rotation

The shoulder complex consists of four distinct articulations: the glenohumeral joint, the acromioclavicular joint, the sternoclavicular joint, and the scapulothoracic articulation. The wide range of motion of the shoulder (exceeding a hemisphere) is the result of synchronous, simultaneous contributions from each joint. The most important function of the shoulder is arm elevation. Several investigators have attempted to relate glenohumeral and scapulothoracic motion during arm elevation in various planes

TABLE 49.13   Arm Elevation: Glenohumeral–Scapulothoracic Rotation

Investigator	Glenohumeral/scapulothoracic motion ratio
Inman et al. [1994]	2 : 1
Freedman and Munro [1966]	1.35 : 1
Doody et al. [1970]	1.74 : 1
Poppen and Walker [1976]	4.3 : 1 (<24° elevation)
	1.25 : 1 (>24° elevation)
Saha [1971]	2.3 : 1 (30–135° elevation)
FIGURE 49.21   Rotation of the scapula on the thorax in the scapular plane. Instant centers of rotation (solid dots) are shown for each 30° interval of motion during shoulder elevation in the scapular plane from zero to 150°. The *x* and *y* axes are fixed in the scapula, whereas the *X* and *Y* axes are fixed in the thorax. From zero to 30° in the scapula rotated about its lower midportion; from 60° onward, rotation took place about the glenoid area, resulting in a medial and upward displacement of the glenoid face and a large lateral displacement of the inferior tip of the scapula. (From Poppen N.K. and Walker P.S. 1976. *J. Bone Joint Surg.* 58A:195. With permission.)

(Table 49.13). About two-thirds of the motion takes place in the glenohumeral joint and about one-third in the scapulothoracic articulation, resulting in a 2 : 1 ratio.

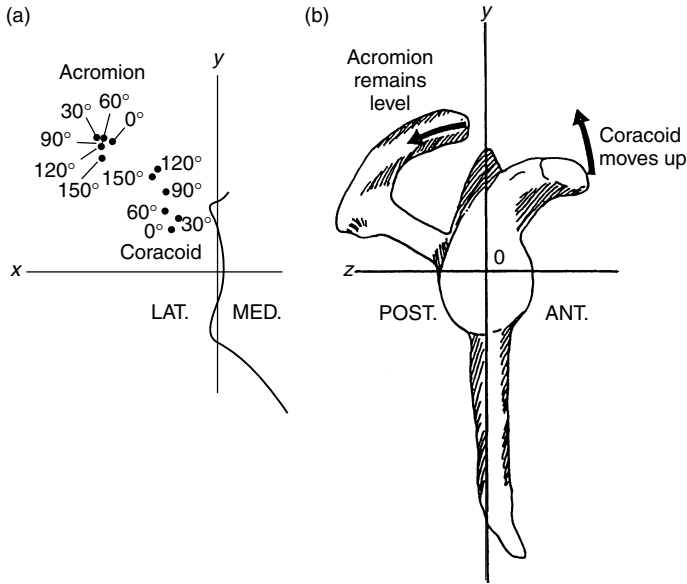
Surface motion at the glenohumeral joint is primarily rotational. The center of rotation of the glenohumeral joint has been defined as a locus of points situated within 6.0 ± 1.8 mm of the geometric center of the humeral head [Poppen and Walker, 1976]. However, the motion is not purely rotational. The humeral head displaces, with respect to the glenoid. From 0 to 30°, and often from 30 to 60°, the humeral head moves upward in the glenoid fossa by about 3 mm, indicating that rolling and/or gliding


FIGURE 49.22   (a) A plot of the tips of the acromion and coracoid process on roentgenograms taken at successive intervals of arm elevation in the scapular plane shows upward movement of the coracoid and only a slight shift in the acromion relative to the glenoid face. This finding demonstrates twisting, or external rotation, of the scapula about the *x*-axis. (b) A lateral view of the scapula during this motion would show the coracoid process moving upward while the acromion remains on the same horizontal plane as the glenoid. (From Poppen N.K. and Walker P.S. 1976. *J. Bone Joint Surg.* 58A: 195. With permission.)

has taken place. Thereafter, the humeral head has only about 1 mm of additional excursion. During arm elevation in the scapular plane, the scapula moves in relation to the thorax [Poppen and Walker, 1976]. From 0 to 30° the scapula rotates about its lower mid portion, and then from 60° onward the center of rotation shifts toward the glenoid, resulting in a large lateral displacement of the inferior tip of the scapula (Figure 49.21). The center of rotation of the scapula for arm elevation is situated at the tip of the acromion as viewed from the edge on (Figure 49.22). The mean amount of scapular twisting at maximum arm elevation is 40°. The superior tip of the scapula moves away from the thorax, and the inferior tip moves toward it.

49.5   Elbow

The bony structures of the elbow are the distal end of the humerus and the proximal ends of the radius and ulna. The elbow joint complex allows two degrees of freedom in motion: flexion/extension and pronation/supination. The elbow joint complex is three separate synovial articulations. The humeral–ulnar joint is the articulation between the trochlea of the distal radius and the trochlear fossa of the proximal ulna. The humero–radial joint is formed by the articulation between the capitulum of the distal humerus and the head of the radius. The proximal radioulnar joint is formed by the head of the radius and the radial notch of the proximal ulna.

49.5.1   Geometry of the Articulating Surfaces

The curved, articulating portions of the trochlea and capitulum are approximately circular in a cross-section. The radius of the capitulum is larger than the central trochlear groove (Table 49.14). The centers of curvature of the trochlea and capitulum lie in a straight line located on a plane that slopes at 45 to 50°

TABLE 49.14   Elbow Joint Geometry

Parameter	Size (mm)
Capitulum radius	10.6 ± 1.1
Lateral trochlear flange radius	10.8 ± 1.0
Central trochlear groove radius	8.8 ± 0.4
Medial trochlear groove radius	13.2 ± 1.4

anterior and distal to the transepicondylar line and is inclined at 2.5° from the horizontal transverse plane [Shiba et al., 1988]. The curves of the ulnar articulations form two surfaces (coronoid and olecranon) with centers on a line parallel to the transepicondylar line but are distinct from it [Shiba et al., 1988]. The carrying angle is an angle made by the intersection of the longitudinal axis of the humerus and the forearm in the frontal plane with the elbow in an extended position. The carrying angle is contributed to, in part, by the oblique axis of the distal humerus and, in part, by the shape of the proximal ulna (Figure 49.23).

49.5.2   Joint Contact

The contact area on the articular surfaces of the elbow joint depends on the joint position and the loading conditions. Increasing the magnitude of the load not only increases the size of the contact area but shifts the locations as well (Figure 49.24). As the axial loading is increased, there is an increased lateralization of the articular contact [Stormont et al., 1985]. The area of contact, expressed as a percentage of the total articulating surface area, is given in Table 49.15. Based on a finite element model of the humero–ulnar joint, Merz et al. [1997] demonstrated that the humero–ulnar joint incongruity brings about a bicentric distribution of contact pressure, a tensile stress exists in the notch that is the same order of magnitude as the compressive stress [Merz, 1997].

49.5.3   Axes of Rotation

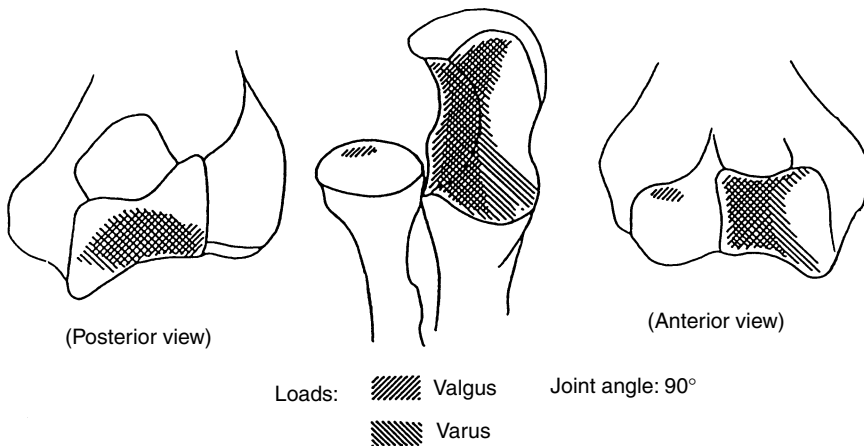
The axes of flexion and extension can be approximated by a line passing through the center of the trochlea, bisecting the angle formed by the longitudinal axes of the humerus and the ulna [Morrey and Chao, 1976]. The instant centers of flexion and extension vary within 2–3 mm of this axis (Figure 49.25). With the elbow fully extended and the forearm fully supinated, the longitudinal axes of humerus and ulna normally intersect at a valgus angle referred to as the *carrying angle*. In adults, this angle is usually 10–15° and
FIGURE 49.23 Components contributing to the carrying angles: $\alpha + \lambda + \psi$. Key: α, angle between C-line and TEL; γ, inclination of central groove (cg); λ, angle between trochlear notch (tn); ψ, reverse angulation of shaft of ulna; TLE, transepicondylar line; C-line, line joining centers of curvature of the trochlea and capitellum; cg, central groove; op, olecranon process; tr, trochlear ridge; cp, coronoid process. $\alpha = 2.5 \pm 0.0$; $\lambda = 17.5 \pm 5.0$ (females) and 12.0 ± 7.0 (males); $\psi = -6.5 \pm 0.7$ (females) and -9.5 ± 3.5 (males). (From Shiba R., Sorbie C., Siu D.W., Bryant J.T., Cooke T.D.V., and Weavers H.W. 1988. *J. Orthop. Res.* 6: 897. With permission.)


FIGURE 49.24 Contact of the ulnohumeral joint with varus and valgus loads and the elbow at 90°. Notice only minimal radiohumeral contact in this loading condition. (From Stormont T.J., An K.N., Morrey B.F., and Chae E.Y. 1985. *J. Biomech.* 18: 329. Reprinted with permission of Elsevier Science Inc.)
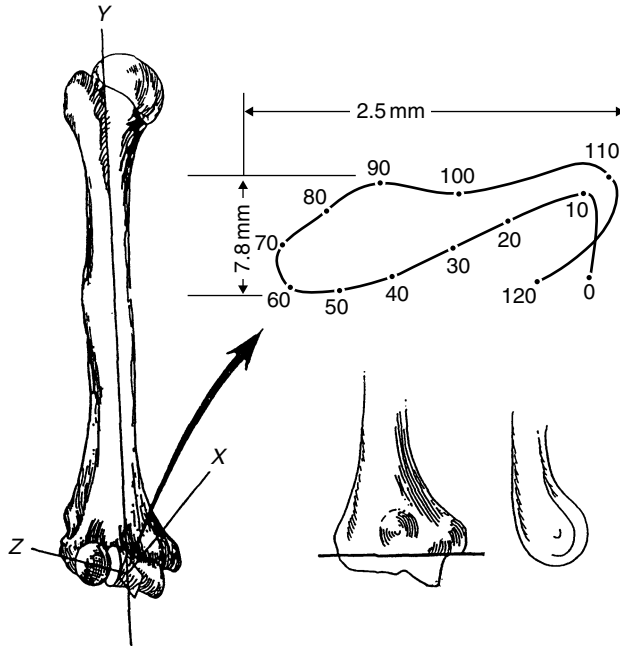

FIGURE 49.25 Very small locus of instant center of rotation for the elbow joint demonstrates that the axis may be replicated by a single line drawn from the inferior aspect of the medial epicondyle through the center of the lateral epicondyle, which is in the center of the lateral projected curvature of the trochlea and capitellum. (From Morrey B.F. and Chao E.Y.S. 1976. *J. Bone Joint Surg.* 58A: 501. With permission.)

normally is greater on average in women [Zuckerman and Matsen, 1989]. As the elbow flexes, the carrying angle varies as a function of flexion (Figure 49.26). In extension there is a valgus angulation of 10°; at full flexion there is a varus angulation of 8° [Morrey and Chao, 1976]. More recently, the three-dimensional kinematics of the ulno–humeral joint under simulated active elbow joint flexion–extension was obtained by using an electromagnetic tracking device [Tanaka et al., 1998]. The optimal axis to best represent flexion–extension motion was found to be close to the line joining the centers of the capitellum and the trochlear groove. Furthermore, the joint laxity under valgus–varus stress was also examined. With the weight of the forearm as the stress, a maximum of 7.6° valgus–varus and 5.3° of axial rotation laxity were observed.

49.6 Wrist

The wrist functions by allowing changes of orientation of the hand relative to the forearm. The wrist joint complex consists of multiple articulations of eight carpal bones with the distal radius, the structures of the ulnocarpal space, the metacarpals, and each other. This collection of bones and soft tissues is capable of a substantial arc of motion that augments hand and finger function.

49.6.1 Geometry of the Articulating Surfaces

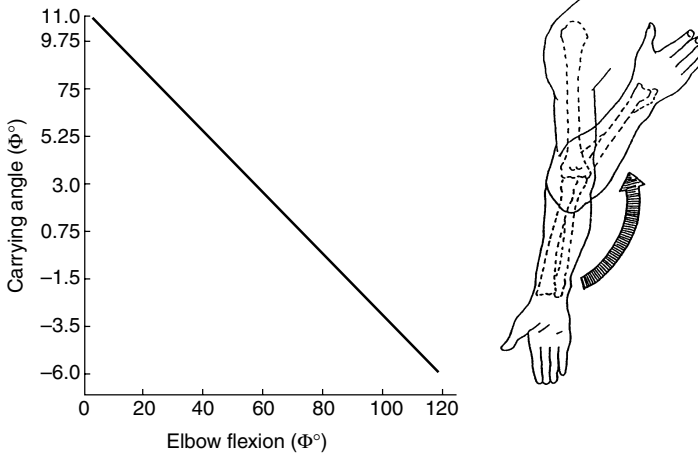
The global geometry of the carpal bones has been quantified for grasp and active isometric contraction of the elbow flexors [Schuind et al., 1992]. During grasping there is a significant proximal migration of the radius of 0.9 mm, apparent shortening of the capitate, a decrease in the carpal height ratio, and an increase in the lunate uncovering index (Table 49.16). There is also a trend toward increase of the distal radioulnar joint with grasping. The addition of elbow flexion with concomitant grasping did not significantly change


FIGURE 49.26 During elbow flexion and extension, a linear change in the carrying angle is demonstrated, typically going from valgus in extension to varus in flexion. (From Morrey B.F. and Chao E.Y.S. 1976. *J. Bone Joint Surg.* 58A: 501. With permission.)

TABLE 49.16 Changes of Wrist Geometry with Grasp

	Resting	Grasp	Analysis of variance (p = level)
Distal radioulnar joint space (mm)	1.6 ± 0.3	1.8 ± 0.6	0.06
Ulnar variance (mm)	-0.2 ± 1.6	0.7 ± 1.8	0.003

the global geometry, except for a significant decrease in the forearm interosseous space [Schuind et al., 1992].

49.6.2 Joint Contact

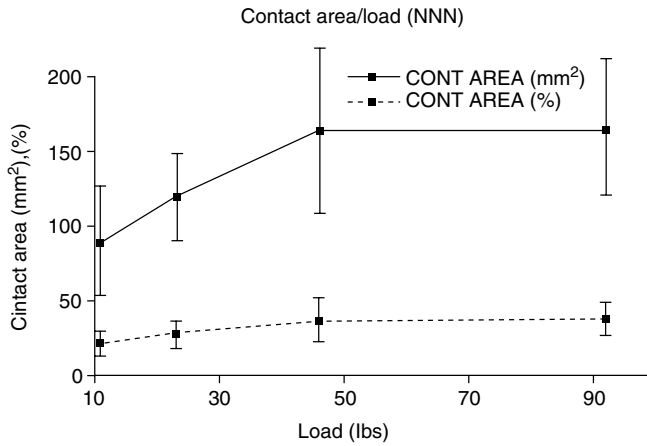
Studies of the normal biomechanics of the proximal wrist joint have determined that the scaphoid and lunate bones have separate, distinct areas of contact on the distal radius/triangular fibrocartilage complex surface [Viegas et al., 1987] so that the contact areas were localized and accounted for a relatively small fraction of the joint surface, regardless of wrist position (average of 20.6%). The contact areas shift from a more volar location to a more dorsal location as the wrist moves from flexion to extension. Overall, the scaphoid contact area is 1.47 times greater than that of the lunate. The


FIGURE 49.27 The nonlinear relation between the contact area and the load at the proximal wrist joint. The contact area was normalized as a percentage of the available joint surface. The load of 11, 23, 46, and 92 lbs was applied at the position of neutral pronation/supination, neutral radioulnar deviation, and neutral flexion/extension. (From Viegas S.F., Patterson R.M., Peterson P.D., Roefs J., Tencer A., and Choi S. 1989. *J. Hand Surg.* 14A: 458. With permission.)

TABLE 49.17 Force Transmission at the Intercarpal Joints

Joint	Force (N)
Radio-ulno-carpal	
Ulno-triquetral	12 ± 3
Ulno-lunate	23 ± 8
Radio-lunate	52 ± 8
Radio-scaphoid	74 ± 13

scapho-lunate contact area ratio generally increases as the wrist position is changed from radial to ulnar deviation and/or from flexion to extension. Palmer and Werner [1984] also studied pressures in the proximal wrist joint and found that there are three distinct areas of contact: the ulno-lunate, radio-lunate, and radio-scaphoid. They determined that the peak articular pressure in the ulno-lunate fossa is 1.4 N/mm^2, in the radio-ulnate fossa is 3.0 N/mm^2, and in the radio-scaphoid fossa is 3.3 N/mm^2. Viegas et al. [1989] found a nonlinear relationship between increasing load and the joint contact area (Figure 49.27). In general, the distribution of load between the scaphoid and lunate was consistent with all loads tested, with 60% of the total contact area involving the scaphoid and 40% involving the lunate. Loads greater than 46 lbs were found to not significantly increase the overall contact area. The overall contact area, even at the highest loads tested, was not more than 40% of the available joint surface.
FIGURE 49.28   The location of the center of rotation during ulnar deviation (left) and extension (right), determined graphically using two metal markers embedded in the capitate. Note that during radial–ulnar deviation the center lies at a point in the capitate situated distal to the proximal end of this bone by a distance equivalent to approximately one-quarter of its total longitudinal length. During flexion–extension, the center of rotation is close to the proximal cortex of the capitate. (From Youm Y., McMurty R.Y., Flatt A.E., and Gillespie T.E. 1978. *J. Bone Joint Surg.* 60A: 423. With permission.)

Horii et al. [1990] calculated the total amount of force born by each joint with the intact wrist in the neutral position in the coronal plane and subjected to a total load of 143 N (Table 49.17). They found that 22% of the total force in the radio-ulno–carpal joint is dissipated through the ulna (14% through the ulno–lunate joint, and 18% through the ulno–triquetral joint) and 78% through the radius (46% through the scaphoid fossa and 32% through the lunate fossa). At the midcarpal joint, the scapho–trapezial joint transmits 31% of the total applied force, the scapho–capitate joint transmits 19%, the luno-capitate joint transmits 29%, and the triquetral-hamate joints transmits 21% of the load.

A limited amount of studies have been done to determine the contact areas in the midcarpal joint. Viegas et al. [1990] have found four general areas of contact: the scapho-trapezial-trapezoid (STT), the scapho-capitate (SC), the capito-lunate (CL), and the triquetral-hamate (TH). The high pressure contact area accounted for only 8% of the available joint surface with a load of 32 lbs and increased to a maximum of only 15% with a load of 118 lbs. The total contact area, expressed as a percentage of the total available joint area for each fossa was: STT = 1.3%, SC = 1.8%, CL = 3.1%, and TH = 1.8%.

The correlation between the pressure loading in the wrist and the progress of degenerative osteoarthritis associated with pathological conditions of the forearm was studied in a cadaveric model [Sato, 1995]. Malunion after distal radius fracture, tear of triangular fibrocartilage, and scapholunate dissociation were all responsible for the alteration of the articulating pressure across the wrist joint. Residual articular incongruity of the distal radius following intra-articular fracture has been correlated with early osteoarthritis. In an *in vitro* model, step-offs of the distal radius articular incongruity were created. Mean contact stress was significantly greater than the anatomically reduced case at only 3 mm of step-off [Anderson et al., 1996].

49.6.3   Axes of Rotation

The complexity of joint motion at the wrist makes it difficult to calculate the instant center of motion. However, the trajectories of the hand during radioulnar deviation and flexion/extension, when they occur in a fixed plane, are circular, and the rotation in each plane takes place about a fixed axis. These axes are located within the head of the capitate and are not altered by the position of the hand in the plane of rotation [Youm et al., 1978]. During radioulnar deviation, the instant center of rotation lies at a point in the capitate situated distal to the proximal end of this bone by a distance equivalent to approximately one-quarter of its total length (Figure 49.28). During flexion/extension, the instant center is close to the

proximal cortex of the capitate, which is somewhat more proximal than the location for the instant center of radioulnar deviation.

Normal carpal kinematics were studied in 22 cadaver specimens using a biplanar radiography method. The kinematics of the trapezium, capitate, hamate, scaphoid, lunate, and triquetrum were determined during wrist rotation in the sagittal and coronal plane [Kobagashi et al., 1997]. The results were expressed using the concept of the screw displacement axis and covered to describe the magnitude of rotation about and translation along three orthogonal axes. The orientation of these axes is expressed relative to the radius during sagittal plane motion of the wrist (Table 49.18). The scaphoid exhibited the greatest magnitude of rotation and the lunate displayed the least rotation. The proximal carpal bones exhibited some ulnar deviation in 60° of wrist flexion. During coronal plane motion (Table 49.19), the magnitude of radial–ulnar deviation of the distal carpal bones was mutually similar and generally of a greater magnitude than that of the proximal carpal bones. The proximal carpal bones experienced some flexion during radial deviation of the wrist and extension during ulnar deviation of the wrist.

49.7 Hand

The hand is an extremely mobile organ that is capable of conforming to a large variety of object shapes and coordinating an infinite variety of movements in relation to each of its components. The mobility of this structure is possible through the unique arrangement of the bones in relation to one another, the articular contours, and the actions of an intricate system of muscles. Theoretical and empirical evidence suggest that limb joint surface morphology is mechanically related to joint mobility, stability, and strength [Hamrick, 1996].

49.7.1 Geometry of the Articulating Surfaces

Three-dimensional geometric models of the articular surfaces of the hand have been constructed. The sagittal contours of the metacarpal head and proximal phalanx grossly resemble the arc of a circle

[Tamai et al., 1988]. The radius of curvature of a circle fitted to the entire proximal phalanx surface ranges from 11 to 13 mm, almost twice as much as that of the metacarpal head, which ranges from 6 to 7 mm (Table 49.20). The local centers of curvature along the sagittal contour of the metacarpal heads are not fixed. The locus of the center of curvature for the subchondral bony contour approximates the locus of the center for the acute curve of an ellipse (Figure 49.29). However, the locus of center of curvature for the articular cartilage contour approximates the locus of the obtuse curve of an ellipse.

The surface geometry of the thumb carpometacarpal (CMC) joint has also been quantified [Athesian et al., 1992]. The surface area of the CMC joint is significantly greater for males than for females (Table 49.21). The minimum, maximum, and mean square curvature of these joints is reported in Table 49.21. The curvature of the surface is denoted by κ and the radius of curvature is $\rho = 1/\kappa$. The curvature is negative when the surface is concave and positive when the surface is convex.

Metacarpal head

Local center of bony contour

49.7.2 Joint Contact

The size and location of joint contact areas of the metacarpophalangeal (MCP) joint changes as a function of the joint flexion angle (Figure 49.30) The radioulnar width of the contact area becomes narrow in the neutral position and expands in both the hyperextended and fully flexed positions [An and Cooney, 1991]. In the neutral position, the contact area occurs in the center of the phalangeal base, this area being slightly larger on the ulnar than on the radial side.

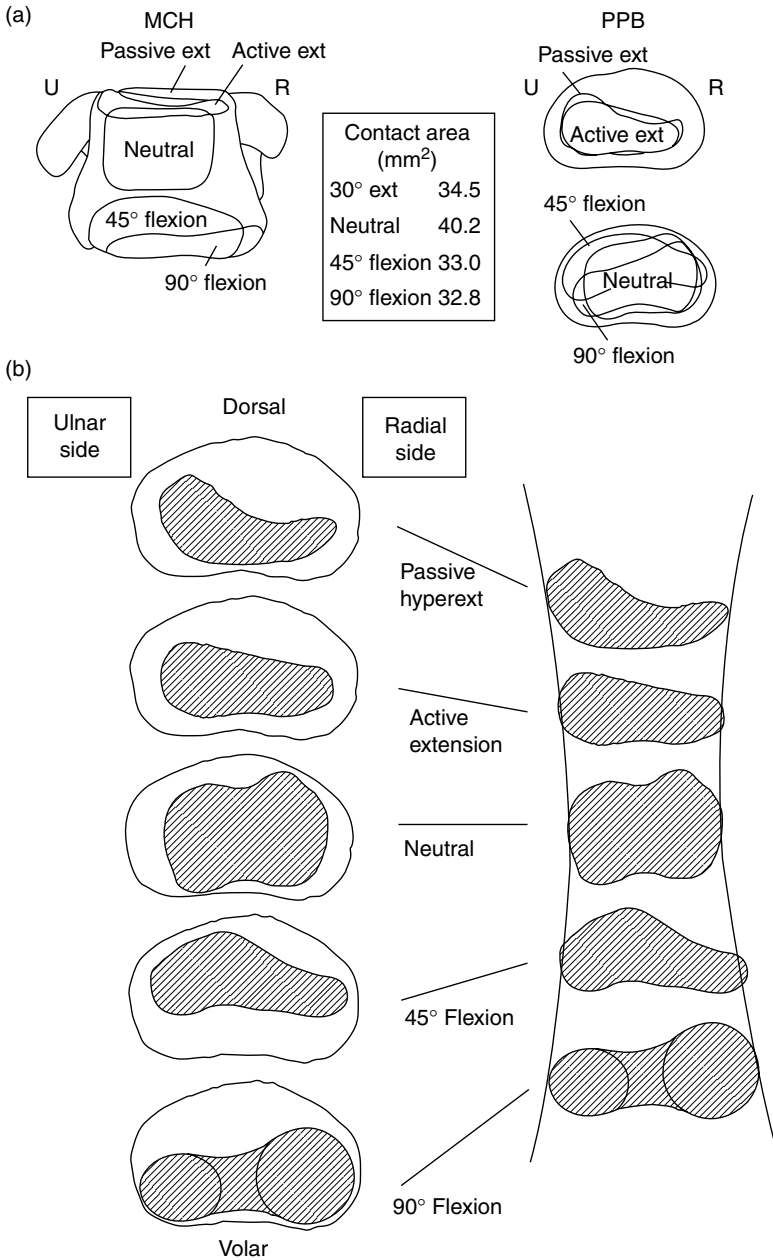
The contact areas of the thumb carpometacarpal joint under the functional position of lateral key pinch and in the extremes of range of motion were studied using a stereophotogrammetric technique [Ateshian et al., 1995]. The lateral pinch position produced contact predominately on the central, volar, and volar–ulnar regions of the trapezium and the metacarpals (Figure 49.31). Pelligrini et al. [1993] noted that the palmar compartment of the trapeziometacarpal joint was the primary contact area during flexion adduction of the thumb in lateral pinch. Detachment of the palmar beak ligament resulted in dorsal translation of the contact area producing a pattern similar to that of cartilage degeneration seen in the osteoarthritic joint.


FIGURE 49.30 (a) Contact area of the MCP joint in five joint positions. (b) End on view of the contact area on each of the proximal phalanx bases. The radioulnar width of the contact area becomes narrow in the neutral position and expands in both the hyperextended and fully flexed positions. (From An K.N. and Cooney W.P. 1991. In B.F. Morrey (Ed.), *Joint Replacement Arthroplasty*, pp. 137–146, New York, Churchill Livingstone. By permission of Mayo Foundation.)

49.7.3 Axes of Rotation

Rolling and sliding actions of articulating surfaces exist during finger joint motion. The geometric shapes of the articular surfaces of the metacarpal head and proximal phalanx, as well as the insertion location
FIGURE 49.31 Summary of the contact areas for all specimens, in lateral pinch with a 25 N load. All results from the right hand are transposed onto the schema of a carpometacarpal joint from the left thumb. (From Ateshian G.A., Ark J.W., Rosenwasser M.P., et al. 1995. *J. Orthop. Res.* 13: 450.)
FIGURE 49.32 Intersections of the instantaneous helical angles with the metacarpal sagittal plane. They are relative to one subject tested twice in different days. The origin of the graph is coincident with the calibrated center of the metacarpal head. The arrow indicates the direction of flexion. (From Fioretti S. 1994. In F. Schuind et al. (Eds.). *Advances in the Biomechanics of the Hand and Wrist*, pp. 363–375, New York, Plenum Press. With permission.)

of the collateral ligaments, significantly govern the articulating kinematics, and the center of rotation is not fixed but rather moves as a function of the angle of flexion [Pagowski and Piekarski, 1977]. The instant centers of rotation are within 3 mm of the center of the metacarpal head [Walker and Erhman, 1975]. Recently the axis of rotation of the MCP joint has been evaluated *in vivo* by Fioretti [1994]. The instantaneous helical axis of the MCP joint tends to be more palmar and tends to be displaced distally as flexion increases (Figure 49.32).

The axes of rotation of the CMC joint have been described as being fixed [Hollister et al., 1992], but others believe that a polycentric center of rotation exists [Imaeda et al., 1994]. Hollister et al. [1992] found that axes of the CMC joint are fixed and are not perpendicular to each other, or to the bones, and do not intersect. The flexion/extension axis is located in the trapezium, and the abduction/adduction axis is on the first metacarpal. In contrast, Imaeda et al. [1994] found that there was no single center of rotation, but rather the instantaneous motion occurred reciprocally between centers of rotations within the trapezium and the metacarpal base of the normal thumb. In flexion/extension,

TABLE 49.22   Location of Center of Rotation of
Trapeziometacarpal Joint

	Mean ± SD (mm)
Circumduction	
X	0.1 ± 1.3
Y	−0.6 ± 1.3
Z	−0.5 ± 1.4
Flexion/extension (in x–y plane)	
X	
Centroid	−4.2 ± 1.0
Radius	2.0 ± 0.5
Y	
Centroid	−0.4 ± 0.9
Radius	1.6 ± 0.5
Abduction/adduction (in x–z plane)	
X	
Centroid	6.7 ± 1.7
Radius	4.6 ± 3.1
Z	
Centroid	−0.2 ± 0.7
Radius	1.7 ± 0.5

Note: The coordinate system is defined with the x-axis corresponding to internal/external rotation, the y-axis corresponding to abduction/adduction, and the z-axis corresponding to flexion/extension. The x-axis is positive in the distal direction, the y-axis is positive in the dorsal direction for the left hand and in the palmar direction for the right hand, and the z-axis is positive in the radial direction. The origin of the coordinate system was at the intersection of a line connecting the radial and ulnar prominences and a line connecting the volar and dorsal tubercles.

Source: Imaeda T., Niebur G., Cooney W.P., Linscheid R.L., and An K.N. 1994. *J. Orthop. Res.* 12: 197.

the axis of rotation was located within the trapezium, but for abduction/adduction the center of rotation was located distally to the trapezium and within the base of the first metacarpal. The average instantaneous center of circumduction was at approximately the center of the trapezial joint surface (Table 49.22).

The axes of rotation of the thumb interphalangeal and metacarpophalangeal joint were located using a mechanical device [Hollister et al., 1995]. The physiologic motion of the thumb joints occur about these axes (Figure 49.33 and Table 49.23). The interphalangeal joint axis is parallel to the flexion crease of the joint and is not perpendicular to the phalanx. The metacarpophalangeal joint has two fixed axes: a fixed flexion–extension axis just distal and volar to the epicondyles, and an abduction–adduction axis related to the proximal phalanx passing between the sesamoids. Neither axis is perpendicular to the phalanges.

49.8   Summary

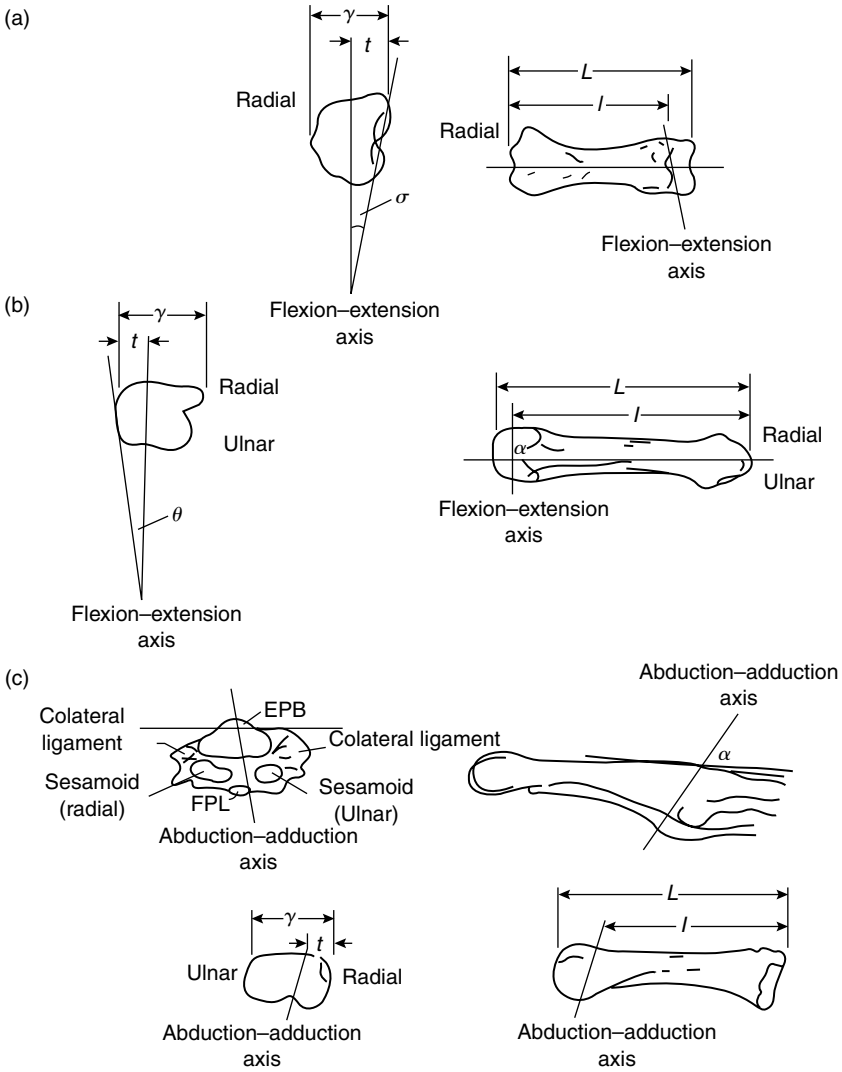
It is important to understand the biomechanics of joint-articulating surface motion. The specific characteristics of the joint will determine the musculoskeletal function of that joint. The unique geometry of the joint surfaces and the surrounding capsule ligamentous constraints will guide the unique characteristics of the articulating surface motion. The range of joint motion, the stability of the joint, and the ultimate functional strength of the joint will depend on these specific characteristics. A congruent joint usually has a relatively limited range of motion but a high degree of stability, whereas a less


FIGURE 49.33 (a) The angles and length and breadth measurements defining the axis of rotation of the interphalangeal joint of the right thumb. (t/T = ratio of anatomic plane diameter; l/L = ratio of length). (b) The angles and length and breadth measurements of the metacarpophalangeal flexion–extension axis' position in the metacarpal. (c) The angles and length and breadth measurements that locate the metacarpophalangeal abduction–adduction axis. The measurements are made in the metacarpal when the metacapophalangeal joint is at neutral flexion extension. The measurements are made relative to the metacarpal because the axis passes through this bone, not the proximal phalanx with which it moves. This method of recording the abduction–adduction measurements allows the measurements of the axes to each other at a neutral position to be made. The metacarpophalangeal abduction–adduction axis passes through the volar plate of the proximal phalanx. (From Hollister A., Giurintano D.J., Buford W.L., et al. *Clin. Orthop. Relat. Res.* 320: 188, 1995.)

congruent joint will have a relatively larger range of motion but less degree of stability. The characteristics of the joint-articulating surface will determine the pattern of joint contact and the axes of rotation. These characteristics will regulate the stresses on the joint surface which will influence the degree of degeneration of articular cartilage in an anatomic joint and the amount of wear of an artificial joint.

TABLE 49.23 Measurement of Axis Location and Values for Axis Position in the Bone[a]

Interphalangeal joint flexion-extension axis (Figure 49.33a)	
t/T	$44 \pm 17\%$
l/L	$90 \pm 5\%$
Θ	$5 \pm 2°$
β	$83 \pm 4°$
Metacarpophalangeal joint flexion-extension axis (Figure 49.33b)	
t/T	$57 \pm 17\%$
l/L	$87 \pm 5\%$
α	$101 \pm 6°$
β	$5 \pm 2°$
Metacarpophalangeal joint abduction-adduction axis (Figure 49.33c)	
t/T	$45 \pm 8\%$
l/L	$83 \pm 13\%$
α	$80 \pm 9°$
β	$74 \pm 8°$
M	

[a] The angle of the abduction-adduction axis with respect to the flexion-extension axis is $84.8 \pm 12.2°$. The location and angulation of the K-wires of the axes with respect to the bones were measured (Θ, α, β) directly with a goniometer. The positions of the pins in the bones were measured (T, L) with a Vernier caliper.

Joint Lubrication

Michael J. Furey
Virginia Polytechnic Institute and State University

The Fabric of the Joints in the Human Body is a subject so much the more entertaining, as it must strike every one that considers it attentively with an Idea of fine Mechanical Composition. Wherever the Motion of one Bone upon another is requisite, there we find an excellent Apparatus for rendering that Motion safe and free: We see, for Instance, the Extremity of one Bone molded into an orbicular Cavity, to receive the Head of another, in order to afford it an extensive Play. Both are covered with a smooth elastic Crust, to prevent mutual Abrasion; connected with strong Ligaments, to prevent Dislocation; and inclosed in a Bag that contains a proper Fluid Deposited there, for lubricating the Two contiguous Surfaces. So much in general.

The above is the opening paragraph of the classic paragraph of the classic paper by the surgeon, Sir William Hunter, "Of the Structure and Diseases of Articulating Cartilages" which he read to a meeting of the Royal Society, June 2, 1743 [1]. Since then, a great deal of research has been carried out on the subject of synovial joint lubrication. However, the mechanisms involved are still unknown.

50.1   Introduction

The purpose of this article is twofold: (1) to introduce the reader to the subject of tribology — the study of friction, wear, and lubrication; and (2) to extend this to the topic of *biotribology*, which includes the lubrication of natural synovial joints. It is not meant to be an exhaustive review of joint lubrication theories; space does not permit this. Instead, major concepts or principles will be discussed not only in the light of what is known about synovial joint lubrication but perhaps more importantly what is not known. Several references are given for those who wish to learn more about the topic. It is clear that synovial joints are by far the most complex and sophisticated tribological systems that exist. We shall see that although numerous theories have been put forth to attempt to explain joint lubrication, the mechanisms involved are still far from being understood. And when one begins to examine possible connections between tribology and degenerative joint disease or osteoarthritis, the picture is even more complex and controversial. Finally, this article does not treat the (1) tribological behavior of artificial joints or partial joint replacements, (2) the possible use of elastic or poroplastic materials as artificial cartilage, and (3) new developments in cartilage repair using transplanted chondrocytes. These are separate topics, which would require detailed discussion and additional space.

50.2   Tribology

The word tribology, derived from the Greek "to rub," covers all frictional processes between solid bodies moving relative to one another that are in contact [2]. Thus tribology may be defined as the study of friction, wear, and lubrication.

Tribological processes are involved whenever one solid slides or rolls against another, as in bearings, cams, gears, piston rings and cylinders, machining and metalworking, grinding, rock drilling, sliding electrical contacts, frictional welding, brakes, the striking of a match, music from a cello, articulation of human synovial joints (e.g., hip joints), machinery, and in numerous less obvious processes (e.g., walking, holding, stopping, writing, and the use of fasteners such as nails, screws, and bolts).

Tribology is a multidisciplinary subject involving at least the areas of materials science, solid and surface mechanics, surface science and chemistry, rheology, engineering, mathematics, and even biology and biochemistry. Although tribology is still an emerging science, interest in the phenomena of friction, wear, and lubrication is an ancient one. Unlike thermodynamics, there are no generally accepted laws in tribology. But there are some important basic principles needed to understand any study of lubrication and wear and even more so in a study of biotribology or biological lubrication phenomena. These basic principles follow.

50.2.1   Friction

Much of the early work in tribology was in the area of friction — possibly because frictional effects are more readily demonstrated and measured. Generally, early theories of friction dealt with dry or unlubricated systems. The problem was often treated strictly from a mechanical viewpoint, with little or no regard for the environment, surface films, or chemistry.

In the first place, *friction may be defined as the tangential resistance that is offered to the sliding of one solid body over another*. Friction is the result of many factors and cannot be treated as something as singular as density or even viscosity. Postulated sources of friction have included (1) the lifting of one asperity over another (increase in potential energy), (2) the interlocking of asperities followed by shear, (3) interlocking followed by plastic deformation or plowing, (4) adhesion followed by shear, (5) elastic hysteresis and waves of deformation, (6) adhesion or interlocking followed by tensile failure, (7) intermolecular attraction, (8) electrostatic effects, and (9) viscous drag. The coefficient of friction, indicated in the literature by μ or f, is defined as the ratio F/W where $F =$ friction force and $W =$ the normal load. It is emphasized that friction is a force and not a property of a solid material or lubricant.

50.2.2 Wear and Surface Damage

One definition of wear in a tribological sense is that it is the *progressive loss of substance from the operating surface of a body as a result of relative motion at the surface*. In comparison with friction, very little theoretical work has been done on the extremely important area of wear and surface damage. This is not too surprising in view of the complexity of wear and how little is known of the mechanisms by which it can occur. Variations in wear can be, and often are, enormous compared with variations in friction. For example, practically all the coefficients of sliding friction for diverse dry or lubricated systems fall within a relatively narrow range of 0.1 to 1. In some cases (e.g., certain regimes of hydrodynamic or "boundary" lubrication), the coefficient of friction may be <0.1 and as low as 0.001. In other cases (e.g., very clean unlubricated metals in vacuum), friction coefficients may exceed one. Reduction of friction by a factor of two through changes in design, materials, or lubricant would be a reasonable, although not always attainable, goal. On the other hand, it is not uncommon for wear rates to vary by a factor of 100, 1000, or even more.

For systems consisting of common materials (e.g., metals, polymers, ceramics), there are at least four main mechanisms by which wear and surface damage can occur between solids in relative motion: (1) abrasive wear, (2) adhesive wear, (3) fatigue wear, and (4) chemical or corrosive wear. A fifth, fretting wear and fretting corrosion, combines elements of more than one mechanism. For complex biological materials such as articular cartilage, most likely other mechanisms are involved.

Again, wear is the removal of material. The idea that friction causes wear and therefore, low friction means low wear, is a common mistake. Brief descriptions of five types of wear; abrasive, adhesive, fatigue, chemical or corrosive, and fretting — may be found in Reference 2 as well as in other references in this article. Next, it may be useful to consider some of the major concepts of lubrication.

50.3 Lubrication

Lubrication is a process of reducing friction *and/or* wear (or other forms of surface damage) between relatively moving surfaces by the application of a solid, liquid, or gaseous substance (i.e., a lubricant). Since friction and wear do not necessarily correlate with each other, the use of the word *and* in place of *and/or* in the above definition is a common mistake to be avoided. The primary function of a lubricant is to reduce friction or wear or both between moving surfaces in contact with each other.

Examples of lubricants are wide and varied. They include automotive engine oils, wheel bearing greases, transmission fluids, electrical contact lubricants, rolling oils, cutting fluids, preservative oils, gear oils, jet fuels, instrument oils, turbine oils, textile lubricants, machine oils, jet engine lubricants, air, water, molten glass, liquid metals, oxide films, talcum powder, graphite, molybdenum disulfide, waxes, soaps, polymers, and the synovial fluid in human joints.

A few general principles of lubrication may be mentioned here:

1. The lubricant must be present at the place where it can function.
2. Almost any substance under carefully selected or special conditions can be shown to reduce friction or wear in a particular test, but that does not mean these substances are lubricants.
3. Friction and wear do not necessarily go together. This is an extremely important principle which applies to nonlubricated (dry) as well as lubricated systems. It is particularly true under conditions of "boundary lubrication," to be discussed later. An additive may reduce friction and increase wear, reduce wear and increase friction, reduce both or increase both. Although the reasons are not fully understood, this is an experimental observation. Thus, friction and wear should be thought of as separate phenomena — an important point when we discuss theories of synovial joint lubrication.
4. The effective or active lubricating film in a particular system may or may not consist of the original or bulk lubricant phase.

In a broad sense, it may be considered that the main function of a lubricant is to keep the surfaces apart so that interaction (e.g., adhesion, plowing, and shear) between the solids cannot occur; thus friction and wear can be reduced or controlled.
FIGURE 50.1   Regimes of lubrication.

The following regimes or types of lubrication may be considered in the order of increasing severity or decreasing lubricant film thickness (Figure 50.1):

1. Hydrodynamic lubrication
2. Elastohydrodynamic lubrication
3. Transition from hydrodynamic and elastohydrodynamic lubrication to boundary lubrication
4. Boundary lubrication

A fifth regime, sometimes referred to as *dry* or *unlubricated*, may also be considered as an extreme or limit. In addition, there is another form of lubrication that does not require relative movement of the bodies either parallel or perpendicular to the surface, that is, as in externally pressurized hydrostatic or aerostatic bearings.

50.3.1   Hydrodynamic Lubrication Theories

In hydrodynamic lubrication, the load is supported by the pressure developed due to relative motion and the geometry of the system. In the regime of hydrodynamic or fluid film lubrication, there is no contact between the solids. The film thickness is governed by the bulk physical properties of the lubricants, the most important being viscosity; friction arises purely from shearing of viscous lubricant.

Contributions to our knowledge of hydrodynamic lubrication, with special focus on journal bearings, have been made by numerous investigators including Reynolds. The classic Reynolds treatment considered the equilibrium of a fluid element and the pressure and shear forces on this element. In this treatment, eight assumptions were made (e.g., surface curvature is large compared to lubricant film thickness, fluid is Newtonian, flow is laminar, viscosity is constant through film thickness). Velocity distributions due to relative motion and pressure buildup were developed and added together. The solution of the basic Reynolds equation for a particular bearing configuration results in a pressure distribution throughout the film as a function of viscosity, film shape, and velocity.

The total load W and frictional (viscous) drag F can be calculated from this information. For rotating disks with parallel axes, the "simple" Reynolds equation yields:

$$\frac{h_o}{R} = 4.9 \left(\frac{\eta U}{W} \right) \tag{50.1}$$

where h_o is the minimum lubricant film thickness, η is the absolute viscosity, U is the average velocity $(U_1 + U_2)/2$, W is the applied normal load per unit width of disk, and R is the reduced radius of curvature $(1/R = 1/R_1 + 1/R_2)$.

The dimensionless term $(\eta U/W)$ is sometimes referred to as the hydrodynamic factor. It can be seen that doubling either the viscosity or velocity doubles the film thickness, and that doubling the applied load halves the film thickness. This regime of lubrication is sometimes referred to as the *rigid isoviscous or classical Martin condition*, since the solid bodies are assumed to be perfectly rigid (non-deformable), and the fluid is assumed to have a constant viscosity.

At high loads with systems such as gears, ball bearings, and other high-contact-stress geometries, two additional factors have been considered in further developments of the hydrodynamic theory of lubrication. One of these is that the surfaces deform elastically; this leads to a localized change in geometry more favorable to lubrication. The second is that the lubricant becomes more viscous under the high pressure existing in the contact zone, according to relationships such as:

$$\eta/\eta_o = \exp \alpha(p - p_o) \tag{50.2}$$

where η is the viscosity at pressure p, η_o is the viscosity at atmospheric pressure p_o, and α is the pressure-viscosity coefficient (e.g., in Pa^{-1}). In this concept, the lubricant pressures existing in the contact zone approximate those of dry contact Hertzian stress. This is the regime of elastohydrodynamic lubrication, sometimes abbreviated as EHL or EHD. It may also be described as the elastic-viscous type or mode of lubrication, since elastic deformation exists and the fluid viscosity is considerably greater due to the pressure effect.

The comparable Dowson-Higginson expression for minimum film thickness between cylinders or disks in contact with parallel axes is:

$$\frac{h_o}{R} = 2.6 \left(\frac{\eta U}{W}\right)^{0.7} \left(\frac{\alpha W}{R}\right)^{0.54} \left(\frac{W}{RE'}\right)^{0.03} \tag{50.3}$$

The term E' represents the reduced modulus of elasticity:

$$\frac{1}{E'} = \frac{(1 - v_1^2)}{E_1} + \frac{(1 - v_2^2)}{E_2} \tag{50.4}$$

where E is the modulus, v is Poisson's ratio, and the subscripts 1 and 2 refer to the two solids in contact. All the other terms are the same as previously stated. In addition to the hydrodynamic factor $(\eta U/W)$, a pressure-viscosity factor $(\alpha W/R)$, and an elastic deformation factor (W/RE') can be considered. Thus, properties of both the lubricant and the solids as materials are included. In examining the elastohydrodynamic film thickness equations, it can be seen that the velocity U is an important factor $(h_o \propto U^{0.7})$ but the load W is rather unimportant $(h_o \propto W^{-0.13})$.

Experimental confirmation of the elastohydrodynamic lubrication theory has been obtained in certain selected systems using electrical capacitance, x-ray transmission, and optical interference techniques to determine film thickness and shape under dynamic conditions. Research is continuing in this area, including studies on micro-EHL or asperity lubrication mechanisms, since surfaces are never perfectly smooth. These studies may lead to a better understanding of not only lubricant film formation in high-contact-stress systems but lubricant film failure as well.

Two other possible types of hydrodynamic lubrication, rigid-viscous and elastic-isoviscous, complete the matrix of four, considering the two factors of elastic deformation and pressure-viscosity effects. In addition, *squeeze film* lubrication can occur when surfaces approach one another. For more information on hydrodynamic and elastohydrodynamic lubrication, see Cameron [3] and Dowson and Higginson [4].

50.3.2 Transition from Hydrodynamic to Boundary Lubrication

Although prevention of contact is probably the most important function of a lubricant, there is still much to be learned about the transition from hydrodynamic and elastohydrodynamic lubrication to boundary lubrication. This is the region in which lubrication goes from the desirable hydrodynamic condition of no contact to the less acceptable "boundary" condition, where increased contact usually leads to higher friction and wear. This regime is sometimes referred to as a condition of *mixed lubrication.*

Several examples of experimental approaches to thin-film lubrication have been reported [3]. It is important in examining these techniques to make the distinction between methods that are used to determine lubricant film thickness under hydrodynamic or elastohydrodynamic conditions (e.g., optical interference, electrical capacitance, or x-ray transmission), and methods that are used to determine the occurrence or frequency of contact. As we will see later, most experimental studies of synovial joint lubrication have focused on friction measurements, using the information to determine the lubrication regime involved; this approach can be misleading.

50.3.2.1 Boundary Lubrication

Although there is no generally accepted definition of boundary lubrication, it is often described as a condition of lubrication in which the friction and wear between two surfaces in relative motion are determined by the surface properties of the solids and the chemical nature of the lubricant rather than its viscosity. An example of the difficulty in defining boundary lubrication can be seen if the term *bulk viscosity* is used in place of viscosity in the preceding sentence — another frequent form. This opens the door to the inclusion of elastohydrodynamic effects which depend in part on the influence of pressure on viscosity. Increased friction under these circumstances could be attributed to increased viscous drag rather than solid-solid contact. According to another common definition, boundary lubrication occurs or exists when the surfaces of the bearing solids are separated by films of molecular thickness. That may be true, but it ignores the possibility that "boundary" layer surface films may indeed be very thick (i.e., 10, 20, or 100 molecular layers). The difficulty is that boundary lubrication is complex.

Although a considerable amount of research has been done on this topic, an understanding of the basic mechanisms and processes involved is by no means complete. Therefore, definitions of boundary lubrication tend to be nonoperational. This is an extremely important regime of lubrication because it involves more extensive solid-solid contact and interaction as well as generally greater friction, wear, and surface damage. In many practical systems, the occurrence of the boundary lubrication regime is unavoidable or at least quite common. The condition can be brought about by high loads, low relative sliding speeds (including zero for stop-and-go, motion reversal, or reciprocating elements) and low lubricant viscosity — factors that are important in the transition from hydrodynamic to boundary lubrication.

The most important factor in boundary lubrication is the chemistry of the tribological system — the contacting solids and total environment including lubricants. More particularly, the surface chemistry and interactions occurring with and on the solid surfaces are important. This includes factors such as physisorption, chemisorption, intermolecular forces, surface chemical reactions, and the nature, structure, and properties of thin films on solid surfaces. It also includes many other effects brought on by the process of moving one solid over another, such as (1) changes in topography and the area of contact, (2) high surface temperatures, (3) the generation of fresh reactive metal surfaces by the removal of oxide and other layers, (4) catalysis, (5) the generation of electrical charges, and (6) the emission of charged particles such as electrons.

In examining the action of boundary lubricant compounds in reducing friction or wear or both between solids in sliding contact, it may be helpful to consider at least the following five modes of film formation on or protection of surfaces: (1) physisorption, (2) chemisorption, (3) chemical reactions with the solid surface, (4) chemical reactions on the solid surface, and (5) mere interposition of a solid or other material. These modes of surface protection are discussed in more detail in Reference 2.

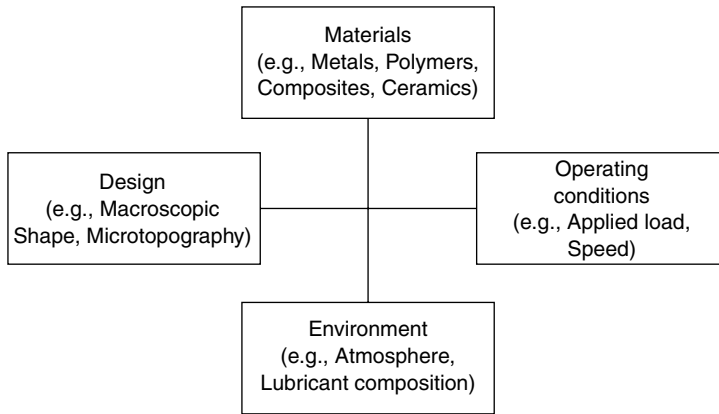
The beneficial and harmful effects of minor changes in chemistry of the environment (e.g., the lubricant) are often enormous in comparison with hydrodynamic and elastohydrodynamic effects. Thus, the


FIGURE 50.2   In any tribological system, friction, wear, and surface damage depend on four interrelated factors.

surface and chemical properties of the solid materials used in tribological applications become especially important. One might expect that this would also be the case in biological (e.g., human joint) lubrication where biochemistry is very likely an important factor.

50.3.2.2   General Comments on Tribological Processes

It is important to recognize that friction and wear depend upon four major factors, that is, materials, design, operating conditions, and total environment (Figure 50.2). This four-block figure may be useful as a guide in thinking about synovial joint lubrication either from a theoretical or experimental viewpoint — the topic discussed in the next section.

Readers are cautioned against the use of various terms in tribology which are either vaguely defined or not defined at all. These would include such terms as "lubricating ability," "lubricity," and even "boundary lubrication." For example, do "boundary lubricating properties" refer to effects on friction or effects on wear and damage? It makes a difference. It is emphasized once again that friction and wear are different phenomena. Low friction does not necessarily mean low wear. We will see several examples of this common error in the discussion of joint lubrication research.

50.4   Synovial Joints

Examples of natural synovial or movable joints include the human hip, knee, elbow, ankle, finger, and shoulder. A simplified representation of a synovial joint is shown in Figure 50.3. The bones are covered by a thin layer of articular cartilage bathed in synovial fluid confined by synovial membrane. Synovial joints are truly remarkable systems — providing the basis of movement by allowing bones to articulate on one another with minimal friction and wear. Unfortunately, various joint diseases occur even among the young — causing pain, loss of freedom of movement, or instability.

Synovial joints are complex, sophisticated systems not yet fully understood. The loads are surprisingly high and the relative motion is complex. Articular cartilage has the deceptive appearance of simplicity and uniformity. But it is an extremely complex material with unusual properties. Basically, it consists of water (approximately 75%) enmeshed in a network of collagen fibers and proteoglycans with high molecular weight. In a way, cartilage could be considered as one of Nature's composite materials. Articular cartilage also has no blood supply, no nerves, and very few cells (chondrocytes).

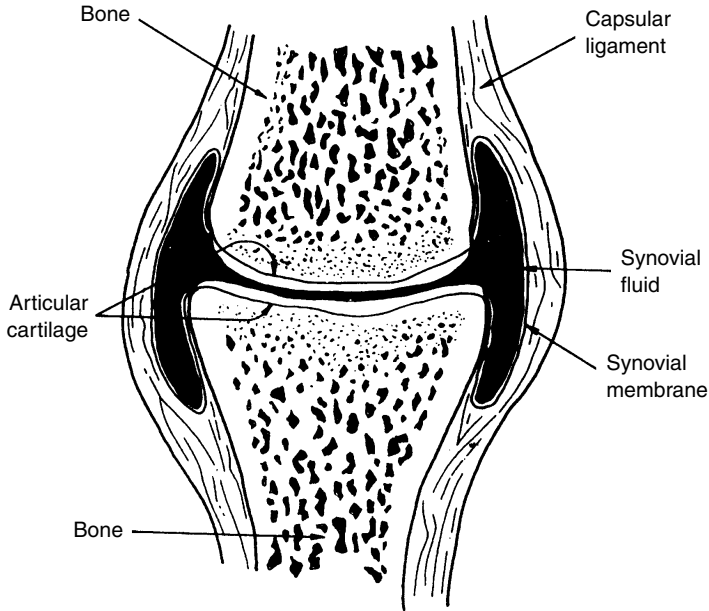
The other major component of an articular joint is *synovial fluid*, named by Paracelsus after "synovia" (egg-white). It is essentially a dialysate of blood plasma with added hyaluronic acid. Synovial fluid contains complex proteins, polysaccharides, and other compounds. Its chief constituent is water (approximately 85%). Synovial fluid functions as a joint lubricant, nutrient for cartilage, and carrier for waste products.


FIGURE 50.3   Representation of a synovial joint.

For more information on the biochemistry, structure, and properties of articular cartilage, Freeman [5], Sokoloff [6], Stockwell [7], and articles referenced in these works are suggested.

50.5   Theories on the Lubrication of Natural and Normal Synovial Joints

As stated, the word *tribology* means the study of friction, wear, and lubrication. Therefore, *biotribology* may be thought of as the study of biological lubrication processes, for example, as in synovial joints. A surprisingly large number of concepts and theories of synovial joint lubrication have been proposed [8–10] (as shown in Table 50.1). And even if similar ideas are grouped together, there are still well over a dozen fundamentally different theories. These have included a wide range of lubrication concepts, for example, hydrodynamic, hydrostatic, elasto-hydrodynamic, squeeze-film, "boundary," mixed-regime, "weeping," osmotic, synovial mucin gel, "boosted," lipid, electrostatic, porous layers, and special forms of boundary lubrication (e.g., "lubricating glycoproteins," structuring of boundary water "surface-active" phospholipids). This chapter will not review these numerous theories, but excellent reviews on the lubrication of synovial joints have been written by McCutchen [11], Swanson [12], and Higginsworth and Unsworth [13]. The book edited by Dumbleton is also recommended [14]. In addition, theses by Droogendijk [15] and Burkhardt [16] contain extensive and detailed reviews of theories of joint lubrication.

McCutchen was the first to propose an entirely new concept of lubrication, "weeping lubrication," applied to synovial joint action [17,18]. He considered unique and special properties of cartilage and how this could affect flow and lubrication. The work of Mow et al. continued along a more complex and sophisticated approach in which a biomechanical model is proposed for the study of the dynamic interaction between synovial fluid and articular cartilage [19,20]. These ideas are combined in the more recent work of Ateshian [21] which uses a framework of the biphasic theory of articular cartilage to model interstitial fluid pressurization. Several additional studies have also been made of effects of porosity and compliance, including the behavior of elastic layers, in producing hydrodynamic and squeeze-film

lubrication. A good review in this area was given by Unsworth who discussed both human and artificial joints [22].

The following general observations are offered on the theories of synovial joint lubrication that have been proposed:

1. Most of the theories are strictly mechanical or rheological — involving such factors as deformation, pressure, and fluid flow.
2. There is a preoccupation with *friction*, which of course is very low for articular cartilage systems.

3. None of the theories consider *wear* — which is neither the same as friction nor related to it.
4. The detailed structure, biochemistry, complexity, and living nature of the total articular cartilage-synovial fluid system are generally ignored.

These are only general impressions. And although mechanical/rheological concepts seem dominant (with a focus on friction), wear and biochemistry are not completely ignored. For example, Simon [23] abraded articular cartilage from human patellae and canine femoral heads with a stainless steel rotary file, measuring the depth of penetration with time and the amount of wear debris generated. Cartilage wear was also studied experimentally by Bloebaum and Wilson [24], Radin and Paul [25], and Lipshitz, Etheredge, and Glimcher [26–28]. The latter researchers carried out several *in vitro* studies of wear of articular cartilage using bovine cartilage plugs or specimens in sliding contact against stainless steel plates. They developed a means of measuring cartilage wear by determining the hydroxyproline content of both the lubricant and solid wear debris. Using this system and technique, effects of variables such as time, applied load, and chemical modification of articular cartilage on wear and profile changes were determined. This work is of particular importance in that they addressed the question of *cartilage wear and damage* rather than friction, recognizing that wear and friction are different phenomena.

Special note is also made of two researchers, Swann and Sokoloff, who considered biochemistry as an important factor in synovial joint lubrication. Swann et al. very carefully isolated fractions of bovine synovial fluid using sequential sedimentation techniques and gel permeation chromatography. They found a high molecular weight glycoprotein to be the major constituent in the articular lubrication fraction from bovine synovial fluid and called this LGP-I (from lubricating glycoprotein). This was based on friction measurements using cartilage in sliding contact against a glass disc. An excellent summary of this work with additional references is presented in a chapter by Swann in *The Joints and Synovial Fluid: I* [6].

Sokoloff et al. [29] examined the "boundary lubricating ability" of several synovial fluids using a latex-glass test system and cartilage specimens obtained at necropsy from knees. Measurements were made of friction. The research was extended to other *in vitro* friction tests using cartilage obtained from the nasal septum of cows and widely differing artificial surfaces [30]. As a result of this work, a new model of boundary lubrication by synovial fluid was proposed — the structuring of boundary water. The postulate involves adsorption of one part of a glycoprotein on a surface followed by the formation of hydration shells around the polar portions of the adsorbed glycoprotein; the net result is a thin layer of viscous "structured" water at the surface. This work is of particular interest in that it involves not only a specific and more detailed mechanism of boundary lubrication in synovial joints but also takes into account the possible importance of water in this system.

In more recent research by Jay, an interaction between hyaluronic acid and a "purified synovial lubricating factor" (PSLF) was observed, suggesting a possible synergistic action in the boundary lubrication of synovial joints [31]. The definition of "lubricating ability" was based on friction measurements made with a latex-covered stainless steel stud in oscillating contact against polished glass.

The above summary of major synovial joint lubrication theories is taken from References 10 and 31 as well as the thesis by Burkhardt [33].

Two more recent studies are of interest since cartilage wear was considered although not as a part of a theory of joint lubrication. Stachowiak et al. [34] investigated the friction and wear characteristics of adult rat femur cartilage against a stainless steel plate using an environmental scanning microscope (ESM) to examine damaged cartilage. One finding was evidence of a load limit to lubrication of cartilage, beyond which high friction and damage occurred. Another study, by Hayes et al. [35] on the influence of crystals on cartilage wear, is particularly interesting not only in the findings reported (e.g., certain crystals can increase cartilage wear), but also in the full description of the biochemical techniques used.

A special note should be made concerning the doctoral thesis by Lawrence Malcom in 1976 [36]. This is an excellent study of cartilage friction and deformation, in which a device resembling a rotary plate rheometer was used to investigate the effects of static and dynamic loading on the frictional behavior of bovine cartilage. The contact geometry consisted of a circular cylindrical annulus in contact with a concave hemispherical section. It was found that dynamically loaded specimens in bovine synovial fluid yielded the

more efficient lubrication based on friction measurements. The Malcom study is thorough and excellent in its attention to detail (e.g., specimen preparation) in examining the influence of type of loading and time effects on cartilage friction. It does not, however, consider cartilage wear and damage except in a very preliminary way. And it does not consider the influence of fluid biochemistry on cartilage friction, wear, and damage. In short, the Malcom work represents a superb piece of systematic research along the lines of mechanical, dynamic, rheological, and viscoelastic behavior — one important dimension of synovial joint lubrication.

50.6 *In Vitro* Cartilage Wear Studies

Over the past fifteen years, studies aimed at exploring possible connections between tribology and mechanisms of synovial joint lubrication and degeneration (e.g., osteoarthritis) have been conducted by the author and his graduate and undergraduate students in the Department of Mechanical Engineering at Virginia Polytechnic Institute and State University. The basic approach used involved *in vitro* tribological experiments using bovine articular cartilage, with an emphasis on the effects of fluid composition and biochemistry on cartilage wear and damage. This research is an outgrowth of earlier work carried out during a sabbatical study in the Laboratory for the Study of Skeletal Disorders, The Children's Hospital Medical Center, Harvard Medical School in Boston. In that study, bovine cartilage test specimens were loaded against a polished steel plate and subjected to reciprocating sliding for several hours in the presence of a fluid (e.g., bovine synovial fluid or a buffered saline reference fluid containing biochemical constituents kindly provided by Dr. David Swann). Cartilage wear was determined by sampling the test fluid and determining the concentration of 4-hydroxyproline — a constituent of collagen. The results of that earlier study have been reported and summarized elsewhere [37–40]. Figure 50.4 shows the average hydroxyproline contents of wear debris obtained from these *in vitro* experiments. These numbers are related to the cartilage wear which occurred. However, since the total quantities of collected fluids varied somewhat, the values shown in the bar graph should not be taken as exact or precise measures of fluid effects on cartilage wear.

The main conclusions of that study were as follows:

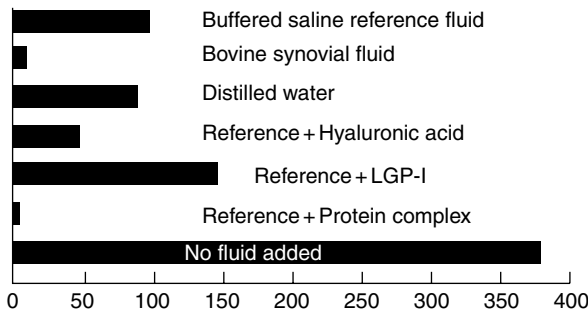
1. Normal bovine synovial fluid is very effective in reducing cartilage wear under these *in vitro* conditions as compared to the buffered saline reference fluid.
2. There is no significant difference in wear between the saline reference and distilled water.
3. The addition of hyaluronic acid to the reference fluid significantly reduces wear; but its effect depends on the source.
4. Under these tests conditions, Swann's LGP-I (Lubricating Glycoprotein-I), known to be extremely effective in reducing friction in cartilage-on-glass tests, does not reduce cartilage wear.


FIGURE 50.4   Relative cartilage wear based on hydroxyproline content of debris (*in vitro* tests with cartilage on stainless steel).
FIGURE 50.5   Friction and wear are different phenomena.

5. However, a protein complex isolated by Swann is extremely effective in reducing wear — producing results similar to those obtained with synovial fluid. The detailed structure of this constituent is complex and has not yet been fully determined.
6. Last, the lack of an added fluid in these experiments leads to extremely high wear and damage of the articular cartilage.

In discussing the possible significance of these findings from a tribological point of view, it may be helpful first of all to emphasize once again that friction and wear are different phenomena. Furthermore, as suggested by Figure 50.5, certain constituents of synovial fluid (e.g., Swann's Lubricating Glycoprotein) may act to reduce friction in synovial joints while other constituents (e.g., Swann's protein complex or hyaluronic acid) may act to reduce cartilage *wear*. Therefore, it is necessary to distinguish between biochemical anti-friction and anti-wear compounds present in synovial fluid.

In more recent years, this study has been greatly enhanced by the participation of interested faculty and students from the Virginia-Maryland College of Veterinary Medicine and Department of Biochemistry and Animal Science at Virginia Tech. One major hypothesis tested is a continuation of previous work showing that the detailed biochemistry of the fluid-cartilage system has a pronounced and possibly controlling influence on cartilage wear. A consequence of the above hypothesis is that a lack or deficiency of certain biochemical constituents in the synovial joint may be one factor contributing to the initiation and progression of cartilage damage, wear, and possibly osteoarthritis. A related but somewhat different hypothesis concerns synovial fluid constituents which may act to increase the wear and further damage of articular cartilage under tribological contact.

To carry out continued research on biotribology, a new device for studies of cartilage deformation, wear, damage, and friction under conditions of tribological contact was designed by Burkhardt [33] and later modified, constructed, and instrumented. A simplified sketch is shown in Figure 50.6. The key features of this test device are shown in Table 50.2. The apparatus is designed to accommodate cartilage-on-cartilage specimens. Motion of the lower specimen is controlled by a computer-driven x–y table, allowing simple oscillating motion or complex motion patterns. An octagonal strain ring with two full semi-conductor bridges is used to measure the normal load as well as the tangential load (friction). An LVDT, not shown in the figure, is used to measure cartilage deformation and linear wear during a test. However, hydroxyproline analysis of the wear debris and washings is used for the actual determination of total cartilage wear on a mass basis.

In one study by Schroeder [41], two types of experiments were carried out, that is, cartilage-on-stainless steel and cartilage-on-cartilage at applied loads up to 70 N — yielding an average pressure of 2.2 MPa in the contact area. Reciprocating motion (40 cps) was used. The fluids tested included (1) a buffered saline solution, (2) saline plus hyaluronic acid, and (3) bovine synovial fluid. In cartilage-on-stainless steel tests, scanning electron microscopy, and histological staining showed distinct effects of the lubricants on surface and subsurface damage. Tests with the buffered saline fluid resulted in the most damage, with large wear tracks visible on the surface of the cartilage plug, as well as subsurface voids and cracks. When hyaluronic acid, a constituent of the natural synovial joint lubricant, was added to the saline reference fluid, less severe damage was observed. Little or no cartilage damage was evident in tests in which the natural synovial joint fluid was used as the lubricant.
FIGURE 50.6 Device for *in vitro* cartilage-on-cartilage wear studies.

TABLE 50.2 Key Features of Test Device Designed for Cartilage Wear Studies [33]

Contact system	Cartilage-on-cartilage
Contact geometry	Flat-on-flat, convex-on-flat, irregular-on-irregular
Cartilage type	Articular, any source (e.g., bovine)
Specimen size	Upper specimen, 4 to 6 mm diam., lower specimen, ca. 15 to 25 mm diam.
Applied load	50–660 N
Average pressure	0.44–4.4 MPa
Type of motion	Linear, oscillating; circular, constant velocity; more complex patterns
Sliding velocity	0 to 20 mm/sec
Fluid temperature	Ambient (20∞C); or controlled humidity
Environment	Ambient or controlled humidity
Measurements	Normal load, cartilage deformation, friction; cartilage wear and damage, biochemical analysis of cartilage specimens, synovial fluid, and wear debris; sub-surface changes

These results were confirmed in a later study by Owellen [42] in which hydroxyproline analysis was used to determine cartilage wear. It was found that increasing the applied load from 20 to 65 N increased cartilage wear by eight-fold for the saline solution and approximately three-fold for synovial fluid. Furthermore, the coefficient of friction increased from an initial low value of 0.01 to 0.02 to a much higher value, for example, 0.20 to 0.30 and higher, during a normal test which lasted 3 h; the greatest change occurred during the first 20 min. Another interesting result was that a thin film of transferred or altered material was observed on the stainless steel disks — being most pronounced with the buffered saline lubricant and not observed with synovial fluid. Examination of the film with Fourier Transfer Infrared Microspectrometry shows distinctive bio-organic spectra which differs from that of the original bovine cartilage. We believe this to be an important finding since it suggests a possible bio-tribochemical effect [43].

In another phase of this research, the emphasis is on the cartilage-on-cartilage system and the influence of potentially beneficial as well as harmful constituents of synovial fluid on wear and damage. In cartilage-on-cartilage tests, the most severe wear and damage occurred during tests with buffered saline as the lubricant. The damage was less severe than in the stainless steel tests, but some visible wear tracks were detectable with scanning electron microscopy. Histological sectioning and staining of both the upper
FIGURE 50.7   Cartilage damage produced by sliding contact.

and lower cartilage samples show evidence of elongated lacunae and coalesced voids that could lead to wear by delamination. An example is shown in Figure 50.7 (original magnification of 500× on 35 mm slide). The proteoglycan content of the subsurface cartilage under the region of contact was also reduced. When synovial fluid was used as the lubricant, no visible wear or damage was detected [44]. These results demonstrate that even in *in vitro* tests with bovine articular cartilage, the nature of the fluid environment can have a dramatic affect on the severity of wear and subsurface damage.

In a more recent study carried out by Berrien in the biotribology program at Virginia Tech, a different approach was taken to examine the role of joint lubrication in joint disease, particularly osteoarthritis. A degradative biological enzyme, collagenase-3, suspected of playing a role in a cartilage degeneration was used to create a physiologically adverse biochemical fluid environment. Tribological tests were performed with the same device and procedures described previously. The stainless steel disk was replaced with a 1 in. diameter plug of bovine cartilage to create a cartilage sliding on cartilage configuration more closely related to the in vivo condition. Normal load was increased to 78.6 N and synovial fluid and buffered saline were used as lubricants. Prior to testing, cartilage plugs were exposed to a fluid medium containing three concentrations of collagenase-3 for 24 h. The major discovery of this work was that exposure to the collagenase-3 enzyme had a substantial adverse effect on cartilage wear *in vitro*, increasing average wear values by three and one-half times those of the unexposed cases. Figure 50.8 shows an example of the effect of enzyme treatment when bovine synovial fluid was used as the lubricant. Scanning electron microscopy showed disruption of the superficial layer and collagen matrix with exposure to collagenase-3, where unexposed cartilage showed none. Histological sections showed a substantial loss of the superficial layer of cartilage and a distinct and abnormal loss of proteoglycans in the middle layer of collagenase-treated cartilage. Unexposed cartilage showed only minor disruption of the superficial layer [45].

This study indicates that some of the biochemical constituents that gain access to the joint space, during normal and pathological functions, can have a significant adverse effect on the wear and damage of the articular cartilage. Future studies will include determination of additional constituents that have harmful effects on cartilage wear and damage. This research, using bovine articular cartilage in *in vitro* sliding contact tests, raises a number of interesting questions:

1. Has "Nature" designed a special biochemical compound which has as its function the protection of articular cartilage?
2. What is the mechanism (or mechanisms) by which biochemical constituents of synovial fluid can act to reduce wear of articular cartilage?
FIGURE 50.8 Effect of collagenase-3 on cartilage wear.

3. Could a lack of this biochemical constituent lead to increased cartilage wear and damage?
4. Does articular cartilage from osteoarthritic patients have reduced wear resistance?
5. Do any of the findings on the importance of synovial fluid biochemistry on cartilage wear in our *in vitro* studies apply to living or *in vitro* systems as well?
6. How does collagenase-3 treatment of cartilage lead to increased wear and does this finding have any significance in the *in vivo* situation? This question is addressed in the next section.

50.7 Biotribology and Arthritis: Are There Connections?

Arthritis is an umbrella term for more than 100 rheumatic diseases affecting joints and connective tissue. The two most common forms are osteoarthritis (OA) and rheumatoid arthritis (RA). Osteoarthritis — also referred to as *osteoarthrosis or degenerative joint disease* — is the most common form of arthritis. It is sometimes simplistically described as the "wear and tear" form of arthritis. The causes and progression of degenerative joint disease are still not understood. Rheumatoid arthritis is a chronic and often progressive disease of the synovial membrane leading to release of enzymes which attack, erode, and destroy articular cartilage. It is an inflammatory response involving the immune system and is more prevalent in females. Rheumatoid arthritis is extremely complex. Its causes are still unknown.

Sokoloff defines degenerative joint disease as "an extremely common, noninflammatory, progressive disorder of movable joints, particularly weight-bearing joints, characterized pathologically by deterioration of articular cartilage and by formation of new bone in the sub-chondral areas and at the margins of the "joint" [46]. As mentioned, osteoarthritis or osteoarthrosis is sometimes referred to as the "wear and tear" form of arthritis; but, wear itself is rarely a simple process even in well-defined systems.

It has been noted by the author that tribological terms occasionally appear in hypotheses which describe the etiology of osteoarthritis (e.g., "reduced wear resistance of cartilage" or "poor lubricity of synovial fluid"). It has also been noted that there is a general absence of hypotheses connecting normal synovial joint *lubrication* (or lack thereof) and synovial joint *degeneration*. Perhaps it is natural (and unhelpful) for a tribologist to imagine such a connection and that, for example, cartilage wear under certain circumstances might be due to or influenced by a lack of proper "boundary lubrication" by the synovial fluid. In this regard, it may be of interest to quote Swanson [12] who said in 1979 that "there exists at present no experimental evidence which certainly shows that a failure of lubrication is or is not a causative factor in the first stages of cartilage degeneration." A statement made by Professor Glimcher [52] may also be appropriate here. Glimcher fully recognized the fundamental difference between friction and wear as well as the difference between joint lubrication (one area of study) and joint degeneration (another area of study). Glimcher said that wearing or abrading cartilage with a steel file is not osteoarthritis; and neither

is digesting cartilage in a test tube with an enzyme. But both forms of cartilage deterioration can occur in a living joint and in a way which is still not understood. It is interesting that essentially none of the many synovial joint lubrication theories consider enzymatic degradation of cartilage as a factor whereas practically all the models of the etiology of degenerative joint disease include this as an important factor.

It was stated earlier that there are at least two main areas to consider, that is, (1) mechanisms of synovial joint lubrication and (2) the etiology of synovial joint degeneration (e.g., as in osteoarthrosis). Both areas are extremely complex. And the key questions as to what actually happens in each have yet to be answered (and perhaps asked). It may therefore be presumptuous of the present author to suggest possible connections between two areas which in themselves are still not fully understood.

Tribological processes in a movable joint involve not only the contacting surfaces (articular cartilage), but the surrounding medium (synovial fluid) as well. Each of these depends on the synthesis and transport of necessary biochemical constituents to the contact region or interface. As a result of relative motion (sliding, rubbing, rolling, and impact) between the joint elements, friction and wear can occur.

It has already been shown and discussed — at least in *in vitro* tests with articular cartilage — that compounds which reduce friction do not necessarily reduce wear; the latter was suggested as being more important [10]. It may be helpful first of all to emphasize once again that friction and wear are different phenomena. Furthermore, certain constituents of synovial fluid (e.g., Swann's Lubricating Glycoprotein) may act to reduce *friction* in synovial joints while other constituents (e.g., Swann's protein complex or hyaluronic acid) may act to reduce cartilage *wear*.

A significant increase in joint friction could lead to a slight increase in local temperatures or possibly to reduce mobility. But the effects of cartilage wear would be expected to be more serious. When cartilage wear occurs, a very special material is lost and the body is not capable of regenerating cartilage of the same quality nor at the desired rate. Thus, there are at least two major tribological dimensions involved — one concerning the nature of the synovial fluid and the other having to do with the properties of articular cartilage itself. Changes in *either* the synovial fluid or cartilage could conceivably lead to increased wear or damage (or friction) as shown in Figure 50.9.

A simplified model or illustration of possible connections between osteoarthritis and tribology is offered in Figure 50.10 taken from Furey [53]. Its purpose is to stimulate discussion. There are other pathways to the disease, pathways which may include genetic factors.

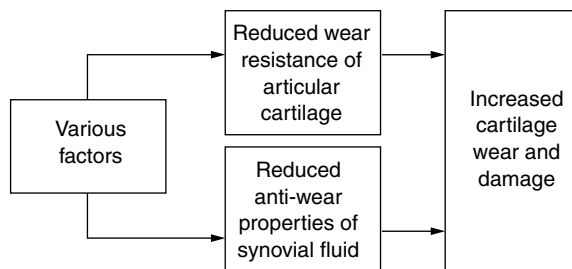
In some cases, the body makes an unsuccessful attempt at repair, and bone growth may occur at the periphery of contact. As suggested by Figure 50.10, this process and the generation of wear particles could lead to joint inflammation and the release of enzymes which further soften and degrade the articular cartilage. This softer, degraded cartilage does not possess the wear-resistance of the original. It has been shown previously that treatment of cartilage with collagenase-3 increases wear significantly, thus supporting the idea of enzyme release as a factor in osteoarthritis. Thus, there exists a feedback process in which the occurrence of cartilage wear can lead to even more damage. Degradative enzymes can also be released by trauma, shock, or injury to the joint. Ultimately, as the cartilage is progressively thinned and bony growth occurs, a condition of osteoarthritis or degenerative joint disease may exist. There are other pathways to the disease, pathways which may include genetic factors. It is not argued that arthritis


FIGURE 50.9   Two tribological aspects of synovial joint lubrication.
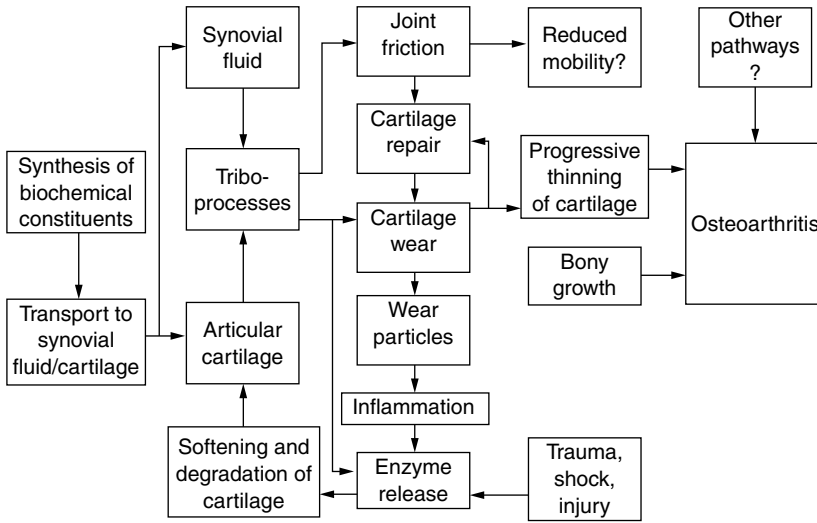

FIGURE 50.10 Osteoarthritis-tribology connections?

is a tribological problem. However, the inclusion of tribological processes in one set of pathways to osteoarthrosis would not seem strange or unusual.

A specific example of a different tribological dimension to the problem of synovial joint lubrication (i.e., third-body abrasion), was shown by the work of Hayes et al. [54]. In an excellent study of the effect of crystals on the wear of articular cartilage, they carried out *in vitro* tests using cylindrical cartilage subchondral bone plugs obtained from equine fetlock joints in sliding contact against a stainless steel plate. They examined the effects of three types of crystals (orthorhombic calcium pyrophosphate tetrahydrate, monoclinic calcium pyrophosphate dehydrate, and calcium hydroxyapatite) on wear using a Ringer's solution as the carrier fluid. Concentration of cartilage wear debris in the fluid was determined by analyzing for inorganic sulphate derived from the proteoglycans present. Several interesting findings were made, one of them being that the presence of the crystals roughly doubled cartilage wear. This is an important contribution which should be read by anyone seriously contemplating research on the tribology of articular cartilage. The careful attention to detail and potential problems, as well as the precise description of the biochemical procedures and diverse experimental techniques used, set a high standard.

50.8   Recapitulation and Final Comments

It is obvious from the unusually large number of theories of synovial joint lubrication proposed, that very little is known about the subject. Synovial joints are undoubtedly the most sophisticated and complex tribological systems that exist or will ever exist. It will require a great deal more research — possibly very different approaches — before we even begin to understand the processes involved.

Some general comments and specific suggestions are offered — not for the purpose of criticizing any particular study but hopefully to provide ideas which may be helpful in further research as well as in the re-interpretation of some past research.

50.8.1   Terms and Definitions

First of all, as mentioned earlier in this chapter, part of the problem has to do with the use and misuse of various terms in tribology — the study of friction, wear, and lubrication. A glance at any number of the published papers on synovial joint lubrication will reveal such terms and phrases as "lubricating ability," "lubricity," "lubricating properties," "lubricating component," and many others, all undefined. We also

see terms like "boundary lubricant," "lubricating glycoprotein," or "lubricin." There is nothing inherently wrong with this but one should remember that lubrication is a process of reducing friction and/or wear between rubbing surfaces. Saying that a fluid is a "good" lubricant does not distinguish between friction and wear. And assuming that friction and wear are correlated and go together is the first pitfall in any tribological study. It cannot be overemphasized that friction and wear are different, though sometimes related, phenomena. Low friction does not mean low wear. The terms and phrases used are therefore extremely important. For example, in a brief and early review article by Wright and Dowson [55], it was stated that "Digestion of hyaluronate does not alter the boundary lubrication," referring to the work of Radin, Swann, and Weisser [56]. In another article, McCutchen re-states this conclusion in another way, saying "…the lubricating ability did not reside in the hyaluronic acid" and later asks the question "Why do the glycoprotein molecules (of Swann) lubricate?" [57] These statements are based on effects of various constituents on friction, not wear. The work of the present author showed that in tests with bovine articular cartilage, Swann's Lubricating Glycoprotein LGP-I which was effective in reducing friction did not reduce cartilage wear. However, hyaluronic acid — shown earlier not to be responsible for friction-reduction — did reduce cartilage wear. Thus, it is important to make the distinction between friction-reduction and wear-reduction. It is suggested that operational definitions be used in place of vague "lubricating ability," etc. terms in future papers on the subject.

50.8.2 Experimental Contact Systems

Secondly, some comments are made on the experimental approaches that have been reported in the literature on synovial joint lubrication mechanisms. Sliding contact combinations in *in vitro* studies have consisted of (1) cartilage-on-cartilage, (2) cartilage-on-some other surface (e.g., stainless steel, glass), and (3) solids other than cartilage sliding against each other in X-on-X or X-on-Y combinations.

The cartilage-on-cartilage combination is of course the most realistic and yet most complex contact system. But variations in shape or macroscopic geometry, microtopography, and the nature of contact present problems in carrying out well-controlled experiments. There is also the added problem of acquiring suitable specimens which are large enough and reasonably uniform.

The next combination — cartilage-on-another material — allows for better control of contact, with the more elastic, deformable cartilage loaded against a well-defined hard surface (e.g., a polished, flat solid made of glass or stainless steel). This contact configuration can provide useful tribological information on effects of changes in biochemical environment (e.g., fluids), on friction, wear, and sub-surface damage. It also could parallel the situation in a partial joint replacement in which healthy cartilage is in contact with a metal alloy.

The third combination, which appears in some of the literature on synovial joint lubrication, does not involve any articular cartilage at all. For example, Jay made friction measurements using a latex-covered stainless steel stud in oscillating contact against polished glass [31]. Williams et al., in a study of a lipid component of synovial fluid, used reciprocating contact of borosilicate glass-on-glass [58]. And in a recent paper on the action of a surface-active phospholipid as the "lubricating component of lubricin," Schwarz and Hills carried out friction measurements using two optically flat quartz plates in sliding contact [59]. In another study, a standard four-ball machine using alloy steel balls was used to examine the "lubricating ability" of synovial fluid constituents. Such tests, in the absence of cartilage, are easiest to control and carry out. However, they are not relevant to the study of synovial joint lubrication. With a glass sphere sliding against a glass flat, almost anything will reduce friction — including a wide variety of chemicals, biochemicals, semi-solids, and fluids. This has little if anything to do with the lubrication of synovial joints.

50.8.3 Fluids and Materials Used as Lubricants in *In Vitro* Biotribology Studies

Fluids used as lubricants in synovial joint lubrication studies have consisted of (1) "normal" synovial fluid (e.g., bovine), (2) buffered saline solution containing synovial fluid constituents (e.g., hyaluronic

acid), and (3) various aqueous solutions of surface active compounds neither derived from nor present in synovial fluid. In addition, a few studies used synovial fluids from patients suffering from either osteoarthritis or rheumatoid arthritis.

The general comment made here is that the use of synovial fluids — whether derived from human or animal sources and whether "healthy" or "abnormal" — is important in *in vitro* studies of synovial joint lubrication. The documented behavior of synovial fluid in producing low friction and wear with articular cartilage sets a reference standard and demonstrates that useful information can indeed come from *in vitro* tests.

Studies that are based on adding synovial fluid constituents to a reference fluid (e.g., a buffered saline solution) can also be useful in attempting to identify which biochemical compound or compounds are responsible for reductions in frictions or wear. But if significant interactions between compounds exist, then such an approach may require an extensive program of tests. It should also be mentioned that in the view of the present author, the use of a pure undissolved constituent of synovial fluid, either derived or synthetic, in a sliding contact test is not only irrelevant but may be misleading. An example would be the use of a pure lipid (e.g., phospholipid) at the interface rather than in the concentration and solution form in which this compound would normally exist in synovial fluid. This is basic in any study of lubrication and particularly in the case of boundary lubrication where major effects on wear or friction can be brought on by minor, seemingly trivial, changes in chemistry.

50.8.4 The Preoccupation with Rheology and Friction

The synovial joint as a system — the articular cartilage and underlying bone structure as well as the synovial fluid as important elements — is extremely complex and far from being understood. It is noted that there is a proliferation of mathematical modeling papers stressing rheology and the mechanics of deformation, flow, and fluid pressures developed in the cartilage model. One recent example is the paper "The Role of Interstitial Fluid Pressurization and Surface Properties on the Boundary Friction of Articular Cartilage" by Ateshian et al. [21]. This study, a genuine contribution, grew out of the early work by Mow and connects also with the "weeping lubrication" model of McCutchen. Both McCutchen and Mow have made significant contributions to our understanding of synovial joint lubrication, although each approach is predominantly rheological and friction-oriented with little regard for biochemistry and wear. This is not to say that rheology is unimportant. It could well be that, as suggested by Ateshian, the mechanism of interstitial fluid pressurization that leads to low friction in cartilage could also lead to low wear rates [60].

50.8.5 The Probable Existence of Various Lubrication Regimes

In an article by Wright and Dowson, it is suggested that a variety of types of lubrication operate in human synovial joints at different parts of a walking cycle stating that, "At heel-strike a squeeze-film situation may develop, leading to elastohydrodynamic lubrication and possibly both squeeze-film and boundary lubrication, while hydrodynamic lubrication may operate during the free-swing phase of walking" [55].

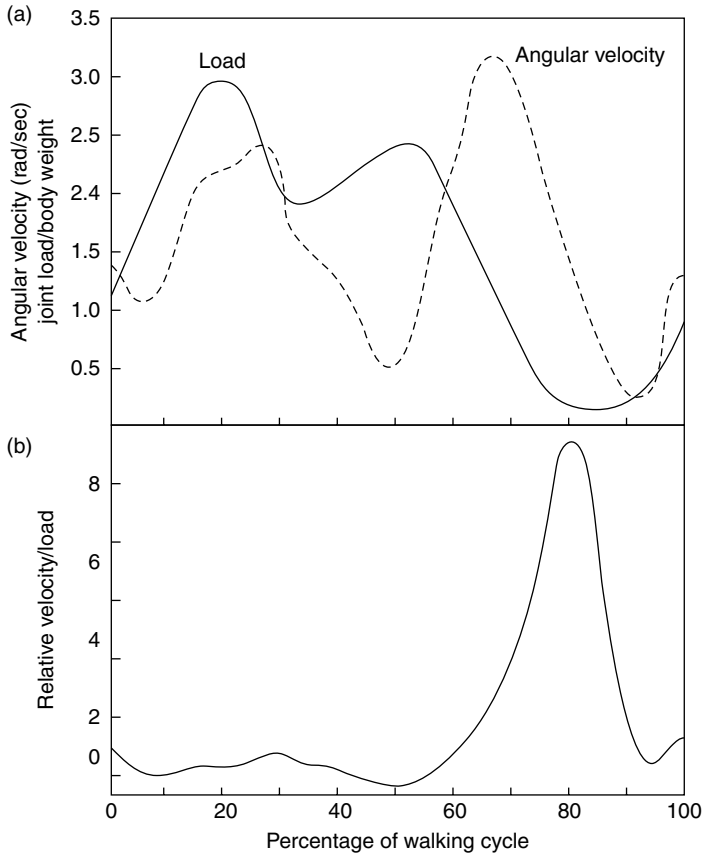
In a simplified approach to examining the various regimes of lubrication that could exist in a human joint, it may be useful to look at Figure 50.11a which shows the variation in force (load) and velocity for a human hip joint at different parts of the walking cycle (taken from Graham and Walker [61]). As discussed earlier in this chapter, theories of hydrodynamic and elastohydrodynamic lubrication all include the hydrodynamic factor ($\eta U/W$) as the key variable, where η = fluid viscosity, U = the relative sliding velocity, and W = the normal load. High values of ($\eta U/W$) lead to thicker hydrodynamic films — a more desirable condition if one wants to keep surfaces apart. It can be seen from Figure 50.11a that there is considerable variation in load and velocity, with peaks and valleys occurring at different parts of the cycle. Note also that in this example, the loads can be quite high (e.g., up to three times body weight). The maximum load occurs at 20% of the walking cycle illustrated in Figure 50.11a, with a secondary maximum occurring at a little over the 50% point. The maximum angular velocity occurs at approximately 67% of the cycle. If one now creates a new curve of relative velocity/load or (U/W) from Figure 50.11a, the result


FIGURE 50.11   (a) Hip joint forces and angular velocities at different parts of the walking cycle (after Graham and Walker [61]). (b) Calculated ratio of velocity to force for the hip joint (from Figure 22.11a).

obtained is shown in Figure 50.11b. We see now a very different and somewhat simplified picture. There is a clear and distinct maximum in the ratio of velocity to load (U/W) at 80% of walking cycle, favoring the formation of a hydrodynamic film of maximum thickness. However, for most of the cycle (e.g., from 0 to 60%), the velocity/load ratio is significantly lower, thus favoring a condition of minimum film thickness and "boundary lubrication." However, we also know that synovial fluid is non-Newtonian; at higher rates of shear, its viscosity decreases sharply, approaching that of water. The shear rate is equal to the relative velocity divided by fluid film thickness (U/h) and is expressed in sec^{-1}. This means that at the regions of low (U/W) ratios or thinner hydrodynamic films, the viscosity term in ($\eta U/W$) is even lower, thus pushing the minima to lower values favoring a condition of boundary lubrication. This is only a simplified view and does not consider those periods in which the relative sliding velocity is zero at motion reversal and where squeeze-film lubrication may come into play. A good example of the complexity of load and velocity variation in a human knee joint — including several zero-velocity periods — may be found in the chapter by Higginson and Unsworth [62] citing the work of Seedhom et al., which deals with biomechanics in the design of a total knee replacement [63].

The major point made here is that (1) there are parts of a walking cycle that would be expected to approach a condition of minimum fluid film thickness and boundary lubrication and (2) it is during these parts of the cycle that cartilage wear and damage resulting from contact is more likely to occur. Thus, approaches to reducing cartilage wear in a synovial joint could be broken down into two categories (i.e., promoting thicker hydrodynamic films and providing special forms of "boundary lubrication.")

50.8.6 Recent Developments

Recent developments in addressing some of the problems that involve cartilage damage and existing joint replacements include (1) progress in promoting cartilage repair [64], (2) possible use of artificial cartilage materials (e.g., synthetic hydrogels) [65,66], and (3) the development and application of more compliant joint replacement materials to promote a more favorable formation of an elastohydrodynamic film [67]. Although these are not strictly "lubricant-oriented" developments, they do and will involve important tribological aspects discussed in this chapter. For example, if new cartilage growth can be promoted by transplanting healthy chondrocytes to a platform in a damaged region of a synovial joint, how long will this cartilage last? If a hydrogel is used as an artificial cartilage, how long will it last? And if softer, elastomeric materials are used as partial joint replacements or coatings, how long will they last? These are questions of wear, not friction. And although the early fundamental studies of hydrogels as artificial cartilage measured only friction, and often only after a few moments of sliding, we know from recent work that even for hydrogels, low friction does not mean low wear [68].

50.9 Conclusions

The following main conclusions relating to the tribological behavior of natural, "normal" synovial joints are presented:

1. An unusually large number of theories and studies of joint lubrication have been proposed over the years. All of the theories focus on friction, none address wear, many do not involve experimental studies with cartilage, and very few consider the complexity and detailed biochemistry of the synovial-fluid articular-cartilage system.

2. It was shown by *in vitro* tests with bovine articular cartilage that the detailed biochemistry of synovial fluid has a significant effect on cartilage wear and damage. "Normal" bovine synovial fluid was found to provide excellent protection against wear. Various biochemical constituents isolated from bovine synovial fluid by Dr. David Swann, of the Shriners Burns Institute in Boston, showed varying effects on cartilage wear when added back to a buffered saline reference fluid. This research demonstrates once again the importance of distinguishing between friction and wear.

3. In a collaborative study of biotribology involving researchers and students in Mechanical Engineering, the Virginia-Maryland College of Veterinary Medicine, and Biochemistry, *in vitro* tribological tests using bovine articular cartilage demonstrated among other things that (1) normal synovial fluid provides better protection than a buffered saline solution in a cartilage-on-cartilage system, (2) tribological contact in cartilage systems can cause subsurface damage, delamination, changes in proteoglycan content, and in chemistry via a "biotribochemical" process not understood, and (3) pre-treatment of articular cartilage with the enzyme collagenase-3 — suspected as a factor in osteoarthritis — significantly increases cartilage wear.

4. It is suggested that these results could change significantly the way mechanisms of synovial joint lubrication are examined. Effects of biochemistry of the system on wear of articular cartilage are likely to be important; such effects may not be related to physical/rheological models of joint lubrication.

5. It is also suggested that connections between tribology/normal synovial joint lubrication and degenerative joint disease are not only possible but likely; however, such connections are undoubtedly complex. It is *not* argued that osteoarthritis is a tribological problem or that it is necessarily the result of a tribological deficiency. Ultimately, a better understanding of how normal synovial joints function from a tribological point of view could conceivably lead to advances in the prevention and treatment of osteoarthritis.

6. Several problems exist that make it difficult to understand and interpret many of the published works on synovial joint lubrication. One example is the widespread use of non-operational and vague terms such as "lubricating activity," "lubricating factor," "boundary lubricating ability," and

similar undefined terms which not only fail to distinguish between friction (which is usually measured) and cartilage wear (which is rarely measured), but tend to lump these phenomena together — a common error. Another problem is that a significant number of the published experimental studies of biotribology do not involve cartilage at all — relying on the use of glass-on-glass, rubber-on-glass, and even steel-on-steel. Such approaches may be a reflection of the incorrect view that "lubricating activity" is a property of a fluid and can be measured independently. Some suggestions are offered.

7. Last, the topic of synovial joint lubrication is far from being understood. It is a complex subject involving at least biophysics, biomechanics, biochemistry, and tribology. For a physical scientist or engineer, carrying out research in this area is a humbling experience.

Analysis of Gait

Roy B. Davis, III
Shriners Hospital for Children

Sylvia Õunpuu
Peter A. DeLuca
*University of Connecticut
Children's Medical Center*

Gait analysis is the quantitative measurement and assessment of human locomotion including both walking and running. A number of different disciplines use gait analysis techniques. Basic scientists seek a better understanding of the mechanisms that normal ambulators use to translate muscular contractions about articulating joints into functional accomplishment, for example, level walking [1] and stair climbing [2]. In sports biomechanics, athletes and their coaches use movement analysis techniques to investigate performance improvement while avoiding injury, for example, Ferber et al. [3], Hunter et al. [4], Kautz and Hull [5], and Tashman et al. [6]. Sports equipment manufacturers seek to quantify the perceived advantages of their products relative to a competitor's offering.

With respect to the analysis of gait in the clinical setting, or clinical gait analysis, medical professionals apply an evolving knowledge base in the interpretation of the walking patterns of impaired ambulators for the planning of treatment protocols, for example, orthotic prescription and surgical intervention. Clinical gait analysis is an evaluation tool that allows the clinician to determine the extent to which an individual's gait has been affected by an already diagnosed disorder [7]. Examples of clinical pathologies currently served by gait analysis include:

- Amputation [8]
- Cerebral palsy [9,10]
- Degenerative joint disease [11,12]
- Joint pain [13]
- Joint replacement [14]
- Poliomyelitis [15]

51-1

- Multiple sclerosis [16]
- Muscular dystrophy [17]
- Myelodysplasia [18,19]
- Rheumatoid arthritis [20]
- Spinal cord injury [21]
- Stroke [22]
- Traumatic brain injury [23]

Generally, gait analysis data collection protocols, measurement precision, and data reduction models have been developed to meet the requirements specific to the research, sport, or clinical setting. For example, gait measurement protocols in a research setting might include an extensive physical examination to characterize the anthropometrics of each subject. This time expenditure may not be possible in a clinical setting. The focus of this chapter is on the methods for the assessment of walking patterns of persons with locomotive impairment, that is, clinical gait analysis. The discussion includes a description of the available measurement technology, the components of data collection and reduction, the type of gait information produced for clinical interpretation, and the strengths and limitations of clinical gait analysis.

51.1 Fundamental Concepts

51.1.1 Clinical Gait Analysis Information

Gait is a cyclic activity for which certain discrete events have been defined as significant. Typically, the *gait cycle* is defined as the period of time from the point of *initial contact* (also referred to as *foot contact*) of the subject's foot with the ground to the next point of initial contact for that same limb. Dividing the gait cycle in stance and swing phases is the point in the cycle where the stance limb leaves the ground, called *toe off* or *foot off*. Gait variables that change over time such as the patient's joint angular displacements are normally presented as a function of the individual's gait cycle for clinical analysis. This is done to facilitate the comparison of different walking trials and the use of a normative database [24]. Data that are currently provided for the clinical interpretation of gait may include:

- A video recording of the individual's gait (before instrumentation) for qualitative review and quality control purposes
- Static physical examination measures, such as passive joint range of motion, muscle strength and tone, and the presence and degree of bony deformity
- Segment and joint angular positions associated with standing posture
- Stride and temporal parameters, such as step length and walking velocity
- Segment and joint angular displacements, commonly referred to as *kinematics*
- The forces and torque applied to the subject's foot by the ground, or ground reaction loads
- The reactive intersegmental moments produced about the lower extremity joints by active and passive soft tissue forces as well as the associated mechanical power of the intersegmental moment, collectively referred to as *kinetics*
- Indications of muscle activity, that is, voltage potentials produced by contracting muscles, known as dynamic *electromyography* (EMG)
- The dynamic pressure distributions on the plantar surface of the foot, referred to as *pedobarography*
- A measure of metabolic energy expenditure, for example, oxygen consumption, energy cost

51.1.2 Data Collection Protocol

The steps involved in the gathering of data for clinical gait analysis usually include a complete physical examination, biplanar videotaping, a static calibration of the "instrumented" subject, and multiple walks

TABLE 51.1   A Typical Gait Data Collection Protocol

Test component	Approximate time (min)
Pretest tasks: test explanation to the adult patient or the pediatric patient and parent, system calibration	10
Videotaping: brace, barefoot, close-up, standing	5–10
Clinical examination: range of motion, muscle strength, etc.	15–30
Motion marker placement	15–20
Motion data collection: subject calibration and multiple walks, per test condition (barefoot and orthosis)	10–60
Electromyography (surface electrodes and fine wire electrodes)	20–60
Data reduction of all trials	15–90
Data interpretation	20–30
Report dictation, generation, and distribution	120–180

along a walkway that is commonly both level and smooth. The time to complete these steps can range from one to three hours (Table 51.1). While the baseline for analysis is barefoot gait, subjects are tested in other conditions as well, for example, lower extremity orthoses and crutches. Requirements and constraints associated with clinical gait data gathering include the following:

- The patient should not be intimidated or distracted by the testing environment
- The measurement equipment and protocols should not alter the subject's gait
- Patient preparation and testing time must be minimized, and rest (or play) intervals must be included in the process as needed
- Data collection techniques must be reasonably repeatable
- Methodology must be sufficiently robust and flexible to allow the evaluation of a variety of gait abnormalities where the dynamic range of motion and anatomy may be significantly different from normal
- The collected data must be validated before the end of the test period, for example, raw data fully processed before the patient leaves the facility

51.2   Measurement Approaches and Systems

The purpose of this section is to provide an overview of the several technologies that are available to measure the dynamic gait variables listed earlier, including stride and temporal parameters, kinematics, kinetics, and dynamic EMG. Methods of data reduction will be described in a following section.

51.2.1   Stride and Temporal Parameters

The timing of the gait cycle events of initial contact and toe off must be measured for the computation of the stride and temporal quantities. These measures may be obtained through a wide variety of approaches ranging from the use of simple tools such as a stopwatch and tape measure to sophisticated arrays of photoelectric monitors. Foot switches may be applied to the plantar surface of the subject's foot over the bony prominences of the heel and metatarsal heads in different configurations depending on the information desired. A typical configuration is the placement of a switch on the heel, first and fifth metatarsal heads, and great toe. In a clinical population, foot switch placement is challenging because of the variability of foot deformities and the associated foot–ground contact patterns. This switch placement difficulty is avoided through the use of either shoe insoles instrumented with one or two large foot switches or entire contact sensitive walkways. These gait events may also be quantified using either the camera-based motion measurement or the force platform technology described below.

51.2.2   Motion Measurement

A number of alternative technologies are available for the measurement of body segment spatial position and orientation. These include the use of electrogoniometry, accelerometry, and video-based digitizers. These approaches are described below.

51.2.2.1   Electrogoniometry

A simple electrogoniometer consists of a rotary potentiometer with arms fixed to the shaft and base for attachment to the body segments juxtaposed to the joint of interest. Multiaxial goniometers extend this capability by providing additional, simultaneous, orthogonal measures of rotational displacement, more appropriate for human joint motion measurement. Electrogoniometers offer the advantages of real-time display and the rapid collection of single joint information on many subjects. These devices are limited to the measurement of relative angles and may be cumbersome in typical clinical applications such as the simultaneous, bilateral assessment of hip, knee, and ankle motion.

51.2.2.2   Accelerometry

Multiaxis accelerometers can be employed to measure both linear and angular accelerations (if multiple transducers are properly configured). Velocity and position data may then be derived through numerical integration although care must be taken with respect to the selection of initial conditions and the handling of gravitational effects.

51.2.2.3   Videocamera-Based Systems

This approach to human motion measurement involves the use of external markers that are placed on the subject's body segments and aligned with specific bony landmarks. Marker trajectories are then monitored by a system of motion capture cameras (generally from 6 to 12) placed around a measurement volume (Figure 51.1). In a frame-by-frame analysis, stereophotogrammetric techniques are then used to produce
FIGURE 51.1   An "instrumented" patient with reflective spheres or markers and EMG electrodes. She walks along a level pathway while being monitored by 6–12 motion cameras (that monitor the displacement the reflective markers) and 2–4 force platforms (that measure ground reaction loads). She might also walk over a foot pressure platform that measures the plantar pressure distribution. Her walk is also videotaped with one or two conventional videocameras. All of these signals (from the motion cameras, force platforms, EMG electrodes, and foot pressure platform) are sent to the central data collection computer in the lab. These signals are then processed by the operator to produce the information used, along with the video recordings and other clinical examination data, to identify gait abnormalities and guide treatment planning.

the instantaneous three-dimensional (3-D) coordinates of each marker (relative to a fixed laboratory coordinate system) from the set of two-dimensional camera images. The processing of the 3-D marker coordinate data is described in a later section.

The videocamera-based systems employ either passive (retroreflective) or active (light-emitting diodes) markers. Passive marker camera systems incorporate strobe light sources (light-emitting diode [LED] rings around the camera lens). The cameras then capture the light returned from the highly reflective markers (usually small spheres). Active marker camera systems record the light that is produced by small LED markers that are placed directly on the subject. Advantages and disadvantages are associated with each approach. For example, the anatomical location (or identity) of each marker used in an active marker system is immediately known because the markers are sequentially pulsed by a controlling computer. User interaction is required currently for marker identification in passive marker systems although algorithms have been developed to expedite this process, that is, automatic tracking. The system of cables required to power and control the LED's of the active marker system may increase the possibility for subject distraction and gait alteration.

51.2.3 Ground Reaction Measurement

51.2.3.1 Force Platforms

The 3-D ground reaction force vector, the vertical ground reaction torque and the point of application of the ground reaction force vector (i.e., center of pressure) are measured with force platforms embedded in the walkway. Force plates with typical measurement surface dimensions of 0.5×0.5 m are comprised of several strain gauges or piezoelectric sensor arrays rigidly mounted together.

51.2.3.2 Pedobarography

The dynamic distributed load that corresponds to the vertical ground reaction force can be evaluated with the use of a flat, two-dimensional array of small piezoresistive sensors. Overall resolution of the transducer is dictated by the size of the individual sensor "cell." Sensor arrays configured as shoe insole inserts or flat plates offer the clinical user two measurement alternatives. Although the currently available technology does afford the clinical practitioner better insight into the qualitative force distribution patterns across the plantar surface of the foot, its quantitative capability is limited because of the challenge of calibration and signal drift (e.g., sensor creep).

51.2.4 Dynamic Electromyography (EMG)

Electrodes placed on the skin's surface and fine wires inserted into muscle are used to measure the voltage potentials produced by contracting muscles. The activity of the lower limb musculature is evaluated in this way with respect to the timing and the intensity of the contraction. Data collection variables that affect the quality of the EMG signal include the placement and distance between recording electrodes, skin surface conditions, distance between electrode and target muscle, signal amplification and filtering, and the rate of data acquisition. The phasic characteristics of the muscle activity may be estimated from the raw EMG signal. The EMG data may also be presented as a rectified and integrated waveform. To evaluate the intensity of the contraction, the dynamic EMG amplitudes are typically normalized by a reference value, for example, the EMG amplitude during a maximum voluntary contraction. This latter requirement is difficult to achieve consistently for patients who have limited isolated control of individual muscles, such as children with cerebral palsy (CP).

51.3 Gait Data Reduction

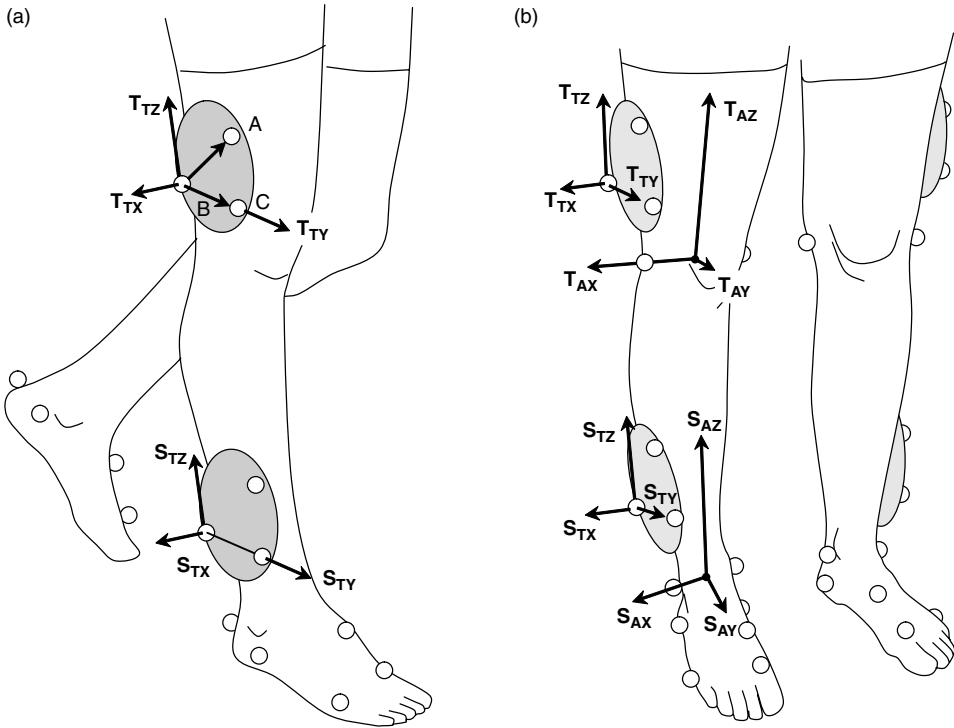
The predominant approach for the collection of clinical gait data involves the placement of external markers on the surface of body segments that are aligned with particular bony landmarks. These markers are commonly attached to the subject as either discrete units or in rigidly connected clusters. As described


FIGURE 51.2 (a) Technical or marker-based coordinate systems "fixed" to the thigh and shank. A body fixed coordinate system may be computed for each cluster of three or more markers. On the thigh, for example, the vector cross product of the vectors from markers B to A and B to C produces a vector that is perpendicular to the cluster plane. From these vectors, the unit vectors $\mathbf{T_{TX}}$ and $\mathbf{T_{TY}}$ may be determined and used to compute the third orthogonal coordinate direction $\mathbf{T_{TZ}}$. (b) A subject calibration relates technical coordinate systems with anatomical coordinate systems, for example, $\{\mathbf{T_T}\}$ with $\{\mathbf{T_A}\}$, through the identification of anatomical landmarks, for example, the medial and lateral femoral condyles and medial and lateral malleoli.

briefly above, the products of the data acquisition process are the 3-D coordinates (relative to an inertially fixed laboratory coordinate system) of each marker trajectory over a gait cycle. If at least three markers or reference points are identified for each body segment, then the six degrees-of-freedom associated with the translation and position of the segment may be determined. The following example illustrates this straightforward process.

Assume that a cluster of three markers has been attached to the thigh and shank of the test subject as shown in Figure 51.2a. A body-fixed coordinate system may be computed for each marker cluster. For example, for the thigh, the vector cross product of the vectors from markers B to A and B to C produces a vector that is perpendicular to the cluster plane. From these vectors, the unit vectors $\mathbf{T_{TX}}$ and $\mathbf{T_{TY}}$ may be determined and used to compute the third orthogonal coordinate direction $\mathbf{T_{TZ}}$. In a similar manner, the marker-based, or technical, coordinate system may be calculated for the shank, that is, $\mathbf{S_{TX}}$, $\mathbf{S_{TY}}$, and $\mathbf{S_{TZ}}$. At this point, one might use these two technical coordinate systems to provide an estimate of the absolute orientation of the thigh or shank or the relative angles between the thigh and shank. This assumes that the technical coordinate systems reasonably approximate the anatomical axes of the body segments, for example, that $\mathbf{T_{TZ}}$ approximates the long axis of the thigh. A more rigorous approach incorporates the use of a subject calibration procedure to relate technical coordinate systems with pertinent anatomical directions [25].

In a subject calibration, usually performed with the subject standing, additional data are collected by the measurement system that relates the technical coordinate systems to the underlying anatomical structure. For example, as shown in Figure 51.2b, the medial and lateral femoral condyles and the medial

and lateral malleoli may be used as anatomical references with the application of additional markers. With the hip center location estimated from markers placed on the pelvis [26,27] and knee and ankle center locations based on the additional markers, anatomical coordinate systems may be computed, for example, $\{T_A\}$ and $\{S_A\}$. The relationship between the respective anatomical and technical coordinate system pairs as well as the location of the joint centers in terms of the appropriate technical coordinate system may be stored, to be recalled in the reduction of each frame of the walking data. In this way, the technical coordinate systems (shown in Figure 51.2b) are transformed into alignment with the anatomical coordinate systems.

Once anatomically aligned body-fixed coordinate systems have been computed for each body segment under investigation, one may compute the angular position of the joints and segments in a number of ways. The classical approach of Euler, or more specifically, Cardan angles is commonly used in clinical gait analysis to describe the motion of the thigh relative to the pelvis (or hip angles), the motion of the shank relative to the thigh (or knee angles), the motion of the foot relative to the shank (or ankle angles), as well as the absolute orientation of the pelvis and foot in space. The joint rotation sequence commonly used for the Cardan angle computation is flexion–extension, adduction–abduction, and transverse plane rotation [28]. Alternatively, joint motion has been described through the use of helical axes [29].

The intersegmental moments that soft tissue (e.g., muscle, ligaments, and joint capsule) forces produce about approximate joint centers may be computed through the use of inverse dynamics, that is, Newtonian mechanics. For example, the free body diagram of the foot shown in Figure 51.3 depicts the various external loads to the foot as well as the intersegmental reactions produced at the ankle. The mass, mass moments of inertia, and location of the center of mass may be estimated from regression-based anthropometric relationships [30–32], and linear and angular velocity and acceleration may be determined by numerical differentiation. If the ground reaction loads, F_G and T, are measured by a force platform, then the unknown ankle intersegmental force, F_A, may be solved for with Newton's translational equation of motion. It is noted that inverse dynamics underestimates the magnitude of the actual joint contact forces. Newton's rotational equation of motion may then be applied to compute the net ankle intersegmental moment, M_A. This process may then be repeated for the shank and thigh by using distal joint loads to solve for the proximal intersegmental reactions. The mechanical power associated with an intersegmental moment and the corresponding joint angular velocity may be computed from the vector dot product of the two vectors, for example, ankle power is computed through $M_A \cdot \omega_A$ where ω_A is the angular velocity of the foot relative to the shank. Readers are referred to descriptions by Õunpuu et al. [33] and Palladino and Davis [34] for more details associated with this process.

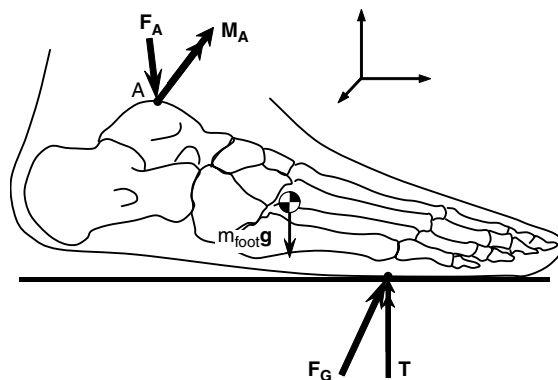
Although sometimes referred to as "muscle moments," these net intersegmental moments reflect the moments produced by several mechanisms, for example, ligamentous forces, passive muscle and tendon


FIGURE 51.3 A free body diagram of the foot that illustrates the external loads to the foot, for example, the ground reaction loads, F_G and T, and the weight of the foot, $m_{foot}g$, as well as the unknown intersegmental reactions produced at the ankle, F_A and M_A, which may be solved for through the application of Newtonian mechanics.

force, and active muscle contractile force, in response to external loads. Currently, the evaluation of individual muscle forces in a patient population is not feasible because optimization strategies that may be successful for normal ambulation, for example, Chao and Rim [35], Anderson and Pandy [36], may not be appropriate for pathological muscle behavior, for example, spasticity, overactivity, hyper- or hypotonicity.

With respect to assumptions associated with these gait models, the body segments are assumed to be rigid, for example, soft tissue movement relative to underlying bony structures is small. The external markers are assumed to move with the underlying anatomical references. In this way, estimated joint center locations are assumed to remain fixed relative to the respective segmental coordinate systems, for example, the knee center is fixed relative to the thigh coordinate system. Moreover, the mass distribution changes during motion are assumed to be negligible. Consequently, marker or instrumentation attachment sites must be carefully selected, for example, over tendonous structures of the distal shank as opposed to the more proximal muscle masses of the gastrocnemius and soleus.

51.4   Illustrative Clinical Example

As indicated earlier, the information available for clinical gait interpretation may include static physical examination measures, stride and temporal data, segment and joint kinematics, joint kinetics, electromyograms, and a video record. With this information, the clinical team can assess the patient's gait deviations, attempt to identify the etiology of the abnormalities and recommend treatment alternatives. In this way, clinicians are able to isolate the biomechanical insufficiency that may produce a locomotive impairment and require a compensatory response from the patient. For example, a patient may excessively elevate a pelvis (compensatory) in order to gain additional foot clearance in swing, which is perhaps inadequate due to a weak ankle dorsiflexor (primary problem).

The following example illustrates how gait analysis data are used in the treatment decision-making process for a six-year-old child with cerebral palsy, left spastic hemiplegia. Initially, all gait and clinical examination data are reviewed and a list of primary problems and possible causes is generated. The reviewed data would include three-dimensional kinematic data (Figure 51.4), and kinetic data (Figure 51.5) and dynamic EMG data (Figure 51.6).

In the sagittal plane, increased left plantar flexion in stance and swing (Figure 51.4, Point A) is secondary to spasticity of the ankle plantar flexor muscles as the patient has normal passive range of motion of the ankle and can stand plantigrade. Premature plantar flexion of the right ankle in mid stance (Figure 51.4, Point B) is a vault compensation as the patient could isolate motion about the right ankle on clinical examination and produce an internal dorsiflexor moment during loading response (Figure 51.5, Point A). Increased left knee flexion at initial contact (Figure 51.4, Point C) is secondary to hamstring muscle spasticity/tightness (appreciated during the clinical examination) as well as overactivity of the hamstrings during gait (seen in the EMG data, Figure 51.6, Point A). Reduced left knee flexion in swing (Figure 51.4, Point D) is secondary to rectus femoris overactivity in mid swing (Figure 51.6, Point B), an absence of power generation at the ankle in terminal stance (Figure 51.5, Point B), reduced power generation at the hip in preswing (Figure 51.5, Point C), and out-of-plane positioning of the lower extremity due to internal hip rotation (Figure 51.4, Point E). Increasing anterior pelvic tilt during left side stance (Figure 51.4, Point F) is related to the patient's limited ability to isolate movement between the pelvis and femur on the left side. In the transverse plane, increased left internal hip rotation (Figure 51.4, Point E), increased left internal foot progression (Figure 51.4, Point G), and asymmetric pelvic rotation with the left side externally rotated (Figure 51.4, Point H) are all secondary to increased internal femoral torsion (noted during the clinical examination). In the coronal plane, asymmetrical hip rotations (Figure 51.4, Point I) are secondary to pelvic transverse plane asymmetry.

After all of the primary gait issues are identified and possible causes are determined, treatment options for each primary issue are proposed. For the child presented earlier here, treatment options include a left femoral derotation osteotomy to correct for internal femoral torsion and associated internal hip rotation. Expected secondary outcomes of this intervention include improved foot progression and symmetrical

pelvic position in the transverse plane. A left intramuscular plantar flexor muscle lengthening is recommended to provide more length to the ankle plantar flexors and reduce the impact of muscle stretch on the spastic plantar flexors, thereby reducing the excessive equinus in stance and swing and providing more stability in stance. A left hamstring muscle lengthening is also recommended to reduce the impact of muscle stretch on hamstring spasticity, thereby improving knee extension at initial contact and overall knee motion in stance. A rectus femoris muscle transfer is recommended to reduce the impact of inappropriate activity of the rectus femoris in mid swing and therefore improve peak knee flexion in swing. The premature plantar flexion of the right ankle in stance is secondary to a vault compensation and therefore, is predicted to resolve secondary to the surgery on the left side, that is, does not require any treatment. A standard protocol in most clinical gait laboratories is to repeat the gait analysis at about one year postsurgery. At this time, surgical hypotheses and progress with respect to resolution of gait abnormalities can be evaluated objectively.

51.5 Gait Analysis: Current Status

As indicated in the modeling discussion earlier, the utility of gait analysis information may be limited by sources of error such as soft tissue displacement relative to bone, estimates of joint center locations,

approximations of the inertial properties of the body segments, and the numerical differentiation of noisy data. Other errors associated with data collection alter the results as well, for example, a marker improperly placed or a force platform inadvertently contacted by the swing limb. The evaluation of small subjects weakens the data because intermarker distances are reduced, thereby reducing the precision of angular

computations, although recent improvements in technology have lessened this challenge to a degree. It is essential that the potential adverse effects of these errors on the gait information be understood and appreciated by the clinical team in the interpretation process.

Controversies related to gait analysis techniques include the use of individually placed markers versus clusters of markers and the application of helical or screw axes versus the use of Euler angles. Recent improvements in technology and computational techniques, for example, Leardini et al. [38], Piazza et al. [39], and Schwartz and Rozumalskia [40], have made the dynamic determination of the instantaneous joint center locations, suggested two decades ago by Cappozzo [25], more viable.

Despite these limitations, gait analysis facilitates the systematic quantitative documentation of walking patterns. With the various gait data, the clinician has the opportunity to separate the primary causes of a gait abnormality from compensatory gait mechanisms. Apparent contradictions between the different types of gait information can result in a more carefully developed understanding of the gait deviations. Gait analysis provides the clinical user the ability to more precisely (than observational gait analysis alone) plan complex multilevel surgeries and evaluate the efficacy of different interventions, for example, surgical approaches and orthotic designs. Through gait analysis, movement in planes of motion not easily observed, such as about the long axes of the lower limb segments, may be quantified. Finally, quantities that cannot be observed may be assessed, for example, muscular activity and joint kinetics. In the future, it is anticipated that our understanding of gait will be enhanced through the application of pattern recognition strategies, coupled dynamics, and the linkage of empirical kinematic and kinetic results with the simulations provided by forward dynamics modeling. The systematic and objective evaluation of gait both before and after intervention will ultimately lead to improved treatment outcome.

Mechanics of Head/Neck

Albert I. King
David C. Viano
Wayne State University

Injury is a major societal problem in the United States. Approximately 140,000 fatalities occur each year due to both intentional and unintentional injuries. Two thirds of these are unintentional, and of these, about one half are attributable to automotive-related injuries. In 1993, the estimated number of automotive-related fatalities dipped under 40,000 for the first time in the last three decades due to a continuing effort by both the industry and the government to render vehicles safer in crash situations. However, for people under 40 years of age, automotive crashes, falls, and other unintentional injuries are the highest risks of fatality in the United States in comparison with all other causes.

The principal aim of impact biomechanics is the prevention of injury through environmental modification, such as the provision of an airbag for automotive occupants to protect them during a frontal crash. To achieve this aim effectively, it is necessary that workers in the field have a clear understanding of the *mechanisms of injury,* be able to describe the *mechanical response* of the tissues involved, have some basic information on *human tolerance* to impact, and be in possession of tools that can be used as *human surrogates* to assess a particular injury [Viano et al., 1989]. This chapter deals with the biomechanics of blunt impact injury to the head and neck.

52.1   Mechanisms of Injury

52.1.1   Head Injury Mechanisms

Among the more popular theories of brain injury due to blunt impact are changes in intracranial pressure and the development of shear strains in the brain. Positive-pressure increases are found in the brain behind the site of impact on the skull. Rapid acceleration of the head, in-bending of the skull, and the propagation of a compressive pressure wave are proposed as mechanisms for the generation of intracranial compression that causes local contusion of brain tissue. At the contrecoup site, there is an opposite response in the form of a negative-pressure pulse that also causes bruising. It is not clear as to whether the injury is due to the negative pressure itself (tensile loading) or to a cavitation phenomenon similar to that seen on the surfaces of propellers of ships (compression loading). The pressure differential across the brain necessarily results in a pressure gradient that can give rise to shear strains developing within the deep structures of the brain. Furthermore, when the head is impacted, it not only translates but also rotates about the neck, causing relative motion of the brain with respect to the skull. Gennarelli [1983] has found that rotational acceleration of the head can cause a diffuse injury to the white matter of the brain in animal models, as evidenced by retraction balls developing along the axons of injured nerves. This injury was described by Strich [1961] as diffuse axonal injury (DAI) that she found in the white matter of autopsied human brains. Other researchers, including Lighthall et al. [1990], have been able to cause the development of DAI in the brain of an animal model (ferrets) by the application of direct impact to the brain without the associated head angular acceleration. Adams et al. [1986] indicated that DAI is the most important factor in severe head injury because it is irreversible and leads to incapacitation and dementia. It is postulated that DAI occurs as a result of the mechanical insult but cannot be detected by staining techniques at autopsy unless the patient survives the injury for at least several hours.

52.1.2   Neck Injury Mechanisms

The neck or the cervical spine is subjected to several forms of unique injuries that are not seen in the thoracolumbar spine. Injuries to the upper cervical spine, particularly at the atlanto-occipital joint, are considered to be more serious and life threatening than those at the lower level. The atlanto-occipital joint can be dislocated either by an axial torsional load or a shear force applied in the anteroposterior direction, or vice versa. A large compression force can cause the arches of Cl to fracture, breaking it up into two or four sections. The odontoid process of C2 is also a vulnerable area. Extreme flexion of the neck is a common cause of odontoid fractures, and a large percentage of these injuries are related to automotive accidents [Pierce and Barr, 1983]. Fractures through the pars interarticularis of C2, commonly known as "hangman's fractures" in automotive collisions, are the result of a combined axial compression and extension (rearward bending) of the cervical spine. Impact of the forehead and face of unrestrained occupants with the windshield can result in this injury. Garfin and Rothman [1983] discussed this injury in relation to hanging and traced the history of this mode of execution. It was estimated by a British judiciary committee that the energy required to cause a hangman's fracture was 1708 Nm (1260 ft lb).

   In automotive-type accidents, the loading on the neck due to head contact forces is usually a combination of an axial or shear load with bending. Bending loads are almost always present, and the degree of axial or shear force depends on the location and direction of the contact force. For impacts near the crown of the head, compressive forces predominate. If the impact is principally in the transverse plane, there is less compression and more shear. Bending modes are infinite in number because the impact can come from any angle around the head. To limit the scope of the discussion, the following injury modes are considered: tension–flexion, tension–extension, compression–flexion, and compression–extension in the midsagittal plane and lateral bending.

52.1.2.1   Tension–Flexion Injuries

Forces resulting from inertial loading of the head–neck system can result in flexion of the cervical spine while it is being subjected to a tensile force. In experimental impacts of restrained subjects undergoing

forward deceleration, Thomas and Jessop [1983] reported atlanto-occipital separation and C1–C2 separation occurring in subhuman primates at 120 g. Similar injuries in human cadavers were found at 34–38 g by Cheng et al. [1982], who used a preinflated driver airbag system that restrained the thorax but allowed the head and neck to rotate over the bag.

52.1.2.2 Tension–Extension Injuries

The most common type of injury due to combined tension and extension of the cervical spine is the "whiplash" syndrome. However, a large majority of such injuries involve the soft tissues of the neck, and the pain is believed to reside in the joint capsules of the articular facets of the cervical vertebrae [Wallis et al., 1997]. In severe cases, teardrop fractures of the anterosuperior aspect of the vertebral body can occur. Alternately, separation of the anterior aspect of the disk from the vertebral endplate is known to occur. More severe injuries occur when the chin impacts the instrument panel or when the forehead impacts the windshield. In both cases, the head rotates rearward and applies a tensile and bending load on the neck. In the case of windshield impact by the forehead, hangman's fracture of C2 can occur. Garfin and Rothman [1983] suggested that it is caused by spinal extension combined with compression on the lamina of C2, causing the pars to fracture.

52.1.2.3 Compression–Flexion Injuries

When a force is applied to the posterosuperior quadrant of the head or when a crown impact is administered while the head is in flexion, the neck is subjected to a combined load of axial compression and forward bending. Anterior wedge fractures of vertebral bodies are commonly seen, but with increased load, burst fractures and fracture-dislocations of the facets can result. The latter two conditions are unstable and tend to disrupt or injure the spinal cord, and the extent of the injury depends on the penetration of the vertebral body or its fragments into the spinal canal. Recent experiments by Pintar et al. [1989, 1990] indicate that burst fractures of lower cervical vertebrae can be reproduced in cadaveric specimens by a crown impact to a flexed cervical spine. A study by Nightingale et al. [1993] showed that fracture-dislocations of the cervical spine occur very early in the impact event (within the first 10 ms) and that the subsequent motion of the head or bending of the cervical spine cannot be used as a reliable indicator of the mechanism of injury.

52.1.2.4 Compression–Extension Injuries

Frontal impacts to the head with the neck in extension will cause compression–extension injuries. These involve the fracture of one or more spinous processes and, possibly, symmetrical lesions of the pedicles, facets, and laminae. If there is a fracture-dislocation, the inferior facet of the upper vertebra is displaced posteriorly and upward and appears to be more horizontal than normal on x-ray.

52.1.2.5 Injuries Involving Lateral Bending

If the applied force or inertial load on the head has a significant component out of the midsagittal plane, the neck will be subjected to lateral or oblique along with axial and shear loading. The injuries characteristic of lateral bending are lateral wedge fractures of the vertebral body and fractures to the posterior elements on one side of the vertebral column.

Whenever there is lateral or oblique bending, there is the possibility of twisting the neck. The associated torsional loads may be responsible for unilateral facet dislocations or unilateral locked facets [Moffat et al., 1978]. However, the authors postulated that pure torsional loads on the neck are rarely encountered in automotive accidents.

52.2 Mechanical Response

52.2.1 Mechanical Response of the Brain

Skull impact response was presented in the previous edition in which remarks were made regarding the unavailability of data on the response of the brain during an injury-producing impact. Such data are
FIGURE 52.1   Brain response to blunt impact.

now available. For intact heads, the motion of the brain inside the skull has been recently studied by Hardy et al. [2001]. Isolated cadaveric heads were subjected to a combined linear and angular acceleration and exposed to a biplanar high-speed x-ray system. Neutral density targets made of tin or tungsten were preinserted into the brain. Video data collected from such impacts showed that most of the motion was in the center of the brain and that target motion was in the form of a figure 8, as shown in Figure 52.1. This motion was limited to ± 5 mm regardless of the severity of the impact. Angular acceleration levels in excess of 10,000 rad/sec^2 were reached.

In another experiment, a Hybrid III dummy head and neck system was accelerated into a variety of plastic foams to assess head response with and without the use of a helmet used in American football. It was found that the helmet reduced the linear acceleration of the head substantially but did not change its angular acceleration significantly. However, it is believed by many that angular acceleration is the cause of brain injury. So if angular acceleration is the culprit, then how does the helmet protect the brain? In an attempt to answer this question, video data from NFL helmet impacts were analyzed and the helmet velocities were computed using stereophotogrammetric methods. The helmet impacts were reproduced in the laboratory by Newman et al. [1999] to yield head angular and linear accelerations, using helmeted Hybrid III dummies. These head accelerations were fed into a brain injury computer model developed by Zhang et al. [2001] to compute brain responses, such as strain (ε), strain rate ($d\varepsilon/dt$), and pressure. A total of 58 cases were studied, involving 25 cases of concussion or mild traumatic brain injury (MTBI), as reported by Pellman et al. [2003]. The results of the model were analyzed statistically to determine the best predictors of MTBI, using the logist analysis. It was found brain response parameters such as the product of strain and strain rate, were good predictors whereas angular acceleration was a poor predictor, as shown in Table 52.1. The chi square value is a measure of the ability of the parameter to predict injury and in this analysis, its ability to predict injury is high if the chi square value is high. These results are consistent with the findings of Viano and Lövsund [1999] who used animal data to determine the parameter most likely to cause DAI in a living brain. It was the product of the velocity (V) of the impactor and depth of penetration of the impactor as percentage of the brain depth (C). For the brain, the product, $V \cdot C$, is analogous to $\varepsilon \cdot d\varepsilon/dt$. Note that HIC is the current Head Injury Criterion used in Federal Motor Vehicle Safety Standard (FMVSS) 208 to assess head injury and GSI is the previous head injury criterion, now referred to as the Gadd Severity Index. The Cumulative Strain at 15% is measure of the volume of brain that experienced a strain of 15% or higher throughout the

TABLE 52.1 List of Best Predictors of MTBI

Rank order	Predictor variable	Chi square	p-value
1	$\varepsilon \cdot d\varepsilon/dt$	41.0	0.0000
2	$d\varepsilon/dt$	33.1	0.0000
3	HIC	31.5	0.0000
4	SI	31.2	0.0000
5	Linear acceleration	28.3	0.0000
6	ε_{max}	28.0	0.0000
7	Max. principal stress	27.3	0.0000
8	Cumulative strain at 15%	26.0	0.0000
9	Angular acceleration	24.9	0.0000
FIGURE 52.2 Loading corridor for neck flexion.

impact. It is concluded that response variable of the brain are better predictors of injury than input variables.

52.2.2 Mechanical Response of the Neck

The mechanical response of the cervical spine was studied by Mertz and Patrick [1967, 1971], Patrick and Chou [1976], Schneider et al. [1975], and Ewing et al. [1978]. Mertz et al. [1973] quantified the response in terms of rotation of the head relative to the torso as a function of bending moment at the occipital condyles. Loading corridors were obtained for flexion and extension, as shown in Figure 52.2 and Figure 52.3. An exacting definition of the impact environments to be used in evaluating dummy necks relative to the loading corridors illustrated in these figures is included in SAE J1460 [1985]. It should be noted that the primary basis for these curves is volunteer data and that the extension of these corridors to dummy tests in the injury-producing range is somewhat surprising.

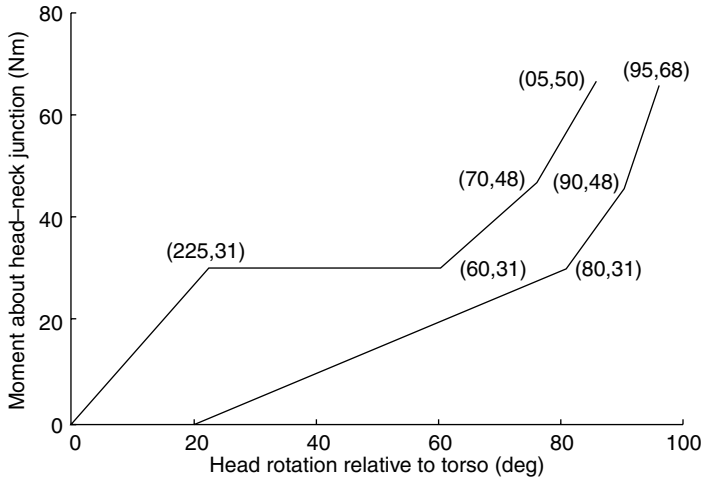
The issue of whiplash is a controversial one principally because researchers in the field cannot agree on an injury mechanism. Currently, five such mechanisms have been proposed. It began with the hyperextension theory, which was discarded when the automotive headrest did not reduce the incidence of injury. The flexion theory is also considered untenable because head and neck flexion after the rear end collision is


FIGURE 52.3 Loading corridor for neck extension.

much less severe than that resulting from a frontal impact and the whiplash syndrome is not frequently seen in frontal impacts. The theory that a momentary increase in pressure in the cerebrospinal fluid during whiplash could induce neck pain was also considered invalid because injury to the nerve roots require prolonged pressure and root compression leads to radiculopathy and not direct neck pain. The fourth theory of impingement of the facet joint surfaces was proposed but has not been demonstrated. It claims that the synovial lining can be trapped between the facets resulting in pain. Finally, the shear theory appears to be the most promising. A shear force is developed at every level of the cervical spine before the head and can be brought forward along with the torso, which is pushed forward by the seat back. This shear force causes relative motion between adjacent cervical vertebrae in the form of relative translation and rotation. Deng et al. [2000] performed a series of cadaveric tests and measured this relative displacement and also estimated the amount of stretch the facet capsules would undergo. Wallis et al. [1997] have shown that removal of nerve endings in the cervical facet capsules can relieve neck pain for an average of about nine months. Figure 52.4 shows the amount of forward motion of C5 relative to C4 and Figure 52.5 shows the estimated stretch of the C4–5 and C5–6 facet capsule. Of interest is the time of occurrence of these events. They occur before the head hits the headrest. It not only explains why the present headrest is in ineffective but also indicates to the safety engineer that the headrest needs to be much closer to the head if it is to be effective.

52.3 Regional Tolerance of the Head and Neck to Blunt Impact

52.3.1 Regional Tolerance of the Head

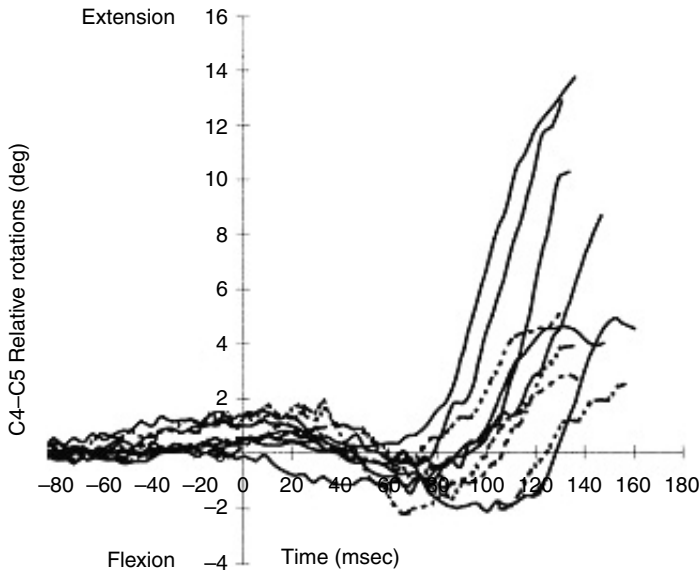
The most commonly measured parameter for head injury is acceleration. It is therefore natural to express human tolerance to injury in terms of head acceleration. The first known tolerance criterion is the Wayne State Tolerance Curve, proposed by Lissner et al. [1960] and subsequently modified by Patrick et al. [1965] by the addition of animal and volunteer data to the original cadaveric data. The modified curve is shown in Figure 52.6. The head can withstand higher accelerations for shorter durations and any exposure above the curve is injurious. When this curve is plotted on logarithmic paper, it becomes a straight line with a slope of −2.5. This slope was used as an exponent by Gadd [1961] in his proposed severity index, now


FIGURE 52.4 Relative displacement of C4 on C5 for 20° seat back angle tests (solid lines) and 0° seat back angle tests (dotted lines) simulating low-speed rear-end collisions, using a cadaver. (Reproduced from *Stapp Car Crash J.* 44: 171–188. With permission.)

known as the *Gadd Severity Index (*GSI):

$$\text{GSI} = \int_0^T a^{2.5} \text{d}t \qquad (52.1)$$

where a is the instantaneous acceleration of the head, and T is the duration of the pulse.

If the integrated value exceeds 1000, a severe injury will result. A modified form of the GSI, now known as the *Head Injury Criterion* (HIC), was proposed by Versace [1970] to identify the most damaging part of the acceleration pulse by finding the maximum value of the following integral:

$$\text{HIC} = (t_2 - t_1) \left[(t_2 - t_1)^{-1} \int_{t_1}^{t_2} a(t) \text{d}t \right]^{2.5} \Bigg|_{\text{max}} \qquad (52.2)$$

where $a(t)$ is the resultant instantaneous acceleration of the head, and $t_2 - t_1$ is the time interval over which HIC is a maximum.

A severe but not life-threatening injury would have occurred if the HIC reached or exceeded 1000. Subsequently, Prasad and Mertz [1985] proposed a probabilistic method of assessing head injury and developed the curve shown in Figure 52.7. At an HIC of 1000, approximately 16% of the population would sustain a severe to fatal injury. It is apparent that this criterion is useful in automotive safety design and in the design of protective equipment for the head, such as football and bicycle helmets. However, there is another school of thought that believes in the injurious potential of angular acceleration in its ability to cause diffuse axonal injury and rupture of the parasagittal bridging veins between the brain and dura mater. The MTBI data referred to above show that this may not be case and that a strain related parameter should be designated as a brain injury criterion, regardless of the input. However, for the moment, HIC remains as the head injury criterion in FMVSS 208 and attempts to replace it have so far been unsuccessful.

As a matter of interest, tolerance data for MTBI, data obtained from the National Football League (NFL) data are presented in Table 52.2, taken from King et al. [2003].
FIGURE 52.5   Estimated cervical facet capsule stretch during the simulated test described in Figure 52.4. (Reproduced from *Stapp Car Crash J.* 44:171–188. With Permission.)

52.3.2   Regional Tolerance of the Neck

Currently, there are no universally accepted tolerance values for the neck for the various injury modes. This is not due to a lack of data but rather to the many injury mechanisms and several levels of injury severity, ranging from life-threatening injuries to the spinal cord to minor soft-tissue injuries that cannot be identified on radiographic or magnetic scans. It is likely that a combined criterion of axial load and bending moment about one or more axes will be adopted as a future FMVSS.
FIGURE 52.6 The Wayne State Tolerance Curve for head injury.

TABLE 52.2 Tolerance Estimates for MTBI

Variable	Tolerance estimate (Probability of injury)		
	25%	50%	75%
HIC	136	235	333
Linear acceleration (m/sec^2)	559	778	965
Angular acceleration (rad/sec^2)	4384	5757	7130
Max. principal strain, ε (%)	25	37	49
Max. principal strain rate, $d\varepsilon/dt$ (sec^{-1})	46	60	79
$\varepsilon \cdot d\varepsilon/dt$ (sec^{-1})	14	20	25

52.4   Human Surrogates of the Head and Neck

52.4.1   The Experimental Surrogate

The most effective experimental surrogate for impact biomechanics research is the unembalmed cadaver. This is also true for the head and neck, despite the fact that the cadaver is devoid of muscle tone because the duration of impact is usually too short for the muscles to respond adequately. It is true, however, that muscle pretensioning in the neck may have to be added under certain circumstances. Similarly, for the brain, the cadaveric brain cannot develop DAI, and the mechanical properties of brain change rapidly after death. If the pathophysiology of the central nervous system is to be studied, the ideal surrogate is an animal brain. Currently, the rat is frequently used as the animal of choice and there is some work in progress using the mini-pig.

52.4.2 The Injury-Assessment Tool

The response and tolerance data acquired from cadaveric studies are used to design human-like surrogates, known as *anthropomorphic test devices* (ATD). These surrogates are required not only to have biofidelity and the ability to simulate human response but also need to provide physical measurements that are representative of human injury. In addition, they are designed to be repeatable and reproducible. The current frontal impact dummy is the Hybrid III family of dummies ranging from the 95th percentile male to the 3-year-old infant. The 50th percentile male dummy is human like in many of its responses, including that of the head and neck. The head consists of an aluminum headform covered by an appropriately designed vinyl "skin" to yield human-like acceleration responses for frontal and lateral impacts against a flat, rigid surface. Two-dimensional physical models of the brain were proposed by Margulies et al. [1990] using a silicone gel in which preinscribed grid lines would deform under angular acceleration. No injury criterion is associated with this gel model.

The dummy neck was designed to yield responses in flexion and extension that would fit within the corridors shown in Figure 52.2 and Figure 52.3. The principal function of the dummy neck is to place the head in the approximate position of a human head in the same impact involving a human occupant.

52.4.3 Computer Models

Models of head impact first appeared over 50 years ago [Holbourn, 1943]. Extensive reviews of such models were made by King and Chou [1977] and Hardy et al. [1994]. The use of the finite-element method (FEM) to simulate the various components of the head appears to be the most effective and popular means of modeling brain response. A recent model by Zhang et al. [2001] is extremely detailed, with over 300,000 elements. It simulates the brain, the meninges, the cerebrospinal fluid and ventricles, the skull, scalp, and most of the facial bones and soft tissues. Validation was attempted against all available experimental data.

It has been used in many applications, including the prediction of MTBI for helmeted football players described earlier. Other less detailed models include those by Kleiven and Hardy [2002], Willinger et al. [1999], and Takhounts et al. [2003].

A large number of neck and spinal models also have been developed over the past four decades. A paper by Kleinberger [1993] provides a brief and incomplete review of these models. However, the method of choice for modeling the response of the neck is the finite-element method, principally because of the complex geometry of the vertebral components and the interaction of several different materials. A partially validated model for impact response was developed by Yang et al. [1998] to simulate both crown impact as well as the whiplash phenomenon due to a rear-end impact.

Biomechanics of Chest and Abdomen Impact

David C. Viano
Albert I. King
Wayne State University

53.1   Introduction

Injury is caused by energy transfer to the body by an impacting object. It occurs when sufficient force is concentrated on the chest or abdomen by striking a blunt object, such as a vehicle instrument panel or side interior, or being struck by a baseball or blunt ballistic mass. The risk of injury is influenced by the object's shape, stiffness, point of contact, and orientation. It can be reduced by energy absorbing padding or crushable materials, which allow the surfaces in contact to deform, extend the duration of impact, and reduce loads. The torso is viscoelastic, so reaction force increases with the speed of body deformation.

The biomechanical response of the body has three components, (1) inertial resistance by acceleration of body masses, (2) elastic resistance by compression of stiff structures and tissues, and (3) viscous resistance by rate-dependent properties of tissue. For low-impact speeds, the elastic stiffness protects from crush injuries; whereas, for high rates of body deformation, the inertial and viscous properties determine the force developed and limit deformation. The risk of skeletal and internal organ injury relates to energy stored or absorbed by the elastic and viscous properties. The reaction load is related to these responses and inertial resistance of body masses, which combine to resist deformation and prevent injury. When tissues are deformed beyond their recoverable limit, injuries occur.

53.2   Chest and Abdomen Injury Mechanisms

The primary mechanism of chest and abdomen injury is compression of the body at high rates of loading. This causes deformation and stretching of internal organs and vessels. When torso compression exceeds

53-1

the rib-cage tolerance, fractures occur and internal organs and vessels can be contused or ruptured. In some chest impacts, internal injury occurs without skeletal damage. This can happen during high-speed loading, such as with a baseball impact causing ventricular fibrillation in a child without rib fractures. Injury is due to the viscous or rate-sensitive nature of human tissue as biomechanical responses differ for low- and high-speed impact.

When organs or vessels are loaded slowly, the input energy is absorbed gradually through deformation, which is resisted by elastic properties and pressure buildup in tissue. This is the situation when the shoulder belt loads the upper body in a frontal crash. When loaded rapidly, reaction force is proportional to the speed of tissue deformation as the viscous properties of the body resist deformation and provide a natural protection from impact. However, there is also a considerable inertial component to the reaction force. In this case, the body develops high internal pressure and injuries can occur before the ribs deflect much. The ability of an organ or other biological system to absorb impact energy without failure is called tolerance.

If an artery is stretched beyond its tensile strength, the tissue will tear. Organs and vessels can be stretched in different ways, which result in different types of injury. Motion of the heart during chest compression stretches the aorta along its axis from points of tethering in the body. This elongation generally leads to a transverse laceration when the strain limit is exceeded. In contrast, an increase in vascular pressure dilates the vessel and produces biaxial strain, which is larger in the transverse than axial direction. If pressure rises beyond the vessel's limit, it will burst. For severe impacts, intra-aortic pressure exceeds 500 to 1000 mm Hg, which is a significant, nonphysiological level, but is tolerable for short durations. When laceration occurs, the predominant mode of aortic failure is axial so the combined effects of stretch and internal pressure contribute to injury. Chest impact also compresses the rib cage causing tensile strain on the outer surface of the ribs. As compression increases, the risk of rib fracture increases. In both cases, the mechanism of injury is tissue deformation. Shah et al. [2001] found right-side impacts caused a higher risk of aortic injury than other impact directions.

The abdomen is more vulnerable to injury than the chest, because there is little bony structure below the ribcage to protect internal organs in front and lateral impact. Blunt impact of the upper abdomen can compress and injure the liver and spleen, before significant whole-body motion occurs. In the liver, compression increases intrahepatic pressure and generates tensile or shear strains. If the tissue is sufficiently deformed, laceration of the major hepatic vessels can result in hemoperitoneum. The injury tolerance of the solid organs in the abdomen is rate sensitive. Abdominal deformation also causes lobes of the liver to move relative to each other, stretching and shearing the vascular attachment at the hilar region.

Effective occupant restraints, safety systems, and protective equipment not only spread impact energy over the strongest body structures but also reduce contact velocity between the body and the impacted surface or striking object. The design of protective systems is aided by an understanding of injury mechanisms, quantification of human tolerance levels and development of numerical relationships between measurable engineering parameter, such as force, acceleration or deformation, and human injury. These relationships are called injury criteria.

53.3 Injury Criteria and Tolerances

53.3.1 Acceleration Injury

Stapp [1970] conducted rocket-sled experiments in the 1940s on belt-restraint systems and achieved a substantial human tolerance to long-duration, whole-body acceleration. Safety belts protected military personnel exposed to rapid but sustained acceleration. The experiments enabled Eiband [1959] to show in Figure 53.1 that the tolerance to whole-body acceleration increased as the exposure duration decreased. This linked human tolerance and acceleration for exposures of 2 to 1000 msec duration. The tolerance data is based on average sled acceleration rather than the acceleration of the volunteer subject, which would be higher due to compliance of the restraint system. Even with this limitation, the data provide useful early guidelines for the development of military and civilian restraint systems.
FIGURE 53.1 Whole-body human tolerance to vehicle acceleration based on impact duration. (Redrawn from Eiband A.M. Human Tolerance to Rapidly Applied Acceleration. A Survey of the Literature. National Aeronautics and Space Administration, Washington DC, NASA Memo No. 5-19-59E, 1959 and Viano D.C., *Bull. NY Acad. Med.*, 2nd Series, 64: 376–421, 1988. With permission.)

More recent side impact tests have led to other tolerance formulas for chest injury. Morgan et al. [1986] evaluated rigid, side-wall cadaver tests and developed TTI, a thoracic trauma index, which is the average rib and spine acceleration. TTI limits human tolerance to 85 to 90 g in vehicle crash tests. Better injury assessment was achieved by Cavanaugh et al. [1993] using average spinal acceleration (ASA), which is the average slope of the integral of spinal acceleration. ASA is the rate of momentum transfer during side impact, and a value of 30 g is proposed. In most cases, the torso can withstand 60 to 80 g peak, whole-body acceleration by a well-distributed load.

53.3.2 Force Injury

Whole-body tolerance is related to Newton's second law of motion, where acceleration of a rigid mass is proportional to the force acting on it, or $F = ma$. While the human body is not a rigid mass, a well-distributed restraint system allows the torso to respond as though it were fairly rigid when load is applied through the shoulder and pelvis. The greater the acceleration, the greater the force and risk of injury. For a high-speed frontal crash, a restrained occupant can experience 60 g acceleration. For a body mass of 76 kg, the inertial load is 44.7 kN (10,000 lb) and is tolerable if distributed over strong skeletal elements for a short period of time.

The ability to withstand high acceleration for short durations implies that tolerance is related to momentum transfer, because an equivalent change in velocity can be achieved by increasing the acceleration and decreasing its duration, as $\Delta V = a\Delta t$. The implication for occupant-protection systems is that the risk of injury can be decreased if the crash deceleration is extended over a greater period of time. For occupant restraint in 25 msec, a velocity change of 14.7 m/sec (32.7 mph) occurs with 60 g whole-body acceleration. This duration can be achieved by crushable vehicle structures and occupant restraints [Mertz and Gadd, 1971].

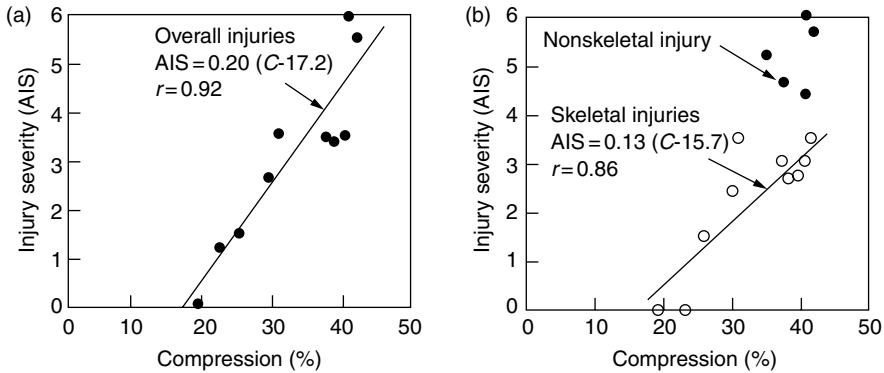
Prior to the widespread use of safety belts, safety engineers needed information on the tolerance of the chest to design energy-absorbing instrument panels and steering systems. The concept was to limit impact force below human tolerance by crushable materials and structures. Using the highest practical crush force, safety was extended to the greatest severity of vehicle crashes. GM Research and Wayne State University collaborated on the development of the first crash sled, which was used to simulate progressively more severe frontal impacts. Embalmed human cadavers were exposed to head, chest, and knee impact on 15 cm (6") diameter load cells until bone fracture was observed on x-ray. Patrick et al. [1965, 1967] demonstrated that blunt chest loading of 3.3 kN (740 lb) could be tolerated with minimal risk of serious injury. This is a pressure of 187 kPa. Gadd and Patrick [1968] later found a tolerance of 8.0 kN (1800 lb) if


FIGURE 53.2 (a) Injury severity from blunt impact of human cadavers as a function of the maximum chest compression (from Viano [1988] with permission). (b) Severity of skeletal injury and incidence of internal organ injury as a function of maximum chest compression for blunt impacts of human cadavers. (From Viano D.C., *Bull. NY Acad. Med.*, 2nd Series, 64: 376–421, 1988. With permission).

the load was distributed over the shoulders and chest by a properly designed steering wheel and column. Cavanaugh et al. [1993] found side-impact tolerance is similar to frontal tolerance, and that shoulder contact is also an important load-path. However, for the abdomen, side padding needs to crush at lower force than the abdominal tolerance to protect the liver and spleen [Viano and Andrzejak, 1993].

53.3.3 Compression Injury

High-speed films of cadaver impacts show that whole-body acceleration does not describe torso impact biomechanics. Tolerance of the chest and abdomen must consider body deformation. Force acting on the body causes two simultaneous responses, (1) compression of the compliant structures of the torso, and (2) acceleration of body masses. The neglected mechanism of injury was compression, which causes the sternum to displace toward the spine as ribs bend and possibly fracture. Acceleration and force, per se, are not sufficient indicators of impact tolerance because they cannot discriminate between the two responses. Numerous studies have shown that acceleration is less related to injury than compression.

The importance of chest deformation was confirmed by Kroell et al. [1971,1974] in blunt thoracic impacts of unembalmed cadavers. Peak spinal acceleration and impact force were poorer injury predictors than the maximum compression of the chest, as measured by the percent change in the anteroposterior thickness of the body. A relationship was found between injury risk and compression and that it involves energy stored by elastic deformation of the body for moderate rates of chest compression. The stored energy (E_s) by a spring representing the ribcage and soft tissues is related to the displacement integral of force: $E_s = \int F dx$. Force in a spring is proportional to deformation: $F = kx$, where k is a spring constant representing the stiffness of the chest and is in the range of 26 kN/m. Stored energy is $E_s = k \int x dx = 0.5kx^2$. Over a compression range of 20 to 40%, stored energy is proportional to deformation or compression, so $E_s \approx C$.

Tests with human volunteers showed that compression up to 20% during moderate-duration loading was fully reversible. Cadaver impacts with compression greater than 20% showed (Figure 53.2a) an increase in rib fractures and internal organ injury as the compression increased to 40%. The deflection tolerance was originally set at 8.8 cm (3.5″) for moderate but recoverable injury. This represents 39% compression. However, at this level of compression, multiple rib fractures and serious injury can occur, so a more conservative tolerance of 32% has been used to avert the possibility of flail chest (Figure 53.2b). This reduces the risk of direct loading on the heart, lungs, and internal organs by a loss of the protective function of the ribcage.

53.3.4 Viscous Injury

The velocity of body deformation is an important factor in impact injury. For example, when a fluid-filled organ is compressed slowly, energy can be absorbed by tissue deformation without damage. When loaded rapidly, the organ cannot deform fast enough and rupture may occur without significant change in shape, even though the load is substantially higher than for the slow-loading condition. This situation depends on the viscous and inertial characteristics of the tissues.

The viscoelastic behavior of soft tissues becomes progressively more important as the velocity of body deformation exceeds 3 m/sec. For lower speeds, such as in slow-crushing loads or for a belt-restrained occupant in a frontal crash, tissue compression is limited by elastic properties resisting skeletal and internal organ injury. For higher speeds of deformation, such as occupant loading by the door in a side impact, an unrestrained occupant or pedestrian impact, or chest impact by a nonpenetrating bullet, maximum compression does not adequately address the viscous and inertial properties of the torso, nor the time of greatest injury risk. In these conditions, the tolerance to compression is progressively lower as the speed of deformation increases, and the velocity of deformation becomes a dominant factor in injury.

Insight on a rate-dependent injury mechanism came from over 20 years of research by Jonsson, Clemedson et al. [1979] on high-speed impact and blast-wave exposures. The studies confirmed that tolerable compression inversely varied with the velocity of impact. The concept was further studied in relation to the abdomen by Lau and Viano [1981] for frontal impacts in the range of 5 to 20 m/sec (10–45 mph). The liver was the target organ. Using a maximum compression of 16%, the severity of injury increased with the speed of loading, including serious mutilation of the lobes and major vessels in the highest-speed impacts. While the compression was within limits of volunteer loading at low speeds, the exposure produced critical injury at higher speeds. Subsequent tests on other animals and target organs verified an interrelationship between body compression, deformation velocity, and injury.

The previous observations led Viano and Lau [1988] to propose a viscous injury mechanism for soft biological tissues. The viscous response (VC) is defined as the product of velocity of deformation (V) and compression (C), which is a time-varying function in an impact. The parameter has physical meaning to absorbed energy (E_a) by a viscous dashpot under impact loading. Absorbed energy is related to the displacement integral of force: $E_a = \int F \, dx$, and force in a dashpot representing the viscous characteristics of the body is proportional to the velocity of deformation: $F = cV$, where c is a dashpot parameter in the range of 0.5 kN/m/sec for the chest. Absorbed energy is: $E_a = c \int V \, dx$, or a time integral by substitution: $E_a = c \int V^2 \, dt$. The integrand is composed of two responses, so: $E_a = c(\int d(Vx) - \int ax \, dt)$, where a is acceleration across the dashpot. The first term is the viscous response and the second an inertial term related to the deceleration of fluid set in motion. Absorbed energy is given by: $E_a = c(Vx - \int ax \, dt)$. The viscous response is proportional to absorbed energy, or $E_a \approx VC$, during the rapid phase of impact loading prior to peak compression.

Subsequent tests by Lau and Viano [1986,1988] verified that serious injury occurred at the time of peak VC, much earlier than peak compression. For blunt chest impact, peak VC occurs in about half the time for maximum compression. Rib fractures also occur progressively with chest compression, as early as 9 to 14 msec — at peak VC — in a cadaver impact requiring 30 msec to reach peak compression. Upper-abdominal injury by steering wheel contact also relates to viscous loading. Lau, Horsch et al. [1987] showed that limiting the viscous response by a self-aligning steering wheel reduced the risk of liver injury, as does force limiting an armrest in side impacts. Animal tests have also shown that VC is a good predictor of functional injury to heart and respiratory systems. In these experiments, Stein et al. [1982] found that the severity of cardiac arrhythmia and traumatic apnea was related to VC. This situation is important to baseball impact protection of children, Viano et al. [1992], and in the definition of human biomechanical responses used in the assessment of bullet-proof protective vests and blunt ballistics [Bir et al., 2004].

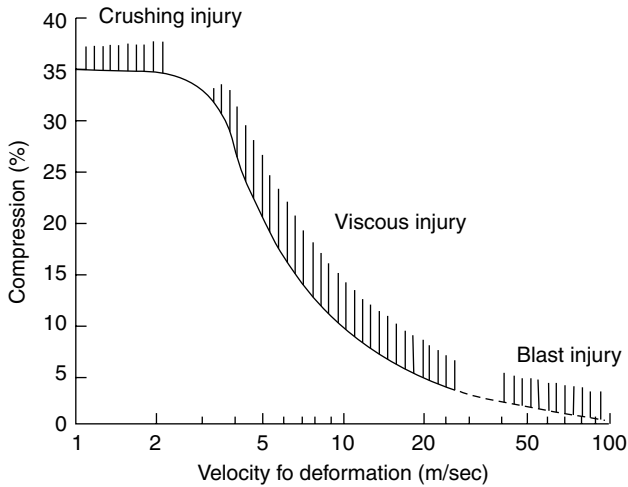
With the increasing use of bullet-proof vests and nonpenetrating munitions by the police and military, blunt, high-velocity impacts are occurring to the chest. Although rarely lethal, there has been a concern for improving the understanding of injury mechanisms and means to establish standards for the technology.


FIGURE 53.3 Biomechanics of chest injury by a crushing injury mechanism limited by tolerable compression at $C_{max} = 35\%$, a viscous injury mechanism limited by the product of velocity and extent of deformation at $VC_{max} = 1.0$ m/sec, and a blast injury mechanism for shock wave loading.

Behind-body-armor standards use the depth of the cavity created in clay after a bullet is stopped by the vest. The roots of this approach involve military research. However, the clay may not adequately simulate the human viscoelastic properties and biomechanical responses. Recent research has defined the blunt ballistic characteristics of the chest and the mechanisms for ventricular fibrillation [Bir and Viano, 1999; Bir et al., 2004].

Sturdivan et al. [2004] developed the Blunt Criterion (BC) in the 1970s. It is energy based and assesses vulnerability to blunt weapons, projectile impacts and behind-body-armor exposures. BC $= \ln[E/(W^{0.33} TD)]$, where $E = \frac{1}{2} MV^2$ is the kinetic energy of the projectile at impact in Joules, M is the projectile mass in kg, V is projectile velocity in m/sec, D is the projectile diameter in cm, W is the mass of the individual in kg and T is body-wall thickness in cm. BC is an energy ratio. The numerator is the striking kinetic energy of the blunt projectile, the energy available to cause injury. The denominator is a semiempirical expression of the capacity of the body to absorb the impact energy without lethal damage to the vulnerable organs, scaled by the mass of the individual. The viscous and blunt criteria are both energy-based and have been correlated for chest and abdominal impacts.

Figure 53.3 summarizes injury mechanisms associated with torso impact deformation. For low speeds of deformation, the limiting factor is crush injury from compression of the body (C). This occurs at $C = 35$–40% depending on the contact area and orientation of loading. For deformation speeds above 3 m/sec, injury is related to a peak viscous response of $VC = 1.0$ m/sec. In a particular situation, injury can occur by a compression or viscous responses, or both, as these responses occur at different times in an impact. At extreme rates of loading, such as in a blast-wave exposure, injury occurs with less than 10–15% compression by high-energy transfer to viscous elements of the body.

53.4   Biomechanical Responses During Impact

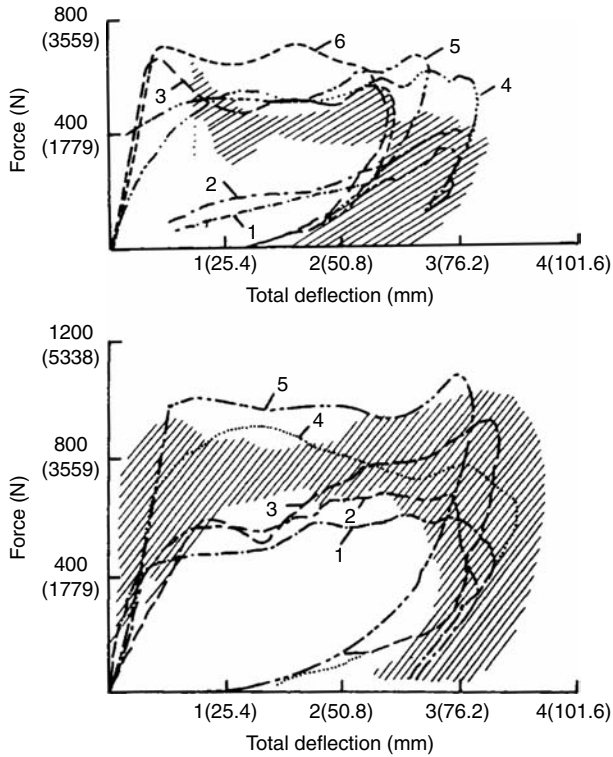
The reaction force developed by the chest varies with the velocity of deformation, and biomechanics is best characterized by a family of force-deflection responses. Figure 53.4 summarizes frontal and lateral chest biomechanics for various impact speeds. The dynamic compliance is related to viscous, inertial, and elastic properties of the body. The initial rise in force is due to inertia as the sternal mass, which is rapidly accelerated to the impact speed as the chest begins to deform. The plateau force is related to the viscous component, which is rate-dependent, and a superimposed elastic stiffness, which increases force


FIGURE 53.4 Frontal and lateral force-deflection response of the human cadaver chest at various speeds of blunt pendulum impact. The initial stiffness is followed by a plateau force until unloading. (From Kroell et al., *Proceedings of the 18th Stapp Car Crash Conference*, pp. 383–457, SAE Paper No. 741187, Society of Automotive Engineers, Warrendale PA, 1974, and Viano, *Proceedings of the 33rd Stapp Car Crash Conference*, pp. 113–142, SAE Paper No. 892432, Society of Automotive Engineers, Warrendale, PA, 1989, summarized by Cavanaugh J.M., The Biomechanics of Thoracic Trauma, In *Accidental Injury: Biomechanics and Prevention*, Nahum A.M. and Melvin J.W., (Eds.), pp. 362–391, Springer-Verlag, New York, 1993. With permission.)

with chest compression. Unloading provides a hysterisis loop representing the energy absorbed by body deformation.

Melvin et al. [1988] analyzed frontal biomechanics of the chest. The dynamic compliance is related to viscous, inertial, and elastic properties of the body. There is an initial rise in force, which is related to the inertia of the sternal mass, which is rapidly accelerated to the impact speed. This is followed by a plateau in force, which is related to the viscous properties and is rate dependent. There is also an elastic stiffness component from chest compression that adds to the force. The force-deflection response can be modeled as an initial stiffness $k = 0.26 + 0.60(V - 1.3)$ and a plateau force $F = 1.0 + 0.75(V - 3.7)$, where k is in kN/cm, F is in kN, and the velocity of impact V is in m/sec. The force F reasonably approximates the plateau level for lateral chest and abdominal impact, but the initial stiffness is lower at $F = 0.12(V - 1.2)$ for side loading [Melvin and Weber, 1988].

The reaction force developed by the chest varies with the velocity of impact, so biomechanics is best characterized by the force-deflection response of the torso (25.6). The dynamic compliance is related to viscous, inertial, and elastic properties of the body. There is an initial rise in force, which is related to inertial responses as the sternal mass is rapidly accelerated to the impact speed. This is followed by a plateau in force, which is related to the viscous response and is rate dependent, and a superimposed stiffness component related to chest compression. By analyzing frontal biomechanics, the chest response can be modeled as an initial stiffness $k = 0.26 + 0.60(V - 1.3)$ and a plateau force $F = 1.0 + 0.75(V - 3.7)$, where k is in kN/cm, F is in kN, and the velocity of impact V is in m/sec. The force F reasonably approximates the

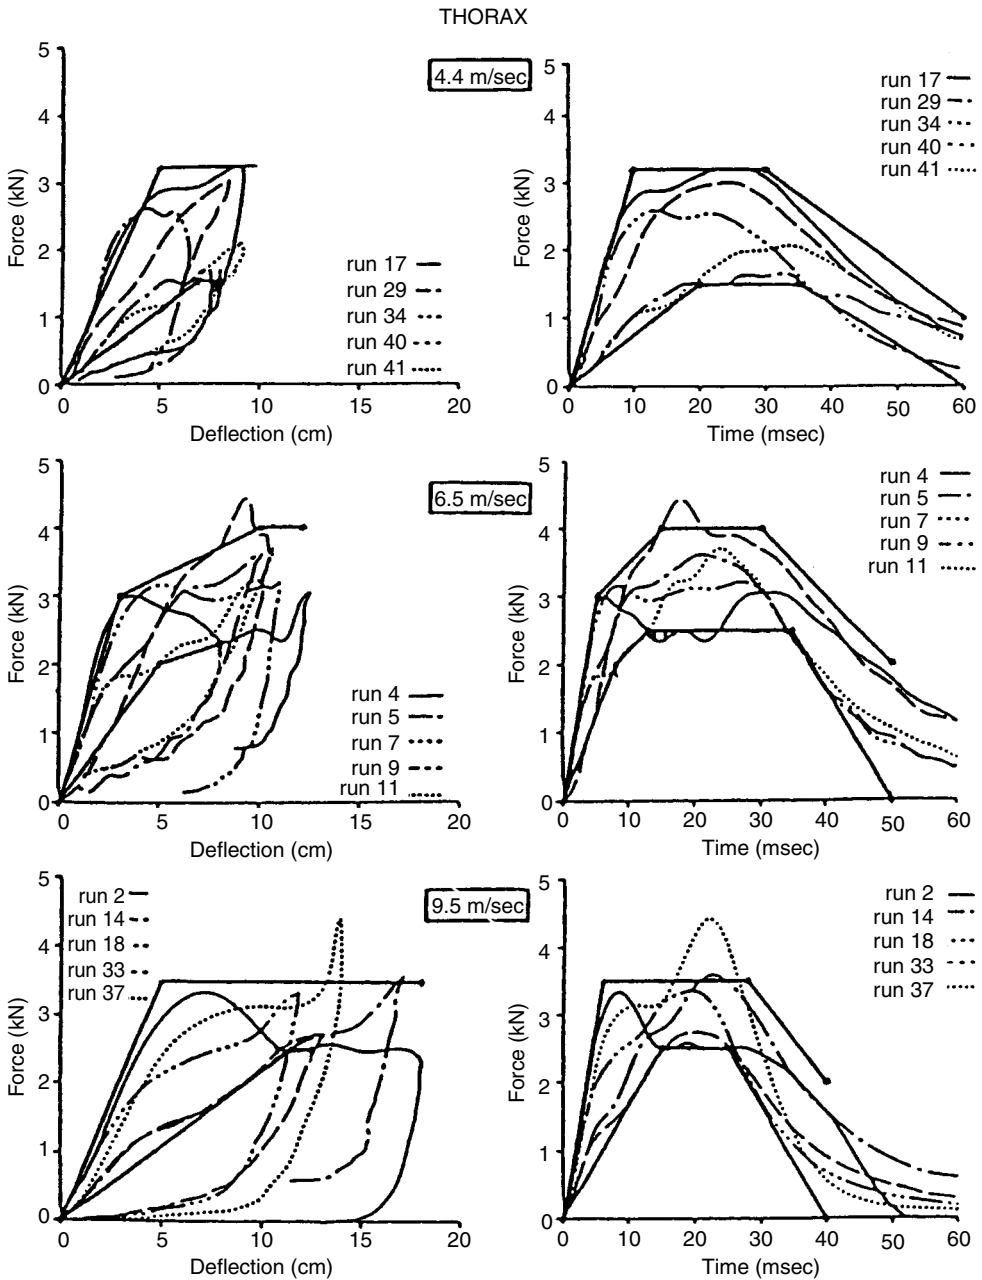
THORAX


FIGURE 53.4   Continued.

plateau level for lateral chest and abdominal impact, but the initial stiffness is lower at $F = 0.12(V - 1.2)$ for side loading.

A simple, but relevant, lumped-mass model of the chest was developed by Lobdell et al. [1973] and is shown in Figure 53.5. The impacting mass is m_1 and skin compliance is represented by k_{12}. An energy-absorbing interface was added by Viano [1987] to evaluate protective padding. Chest structure is represented by a parallel Voigt and Maxwell spring-dashpot system, which couples the sternal m_2 and spinal m_3 masses. When subjected to a blunt sternal impact, the model follows established force-deflection corridors. The biomechanical model is effective in studying compression and viscous responses.
FIGURE 53.5 Lumped-mass model of the human thorax with impacting mass and energy-absorbing material interface. The biomechanical parameters are given for mass, spring, and damping characteristics of the chest in blunt frontal impact. (Modified from Lobdell et al. Impact Response of the Human Thorax, In *Human Impact Response Measurement and Simulation*, King W.F. and Mertz H.J., (Eds.), Plenum Press, New York, pp. 201–245, 1973 by Viano, D.C., *Proceedings of the 31st Stapp Car Crash Conference*, pp. 185–224, SAE Paper No. 872213, Society of Automotive Engineers, Warrendale, PA, 1987. With permission.)

It also simulates military exposures to high-speed, nonpenetrating projectiles (Figure 53.6), even though the loading conditions are quite different from the cadaver database used to develop the model. This mechanical system characterizes the elastic, viscous, and inertial components of the torso.

The Hybrid III dummy was the first to demonstrate humanlike chest responses typical of the biomechanical data for frontal impacts [Foster et al., 1977]. Rouhana [1989] developed a frangible abdomen, useful in predicting injury for lap-belt submarining. More recent work by Schneider et al. [1992] led to a new prototype frontal dummy. Lateral impact tests of cadavers against a rigid wall and blunt pendulum led to side-impact dummies, such as the Eurosid and Biosid [Mertz, 1993]. Even more recently, a small female-sized side-impact dummy has been developed [Scherer et al., 1998].

53.5 Injury Risk Assessment

Over years of study, tolerances have been established for most responses of the chest and abdomen. Table 53.1 provides tolerance levels from reviews by Cavanaugh [1993], and Rouhana [1993], Viano et al. [1989]. While these are single thresholds, they are commonly used to evaluate safety systems. The implication is that for biomechanical responses below tolerance, there is no injury, and for responses above tolerance, there is injury. An additional factor is biomechanical response scaling for individuals of different size and weight. The commonly accepted procedure involves equal stress and velocity, which enabled Mertz et al. [1989] to predict injury tolerances and biomechanical responses for different size adult dummies.
FIGURE 53.6 Tolerance levels for blunt loading as a function of impact mass and velocity. The plot includes information from automotive impact situations and from high-speed military projectile impacts. The Lobdell model is effective over the entire range of impact conditions. (Modified from Quatros J.H., *Proceedings of the 14th International Symposium on Ballistics*, Quebec, Canada, September 26–29, 1993. With permission.)

TABLE 53.1   Human Tolerance for Chest and Abdomen Impact

Criteria	Chest		Abdomen		Criteria
	Frontal	Lateral	Frontal	Lateral	
Acceleration					*Acceleration*
3 msec limit	60 g				
TTI		85–90 g			
ASA		30 g			
AIS 4+		45 g		39 g	AIS 4+
Force					*Force*
Sternum	3.3 kN

Source: Modified from Viano et al. *J. Biomech.* 22: 403–417, 1989.

Injury risk assessment is frequently used. It evaluates the probability of injury as a continuous function of a biomechanical response. A Logist function relates injury probability p to a biomechanical response x by $p(x) = [1 + \exp(\alpha - \beta x)]^{-1}$ where α and β are parameters derived from statistical analysis of biomechanical data. This function provides a sigmoidal relationship with three distinct regions in Figure 53.7. For low biomechanical response levels, there is a low probability of injury. Similarly, for very high levels, the risk asymptotes to 100%. The transition region between the two extremes involves risk, which is proportional to the biomechanical response. A sigmoidal function is typical of human tolerance because it represents the distribution in weak through strong subjects in a population exposed to impact. Table 53.2 summarizes available parameters for chest and abdominal injury risk assessment.

Cardiac Biomechanics

Andrew D. McCulloch
University of California-San Diego

54.1 Introduction

The primary function of the heart, to pump blood through the circulatory system, is fundamentally mechanical. In this chapter, cardiac function is discussed in the context of the mechanics of the ventricular walls from the perspective of the determinants of myocardial stresses and strains (Table 54.1). Many physiological, pathophysiological, and clinical factors are directly or indirectly affected by myocardial stress and strain (Table 54.2). Of course, the factors in Table 54.1 and Table 54.2 are closely interrelated — most of the factors affected by myocardial stress and strain in turn affect the stress and strain in the ventricular wall. For example, changes in wall stress due to altered hemodynamic load may cause ventricular remodeling, which in turn alters geometry, structure, and material properties. This chapter is organized around the governing determinants in Table 54.1, but mention is made where appropriate to some of the factors in Table 54.2.

54.2 Cardiac Geometry and Structure

The mammalian heart consists of four pumping chambers, the left and right atria and ventricles communicating through the atrioventricular (mitral and tricuspid) valves, which are structurally connected by chordae tendineae to papillary muscles that extend from the anterior and posterior aspects of the right and left ventricular lumens. The muscular cardiac wall is perfused via the coronary vessels that originate at the left and right coronary ostia located in the sinuses of Valsalva immediately distal to the aortic valve leaflets. Surrounding the whole heart is the collagenous parietal pericardium that fuses with

Med.*, 69, 576–583, 1980 [130] Grossman, et al., *J. Clin. Invest.*, 56, 56–64, 1975 [131]. Rat data are from unpublished observations in the author's laboratory.

the diaphragm and great vessels. These are the anatomical structures that are most commonly studied in the field of cardiac mechanics. Particular emphasis in this chapter is given to the ventricular walls, which are the most important for the pumping function of the heart. Most studies of cardiac mechanics have focused on the left ventricle, but many of the important conclusions apply equally to the right ventricle.

54.2.1 Ventricular Geometry

From the perspective of engineering mechanics, the ventricles are three-dimensional thick-walled pressure vessels with substantial variations in wall thickness and principal curvatures both regionally and temporally through the cardiac cycle. The ventricular walls in the normal heart are thickest at the equator and base of the left ventricle and thinnest at the left ventricular apex and right ventricular free wall. There are also variations in the principal dimensions of the left ventricle with species, age, phase of the cardiac cycle, and disease (Table 54.3). But, in general, the ratio of wall thickness to radius is too high to be treated accurately by all but the most sophisticated thick-wall shell theories [1].

Ventricular geometry has been studied in most quantitative detail in the dog heart [2,3]. Geometric models have been very useful in the analysis, especially the use of confocal and nonconfocal ellipses of revolution to describe the epicardial and endocardial surfaces of the left and right ventricular walls (Figure 54.1). The canine left ventricle is reasonably modeled by a thick ellipsoid of revolution truncated at the base. The crescentic right ventricle wraps about 180° degrees around the heart wall circumferentially and extends longitudinally about two-thirds of the distance from the base to the apex. Using a truncated ellipsoidal model, left ventricular geometry in the dog can be defined by the major and minor radii of two surfaces, the left ventricular endocardium, and a surface defining the free wall epicardium and the septal endocardium of the right ventricle. Streeter and Hanna [2] described the position of the basal plane using a truncation factor f_b defined as the ratio between the longitudinal distances from equator-to-base and equator-to-apex. Hence, the overall longitudinal distance from base to apex is $(1 + f_b)$ times the major radius of the ellipse. Since variations in f_b between diastole and systole are relatively small (0.45 to 0.51), they suggested a constant value of 0.5.

The focal length d of an ellipsoid is defined from the major and minor radii (a and b) by $d^2 = a^2 - b^2$, and varies only slightly in the dog from endocardium to epicardium between end-diastole (37.3 to 37.9 mm) and end-systole (37.7 to 37.1 mm) [2]. Hence, within the accuracy that the boundaries of the left ventricular wall can be treated as ellipsoids of revolution, the assumption that the ellipsoids are confocal appears to be a good one. This has motivated the choice of prolate spheroidal (elliptic-hyperbolic-polar) coordinates
FIGURE 54.1 Truncated ellipsoid representation of ventricular geometry, showing major left ventricular radius (a), minor radius (b), focal length (d) and prolate spheroidal coordinates (λ, μ, θ).

(λ, μ, θ) as a system for economically representing ventricular geometries obtained postmortem or by noninvasive tomography [3,4]. The Cartesian coordinates of a point are given in terms of its prolate spheroidal coordinates by

$$
\begin{aligned}
x_1 &= d \cosh \lambda \cos \mu \\
x_2 &= d \sinh \lambda \sin \mu \cos \theta \\
x_3 &= d \sinh \lambda \sin \mu \sin \theta
\end{aligned}
\tag{54.1}
$$

Here, the focal length d defines a family of coordinate systems that vary from spherical polar when $d = 0$ to cylindrical polar in the limit when $d \to \infty$. A surface of constant transmural coordinate λ (Figure 54.1) is an ellipse of revolution with major radius $a = d \cosh \lambda$ and minor radius $b = d \sinh \lambda$. In an ellipsoidal model with a truncation factor of 0.5, the longitudinal coordinate μ varies from zero at the apex to 120° at the base. Integrating the Jacobian in prolate spheroidal coordinates gives the volume of the wall or cavity:

$$
\begin{aligned}
d^3 \int_0^{2\pi} & \int_0^{\mu_2} \int_{\lambda_1}^{\lambda_2} ((\sinh^2 \lambda + \sin^2 \mu) \sinh \lambda \sin \mu) \mathrm{d}\lambda \, \mathrm{d}\mu \, \mathrm{d}\theta \\
&= \frac{2\pi d^3}{3} \left| (1 - \cos \mu_2) \cosh^3 \lambda - (1 - \cos^3 \mu_2) \cosh \lambda \right|_{\lambda_1}^{\lambda_2}
\end{aligned}
\tag{54.2}
$$

The scaling between heart mass M_{H} and body mass M within or between species is commonly described by the allometric formula,

$$
M_{\mathrm{H}} = k M^{\alpha}
\tag{54.3}
$$

Using combined measurements from a variety of mammalian species with M expressed in kilograms, the coefficient k is 5.8 g and the power α is close to unity (0.98) [5]. Within individual species, the ratio of heart weight to body weight is somewhat lower in mature rabbits and rats (about 2 g/kg) than in humans (5 g/kg) and higher in horses and dogs (8 g/kg) [6]. The rate α of heart growth with body weight decreases

with age in most species but not in humans. At birth, left and right ventricular weights are similar, but the left ventricle is substantially more massive than the right by adulthood.

54.2.2 Myofiber Architecture

The cardiac ventricles have a complex three-dimensional muscle fiber architecture (for a comprehensive review see Streeter) [7]. Although the myocytes are relatively short, they are connected such that at any point in the normal heart wall there is a clear predominant fiber axis that is approximately tangent with the wall (within 3 to 5° in most regions, except near the apex and papillary muscle insertions). Each ventricular myocyte is connected via gap junctions at intercalated disks to an average of 11.3 neighbors, 5.3 on the sides and 6.0 at the ends [8]. The classical anatomists dissected discrete bundles of fibrous swirls, though later investigations showed that the ventricular myocardium could be unwrapped by blunt dissection into a single continuous muscle "ban" [9]. However, more modern histological techniques have shown that in the plane of the wall, the mean muscle fiber angle makes a smooth transmural transition from epicardium to endocardium (Figure 54.2). About the mean, myofiber angle dispersion is typically 10 to 15° [10] except in certain pathologies. Similar patterns have been described for humans, dogs, baboons, macaques, pigs, guinea pigs, and rats. In the left ventricle of humans or dogs, the muscle fiber angle typically varies continuously from about −60° (i.e., 60° clockwise from the circumferential axis) at the epicardium to about +70° at the endocardium. The rate of change of fiber angle is usually greatest at the epicardium, so that circumferential (0°) fibers are found in the outer half of the wall, and begins to slow approaching the inner third near the trabeculata–compacta interface. There are also small increases in fiber orientation from end-diastole to systole (7 to 19°), with greatest changes at the epicardium and apex [11].

Regional variations in ventricular myofiber orientations are generally smooth except at the junction between the right ventricular free wall and septum. A detailed study in the dog that mapped fiber angles throughout the entire right and left ventricles described the same general transmural pattern in all regions including the septum and right ventricular free wall, but with definite regional variations [3]. Transmural differences in fiber angle were about 120 to 140° in the left ventricular free wall, larger in the septum (160 to 180°) and smaller in the right ventricular free wall (100 to 120°). A similar study of fiber angle distributions in the rabbit left and right ventricles has recently been reported [12]. For the most part, fiber angles in the rabbit heart were very similar to those in the dog, except for on the anterior wall, where average fiber orientations were 20 to 30° counterclockwise of those in the dog. While the most reliable reconstructions of ventricular myofiber architecture have been made using quantitative histological techniques, diffusion tensor magnetic resonance imaging (MRI) has proven to be a reliable technique for estimating fiber orientation nondestructively in fixed [13,14] and even intact beating human hearts [15].

The locus of fiber orientations at a given depth in the ventricular wall has a spiral geometry that may be modeled as a general helix by simple differential geometry. The position vector **x** of a point on a helix inscribed on an ellipsoidal surface that is symmetric about the x_1 axis and has major and minor radii, a and b, is given by the parametric equation,

$$\mathbf{x} = a \sin t \boldsymbol{e}_1 + b \cos t \sin w t \boldsymbol{e}_2 + b \cos t \cos w t \boldsymbol{e}_3 \tag{54.4}$$

where the parameter is t, and the helix makes $w/4$ full turns between apex and equator. A positive w defines a left-handed helix with a positive pitch. The fiber angle or helix pitch angle η, varies along the arc length:

$$\sin \eta = \sqrt{\frac{a^2 \cos^2 t + b^2 \sin^2 t}{(a^2 + b^2 w^2) \cos^2 t + b^2 \sin^2 t}} \tag{54.5}$$

Epicardium
Endocardium

FIGURE 54.2 Cardiac muscle fiber orientations vary continuously through the left ventricular wall from a negative angle at the epicardium (0%) to near zero (circumferential) at the midwall (50%) and to increasing positive values toward the endocardium (100%). (Courtesy Jyoti Rao, Micrographs of murine myocardium from the author's laboratory.)

If another, deformed configuration $\hat{\mathbf{x}}$ is defined in the same way as Equation 54.4, the fiber-segment-extension ratio $d\hat{s}/ds$ associated with a change in the ellipsoid geometry [16] can be derived from

$$\frac{d\hat{s}/dt}{ds/dt} = \frac{|d\hat{x}/dt|}{|dx/dt|} \tag{54.6}$$

Although the traditional notion of discrete myofiber bundles has been revised in view of the continuous transmural variation of muscle fiber angle in the plane of the wall, there is a transverse laminar structure in the myocardium that groups fibers together in sheets an average of 4 ± 2 myocytes thick ($48 \pm 20\ \mu$m), separated by histologically distinct cleavage planes [17–19]. LeGrice and colleagues [19] investigated

these structures in a detailed morphometric study of four dog hearts. They describe an ordered laminar arrangement of myocytes with extensive cleavage planes running approximately radially from endocardium toward epicardium in transmural section. Like the fibers, the sheets also have a branching pattern with the number of branches varying considerably through the wall thickness. Recent reports suggest that, in addition to fiber orientations, diffusion tensor MRI may be able to detect laminar sheet orientations [20]. The tensor of diffusion coefficients in the myocardium detected by MRI has shown to be orthotropic, and the principal axis of slowest diffusion was seen to coincide with the direction normal to the sheet planes.

The fibrous architecture of the myocardium has motivated models of myocardial material symmetry as transversely isotropic. The transverse laminae are the first structural evidence for material orthotropy and have motivated the development of models describing the variation of fiber, sheet, and sheet-normal axes throughout the ventricular wall [21]. This has led to the idea that the laminar architecture of the ventricular myocardium affects the significant transverse shears [22] and myofiber rearrangement [18] described in the intact heart during systole. By measuring three-dimensional distributions of strain across the wall thickness using biplane radiography of radiopaque markers, LeGrice and colleagues [23] found that the cleavage planes coincide closely with the planes of maximum shearing during ejection, and that the consequent reorientation of the myocytes may contribute 50% or more of normal systolic wall thickening. Arts et al. [24] showed that the distributions of sheet orientations measured within the left ventricular wall of the dog heart coincided closely with those predicted from observed three-dimensional wall strains using the assumption that laminae are oriented in planes that contain the muscle fibers and maximize interlaminar shearing. This assumption also leads to the conclusion that two families of sheet orientations may be expected. Indeed, a retrospective analysis of the histology supported this prediction and more recent observations confirm the presence of two distinct populations of sheet plane in the inner half of the ventricular wall.

A detailed description of the morphogenesis of the muscle fiber system in the developing heart is not available but there is evidence of an organized myofiber pattern by day 12 in the fetal mouse heart that is similar to that seen at birth (day 20) [25]. Abnormalities of cardiac muscle fiber patterns have been described in some disease conditions. In hypertrophic cardiomyopathy, which is often familial, there is substantial myofiber disarray, typically in the interventricular septum [10,26].

54.2.3 Extracellular Matrix Organization

The cardiac extracellular matrix consists primarily of the fibrillar collagens, type I (85%) and III (11%), synthesized by the cardiac fibroblasts, the most abundant cell type in the heart. Collagen is the major structural protein in connective tissues, but only comprises 2 to 5% of the myocardium by weight, compared with the myocytes, which make up 90% [27]. The collagen matrix has a hierarchical organization (Figure 54.3), and has been classified according to conventions established for skeletal muscle into endomysium, perimysium, and epimysium [28,29]. The endomysium is associated with individual cells and includes a fine weave surrounding the cell and transverse structural connections 120 to 150 nm long connecting adjacent myocytes, with attachments localized near the z-line of the sarcomere. The primary purpose of the endomysium is probably to maintain registration between adjacent cells. The perimysium groups cells together and includes the collagen fibers that wrap bundles of cells into the laminar sheets described above as well as large coiled fibers typically 1 to 3μm in diameter composed of smaller collagen fibrils (40 to 50 nm) [30]. The helix period of the coiled perimysial fibers is about 20μm and the convolution index (ratio of fiber arclength to midline length) is approximately 1.3 in the unloaded state of the ventricle [31,32]. These perimysial fibers are most likely to be the major structural elements of the collagen extracellular matrix though they probably contribute to myocardial strain energy by uncoiling rather than stretching [31]. Finally, a thick epimysial collagen sheath surrounds the entire myocardium forming the protective epicardium (visceral pericardium) and endocardium.

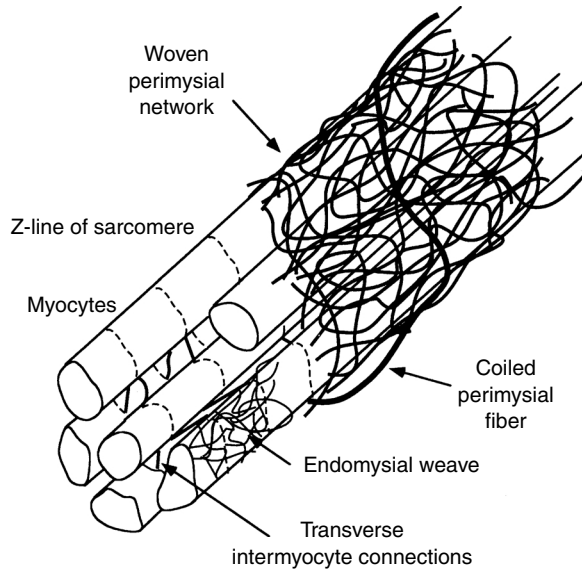
Collagen content, organization, cross-linking and ratio of types I to III change with age and in various disease conditions including myocardial ischemia and infarction, hypertension and hypertrophy


FIGURE 54.3 Schematic representation of cardiac tissue structure showing the association of endomysial and perimysial collagen fibers with cardiac myocytes. (Courtesy Dr. Deidre MacKenna.)

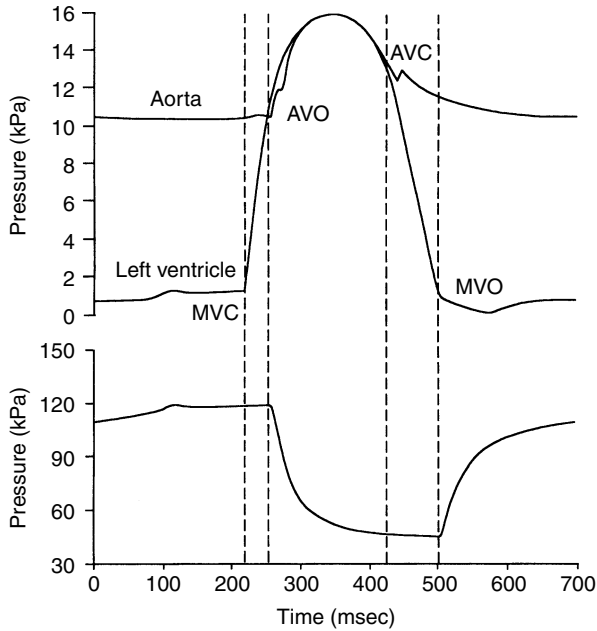

FIGURE 54.4 Left ventricular pressure, aortic pressure, and left ventricular volume during a single cardiac cycle showing the times of mitral valve closure (MVC), aortic valve opening (AVO), aortic valve closure (AVC) and mitral valve opening (MVO).

(Table 54.4). Changes in myocardial collagen content and organization coincide with alterations in diastolic myocardial stiffness [33]. Collagen intermolecular cross-linking is mediated by two separate mechanisms. The formation of enzymatic hydroxylysyl pyridinoline cross-links is catalyzed by lysyl oxidase, which requires copper as a cofactor. Nonenzymatic collagen cross-links known as advanced glycation endproducts can be formed in the presence of reducing sugars. This mechanism has been seen to significantly increase ventricular wall stiffness independent of changes in tissue collagen content, not only in diabetics, but also in an animal model of volume overload hypertrophy [34]. Hence the collagen matrix plays an important role in determining the elastic material properties of the ventricular myocardium.

54.3 Cardiac Pump Function

54.3.1 Ventricular Hemodynamics

The most basic mechanical parameters of the cardiac pump are blood pressure and volume flowrate, especially in the major pumping chambers, the ventricles. From the point of view of wall mechanics, the ventricular pressure is the most important boundary condition. Schematic representations of the time-courses of pressure and volume in the left ventricle are shown in Figure 54.4. Ventricular filling immediately following mitral valve opening (MVO) is initially rapid because the ventricle produces a diastolic suction as the relaxing myocardium recoils elastically from its compressed systolic configuration below the resting chamber volume. The later slow phase of ventricular filling (diastasis) is followed finally by atrial contraction. The deceleration of the inflowing blood reverses the pressure gradient across the valve leaflets and causes them to close mital valve closure (MVC). Valve closure may not, however, be completely passive, because the atrial side of the mitral valve leaflets, which unlike the pulmonic and aortic valves are cardiac in embryological origin, have muscle and nerve cells, and are electrically coupled to atrial conduction [35].

Ventricular contraction is initiated by excitation, which is almost synchronous (the duration of the QRS complex of the ECG is only about 60 msec in the normal adult) and begins about 0.1 to 0.2 sec after atrial depolarization. Pressure rises rapidly during the isovolumic contraction phase (about 50 msec in adult humans), and the aortic valve opens (AVO) when the developed pressure exceeds the aortic pressure (afterload). Most of the cardiac output is ejected within the first quarter of the ejection phase before the pressure has peaked. The aortic valve closes (AVC) 20 to 30 msec after AVO when the ventricular pressure falls below the aortic pressure owing to the deceleration of the ejecting blood. The dichrotic notch, a characteristic feature of the aortic pressure waveform and a useful marker of aortic valve closure, is caused by pulse wave reflections in the aorta. Since the pulmonary artery pressure against which the right ventricle pumps is much lower than the aortic pressure, the pulmonic valve opens before and closes after the aortic valve. The ventricular pressure falls during isovolumic relaxation, and the cycle continues. The rate of pressure decay from the value P_0 at the time of the peak rate of pressure fall until MVO is commonly characterized by a single exponential time constant, that is,

$$P(t) = P_0 e^{-t/\tau} + P_\infty \tag{54.7}$$

where P_∞ is the (negative) baseline pressure to which the ventricle would eventually relax if MVO were prevented [36]. In dogs and humans, τ is normally about 40 msec, but it is increased by various factors including elevated afterload, asynchronous contraction associated with abnormal activation sequence or regional dysfunction, and slowed cytosolic calcium reuptake to the sarcoplasmic reticulum associated with cardiac hypertrophy and failure. The pressure and volume curves for the right ventricle look essentially the same; however, the right ventricular and pulmonary artery pressures are only about a fifth of the corresponding pressures on the left side of the heart. The intraventricular septum separates the right and left ventricles and can transmit forces from one to the other. An increase in right ventricular volume may increase the left ventricular pressure by deformation of the septum. This direct interaction is most significant during filling [37].

The phases of the cardiac cycle are customarily divided into systole and diastole. The end of diastole — the start of systole — is generally defined as the time of MVC. Mechanical end-systole is usually defined as the end of ejection, but Brutsaert and colleagues proposed extending systole until the onset of diastasis (see the review by Brutsaert and Sys [38]), since there remains considerable myofilament interaction and active tension during relaxation. The distinction is important from the point of view of cardiac muscle mechanics: the myocardium is still active for much of diastole and may never be fully relaxed at sufficiently high heart rates (over 150 beats per minute). Here, we will retain the traditional definition of diastole, but consider the ventricular myocardium to be "passive" or "resting" only in the final slow-filling stage of diastole.

54.3.2 Ventricular Pressure–Volume Relations and Energetics

A useful alternative to Figure 54.4 for displaying ventricular pressure and volume changes is the pressure–volume loop shown in Figure 54.5a. During the last 20 years, the ventricular pressure–volume relationship has been explored extensively, particularly by Sagawa, and colleagues [39], who wrote a comprehensive book on the approach. The isovolumic phases of the cardiac cycle can be recognized as the vertical segments of the loop, the lower limb represents ventricular filling, and the upper segment is the ejection phase. The difference on the horizontal axis between the vertical isovolumic segments is the stroke volume, which expressed as a fraction of the end-diastolic volume is the ejection fraction. The effects of altered loading on the ventricular pressure–volume relation have been studied in many preparations, but the best controlled experiments have used the isolated cross-circulated canine heart in which the ventricle fills and ejects against a computer-controlled volume servo-pump.

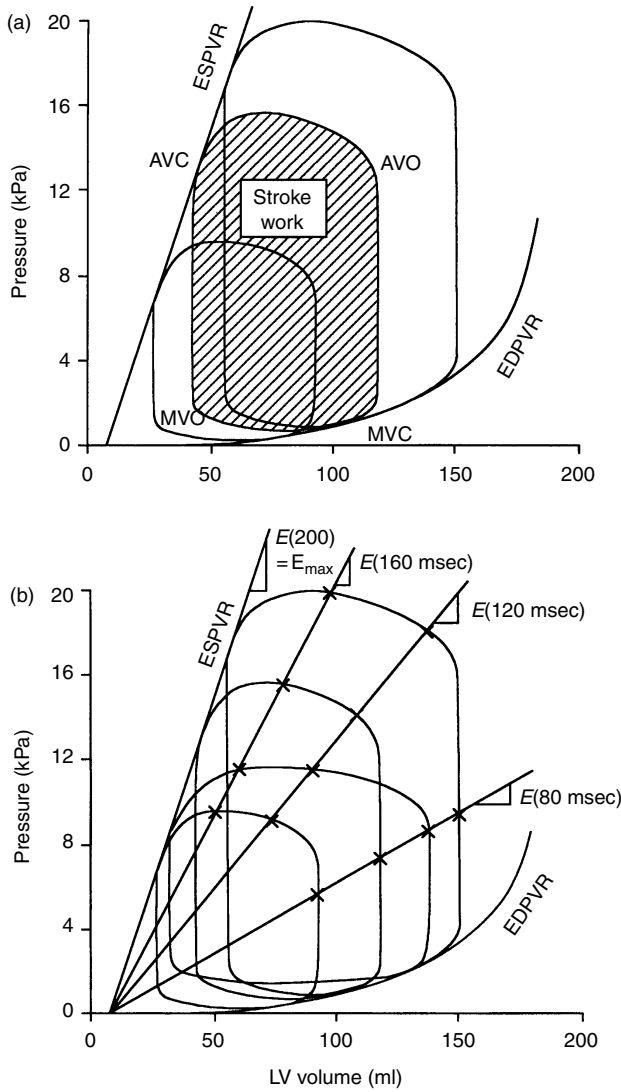
Changes in the filling pressure of the ventricle (preload) move the end-diastolic point along the unique end-diastolic pressure–volume relation (EDPVR), which represents the passive filling mechanics of the chamber that are determined primarily by the thick-walled geometry and nonlinear elasticity of the resting


FIGURE 54.5 Schematic diagram of left ventricular pressure–volume loops: (a) End-systolic pressure–volume relation (ESPVR), end-diastolic pressure–volume relation (EDPVR) and stroke work. The three P–V loops show the effects of changes in preload and afterload. (b) Time-varying elastance approximation of ventricular pump function (see text).

ventricular wall. Alternatively, if the afterload seen by the left ventricle is increased, stroke volume decreases in a predictable manner. The locus of end-ejection points (AVC) forms the end-systolic pressure–volume relation (ESPVR), which is approximately linear in a variety of conditions and also largely independent of the ventricular load history. Hence, the ESPVR is almost the same for isovolumic beats as for ejecting beats, although consistent effects of ejection history have been well characterized [40]. Connecting pressure–volume points at corresponding times in the cardiac cycle also results in a relatively linear relationship throughout systole with the intercept on the volume axis V_0 remaining nearly constant (Figure 54.5b). This leads to the valuable approximation that the ventricular volume $V(t)$ at any instance during systole is simply proportional to the instantaneous pressure $P(t)$ through a time-varying elastance $E(t)$:

$$P(t) = E(t)\{V(t) - V_0\} \tag{54.8}$$

The maximum elastance E_{max}, the slope of the ESPVR, has acquired considerable significance as an index of cardiac contractility that is independent of ventricular loading conditions. As the inotropic state of the myocardium increases, for example with catecholamine infusion, E_{max} increases, and with a negative inotropic effect such as a reduction in coronary artery pressure, it decreases.

The area of the ventricular pressure–volume loop is the external work (EW) performed by the myocardium on the ejecting blood:

$$EW = \int_{EDV}^{ESV} P(t) dV \tag{54.9}$$

Plotting this stroke work against a suitable measure of preload gives a ventricular function curve, which illustrates the single most important intrinsic mechanical property of the heart pump. In 1914, Patterson and Starling [41] performed detailed experiments on the canine heart–lung preparation, and Starling summarized their results with his famous "Law of the Heart," which states that the work output of the heart increases with ventricular filling. The so-called Frank–Starling mechanism is now well recognized to be an intrinsic mechanical property of cardiac muscle (see Section 54.4).

External stroke work is closely related to cardiac energy utilization. Since myocardial contraction is fueled by ATP, 90 to 95% of which is normally produced by oxidative phosphorylation, cardiac energy consumption is often studied in terms of myocardial oxygen consumption, VO_2 (ml $O_2.g^{-1}.beat^{-1}$). Since energy is also expended during nonworking contractions, Suga and colleagues [42] defined the pressure–volume area (PVA) ($J.g^{-1}.beat^{-1}$) as the loop area (external stroke work) plus the end-systolic potential energy (internal work), which is the area under the ESPVR left of the isovolumic relaxation line (Figure 54.5a),

$$PVA = EW + PE \tag{54.10}$$

The PVA has strong linear correlation with VO_2 independent of ejection history. Equation 54.11 has typical values for the dog heart:

$$VO_2 = 0.12(PVA) + 2.0 \times 10^{-4} \tag{54.11}$$

The intercept represents the sum of the oxygen consumption for basal metabolism and the energy associated with activation of the contractile apparatus, which is primarily used to cycle intracellular Ca^{2+} for excitation–contraction coupling [42]. The reciprocal of the slope is the contractile efficiency [43,44]. The VO_2–PVA relation shifts its elevation but not its slope with increments in E_{max} with most positive and negative inotropic interventions [43,45–48]. However, ischemic-reperfused viable but "stunned" myocardium has a smaller O_2 cost of PVA [49].

Although the PVA approach has also been useful in many settings, it is fundamentally phenomenological. Because the time-varying elastance assumptions ignores the well-documented load-history dependence of cardiac muscle tension, [50–52] theoretical analyses that attempt to reconcile PVA with crossbridge mechanoenergetics [53] are usually based on isometric or isotonic contractions. So that regional oxygen consumption in the intact heart can be related to myofiber biophysics, regional variations on the pressure–volume area have been proposed, such as the tension-area area [54], normalization of E_{max} [55], and the fiber stress-strain area [56].

In mammals, there are characteristic variations in cardiac function with heart size. In the power law relation for heart rate as a function of body mass (analogous to Equation 54.3), the coefficient k is 241 beats.min^{-1} and the power α is -0.25 [5]. In the smallest mammals, like soricine shrews that weigh only a few grams, maximum heart rates exceeding 1000 beats.min^{-1} have been measured [57]. Ventricular cavity volume scales linearly with heart weight, and ejection fraction and blood pressure are reasonably invariant from rats to horses. Hence, stroke work also scales directly with heart size [58], and thus work rate and energy consumption would be expected to increase with decreased body size in the same manner as heart rate. However, careful studies have demonstrated only a twofold increase in myocardial heat production as body mass decreases in mammals ranging from humans to rats, despite a 4.6-fold increase in heart

rate [59]. This suggests that cardiac energy expenditure does not scale in proportion to heart rate and that cardiac metabolism is a lower proportion of total body metabolism in the smaller species.

The primary determinants of the EDPVR are the material properties of resting myocardium, the chamber dimensions and wall thickness, and the boundary conditions at the epicardium, endocardium, and valve annulus [60]. The EDPVR has been approximated by an exponential function of volume (see e.g., chapter 9 in Gaasch and Lewinter [61]), though a cubic polynomial also works well. Therefore, the passive chamber stiffness dP/dV is approximately proportional to the filling pressure. Important influences on the EDPVR include the extent of relaxation, ventricular interaction and pericardial constraints, and coronary vascular engorgement. The material properties and boundary conditions in the septum are important since they determine how the septum deforms [62,63]. Through septal interaction, the EDPVR of the left ventricle may be directly affected by changes in the hemodynamic loading conditions of the right ventricle. The ventricles also interact indirectly since the output of the right ventricle is returned as the input to the left ventricle via the pulmonary circulation. Slinker and Glantz [64], using pulmonary artery and venae caval occlusions to produce direct (immediate) and indirect (delayed) interaction transients, concluded that the direct interaction is about half as significant as the indirect coupling. The pericardium provides a low friction mechanical enclosure for the beating heart that constrains ventricular overextension [65] Since the pericardium has stiffer elastic properties than the ventricles [66], it contributes to direct ventricular interactions. The pericardium also augments the mechanical coupling between the atria and ventricles [67]. Increasing coronary perfusion pressure has been seen to increase the slope of the diastolic pressure–volume relation (an "erectile" effect) [68,69].

54.4 Myocardial Material Properties

54.4.1 Muscle Contractile Properties

Cardiac muscle mechanics testing is far more difficult than skeletal muscle testing mainly owing to the lack of ideal test specimens like the long single fiber preparations that have been so valuable for studying the mechanisms of skeletal muscle mechanics. Moreover, under physiological conditions, cardiac muscle cannot be stimulated to produce sustained tetanic contractions due to the absolute refractory period of the myocyte cell membrane. Cardiac muscle also exhibits a mechanical property analogous to the relative refractory period of excitation. After a single isometric contraction, some recovery time is required before another contraction of equal amplitude can be activated. The time constant for this mechanical restitution property of cardiac muscle is about 1 sec [70].

Unlike skeletal muscle, in which maximal active force generation occurs at a sarcomere length that optimizes myofilament overlap ($\sim 2.1\,\mu$m), the isometric twitch tension developed by isolated cardiac muscle continues to rise with increased sarcomere length in the physiological range (1.6 to 2.4 μm) (Figure 54.6a). Early evidence for a descending limb of the cardiac muscle isometric length–tension curve was found to be caused by shortening in the central region of the isolated muscle at the expense of stretching at the damaged ends where specimen was tethered to the test apparatus. If muscle length is controlled so that sarcomere length in the undamaged part of the muscle is indeed constant, or if the developed tension is plotted against the instantaneous sarcomere length rather than the muscle length, the descending limb is eliminated [71]. Thus, the increase with chamber volume of end-systolic pressure and stroke work is reflected in isolated muscle as a monotonic increase in peak isometric tension with sarcomere length (Figure 54.6b). Note that the active tension shown in Figure 54.6 is the total tension minus the resting tension, which, unlike in skeletal muscle, becomes very significant at sarcomere lengths over 2.3 μm. The increase in slope of the ESPVR associated with increased contractility is mirrored by the effects of increased calcium concentration in the length–tension relation. The duration as well as the tension developed in the active cardiac twitch also increases substantially with sarcomere length (Figure 54.6a).

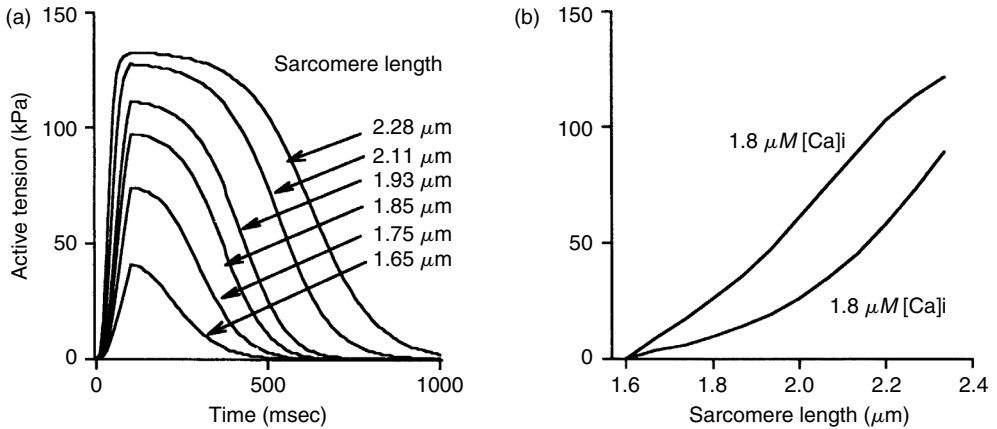
The relationship between cytosolic calcium concentration and isometric muscle tension has mostly been investigated in muscle preparations in which the sarcolemma has been chemically permeabilized. Because


FIGURE 54.6 Cardiac muscle isometric twitch tension generated by a model of rat cardiac contraction (courtesy Dr. Julius Guccione): (a) Developed twitch tension as a function of time and sarcomere length; (b) Peak isometric twitch tension vs. sarcomere length for low and high calcium concentration.

there is evidence that this chemical "skinning" alters the calcium sensitivity of myofilament interaction, recent studies have also investigated myofilament calcium sensitivity in intact muscles tetanized by high-frequency stimulation in the presence of a compound such as ryanodine that open calcium release sites in the sarcoplasmic reticulum. Intracellular calcium concentration was estimated using calcium-sensitive optical indicators such as Fura. The myofilaments are activated in a graded manner by micromolar concentrations of calcium, which binds to troponin-C according to a sigmoidal relation [72]. Half-maximal tension in cardiac muscle is developed at intracellular calcium concentrations of 10^{-6} to 10^{-5} M (the C_{50}) depending on factors such as species and temperature [70]. Hence, relative isometric tension T_0/T_{max} may be modeled using [73,74].

$$\frac{T_0}{T_{max}} = \frac{[Ca]^n}{[Ca]^n + C_{50}^n} \tag{54.12}$$

The Hill coefficient (n) governs the steepness of the sigmoidal curve. A wide variety of values have been reported but most have been in the range 3 to 6 [75–78]. The steepness of the isometric length–tension relation (Figure 54.6b), compared with that of skeletal muscle is due to length-dependent calcium sensitivity. That is, the C_{50} (M) and n both change with sarcomere length, L (μm). Hunter et al. [74] used the following approximations to fit the data of Kentish et al. [76] from rat right ventricular trabeculae:

$$n = 4.25\{1 + 1.95(L/L_{ref} - 1)\}, \quad pC_{50} = -\log_{10}C_{50} = 5.33\{1 + 0.31(L/L_{ref} - 1)\} \tag{54.13}$$

where the reference sarcomere length L_{ref} was taken to be 2.0 μm.

The isotonic force–velocity relation of cardiac muscle is similar to that of skeletal muscle, and A.V. Hill's well-known hyperbolic relation is a good approximation except at larger forces greater than about 85% of the isometric value. The maximal (unloaded) velocity of shortening is essentially independent of preload, but does change with time during the cardiac twitch and is affected by factors that affect contractile ATPase activity and hence crossbridge cycling rates. deTombe and colleagues [79] using sarcomere length-controlled isovelocity release experiments found that viscous forces imposes a significant internal load-opposing sarcomere shortening. If the isotonic shortening response is adjusted for the confounding effects of passive viscoelasticity, the underlying crossbridge force–velocity relation is found to be linear.

Cardiac muscle contraction also exhibits other significant length-history-dependent properties. An important example is "deactivation" associated with length transients. The isometric twitch tension redeveloped following a brief length transient that dissociates crossbridges, reaches the original isometric value when the transient is imposed early in the twitch before the peak tension is reached. But following transients applied at times after the peak twitch tension has occurred, the fraction of tension redeveloped declines progressively since the activator calcium has fallen to levels below that necessary for all crossbridges to reattach [80].

There have been many model formulations of cardiac muscle contractile mechanics, too numerous to summarize here. In essence they may be grouped into three categories. Time-varying elastance models include the essential dependence of cardiac active force development on muscle length and time. These models would seem to be well suited to the continuum analysis of whole heart mechanics [1,81,82] by virtue of the success of the time-varying elastance concept of ventricular function (see Section 54.3.2). In "Hill" models the active fiber stress development is modified by shortening or lengthening according to the force–velocity relation, so that fiber tension is reduced by increased shortening velocity [83,84]. Fully history-dependent models are more complex and are generally based on A.F. Huxley's crossbridge theory [52,85–87]. A statistical approach known as the distribution moment model has also been shown to provide an excellent approximation to crossbridge theory [88]. An alternative more phenomenological approach is Hunter's fading memory theory, which captures the complete length-history dependence of cardiac muscle contraction without requiring all the biophysical complexity of crossbridge models [74]. The appropriate choice of model will depend on the purpose of the analysis. For many models of global ventricular function, a time-varying elastance model will suffice, but for an analysis of sarcomere dynamics in isolated muscle or the ejecting heart, a history-dependent analysis is more appropriate.

Although Hill's basic assumption that resting and active muscle fiber tension are additive is axiomatic in one-dimensional tests of isolated cardiac mechanics, there remains little experimental information on how the passive and active material properties of myocardium superpose in two or three dimensions. The simplest and commonest assumption is that active stress is strictly one-dimensional and adds to the fiber component of the three-dimensional passive stress. However, even this addition will indirectly affect all the other components of the stress response, since myocardial elastic deformations are finite, nonlinear and approximately isochoric (volume conserving). In an interesting and important new development, biaxial testing of tetanized and barium-contracted ventricular myocardium has shown that developed systolic stress also has a large component in directions transverse to the mean myofiber axis that can exceed 50% of the axial fiber component [89]. The magnitude of this transverse active stress depended significantly on the biaxial loading conditions. Moreover, evidence from osmotic swelling and other studies suggests that transverse strain can affect contractile tension development along the fiber axis by altering myofibril lattice spacing [90,91]. The mechanisms of transverse active stress development remain unclear but two possible contributors are the geometry of the crossbridge head itself, which is oriented oblique to the myofilament axis [92], and the dispersion of myofiber orientation [10].

54.4.2 Resting Myocardial Properties

Since, by the Frank–Starling mechanism, end-diastolic volume directly affects systolic ventricular work, the mechanics of resting myocardium also have fundamental physiological significance. Most biomechanics studies of passive myocardial properties have been conducted in isolated, arrested whole heart or tissue preparations. Passive cardiac muscle exhibits most of the mechanical properties characteristic of soft tissues in general [93]. In cyclic uniaxial loading and unloading, the stress–strain relationship is nonlinear with small but significant hysteresis. Depending on the preparation used, resting cardiac muscle typically requires from 2 to 10 repeated loading cycles to achieve a reproducible (preconditioned) response. Intact cardiac muscle experiences finite deformations during the normal cardiac cycle, with maximum Lagrangian strains (which are generally radial and endocardial) that may easily exceed 0.5 in magnitude. Hence, the classical linear theory of elasticity is quite inappropriate for resting myocardial mechanics. The hysteresis of the tissue is consistent with a viscoelastic response, which is undoubtedly
FIGURE 54.7   Representative stress–strain curves for passive rat myocardium computed using Equation 17 and Equation 19. Fiber and crossfiber stress are shown for equibiaxial strain. (Courtesy Dr. Jeffrey Omens.)

related to the substantial water content of the myocardium (about 80% by mass). Changes in water content, such as edema, can cause substantial alterations in the passive stiffness and viscoelastic properties of myocardium. The viscoelasticity of passive cardiac muscle has been characterized in creep and relaxation studies of papillary muscle from cat and rabbit. In both species, the tensile stress in response to a step in strain relaxes 30 to 40% in the first 10 seconds [94,95]. The relaxation curves exhibit a short exponential time constant (<0.02 sec) and a long one (about 1000 sec), and are largely independent of the strain magnitude, which supports the approximation that myocardial viscoelasticity is quasilinear. Myocardial creep under isotonic loading is 2 to 3% of the original length after 100 sec of isotonic loading and is also quasilinear with an exponential timecourse. There is also evidence that passive ventricular muscle exhibits other anelastic properties such as maximum-strain-dependent "strain softening" [96,97], a well-known property in elastomers first described by Mullins [98].

Since the hysteresis of passive cardiac muscle is small and only weakly affected by changes in strain rate, the assumption of pseudoelasticity [93] is often appropriate. That is, the resting myocardium is considered to be a finite elastic material with different elastic properties in loading vs. unloading. Although various preparations have been used to study resting myocardial elasticity, the most detailed and complete information has come from biaxial and multiaxial tests of isolated sheets of cardiac tissue, mainly from the dog [99–101]. These experiments have shown that the arrested myocardium exhibits significant anisotropy with substantially greater stiffness in the muscle fiber direction than transversely. In equibiaxial tests of muscle sheets cut from planes parallel to the ventricular wall, fiber stress was greater than the transverse stress (Figure 54.7) by an average factor of close to 2.0 [102]. Moreover, as suggested by the structural organization of the myocardium described in Section 54.2, there may also be significant anisotropy in the plane of the tissue transverse to the fiber axis.

The biaxial stress–strain properties of passive myocardium display some heterogeneity. Recently, Novak et al. [103] measured regional variations of biaxial mechanics in the canine left ventricle. Specimens from the inner and outer thirds of the left ventricular free wall were stiffer than those from the midwall and interventricular septum, but the degree of anisotropy was similar in each region. Significant species variations in myocardial stiffness have also been described. Using measurements of two-dimensional regional strain during left ventricular inflation in the isolated whole heart, a parameter optimization approach showed that canine cardiac tissue was several times stiffer than that of the rat, though the nonlinearity and anisotropy were similar [104]. Biaxial testing of the collagenous parietal pericardium

and epicardium have shown that these tissues have distinctly different properties than the myocardium being very compliant and isotropic at low-biaxial strains (<0.1 to 0.15) but rapidly becoming very stiff and anisotropic as the strain is increased [66,100].

Various constitutive models have been proposed for the elasticity of passive cardiac tissues. Because of the large deformations and nonlinearity of these materials, the most useful framework has been provided by the pseudostrain-energy formulation for hyperelasticity. For a detailed review of the material properties of passive myocardium and approaches to constitutive modeling, the reader is referred to chapters 1 to 6 of Glass et al [105]. In hyperelasticity, the components of the stress* are obtained from the strain energy W as a function of the Lagrangian (Green's) strain E_{RS}.

The myocardium is generally assumed to be an incompressible material, which is a good approximation in the isolated tissue, although in the intact heart there can be a significant redistribution of tissue volume associated with phasic changes in regional coronary blood volume. Incompressibility is included as a kinematic constraint in the finite elasticity analysis, which introduces a new pressure variable that is added as a Lagrange multiplier in the strain energy. The examples that follow are various strain–energy functions, with representative parameter values (for W in kPa, i.e., mJ.ml^{-1}) that have been suggested for cardiac tissues. For the two-dimensional properties of canine myocardium, Yin and colleagues [102] obtained reasonable fits to experimental data with an exponential function,

$$W = 0.47 e^{(35E_{11}^{1.2} + 20E_{22}^{1.2})} \tag{54.14}$$

where E_{11} is the fiber strain and E_{22} is the crossfiber in-plane strain. Humphrey and Yin [106] proposed a three-dimensional form for W as the sum of an isotropic exponential function of the first principal invariant I_1 of the right Cauchy–Green deformation tensor and another exponential function of the fiber stretch ratio λ_F:

$$W = 0.21 \left(e^{9.4(I_1-3)} - 1 \right) + 0.35 \left(e^{66(\lambda_F - 1)^2} - 1 \right) \tag{54.15}$$

The isotropic part of this expression has also been used to model the myocardium of the embryonic chick heart during the ventricular looping stages, with coefficients of 0.02 kPa during diastole and 0.78 kPa at end-systole, and exponent parameters of 1.1 and 0.85, respectively [107]. Another related transversely isotropic strain-energy function was used by Guccione et al. [108] and Omens et al. [109] to model material properties in the isolated mature rat and dog hearts:

$$W = 0.6(e^Q - 1) \tag{54.16}$$

where, in the dog

$$Q = 26.7E_{11}^2 + 2.0(E_{22}^2 + E_{33}^2 + E_{23}^2 + E_{32}^2) + 14.7(E_{12}^2 + E_{21}^2 + E_{13}^2 + E_{31}^2) \tag{54.17}$$

and, in the rat

$$Q = 9.2E_{11}^2 + 2.0(E_{22}^2 + E_{33}^2 + E_{23}^2 + E_{32}^2) + 3.7(E_{12}^2 + E_{21}^2 + E_{13}^2 + E_{31}^2) \tag{54.18}$$

In Equation 54.17 and Equation 54.18, normal and shear strain components involving the radial (x_3) axis are included. Humphrey and colleagues [110] determined a new polynomial form directly from biaxial tests. Novak et al. [103] gave representative coefficients for canine myocardium from three layers of the left ventricular free wall. For the outer third, they obtained

$$W = 4.8(\lambda_F - 1)^2 + 3.4(\lambda_F - 1)^3 + 0.77(I_1 - 3) - 6.1(I_1 - 3)(\lambda_F - 1) + 6.2(I_1 - 3)^2 \tag{54.19}$$

---

* In a hyperelastic material, the *second Piola Kirchhoff* stress tensor is given by, $P_{RS} 1/2((\partial W/\partial E_{RS}) + (\partial W/\partial E_{SR}))$.

for the midwall region

$$W = 5.3(\lambda_F - 1)^2 + 7.5(\lambda_F - 1)^3 + 0.43(I_1 - 3) - 7.7(I_1 - 3)(\lambda_F - 1) + 5.6(I_1 - 3)^2 \qquad (54.20)$$

and for the inner layer of the wall

$$W = 0.51(\lambda_F - 1)^2 + 27.6(\lambda_F - 1)^3 + 0.74(I_1 - 3) - 7.3(I_1 - 3)(\lambda_F - 1) + 7.0(I_1 - 3)^2 \qquad (54.21)$$

A power law strain–energy function expressed in terms of circumferential, longitudinal and transmural extension ratios (λ_1, λ_2, and λ_3) was used [111] to describe the biaxial properties of sheep myocardium 2 weeks after experimental myocardial infarction, in the scarred infarct region:

$$W = 0.36 \left(\frac{\lambda_1^{32}}{32} + \frac{\lambda_2^{30}}{30} + \frac{\lambda_3^{31}}{31} - 3 \right) \qquad (54.22)$$

and in the remote, noninfarcted tissue:

$$W = 0.11 \left(\frac{\lambda_1^{22}}{22} + \frac{\lambda_2^{26}}{26} + \frac{\lambda_3^{24}}{24} - 3 \right) \qquad (54.23)$$

Finally, based on the observation that resting stiffness rises steeply at strains that extend coiled collagen fibers to the limit of uncoiling, Hunter and colleagues have proposed a pole-zero constitutive relation in which the stresses rise asymptotically as the strain approaches a limiting elastic strain [74].

The strain in the constitutive equation must generally be referred to the stress-free state of the tissue. However, the unloaded state of the passive left ventricle is not stress-free; residual stress exists in the intact, unloaded myocardium, as shown by Omens and Fung [112]. Cross-sectional equatorial rings from potassium-arrested rat hearts spring open elastically when the left ventricular wall is resected radially. The average opening angle of the resulting curved arc is $45 \pm 10°$ in the rat. Subsequent radial cuts produce no further change. Hence, a slice with one radial cut is considered to be stress-free, and there is a nonuniform distribution of residual strain across the intact wall, being compressive at the endocardium and tensile at the epicardium, with some regional differences. Stress analyses of the diastolic left ventricle have shown that residual stress acts to minimize the endocardial stress concentrations that would otherwise be associated with diastolic loading [108]. An important physiological consequence of residual stress is that sarcomere length is nonuniform in the unloaded resting heart. Rodriguez et al. [113] showed that sarcomere length is about 0.13 μm greater at epicardium than endocardium in the unloaded rat heart, and this gradient vanishes when residual stress is relieved. Three-dimensional studies have also revealed the presence of substantial transverse residual shear strains [114]. Residual stress and strain may have an important relationship to cardiac growth and remodeling. Theoretical studies have shown that residual stress in tissues can arise from growth fields that are kinematically incompatible [115,116].

54.5 Regional Ventricular Mechanics: Stress and Strain

Although ventricular pressures and volumes are valuable for assessing the global pumping performance of the heart, myocardial stress and strain distributions are needed to characterize regional ventricular function, especially in pathological conditions, such as myocardial ischemia and infarction, where profound localized changes may occur. The measurement of stress in the intact myocardium involves resolving the local forces acting on defined planes in the heart wall. Attempts to measure local forces [117,118] have had limited success because of the large deformations of the myocardium and the uncertain nature of the mechanical coupling between the transducer elements and the tissue. Efforts to measure intramyocardial

pressures using miniature implanted transducers have been more successful but have also raised controversy over the extent to which they accurately represent changes in interstitial fluid pressure. In all cases, these methods provide an incomplete description of three-dimensional wall stress distributions. Therefore, the most common approach for estimating myocardial stress distributions is the use of mathematical models based on the laws of continuum mechanics. Although there is no room to review these analyses here, the important elements of such models are the geometry and structure, boundary conditions, and material properties, described in the foregoing sections. An excellent review of ventricular wall stress analysis is given by Yin [119]. The most versatile and powerful method for ventricular stress analysis is the finite element method, which has been used in cardiac mechanics for over 20 years [120]. However, models must also be validated with experimental measurements. Since the measurement of myocardial stresses is not yet reliable, the best experimental data for model validation are measurements of strains in the ventricular wall.

The earliest myocardial strain gauges were mercury-in-rubber transducers sutured to the epicardium. These days, local segment length changes are routinely measured with various forms of the piezoelectric crystal sonomicrometer. However, since the ventricular myocardium is a three-dimensional continuum, the local strain is only fully defined by all the normal and shear components of the myocardial strain tensor. Villarreal et al. [121] measured two-dimensional midwall strain components by arranging three piezoelectric crystals in a small triangle so that three segment lengths could be measured simultaneously. They showed that the principal axis of greatest shortening is not aligned with circumferential midwall fibers, and that this axis changes with altered ventricular loading and contractility. Therefore, uniaxial segment measurements do not reveal the full extent of alterations in regional function caused by an experimental intervention. Another approach to measuring regional myocardial strains is the use of clinical imaging techniques, such as contrast ventriculography, high-speed x-ray tomography, MRI or two-dimensional echocardiography. But the conventional application of these techniques is not suitable for measuring regional strains because they cannot be used to identify the motion of distinct myocardial points. They only produce a profile or silhouette of a surface, except in the unusual circumstance when radiopaque markers are implanted in the myocardium during cardiac surgery or transplantation [122]. Hunter and Zerhouni [123] describe the prospects for noninvasive imaging of discrete points in the ventricular wall. The most promising method is the use of MRI tagging methods, which are now being used to map three-dimensional ventricular strain fields in conscious subjects [4].

In experimental research, implantable radiopaque markers are used for tracking myocardial motions with high spatial and temporal resolution. Meier et al. [124,125] placed triplets of metal markers 10 to 15 mm apart near the epicardium of the canine right ventricle and reconstructed their positions from biplane cinéradiographic recordings. By polar decomposition, they obtained the two principal epicardial strains, the principal angle, and the local rotation in the region. The use of radiopaque markers was extended to three dimensions by Waldman and colleagues [22], who implanted three closely separated columns of 5 to 6 metal beads in the ventricular wall. With this technique, it is possible to find all six components of strain and all three rigid-body rotation angles at sites through the wall. For details of this method, see the review by Waldman in chapter 7 of Glass et al [105]. An enhancement to this method uses high-order finite element interpolation of the marker positions to compute continuous transmural distributions of myocardial deformation [126].

Studies and models such as these are producing an increasingly detailed picture of regional myocardial stress and strain distributions. Of the many interesting observations, there are some useful generalizations, particularly regarding the strain. Myocardial deformations are large and three dimensional, and hence the nonlinear finite strain tensors are more appropriate measures than the linear infinitesimal Cauchy strain. During filling in the normal heart, the wall stretches biaxially but nonuniformly in the plane of the wall, and thins in the transmural direction. During systole, shortening is also two dimensional and the wall thickens. There are substantial regional differences in the timecourse, magnitude, and pattern of myocardial deformations. In humans and dogs, in-plane systolic myocardial shortening and diastolic lengthening vary with longitudinal position on the left and right ventricular free walls generally increasing in magnitude from base to apex.

Both during systole and diastole, there are significant shear strains in the wall. In-plane (torsional) shears are negative during diastole, consistent with a small left-handed torsion of the left ventricle during filling, and positive as the ventricular twist reverses during ejection. Consequently, the principal axes of greatest diastolic segment lengthening and systolic shortening are not circumferential or longitudinal but at oblique axes, which are typically rotated 10 to 60° clockwise from circumferential. There are circumferential variations in regional left ventricular strain. The principal axes of greatest diastolic lengthening and systolic shortening tend to be more longitudinal on the posterior wall and more circumferentially oriented on the anterior wall. Perhaps the most significant regional variations are transmural. In-plane and transmural, normal or principal strains, are usually significantly greater in magnitude at the endocardium than the epicardium both in filling and ejection. However, when the strain is resolved in the local muscle fiber direction, the transmural variation of fiber strain becomes insignificant. The combination of torsional deformation and the transmural variation in fiber direction means that systolic shortening and diastolic lengthening tend to be maximized in the fiber direction at the epicardium and minimized at the endocardium. Hence, whereas maximum shortening and lengthening are closely aligned with muscle fibers at the subepicardium, they are almost perpendicular to the fibers at the subendocardium. In the left ventricular wall there are also substantial transverse shear strains (i.e., in the circumferential-radial and longitudinal-radial planes) during systole, though during filling they are smaller. Their functional significance remains unclear, though they change substantially during acute myocardial ischemia or ventricular pacing and are apparently associated with the transverse laminae described earlier [23].

Sophisticated continuum mechanics models are needed to determine the stress distributions associated with these complex myocardial deformations. With modern finite element methods it is now possible to include in the analysis the three-dimensional geometry and fiber architecture, finite deformations, nonlinear material properties, and muscle contraction of the ventricular myocardium. Some models have included other factors such as viscoelasticity, poroelasticity, coronary perfusion, growth and remodeling, regional ischemia, residual stress and electrical activation. To date, continuum models have provided some valuable insight into regional cardiac mechanics. These include the importance of muscle fiber orientation, torsional deformations and residual stress, and the substantial inhomogeneities associated with regional variations in geometry and fiber angle or myocardial ischemia and infarction. A new arena in which models promise to make important contributions is the rapidly growing field of cardiac resynchronization therapy [127]. The use of biventricular pacing in cases of congestive heart failure that are accompanied by electrical conduction asynchrony has been seen to significantly improve ventricular pump function. However the improvement in mechanical function is not well predicted by the improvement in electrical synchrony. New electromechanical models promise to provide insights into the mechanisms of cardiac resynchronization therapy and potentially to optimize the pacing protocols used [128].

Heart Valve Dynamics

Ajit P. Yoganathan
Jack D. Lemmon
Jeffrey T. Ellis
Georgia Institute of Technology

The heart has four valves that control the direction of blood flow through the heart, permitting forward flow and preventing back flow. On the right side of the heart, the tricuspid and pulmonic valves regulate the flow of blood that is returned from the body to the lungs for oxygenation. The mitral and aortic valves control the flow of oxygenated blood from the left side of the heart to the body. The aortic and pulmonic valves allow blood to be pumped from the ventricles into arteries on the left and right side of the heart, respectively. Similarly, the mitral and tricuspid valves lie between the atria and ventricles of the left and right sides of the heart, respectively. The aortic and pulmonic valves open during systole when the ventricles are contracting, and close during diastole when the ventricles are filling through the open mitral and tricuspid valves. During isovolumic contraction and relaxation, all four valves are closed (Figure 55.1).

When closed, the pulmonic and tricuspid valves must withstand a pressure of approximately 30 mmHg. However, the closing pressures on the left side of the heart are much higher. The aortic valve withstands pressures of approximately 100 mmHg, while the mitral valve closes against pressures up to 150 mmHg. Since diseases of the valves on the left side of the heart are more prevalent, most of this chapter will focus on the aortic and mitral valves. Where pertinent, reference will be made to the pulmonic and tricuspid valves.

55.1 Aortic and Pulmonic Valves

The aortic valve is composed of three semilunar cusps, or leaflets, contained within a connective tissue sleeve. The valve cusps are attached to a fibrous ring embedded in the fibers of the ventricular septum and the anterior leaflet of the mitral valve. Each of the leaflets is lined with endothelial cells and has a dense collagenous core adjacent to the high pressure aortic side. The side adjacent to the aorta is termed the fibrosa and is the major fibrous layer within the belly of the leaflet. The layer covering the ventricular side of the valve is called the ventricularis and is composed of both collagen and elastin. The ventricularis is thinner than the fibrosa and presents a very smooth surface to the flow of blood [Christie, 1990]. The central portion of the valve, called the spongiosa, contains variable loose connective tissue and proteins and is normally not vascularized. The collagen fibers within the fibrosa and ventricularis are unorganized in the unstressed state. When a stress is applied, they become oriented primarily in

55-1
FIGURE 55.1   Typical pressure and flow curves for the aortic and mitral valves.

the circumferential direction with a lower concentration of elastin and collagen in the radial direction [Christie, 1990; Thubrikar, 1990].

  The fibrous annular ring of the aortic valve separates the aorta from the left ventricle and superior to this ring is a structure called the sinus of Valsalva, or aortic sinus. The sinus is comprised of three bulges at the root of the aorta, with each bulge aligned with the belly or central part of the specific valve leaflet. Each valve cusp and corresponding sinus is named according to its anatomical location within the aorta. Two of these sinuses give rise to coronary arteries that branch off the aorta, providing blood flow to the heart itself. The right coronary artery is based at the right or right anterior sinus, the left coronary artery exits the left or left posterior sinus, and the third sinus is called the non-coronary or right posterior sinus. Figure 55.2 shows the configuration of the normal aortic sinuses and valve in the closed position. Because the length of the aortic valve cusps is greater than the annular radius, a small overlap of tissue from each leaflet protrudes and forms a coaptation surface within the aorta when the valve is closed [Emery and Arom, 199l]. This overlapped tissue, called the lunula, may help to ensure that the valve is sealed. When the valve is open, the leaflets extend to the upper edge of the sinuses of Valsalva. The anatomy of the pulmonic valve is similar to that of the aortic valve, but the surrounding structure is slightly different.
FIGURE 55.2 The aortic sinuses and valve in the closed position. The noncoronary cusp (NCC) is in front. The left and right coronary cusps (LCC and RCC) are positioned as marked. The aorta is above the closed valve in this orientation and the left ventricle is below the dashed line.

The main differences are that the sinuses are smaller in the pulmonary artery and the pulmonic valve annulus is slightly larger than that of the aortic valve.

The dimensions of the aortic and pulmonic valves and their leaflets have been measured in a number of ways. Before noninvasive measurement techniques such as echocardiography became available, valve measurements were recorded from autopsy specimens. An examination of 160 pathologic specimens revealed the aortic valve diameter to be 23.2 ± 3.3 mm, whereas the diameter of the pulmonic valve was measured at 24.3 ± 3.0 mm [Westaby et al., 1984]. However, according to M-mode echocardiographic measurements, the aortic root diameter at end systole was 35 ± 4.2 mm and 33.7 ± 4.4 mm at the end of diastole [Gramiak and Shah, 1970]. The differences in these measurements reflect the fact that the autopsy measurements were not performed under physiologic pressure conditions and that intrinsic differences in the measurement techniques exist. On average, pulmonic leaflets are thinner than aortic leaflets: 0.49 vs. 0.67 mm [David et al., 1994], although the leaflets of the aortic valve show variable dimensions depending on the respective leaflet. For example, the posterior leaflet tends to be thicker, have a larger surface area, and weigh more than the right or left leaflet [Silver and Roberts, 1985; Sahasakul et al., 1988], and the average width of the right aortic leaflet is greater than that of the other two [Vollebergh and Becker, 1977].

55.1.1 Mechanical Properties

Due to the location and critical function of the aortic valve, it is difficult to obtain measurements of its mechanical properties *in vivo;* however, reports are available from a small number of animal studies. This section will reference the *in vivo* data whenever possible and defer to the *in vitro* data when necessary. Since little mathematical modeling of the aortic valve's material properties has been reported, it will be sufficient to describe the known mechanical properties of the valve. Like most biological tissues, the aortic valve is anisotropic, inhomogeneous, and viscoelastic. The collagen fibers within each valve cusp are aligned along the circumferential direction. Vesely and Noseworthy [1992] found that both the ventricularis and fibrosa were stiffer in the circumferential direction than in the radial direction. However, the ventricularis

was more extensible radially than circumferentially, while the fibrosa had uniform extensibility in both directions.

There are also elastin fibers, at a lesser concentration, that are oriented orthogonal to the collagen. It is this fiber structure that accounts for the anisotropic properties of the valve. The variation in thickness and composition across the leaflets is responsible for their inhomogeneous material properties. Although the aortic valve leaflet as a whole is asymmetric in its distensibility, the basal region tends to be relatively isotropic while the central region shows the greatest degree of anisotropy [Lo and Vesely, 1995]. The role and morphology of elastin and how elastin is coupled to collagen remain points of investigation. Scott and Vesely [1996] have shown that the elastin in the ventricularis consists of continuous amorphous sheets or compact meshes, while elastin in the fibrosa consists of complex arrays of large tubes that extend circumferentially across the leaflet. These tubes may surround the large circumferential collagen bundles in the fibrosa. Mechanical testing of elastin structures from the fibrosa and ventricularis separately have shown that the purpose of elastin in the aortic valve leaflet is to maintain a specific collagen fiber configuration and return the fibers to that state during cyclic loading [Vesely, 1998]. The valve's viscoelastic properties are actually dominated by the elastic component (over the range of *in vitro* testing) so that the viscous effects, which are largely responsible for energy losses, are small [Thubrikar, 1990]. In addition to the collagen and elastin, clusters of lipids have been observed in the central spongiosa of porcine aortic valves. Vesely et al. [1994] have shown that the lipids tend to be concentrated at the base of the valve leaflets, while the coaptation regions and free edges of the leaflets tend to be devoid of these lipids. In addition, the spatial distribution of the lipids within the spongiosal layer of the aortic leaflets corresponded to areas in which calcification is commonly observed on bioprosthetic valves suggesting that these lipid clusters may be potential nucleation sites for calcification. In contrast, pulmonic leaflets showed a substantially lower incidence of lipids [Dunmore-Buyze et al., 1995]. The aortic valve leaflets have also been shown to be slightly stiffer than pulmonary valve leaflets, although the extensibilities and relaxation rates of the two tissues are similar [Leeson-Dietrich et al., 1995].

Using marker fluoroscopy, in which the aortic valve leaflets were surgically tagged with radio-opaque markers and imaged with high speed x-rays, the leaflets have been shown to change length during the cardiac cycle [Thubrikar, 1990]. The cusps are longer during diastole than systole in both the radial and circumferential direction. The variation in length is greatest in the radial direction, approximately 20%, while the strain in the circumferential direction is about 10% of the normal systolic length [Lo and Vesely, 1995]. The difference in strain is due to the presence of the compliant elastin fibers aligned in this radial direction. The length change in both directions results in an increased valve surface area during diastole. During systole, the shortening of the valve leaflets helps to reduce obstruction of the aorta during the systolic ejection of blood. It should be noted that this change in area is by no means an active mechanism within the aortic valve; the valve simply reacts to the stresses it encounters in a passive manner.

In addition to this change in surface area, the aortic valve leaflets also undergo bending in the circumferential direction during the cardiac cycle. In diastole when the valve is closed, each leaflet is convex toward the ventricular side. During systole when the valve is open, the curvature.changes and each leaflet is concave toward the ventricle. This bending is localized on the valve cusp near the wall of the aorta. This location is often thicker than the rest of the leaflet. The total diastolic stress in a valve leaflet has been estimated at 2.5×10^6 dyn/cm^2 for a strain of 15% [Thubrikar, 1990]. The stress in the circumferential direction was found to be the primary load bearing element in the aortic valve. Due to the collagen fibers oriented circumferentially, the valve is relatively stiff in this direction. The strain that does occur circumferentially is primarily due to scissoring of the fibrous matrix and straightening of collagen fibers that are kinked or crimped in the presence of no external stress. However, in the radial direction, because elastin is the primary element, the valve can undergo a great deal of strain, ranging from 20 to 60% in tissue specimens [Christie, 1990; Lo and Vesely, 1995]. In the closed position, the radial stress levels are actually small compared to those in the circumferential direction. This demonstrates the importance of the lunula in ensuring that the valve seals tightly to prevent leakage. Because of their anatomical location, the lunula cause these high circumferential stress levels by enabling the aortic pressure to pull each leaflet in the circumferential direction towards the other leaflets.

The composition, properties, and dimensions of the aortic valve change with age and in the presence of certain diseases. The valve leaflets become thicker, the lunula become fenestrated, or mesh-like, and in later stages of disease the central portion of the valve may become calcified [Davies, 1980]. This thickening of the valve typically occurs on the ventricular side of the valve, in the region where the tips of the leaflets come together. Another site of calcification and fibrosis is the point of maximum cusp flexion and is thought to be a response to fatigue in the normal valve tissue.

55.1.2 Valve Dynamics

The aortic valve opens during systole when the ventricle is contracting and then closes during diastole as the ventricle relaxes and fills from the atrium. Systole lasts about one third of the cardiac cycle and begins when the aortic valve opens, which typically takes only 20 to 30 msec [Bellhouse, 1969]. Blood rapidly accelerates through the valve and reaches a peak velocity after the leaflets have opened to their full extent and start to close again. Peak velocity is reached during the first third of systole and the flow begins to decelerate rapidly after the peak is reached, albeit not as fast as its initial acceleration. The adverse pressure gradient that is developed affects the low momentum fluid near the wall of the aorta more than that at the center; this causes reverse flow in the sinus region [Reul and Talukdar, 1979]. Figure 55.2 illustrates the pressure and flow relations across the aortic valve during the cardiac cycle. During systole, the pressure difference required to drive the blood through the aortic valve is on the order of a few millimeters of mercury; however, the diastolic pressure difference reaches 80 mmHg in normal individuals. The valve closes near the end of the deceleration phase of systole with very little reverse flow through the valve.

During the cardiac cycle the heart undergoes translation and rotation due to its own contraction pattern. As a result, the base of the aortic valve varies in size and also translates, mainly along the axis of the aorta. Using marker fluoroscopy to study the base of the aortic valve in dogs, Thubrikar et al. [1993] found that the base perimeter is at its largest at end diastole and decreases in size during systole; it then reaches a minimum at the end of systole and increases again during diastole. The range of this perimeter variation during the cardiac cycle was 22% for an aortic pressure variation of 120/80 mmHg. The valve annulus also undergoes translation, primarily parallel to the aortic axis. The aortic annulus moves downward toward the ventricle during systole and then recoils back toward the aorta as the ventricle fills during diastole. The annulus also experiences a slight side-to-side translation with its magnitude approximately one half the displacement along the aortic axis.

During systole, vortices develop in all three sinuses behind the leaflets of the aortic valve. The function of these vortices was first described by Leonardo da Vinci in 1513, and they have been researched extensively in this century primarily through the use of *in vitro* models [Bellhouse, 1969; Reul and Talukdar, 1979]. It has been hypothesized that the vortices help to close the aortic valve so that blood is prevented from returning to the ventricle during the closing process. These vortices create a transverse pressure difference that pushes the leaflets toward the center of the aorta and each other at the end of systole, thus minimizing any possible closing volume. However, as shown *in vitro* by Reul and Talukdar [1979], the axial pressure difference alone is enough to close the valve. Without the vortices in the sinuses, the valve still closes but its closure is not as quick as when the vortices are present. The adverse axial pressure difference within the aorta causes the low inertia flow within the developing boundary layer along the aortic wall to decelerate first and to reverse direction. This action forces the belly of the leaflets away from the aortic wall and toward the closed position. When this force is coupled with the vortices that push the leaflet tips toward the closed position, a very efficient and fast closure is obtained. Closing volumes have been estimated to be less than 5% of the forward flow [Bellhouse and Bellhouse, 1969].

The parameters that describe the normal blood flow through the aortic valve are the velocity profile, time course of the blood velocity or flow, and magnitude of the peak velocity. These are determined in part by the pressure difference between the ventricle and aorta and by the geometry of the aortic valve complex. As seen in Figure 55.3, the velocity profile at the level of the aortic valve annulus is relatively flat. However there is usually a slight skew toward the septal wall (less than 10% of the center-line velocity) which is caused by the orientation of the aortic valve relative to the long axis of the left ventricle. This skew
FIGURE 55.3 Velocity profiles measured 2 cm downstream of the aortic valve with hot film anemometry in dogs [Paulsen and Hasenkam, 1983]. The timing of the measurements during the cardiac cycle is shown by the marker on the aortic flow curve.

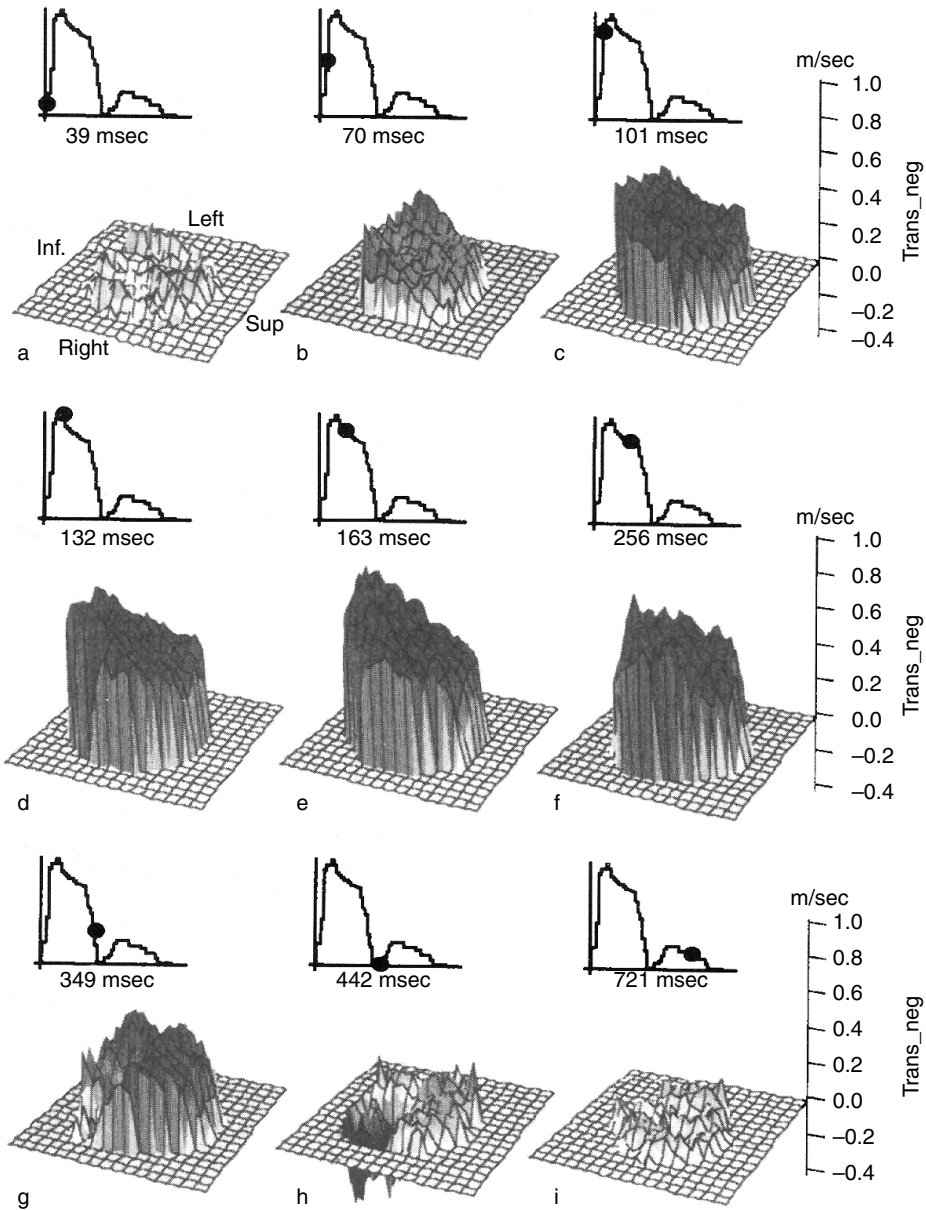
in the velocity profile has been shown by many experimental techniques, including hot film anemometry, Doppler ultrasound, and MRI [Paulsen and Hasenkam, 1983; Rossvol et al., 1991; Kilner et al., 1993]. In healthy individuals, blood flows through the aortic valve at the beginning of systole and then rapidly accelerates to its peak value of 1.35 ± 0.35 m/sec; for children this value is slightly higher at 1.5 ± 0.3 m/sec [Hatle and Angelson, 1985]. At the end of systole there is a very short period of reverse flow that can be measured with Doppler ultrasound. This reverse flow is probably either a small closing volume or the velocity of the valve leaflets as they move toward their closed position. The flow patterns just downstream of the aortic valve are of particular interest because of their complexity and relation to arterial disease. Highly skewed velocity profiles and corresponding helical flow patterns have been observed in the human aortic arch using magnetic resonance phase velocity mapping [Kilner et al., 1993].


FIGURE 55.4 Velocity profiles downstream of the human pulmonary valve obtained with magnetic resonance phase velocity mapping [Sloth, 1994]. Again the timing of the measurements is shown by the market on the flow curve.

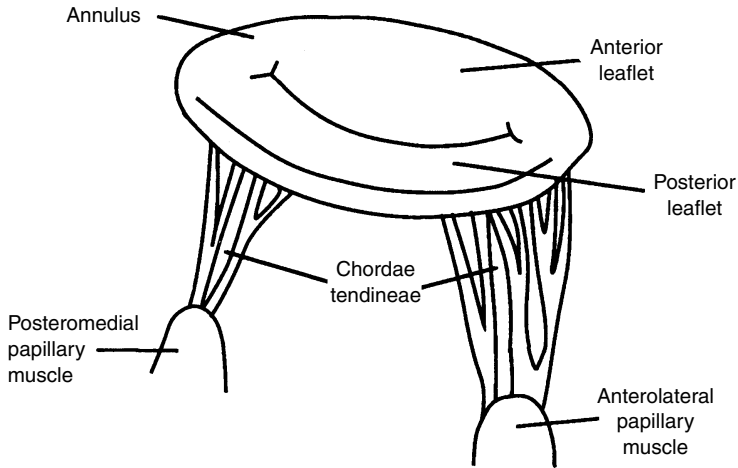
The pulmonic valve flow behaves similarly to that of the aortic valve, but the magnitude of the velocity is not as great. Typical peak velocities for healthy adults are 0.75 ± 0.15 m/sec; again these values are slightly higher for children at 0.9 ± 0.2 m/sec [Weyman, 1994]. As seen in Figure 55.4 a rotation of the peak velocity can be observed in the pulmonary artery velocity profile. During acceleration, the peak velocity is observed inferiorly with the peak rotating counterclockwise throughout the remainder of the ejection phase [Sloth et al., 1994]. The mean spatial profile is relatively flat, however, although there is a region of reverse flow that occurs in late systole which may be representative of flow separation. Typically, there is only a slight skew to the profile. The peak velocity is generally within 20% of the spatial mean throughout the cardiac cycle. Secondary flow patterns can also be observed in the pulmonary artery and


FIGURE 55.5   Schematic of the mitral valve showing the valve leaflets, papillary muscles, and chordae tendineae.

its bifurcation. *In vitro* laser Doppler anemometry experiments have shown that these flow patterns are dependent on the valve geometry and thus can be used to evaluate function and fitness of the heart valve and [Sung and Yoganathan, 1990].

55.2   Mitral and Tricuspid Valves

The mitral (Figure 55.5) and tricuspid valves are similar in structure with both valves composed of four primary elements (1) the valve annulus, (2) the valve leaflets, (3) the papillary muscles, and (4) the chordae tendineae. The base of the mitral leaflets form the mitral annulus, which attaches to the atrial and ventricular walls, and aortic root. At the free edge of the leaflets, the chordae tendinae insert at multiple locations and extend to the tips of the papillary muscles. This arrangement provides continuity between the valve and ventricular wall to enhance valvular function. The valvular apparatus, or complex, requires an intricate interplay between all components throughout the cardiac cycle.

The mitral annulus is an elliptical ring composed of dense collagenous tissue surrounded by muscle. It goes through dynamic changes during the cardiac cycle by not only changing in size, but also by moving three-dimensionally. The circumference of the mitral annulus ranges from 8 to 12 cm during diastole. Recent studies involving the measurement of annular shape have also shown that the mitral annulus is not planar, but instead has a three-dimensional form. The annulus actually forms a saddle, or ski-slope shape [Levine et al., 1987; Komoda et al., 1994; Pai et al., 1995; Glasson et al., 1996]. This three-dimensional shape must be taken into account when non-invasively evaluating valvular function.

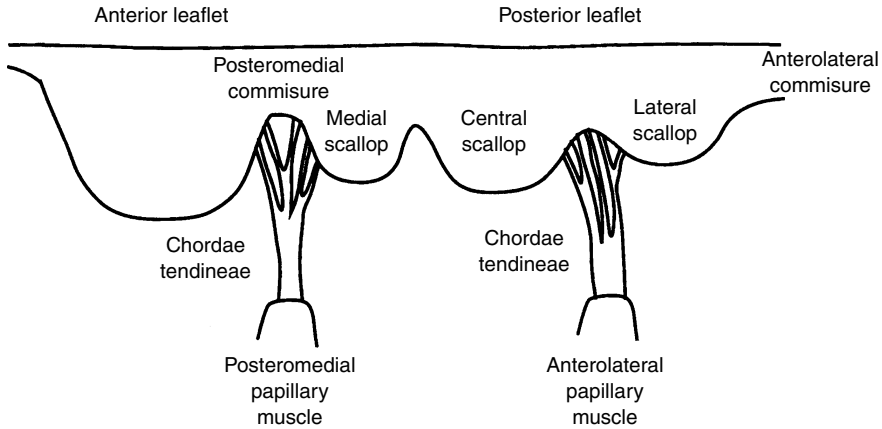
The mitral valve is a bileaflet valve comprised of an anterior and posterior leaflet. The leaflet tissue is primarily collagen-reinforced endothelium, but also contains striated muscle cells, non-myelinated nerve fibers, and blood vessels. The anterior and posterior leaflets of the valve are actually one continuous piece of tissue, as shown in Figure 55.6. The free edge of this tissue shows several indentations of which two are regularly placed, called the commisures. The commisures separate the tissue into the anterior and posterior leaflets. The location of the commisures can be identified by the fan-like distribution of chordae tendinae and the relative positioning of the papillary muscles. The combined surface area of both leaflets is approximately twice the area of the mitral orifice; this extra surface area permits a large line of coaptation and ample coverage of the mitral orifice during normal function and provides compensation in cases of disease [He, 1997, 1999]. The posterior leaflet encircles roughly two-thirds of the mitral annulus and is essentially an extension of the mural endocardium from the free walls of the left atrium. The anterior leaflet portion of the annulus is a line of connection, for the leaflet, the wall of the ascending aorta, the aortic valve, and the atrial septum. The anterior leaflet is slightly larger than the posterior leaflet,


FIGURE 55.6 Diagram of the mitral valve as a continuous piece of tissue. The posterior and anterior leaflets are indicated, as are the scallops, chordae tendineae, and papillary muscles.

and is roughly semi-lunar in shape as opposed to the quadrangular shaped posterior leaflet. The normal width and height of the anterior leaflet is approximately 3.3 and 2.3 cm, respectively. The height of the posterior leaflet is 1.3 cm, while the commisure height is less than 1.0 cm. The posterior leaflet typically has indentations, called scallop, that divide the leaflet into three regions (1) the medial, (2) central, and (3) lateral scallop [Silverman and Hurst, 1968; Raganathan et al., 1970; Roberts, 1983; Barlow, 1987; Kunzelmar et al., 1994].

The mitral leaflet tissue can be divided into both a rough and clear zone. The rough zone is the thicker part of the leaflet and is defined from the free edge of the valve to the valve's line of closure. The term "rough" is used to denote the texture of the leaflet due to the insertion of the chordae tendineae in this area. The clear zone is thinner and translucent and extends from the line of closure to the annulus in the anterior leaflet and to the basal zone in the posterior leaflet. Unlike the mitral valve, the tricuspid valve has three leaflets (1) an anterior leaflet, (2) a posterior leaflet with a variable number of scallops, and (3) a septal leaflet. The tricuspid valve is larger and structurally more complicated than the mitral valve and the separation of the valve tissue into distinct leaflets is less pronounced than with the mitral valve. The surface of the leaflets is similar to that of the mitral valve; however, the basal zone is present in all of the leaflets [Silver et al., 1971].

Chordae tendineae from both leaflets attach to each of the papillary muscles. The chordae tendineae consist of an inner core of collagen surrounded by loosely meshed elastin and collagen fibers with an outer layer of endothelial cells. In the mitral complex structure, there are marginal and basal chordae that insert into the mitral leaflets. From each papillary muscle, several chordae originate and branch into the marginal and basal chordae. The thinner marginal chordae insert into the leaflet free edge at multiple insertion points, while the thicker basal chordae insert into the leaflets at a higher level towards the annulus. The marginal chordae function to keep the leaflets stationary while the basal chordae seem to act more as supports [Kunzelman, 1994].

The left side of the heart has two papillary muscles, called anterolateral and posteromedial, that attach to the ventricular free wall and tether the mitral valve in place via the chordae tendinae. This tethering prevents the mitral valve from prolapsing into the atrium during ventricular ejection. On the right side of the heart, the tricuspid valve has three papillary muscles. The largest one, the anterior papillary muscle, attaches to the valve at the commissure between the anterior and posterior leaflets. The posterior papillary muscle is located between the posterior and septal leaflets. The smallest papillary muscle, called the septal muscle, is sometimes not even present. Improper tethering of the leaflets will result in valve prolapse during ventricular contraction, permitting the valve leaflets to extend into the atrium. This incomplete apposition of the valve leaflets can cause regurgitation, which is leaking of the blood being ejected back into the atrium.

55.2.1 Mechanical Properties

Studies on the mechanical behavior of the mitral leaflet tissue have been conducted to determine the key connective tissue components which influence the valve function. Histological studies have shown that the tissue is composed of three layers which can be identified by differences in cellularity and collagen density. Analysis of the leaflets under tension indicated that the anterior leaflet would be more capable of supporting larger tensile loads than the posterior leaflet. The differences between the mechanical properties between the two leaflets may require different material selection for repair or replacement of the individual leaflets [Kunzelman et al., 1993a,b].

Studies have also been done on the strength of the chordae tendinae. The tension of chordae tendineae in dogs was monitored throughout the cardiac cycle by Salisbury and co-workers [1963]. They found that the tension only paralleled the left ventricular pressure tracings during isovolumic contraction, indicating slackness at other times in the cycle. Investigation of the tensile properties of the chordae tendineae at different strain rates by Lim and Bouchner [1975] found that the chordae had a non-linear stress–strain relationship. They found that the size of the chordae had a more significant effect on the development of the tension than did the strain rate. The smaller chordae with a cross-sectional area of 0.001 to 0.006 cm^2 had a modulus of 2×10^9 dyn/cm^2, while larger chordae with a cross-sectional area of 0.006 to 0.03 cm^2 had a modulus of 1×10^9 dyn/cm^2.

A theoretical study of the stresses sustained by the mitral valve was performed by Ghista and Rao [1972]. This study determined that the stress level can reach as high as 2.2×10^6 dynes/cm^2 just prior to the opening of the aortic valve, with the left ventricular pressure rising to 150 mmHg. A mathematical model has also been created for the mechanics of the mitral valve. It incorporates the relationship between chordae tendineae tension, left ventricular pressure, and mitral valve geometry [Arts et al., 1983]. This study examined the force balance on a closed valve, and determined that the chordae tendinae force was always more than half the force exerted on the mitral valve orifice by the transmitral pressure gradient. During the past 10 years, computational models of mitral valve mechanics have been developed, with the most advanced modeling being three-dimensional finite element models (FEM) of the complete mitral apparatus. Kunzelman and co-workers [1993, 1998] have developed a model of the mitral complex that includes the mitral leaflets, chordae tendinae, contracting annulus, and contracting papillary muscles. From these studies, the maximum principal stresses found at peak loading (120 mmHg) were 5.7×10^6 dyn/cm^2 in the annular region, while the stresses in the anterior leaflet ranged from 2×10^6 to 4×10^6 dyn/cm^2. This model has also been used to evaluate mitral valve disease, repair in chordal rupture, and valvular annuloplasty.

55.2.2 Valve Dynamics

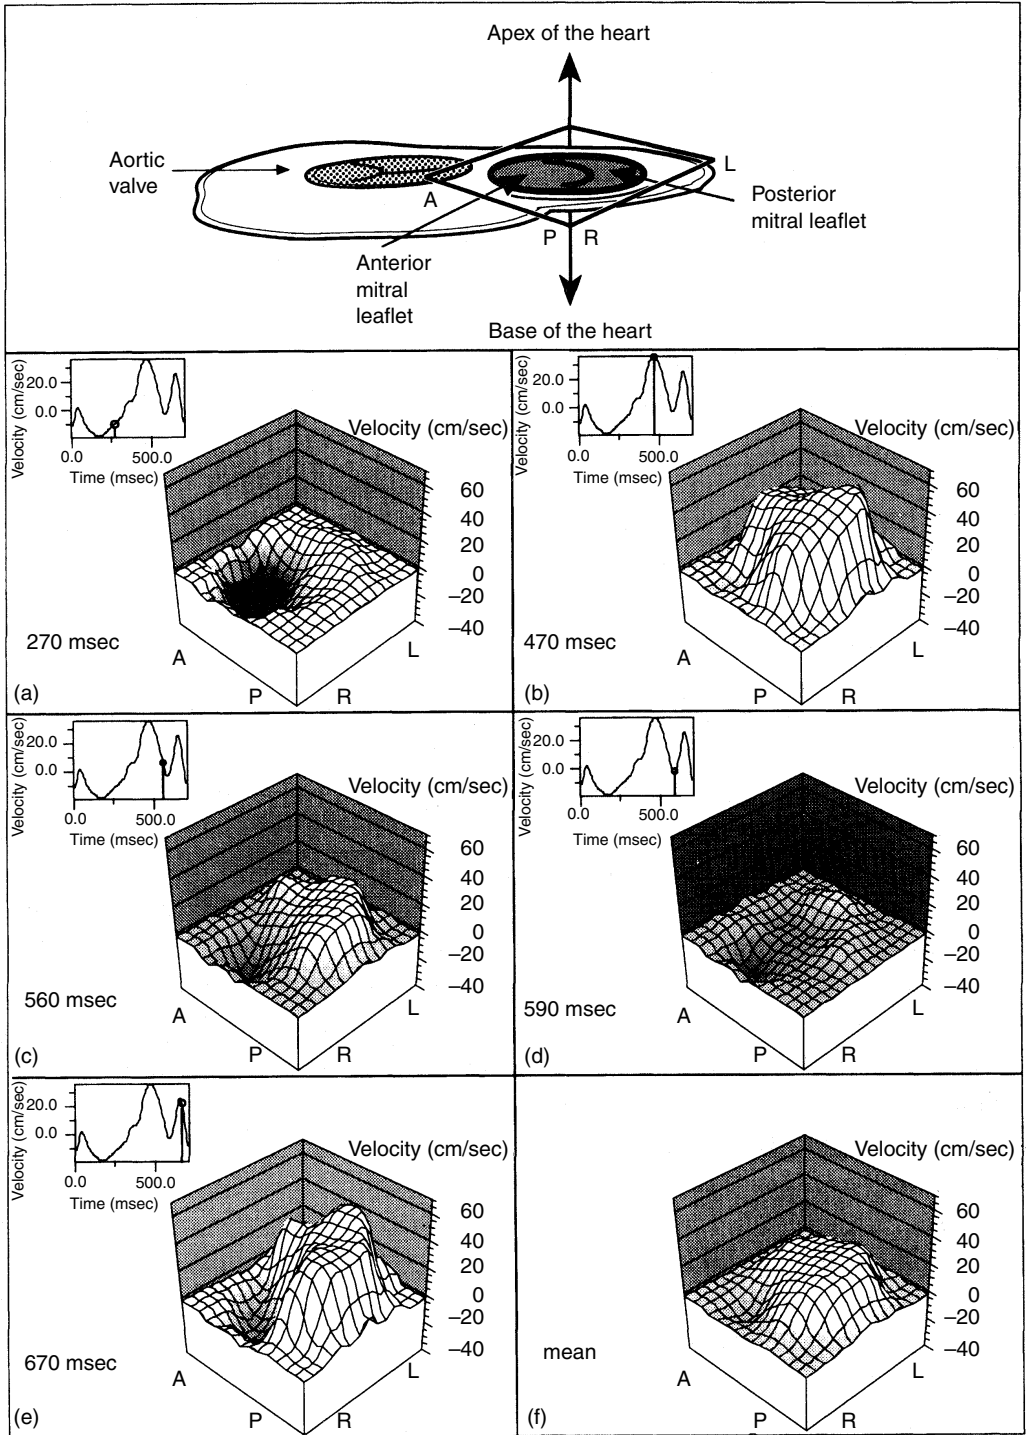
The valve leaflets, chordae tendineae, and papillary muscles all participate to ensure normal functioning of the mitral valve. During isovolumic relaxation, the pressure in the left atrium exceeds that of the left ventricle, and the mitral valve cusps open. Blood flows through the open valve from the left atrium to the left ventricle during diastole. The velocity profiles at both the annulus and the mitral valve tips have been shown to be skewed [Kim et al., 1994] and therefore are not flat as is commonly assumed. This skewing of the inflow profile is shown in Figure 55.7. The initial filling is enhanced by the active relaxation of the ventricle, maintaining a positive transmitral pressure. The mitral velocity flow curve shows a peak in the flow curve, called the E-wave, which occurs during the early filling phase. Normal peak E-wave velocities in healthy individuals range from 50 to 80 cm/sec [Samstad et al., 1989; Oh et al., 1997]. Following active ventricular relaxation, the fluid begins to decelerate and the mitral valve undergoes partial closure. Then the atrium contracts and the blood accelerates through the valve again to a secondary peak, termed the A-wave. The atrium contraction plays an, important role in additional filling of the ventricle during late diastole. In healthy individuals, velocities during the A-wave are typically lower than those of the E-wave, with a normal E/A velocity ratio ranging from 1.5 to 1.7 [Oh et al., 1997]. Thus, normal diastolic filling of


FIGURE 55.7 Two-dimensional transmitral velocity profiles recorded at the level of the mitral annulus in a pig [Kim et al., 1994]. (a) systole; (b) peak E-wave; (c) deceleration phase of early diastole; (d) mid-diastolic period (diastasis); (e) peak A-wave; (f) time averaged diastolic cross-sectional mitral velocity profile. (Reprinted with permission from the American College of Cardiology, *J. Am. Coll. Cardiol.* 24: 532–545.)

the left ventricle shows two distinct peaks in the flow curve with no flow leaking back through the valve during systole.

The tricuspid flow profile is similar to that of the mitral valve, although the velocities in the tricuspid valve are lower because it has a larger valve orifice. In addition, the timing of the valve opening is slightly different. Since the peak pressure in the right ventricle is less than that of the left ventricle, the time for right ventricular pressure to fall below the right atrial pressure is less than the corresponding time period for the left side of the heart. This leads to a shorter right ventricular isovolumic relaxation and thus an earlier tricuspid opening. Tricuspid closure occurs after the mitral valve closes since the activation of the left ventricle precedes that of the right ventricle [Weyman, 1994].

A primary focus in explaining the fluid mechanics of mitral valve function has been understanding the closing mechanism of the valve. Bellhouse [1972] first suggested that the vortices generated by ventricular filling were important for the partial closure of the mitral valve following early diastole. Their *in vitro* experiments suggested that without the strong outflow tract vortices, the valve would remain open at the onset of ventricular contraction, thus resulting in a significant amount of mitral regurgitation before complete closure. Later *in vitro* experiments by Reul and Talukdar [1981] in a left ventricle model made from silicone suggested that an adverse pressure differential in mid-diastole could explain both the flow deceleration and the partial valve closure, even in the absence of a ventricular vortex. Thus, the studies by Reul and Talukdar suggest that the vortices may provide additional closing effects at the initial stage; however, the pressure forces are the dominant effect in valve closure. A more unified theory of valve closure put forth by Yellin and co-workers [1981] includes the importance of chordal tension, flow deceleration, and ventricular vortices, with chordal tension being a necessary condition for the other two. Their animal studies indicated that competent valve closure can occur even in the absence of vortices and flow deceleration. Recent studies using magnetic resonance imaging to visualize the three-dimensional flow field in the left ventricle showed that in normal individuals a large anterior vortex is present at initial partial closure of the valve, as well as following atrial contraction [Kim et al., 1995]. Studies conducted in our laboratory using magnetic resonance imaging of healthy individuals clearly show the vortices in the left ventricle [Walker et al., 1996], which may be an indication of normal diastolic function. An example of these vortices is presented in Figure 55.8.

Another area of interest has been the motion of the mitral valve complex. The heart moves throughout the cardiac cycle; similarly, the mitral apparatus moves and changes shape. Recent studies have been conducted which examined the three-dimensional dynamics of the mitral annulus during the cardiac cycle [Ormiston et al., 1981; Komoda et al., 1994; Pai et al., 1995; Glasson et al., 1996]. These studies
FIGURE 55.8 Magnetic resonance image of a healthy individual during diastole. An outline of the interior left ventricle (LV) is indicated in white as are the mitral valve leaflets (MV) and the aorta (AO). Velocity vectors were obtained from MRI phase velocity mapping and superimposed on the anatomical image.

have shown that during systole the annular circumference decreases from the diastolic value due to the contraction of the ventricle, and this reduction in area ranges from 10 to 25%. This result agrees with an animal study of Tsakiris and co-workers [1971] that looked at the difference in the size, shape, and position of the mitral annulus at different stages in the cardiac cycle. They noted an eccentric narrowing of the annulus during both atrial and ventricular contractions that reduced the mitral valve area by 10 to 36% from its peak diastolic area. This reduction in the annular area during systole is significant, resulting in a smaller orifice area for the larger leaflet area to cover. Not only does the annulus change size, but it also translates during the cardiac cycle. The movement of the annulus towards the atrium has been suggested to play a role in ventricular filling, possibly increasing the efficiency of blood flow into the ventricle. During ventricular contraction, there is a shortening of the left ventricular chamber along its longitudinal axis, and the mitral and tricuspid annuli move towards the apex [Simonson and Schiller, 1989; Hammarström et al., 1991; Alam and Rosenhamer, 1992; Pai et al., 1995].

The movement of the papillary muscles is also important in maintaining proper mitral valve function. The papillary muscles play an important role in keeping the mitral valve in position during ventricular contraction. Abnormal strain on the papillary muscles could cause the chordae to rupture, resulting in mitral regurgitation. It is necessary for the papillary muscles to contract and shorten during systole to prevent mitral prolapse; therefore, the distance between the apex of the heart to the mitral apparatus is important. The distance from the papillary muscle tips to the annulus was measured in normal individuals during systole and was found to remain constant [Sanfilippo et al., 1992]. In patients with mitral valve prolapse, however, this distance decreased, corresponding to a superior displacement of the papillary muscle towards the annulus.

The normal function of the mitral valve requires a balanced interplay between all of the components of the mitral apparatus, as well as the interaction of the atrium and ventricle. Engineering studies into mitral valve function have provided some insight into its mechanical properties and function. Further fundamental and detailed studies are needed to aid surgeons in repairing the diseased mitral valve and in understanding the changes in function due to mitral valve pathologies. In addition, these studies are crucial for improving the design of prosthetic valves that more closely replicate native valve function.

Arterial Macrocirculatory Hemodynamics

Baruch B. Lieber
State University
of New York-Buffalo

The arterial circulation is a multiply branched network of compliant tubes. The geometry of the network is complex, and the vessels exhibit nonlinear **viscoelastic** behavior. Flow is pulsatile, and the blood flowing through the network is a suspension of red blood cells and other particles in plasma which exhibits complex *non-Newtonian* properties. Whereas the development of an exact biomechanical description of arterial hemodynamics is a formidable task, surprisingly useful results can be obtained with greatly simplified models.

The geometrical parameters of the canine **systemic** and **pulmonary** circulations are summarized in Table 56.1. Vessel diameters vary from a maximum of 19 mm in the proximal aorta to 0.008 mm (8 μm) in the capillaries. Because of the multiple branching, the total cross-sectional area increases from 2.8 cm^2 in the proximal aorta to 1357 cm^2 in the capillaries. Of the total blood volume, approximately 83% is in the systemic circulation, 12% is in the pulmonary circulation, and the remaining 5% is in the heart. Most of the systemic blood is in the venous circulation, where changes in compliance are used to control mean circulatory blood pressure. This chapter will be concerned with flow in the larger arteries, classes 1 to 5 in the systemic circulation and 1 to 3 in the pulmonary circulation in Table 56.1. Flow in the microcirculation is discussed in Chapter 59, and venous hemodynamics is covered in Chapter 60.

56.1 Blood Vessel Walls

The detailed properties of blood vessels were described earlier in this section, but a few general observations are made here to facilitate the following discussion. Blood vessels are composed of three layers, the intima, media, and adventitia. The inner layer, or intima, is composed primarily of **endothelial** cells, which line

56-1

the vessel and are involved in control of vessel diameter. The media, composed of **elastin, collagen,** and smooth muscle, largely determines the elastic properties of the vessel. The outer layer, or adventitia, is composed mainly of connective tissue. Unlike in structures composed of passive elastic materials, vessel diameter and elastic modulus vary with smooth-muscle tone. Dilation in response to increases in flow and **myogenic** constriction in response to increases in pressure have been observed in some arteries. Smooth-muscle tone is also affected by circulating **vasoconstrictors** such as norepinephrine and **vasodilators** such as nitroprusside. Blood vessels, like other soft biological tissues, generally do not obey Hooke's law, becoming stiffer as pressure is increased. They also exhibit viscoelastic characteristics such as hysteresis and creep. Fortunately, for many purposes a linear elastic model of blood vessel behavior provides adequate results.

56.2　Flow Characteristics

Blood is a complex substance containing water, inorganic ions, proteins, and cells. Approximately 50% is plasma, a nearly **Newtonian** fluid consisting of water, ions, and proteins. The balance contains erythrocytes (red blood cells), leukocytes (white blood cells), and platelets. Whereas the behavior of blood in vessels

smaller than approximately 100 μm exhibits significant non-Newtonian effects, flow in larger vessels can be described reasonably accurately using the Newtonian assumption. There is some evidence suggesting that in blood analog fluids wall shear stress distributions may differ somewhat from Newtonian values [Liepsch et al., 1991].

Flow in the arterial circulation is predominantly laminar with the possible exception of the proximal aorta and main pulmonary artery. In steady flow, transition to turbulence occurs at Reynolds numbers (N_R) above approximately 2300

$$N_R = \frac{2rV}{\nu} \tag{56.1}$$

where r = vessel radius, V = velocity, ν = kinematic viscosity = viscosity/density.

Flow in the major systemic and pulmonary arteries is highly pulsatile. Peak-to-mean flow amplitudes as high as 6 to 1 have been reported in both human and dog [Milnor, 1989, p. 149]. Womersley's [1957] analysis of incompressible flow in rigid and elastic tubes showed that the importance of pulsatility in the velocity distributions depended on the parameter

$$N_w = r\sqrt{\frac{\omega}{\nu}} \tag{56.2}$$

where ω = frequency.

This is usually referred to as the *Womersley number* (N_w) or *α-parameter*. Womersley's original report is not readily available; however, Milnor provides a reasonably complete account [Milnor, 1989, pp. 106–121].

Mean and peak Reynolds numbers in human and dog are given in Table 56.2, which also includes mean, peak, and minimum velocities as well as the Womersley number. Mean Reynolds numbers in the entire systemic and pulmonary circulations are below 2300. Peak systolic Reynolds numbers exceed 2300 in the aorta and pulmonary artery, and some evidence of transition to turbulence has been reported. In dogs, distributed flow occurs at Reynolds numbers as low as 1000, with higher Womersley numbers increasing the transition Reynolds number [Nerem and Seed, 1972]. The values in Table 56.2 are typical for individuals at rest. During exercise, cardiac output and hence Reynolds numbers can increase severalfold. The Womersley number also affects the shape of the instantaneous velocity profiles as discussed below.

TABLE 56.2 Normal Average Hemodynamics Values in Man and Dog

	Dog (20 kg)			Man (70 kg, 1.8 m^2)		
	N_w	Velocity (cm/sec)	N_R	N_w	Velocity (cm/sec)	N_R
Systemic Vessels						
Ascending aorta	16	15.8 (89/0)[a]	870 (4900)[b]	21	18 (112/0)[a]	1500 (9400)[a]
Abdominal aorta	9	12 (60.0)	370 (1870)	12	14 (75/0)	640 (3600)
Renal artery	3	41 (74/26)	440 (800)	4	40 (73/26)	700 (1300)
Femoral artery	4	10 (42/1)	130 (580)	4	12 (52/2)	200 (860)
Femoral vein	5	5	92	7	4	104

56.3 Wave Propagation

The viscoelasticity of blood vessels affects the hemodynamics of arterial flow. The primary function of arterial elasticity is to store blood during systole so that forward flow continues when the aortic valve is closed. Elasticity also causes a finite wave propagation velocity, which is given approximately by the Moens–Korteweg relationship

$$c = \sqrt{\frac{Eh}{2\rho r}} \tag{56.3}$$

where E = wall elastic modulus, h = wall thickness, ρ = blood density, r = vessel radius.

Although Moens [1878] and Korteweg [1878] are credited with this formulation, Fung [1984, p. 107] has pointed out that the formula was first derived much earlier [Young, 1808]. Wave speeds in arterial blood vessels from several species are given in Table 56.3. In general, wave speeds increase toward the periphery as vessel radius decreases and are considerably lower in the main pulmonary artery than in the aorta owing primarily to the lower pressure and consequently lower elastic modulus.

Wave reflections occur at branches where there is not perfect **impedance** matching of parent and daughter vessels. The input impedance of a network of vessels is the ratio of pressure to flow. For rigid vessels with laminar flow and negligible inertial effects, the input impedance is simply the resistance and is independent of pressure and flow rate. For elastic vessels, the impedance is dependent on the frequency of the fluctuations in pressure and flow. The impedance can be described by a complex function expressing

the amplitude ratio of pressure to flow oscillations and the phase difference between the peaks.

$$\bar{Z}_i(\omega) = \frac{\bar{P}(\omega)}{\bar{Q}(\omega)}$$

$$|\bar{Z}_i(\omega)| = \left| \frac{\bar{P}(\omega)}{\bar{Q}(\omega)} \right| \tag{56.4}$$

$$\theta_i(\omega) = \theta[(\bar{P}(\omega))] - \theta[(\bar{Q}(\omega))]$$

where $\bar{Z}_i$ is the complex impedance, $|\bar{Z}_i|$ is the amplitude, and θ_i is the phase.

For an infinitely long straight tube with constant properties, input impedance will be independent of position in the tube and dependent only on vessel and fluid properties. The corresponding value of input impedance is called the *characteristic impedance* Z_0 given by

$$Z_0 = \frac{\rho c}{A} \tag{56.5}$$

where A = vessel cross-sectional area.

In general, the input impedance will vary from point to point in the network because of variations in vessel sizes and properties. If the network has the same impedance at each point (perfect impedance matching), there will be no wave reflections. Such a network will transmit energy most efficiently. The reflection coefficient R, defined as the ratio of reflected to incident wave amplitude, is related to the relative characteristic impedance of the vessels at a junction. For a parent tube with characteristic impedance Z_0 branching into two daughter tubes with characteristic impedances Z_1 and Z_2, the reflection coefficient is given by

$$R = \frac{Z_0^{-1} - (Z_1^{-1} + Z_2^{-1})}{Z_0^{-1} + (Z_1^{-1} + Z_2^{-1})} \tag{56.6}$$

and perfect impedance matching requires

$$\frac{1}{Z_0} = \frac{1}{Z_1} + \frac{1}{Z_2} \tag{56.7}$$

The arterial circulation exhibits partial impedance matching; however, wave reflections do occur. At each branch point, local reflection coefficients typically are less than 0.2. Nonetheless, global reflection coefficients, which account for all reflections distal to a given site, can be considerably higher [Milnor, 1989, p. 217].

In the absence of wave reflections, the input impedance is equal to the characteristic impedance. Womersley's analysis predicts that impedance modulus will decrease monotonically with increasing frequency, whereas the phase angle is negative at low frequency and becomes progressively more positive with increasing frequency. Typical values calculated from Womersley's analysis are shown in Figure 56.1. In the actual circulation, wave reflections cause oscillations in the modulus and phase. Figure 56.2 shows input impedance measured in the ascending aorta of a human. Measurements of input resistance, characteristic impedance, and the frequency of the first minimum in the input impedance are summarized in Table 56.4.

56.4 Velocity Profiles

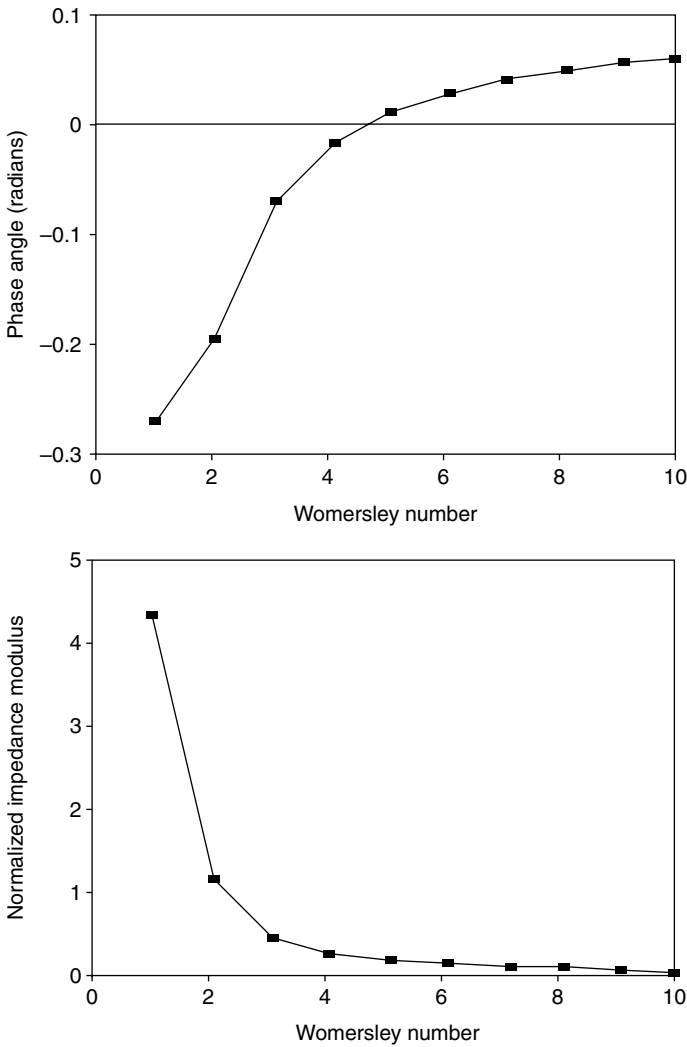
Typical pressure and velocity fluctuations throughout the cardiac cycle in man are shown in Figure 56.3 Although mean pressure decreases slightly toward the periphery due to viscous effects, peak pressure shows small increases in the distal aorta due to wave reflection and vessel taper. A rough estimate of mean


FIGURE 56.1 Characteristic impedance calculated from Womersley's analysis. The top panel contains the phase of the impedance and the bottom panel the modulus, both plotted as a function of the Womersley number N_w, which is proportional to frequency. The curves shown are for an unconstrained tube and include the effects of wall viscosity. The original figure has an error in the scale of the ordinate which has been corrected. (From Milnor, W.R. 1989. *Hemodynamics*, 2nd ed., p. 172, Baltimore, Williams and Wilkins. With permission.)

pressure can be obtained as 1/3 of the sum of systolic pressure and twice the diastolic pressure. Velocity peaks during systole, with some backflow observed in the aorta early in diastole. Flow in the aorta is nearly zero through most of the diastole; however, more peripheral arteries such as the iliac and renal show forward flow throughout the cardiac cycle. This is a result of capacitive discharge of the central arteries as arterial pressure decreases.

Velocity varies across the vessel due to viscous and inertial effects as mentioned earlier. The velocities in Figure 56.3 were measured at one point in the artery. Velocity profiles are complex because the flow is pulsatile and vessels are elastic, curved, and tapered. Profiles measured in the thoracic aorta of a dog at normal arterial pressure and cardiac output are shown in Figure 56.4. Backflow occurs during diastole, and profiles are flattened even during peak systolic flow. The shape of the profiles varies considerably with mean aortic pressure and cardiac output [Ling et al., 1973].
FIGURE 56.2 Input impedance derived from the pressure and velocity data in the ascending aorta of Figure 56.3. The top panel contains the modulus and the bottom panel the phase, both plotted as functions of frequency. The peripheral resistance (DC impedance) for this plot was 16,470 dyne sec/cm^5. FIGURE 56.3   Simultaneous pressure and blood velocity patterns recorded at points in the systemic circulation of a human. Velocities were recorded with a catheter-tip electromagnetic flowmeter probe. The catheter included a lumen for simultaneous pressure measurement V is the velocity (cm/sec), P is the pressure (mmHg). (From Mills, C.J., Gabe, I.T., Gault, J.N. et al., 1970. *Cardiovasc. Res.* 40: 405. With permission.)

In more peripheral arteries the profiles are resembling parabolic ones as in fully developed laminar flow. The general features of these fully developed flow profiles can be modeled using Womersley's approach, although nonlinear effects may be important in some cases. The qualitative features of the profile depend on the Womersley number N_w. Unsteady effects become more important as N_w increases. Below a value of about 2 the instantaneous profiles are close to the steady parabolic shape. Profiles in the aortic arch are skewed due to curvature of the arch.

56.5   Pathology

Atherosclerosis is a disease of the arterial wall which appears to be strongly influenced by hemodynamics. The disease begins with a thickening of the intimal layer in locations which correlate with the shear stress distribution on the endothelial surface [Friedman et al., 1993]. Over time the lesion continues to grow until a significant portion of the vessel lumen is occluded. The peripheral circulation will dilate
FIGURE 56.4 Velocity profiles obtained with a hot-film anemometer probe in the descending thoracic aorta of a dog at normal arterial pressure and cardiac output. The velocity at $t =$ time/(cardiac period) is plotted as a function of radial position. Velocity w is normalized by the maximum velocity w_m and radial position at each time by the instantaneous vessel radius $R(t)$. The aortic valve opens at $t = 0$. Peak velocity occurs 11% of the cardiac period after aortic valve opening. (From Ling, S.C., Atabek, W.G., Letzing, W.G. et al. 1973. *Circ. Res.* 33: 198. With permission.)

to compensate for the increase in resistance of the large vessels, compromising the ability of the system to respond to increases in demand during exercise. Eventually the circulation is completely dilated, and resting flow begins to decrease. A blood clot may form at the site or lodge in a narrowed segment, causing an acute loss of blood flow. The disease is particularly dangerous in the coronary and carotid arteries due to the critical oxygen requirements of the heart and brain.

In addition to intimal thickening, the arterial wall properties also change with age. Most measurements suggest that arterial elastic modulus increases with age (hardening of the arteries); however, in some cases arteries to become more compliant (inverse of elasticity) [Learoyd and Taylor, 1966]. Local weakening of the wall may also occur, particularly in the descending aorta, giving rise to an **aneurysm**, which, if ruptures, can cause sudden death.

Defining Terms

Aneurysm: A ballooning of a blood vessel wall caused by weakening of the elastic material in the wall.

Atherosclerosis: A disease of the blood vessels characterized by thickening of the vessel wall and eventual occlusion of the vessel.

Collagen: A protein found in blood vessels which is much stiffer than elastin.

Elastin: A very elastic protein found in blood vessels.

Endothelial: The inner lining of blood vessels.

Impedance: A (generally) complex number expressing the ratio of pressure to flow.

Myogenic: A change in smooth-muscle tone due to stretch or relaxation, causing a blood vessel to resist changes in diameter.

Newtonian: A fluid whose stress-rate-of-strain relationship is linear, following Newton's law. The fluid will have a viscosity whose value is independent of rate of strain.

Pulmonary: The circulation which delivers blood to the lungs for reoxygenation and carbon dioxide removal.

Systemic: The circulation which supplies oxygenated blood to the tissues of the body.

Vasoconstrictor: A substance which causes an increase in smooth-muscle tone, thereby constricting blood vessels.

Vasodilator: A substance which causes a decrease in smooth-muscle tone, thereby dilating blood vessels.
Viscoelastic: A substance which exhibits both elastic (solid) and viscous (liquid) characteristics.

Further Information

A good introduction to cardiovascular biomechanics, including arterial hemodynamics, is provided by K.B. Chandran in *Cardiovascular Biomechanics.* Y. C. Fung's *Biodynamics — Circulation* is also an excellent starting point, somewhat more mathematical than Chandran. Perhaps the most complete treatment of the subject is in *Hemodynamics* by W.R. Milnor, from which much of this chapter was taken. Milnor's book is quite mathematical and may be difficult for a novice to follow.

Current work in arterial hemodynamics is reported in a number of engineering and physiological journals, including the *Annals of Biomedical Engineering, Journal of Biomechanical Engineering, Circulation Research,* and *The American Journal of Physiology, Heart and Circulatory Physiology.* Symposia sponsored by the American Society of Mechanical Engineers, Biomedical Engineering Society, American Heart Association, and the American Physiological Society contain reports of current research.

Mechanics of Blood Vessels

Thomas R. Canfield
Argonne National Laboratory

Philip B. Dobrin
Hines VA Hospital and Loyola University Medical Center

57.1 Assumptions

This chapter is concerned with the mechanical behavior of blood vessels under static loading conditions and the methods required to analyze this behavior. The assumptions underlying this discussion are for *ideal* blood vessels that are at least regionally homogeneous, incompressible, elastic, and cylindrically orthotropic. Although physiologic systems are *nonideal,* much understanding of vascular mechanics has been gained through the use of methods based upon these ideal assumptions.

57.1.1 Homogeneity of the Vessel Wall

On visual inspection, blood vessels appear to be fairly homogeneous and distinct from surrounding connective tissue. The inhomogeneity of the vascular wall is realized when one examines the tissue under a low-power microscope, where one can easily identify two distinct structures: the media and adventitia. For this reason the assumption of vessel wall homogeneity is applied cautiously. Such an assumption may be valid only within distinct macroscopic structures. However, few investigators have incorporated macroscopic inhomogeneity into studies of vascular mechanics [1].

57.1.2 Incompressibility of the Vessel Wall

Experimental measurement of wall compressibility of 0.06% at 270 cm of H_2O indicates that the vessel can be considered incompressible when subjected to physiologic pressure and load [2]. In terms of the

57-1

mechanical behavior of blood vessels, this is small relative to the large magnitude of the distortional strains that occur when blood vessels are deformed under the same conditions. Therefore, vascular compressibility may be important to understanding other physiologic processes related to blood vessels, such as the transport of interstitial fluid.

57.1.3 Inelasticity of the Vessel Wall

That blood vessel walls exhibit inelastic behavior such as length-tension and pressure-diameter hysteresis, stress relaxation, and creep has been reported extensively [3,4]. However, blood vessels are able to maintain stability and contain the pressure and flow of blood under a variety of physiologic conditions. These conditions are dynamic but slowly varying with a large static component.

57.1.4 Residual Stress and Strain

Blood vessels are known to retract both longitudinally and circumferentially are excision. This retraction is caused by the relief of distending forces resulting from internal pressure and longitudinal tractions. The magnitude of retraction is influenced by several factors. Among these factors are growth, aging, and hypertension. Circumferential retraction of medium-caliber blood vessels, such as the carotid, iliac, and bracheal arteries, can exceed 70% following reduction of internal blood pressure to zero. In the case of the carotid artery, the amount of longitudinal retraction tends to increase during growth and to decrease in subsequent aging [5]. It would seem reasonable to assume that blood vessels are in a nearly stress-free state when they are fully retracted and free of external loads. This configuration also seems to be a reasonable choice for the reference configuration. However, this ignores residual stress and strain effects that have been the subject of current research [6–11].

Blood vessels are formed in a dynamic environment which gives rise to imbalances between the forces that tend to extend the diameter and length and the internal forces that tend to resist the extension. This imbalance is thought to stimulate the growth of elastin and collagen and to effectively reduce the stresses in the underlying tissue. Under these conditions it is not surprising that a residual stress state exists when the vessel is fully retracted and free of external tractions. This process has been called *remodeling* [7]. Striking evidence of this remodeling is found when a cylindrical slice of the fully retracted blood vessel is cut longitudinally through the wall. The cylinder springs open, releasing bending stresses kept in balance by the cylindrical geometry [11].

57.2 Vascular Anatomy

A blood vessel can be divided anatomically into three distinct cylindrical sections when viewed under the optical microscope. Starting at the inside of the vessel, they are the intima, the media, and the adventitia. These structures have distinct functions in terms of the blood vessel physiology and mechanical properties.

The intima consists of a thin monolayer of endothelial cells that line the inner surface of the blood vessel. The endothelial cells have little influence on blood vessel mechanics but do play an important role in hemodynamics and transport phenomena. Because of their anatomical location, these cells are subjected to large variations in stress and strain as a result of pulsatile changes in blood pressure and flow.

The media represents the major portion of the vessel wall and provides most of the mechanical strength necessary to sustain structural integrity. The media is organized into alternating layers of interconnected smooth muscle cells and elastic lamellae. There is evidence of collagen throughout the media. These small collagen fibers are found within the bands of smooth muscle and may participate in the transfer of forces between the smooth muscle cells and the elastic lamellae. The elastic lamellae are composed principally of the fiberous protein elastin. The number of elastic lamellae depends upon the wall thickness and the anatomical location [12]. In the case of the canine carotid, the elastic lamellae account for a major component of the static structural response of the blood vessel [13]. This response is modulated
FIGURE 57.1 Cylindrical geometry of a blood vessel: *top:* stress-free reference configuration; *middle:* fully retracted vessel free of external traction; *bottom:* vessel *in situ* under longitudinal tether and internal pressurization.

by the smooth-muscle cells, which have the ability to actively change the mechanical characteristics of the wall [14].

The adventitia consists of loose, more disorganized fiberous connective tissue, which may have less influence on mechanics.

57.3 Axisymmetric Deformation

In the following discussion we will concern ourselves with deformation of cylindrical tubes, see Figure 57.1. Blood vessels tend to be nearly cylindrical *in situ* and tend to remain cylindrical when a cylindrical section is excised and studied *in vitro*. Only when the vessel is dissected further does the geometry begin to deviate from cylindrical. For this deformation there is a unique coordinate mapping

$$(R, \Theta, Z) \rightarrow (r, \theta, z) \tag{57.1}$$

where the undeformed coordinates are given by (R, Θ, Z) and the deformed coordinates are given by (r, θ, z). The deformation is given by a set of restricted functions

$$r = r(R) \tag{57.2}$$

$$\theta = \beta \Theta \tag{57.3}$$

$$z = \mu Z + C_1 \tag{57.4}$$

where the constants μ and β have been introduced to account for a uniform longitudinal strain and a symmetric residual strain that are both independent of the coordinate Θ.

If $\beta = 1$, there is no residual strain. If $\beta \neq 1$, residual stresses and strains are present. If $\beta > 1$, a longitudinal cut through the wall will cause the blood vessel to open up, and the new cross-section will form a c-shaped section of an annulus with larger internal and external radii. If $\beta < 1$, the cylindrical shape is unstable, but a thin section will tend to overlap itself. In Choung and Fung's formulation, $\beta = \pi/\Theta_o$, where the angle Θ_o is half the angle spanned by the open annular section [6].

For cylindrical blood vessels there are two assumed constraints. The first assumption is that the longitudinal strain is uniform through the wall and therefore

$$\lambda_z = \mu = \text{a constant} \tag{57.5}$$

for any cylindrical configuration. Given this, the principal stretch ratios are computed from the above function as

$$\lambda_r = \frac{dr}{dR} \tag{57.6}$$

$$\lambda_\theta = \beta \frac{r}{R} \tag{57.7}$$

$$\lambda_z = \mu \tag{57.8}$$

The second assumption is wall incompressibility, which can be expressed by

$$\lambda_r \lambda_\theta \lambda_z \equiv 1 \tag{57.9}$$

or

$$\beta\mu \frac{r}{R} \frac{dr}{dR} = 1 \tag{57.10}$$

and therefore

$$r\, dr = \frac{1}{\beta\mu} R\, dR \tag{57.11}$$

Integration of this expression yields the solution

$$r^2 = \frac{1}{\beta\mu} R^2 + c_2 \tag{57.12}$$

where

$$c_2 = r_e^2 - \frac{1}{\beta\mu} R_e^2 \tag{57.13}$$

As a result, the principal stretch ratios can be expressed in terms of R as follows:

$$\lambda_r = \frac{R}{\sqrt{\beta\mu(R^2 + \beta\mu c_2)}} \tag{57.14}$$

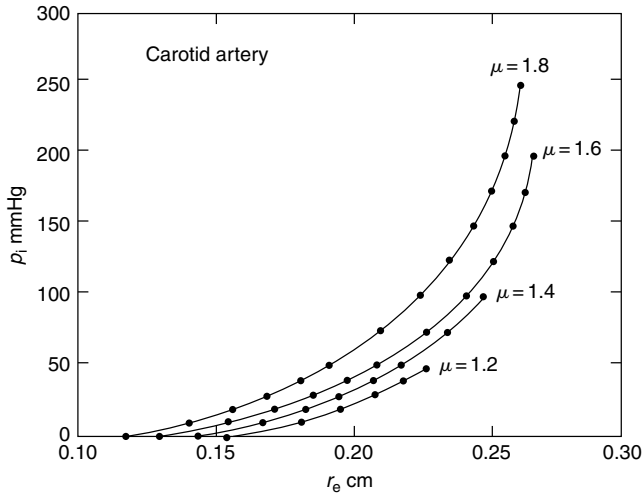
$$\lambda_\theta = \sqrt{\frac{1}{\beta\mu} + \frac{c_2}{R^2}} \tag{57.15}$$


FIGURE 57.2   Pressure–radius curves for the canine carotid artery at various degrees of longitudinal extension.
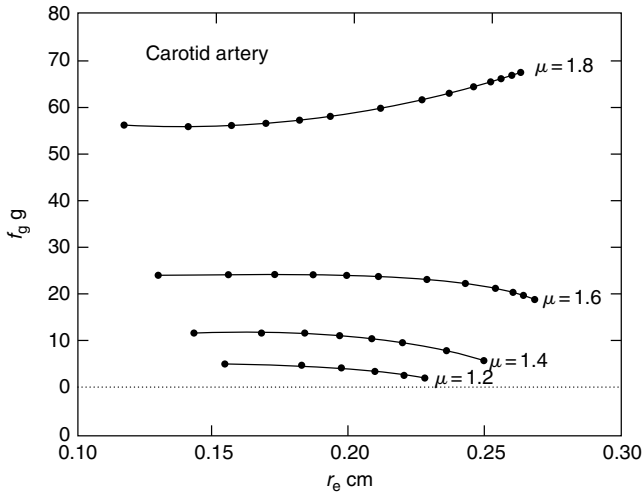

FIGURE 57.3   Longitudinal distending force as a function of radius at various degrees of longitudinal extension.

57.4   Experimental Measurements

The basic experimental setup required to measure the mechanical properties of blood vessels *in vitro* is described in Reference 14. It consists of a temperature-regulated bath of physiologic saline solution to maintain immersed cylindrical blood vessel segments, devices to measure diameter, an apparatus to hold the vessel at a constant longitudinal extension and to measure longitudinal distending force, and a system to deliver and control the internal pressure of the vessel with 100% oxygen. Typical data obtained from this type of experiment are shown in Figure 57.2 and Figure 57.3.

57.5   Equilibrium

When blood vessels are excised, they retract both longitudinally and circumferentially. Restoration to natural dimensions requires the application of internal pressure, p_i, and a longitudinal tether force,

F_T. The internal pressure and longitudinal tether are balanced by the development of forces within the vessel wall. The internal pressure is balanced in the circumferential direction by a wall tension, T. The longitudinal tether force and pressure are balanced by the retractive force of the wall, F_R

$$T = p_i r_i \tag{57.16}$$

$$F_R = F_T + p_i \pi r_i^2 \tag{57.17}$$

The first equation is the familiar law of Laplace for a cylindrical tube with internal radius r_i. It indicates that the force due to internal pressure, p_i, must be balanced by a tensile force (per unit length), T, within the wall. This tension is the integral of the circumferentially directed force intensity (or stress, σ_θ) across the wall:

$$T = \int_{r_i}^{r_e} \sigma_\theta \, dr = \bar{\sigma}_\theta h \tag{57.18}$$

where $\bar{\sigma}_\theta$ is the mean value of the circumferential stress and h is the wall thickness. Similarly, the longitudinal tether force, F_T, and extending force due to internal pressure are balanced by a retractive internal force, F_R, due to axial stress, σ_z, in the blood vessel wall:

$$F_R = 2\pi \int_{r_i}^{r_e} \sigma_z r \, dr = \bar{\sigma}_z \pi h (r_e + r_i) \tag{57.19}$$

where $\bar{\sigma}_z$ is the mean value of this longitudinal stress. The mean stresses are calculated from the above equation as

$$\bar{\sigma}_\theta = p_i \frac{r_i}{h} \tag{57.20}$$

$$\bar{\sigma}_z = \frac{F_T}{\pi h (r_e + r_i)} + \frac{p_i}{2} \frac{r_i}{h} \tag{57.21}$$

The mean stresses are a fairly good approximation for thin-walled tubes where the variations through the wall are small. However, the range of applicability of the thin-wall assumption depends upon the material properties and geometry. In a linear elastic material, the variation in σ_θ is less than 5% for $r/h > 20$. When the material is nonlinear or the deformation is large, the variations in stress can be more severe (see Figure 57.10).

The stress distribution is determined by solving the equilibrium equation,

$$\frac{1}{r} \frac{d}{dr} (r \sigma_r) - \frac{\sigma_\theta}{r} = 0 \tag{57.22}$$

This equation governs how the two stresses are related and must change in the cylindrical geometry. For uniform extension and internal pressurization, the stresses must be functions of a single radial coordinate, r, subject to the two boundary conditions for the radial stress:

$$\sigma_r (r_i, \mu) = -p_i \tag{57.23}$$

$$\sigma_r (r_e, \mu) = 0 \tag{57.24}$$

57.6 Strain Energy Density Functions

Blood vessels are able to maintain their structural stability and contain steady oscillating internal pressures. This property suggests a strong elastic component, which has been called the *pseudoelasticity* [4]. This

elastic response can be characterized by a single potential function called the *strain energy density.* It is a scalar function of the strains that determines the amount of stored elastic energy per unit volume. In the case of a cylindrically orthotropic tube of incompressible material, the strain energy density can be written in the following functional form:

$$W = W^{\star}(\lambda_r, \lambda_\theta, \lambda_z) + \lambda_r \lambda_\theta \lambda_z p \tag{57.25}$$

where p is a scalar function of position, R. The stresses are computed from the strain energy by the following:

$$\sigma_i = \lambda_i \frac{\partial W^{\star}}{\partial \lambda_i} + p \tag{57.26}$$

We make the following transformation [15]

$$\lambda = \frac{\beta r}{\sqrt{\beta \mu (r^2 - c_2)}} \tag{57.27}$$

which upon differentiation gives

$$r \frac{d\lambda}{dr} = \beta^{-1}(\beta\lambda - \mu\lambda^3) \tag{57.28}$$

After these expressions and the stresses in terms of the strain energy density function are introduced into the equilibrium equation, we obtain an ordinary differential equation for p

$$\frac{dp}{d\lambda} = \frac{\beta W^{\star}_{,\lambda_\theta} - W^{\star}_{,\lambda_r}}{\beta\lambda = \mu\lambda^3} - \frac{d W^{\star}_{,\lambda_r}}{d\lambda} \tag{57.29}$$

subject to the boundary conditions

$$p(R_i) = p_i \tag{57.30}$$

$$p(R_e) = 0 \tag{57.31}$$

57.6.1 Isotropic Blood Vessels

A blood vessel generally exhibits anisotropic behavior when subjected to large variations in internal pressure and distending force. When the degree of anisotropy is small, the blood vessel may be treated as isotropic. For isotropic materials it is convenient to introduce the strain invariants:

$$I_1 = \lambda_r^2 + \lambda_\theta^2 + \lambda_z^2 \tag{57.32}$$

$$I_2 = \lambda_r^2\lambda_\theta^2 + \lambda_\theta^2\lambda_z^2 + \lambda_z^2\lambda_r^2 \tag{57.33}$$

$$I_3 = \lambda_r^2\lambda_\theta^2\lambda_z^2 \tag{57.34}$$

These are measures of strain that are independent of the choice of coordinates. If the material is incompressible

$$I_3 = j^2 \equiv 1 \tag{57.35}$$

and the strain energy density is a function of the first two invariants, then

$$W = W(I_1, I_2) \tag{57.36}$$

The least complex form for an incompressible material is the first-order polynomial, which was first proposed by Mooney to characterize rubber:

$$W^\star = \frac{G}{2}[(I_1 - 3) + k(I_2 - 3)] \tag{57.37}$$

It involves only two elastic constants. A special case, where $k = 0$, is the neo-Hookean material, which can be derived from thermodynamics principles for a simple solid. Exact solutions can be obtained for the cylindrical deformation of a thick-walled tube. In the case where there is no residual strain, we have the following:

$$P = -G(1 + k\mu^2)\left[\frac{\log \lambda}{\mu} + \frac{1}{2\mu^2\lambda^2}\right] + c_0 \tag{57.38}$$

$$\sigma_r = G\left[\frac{1}{\lambda^2\mu^2} + k\left(\frac{1}{\mu^2} + \frac{1}{\lambda^2}\right)\right] + p \tag{57.39}$$

$$\sigma_\theta = G\left[\lambda^2 + k\left(\frac{1}{\mu^2} + \lambda^2\mu^2\right)\right] + p \tag{57.40}$$

$$\sigma_z = G\left[\mu^2 + k\left(\lambda^2\mu^2 + \frac{1}{\lambda^2}\right)\right] + p \tag{57.41}$$

However, these equations predict stress softening for a vessel subjected to internal pressurization at fixed lengths, rather than the stress stiffening observed in experimental studies on arteries and veins (see Figure 57.4 and Figure 57.5).

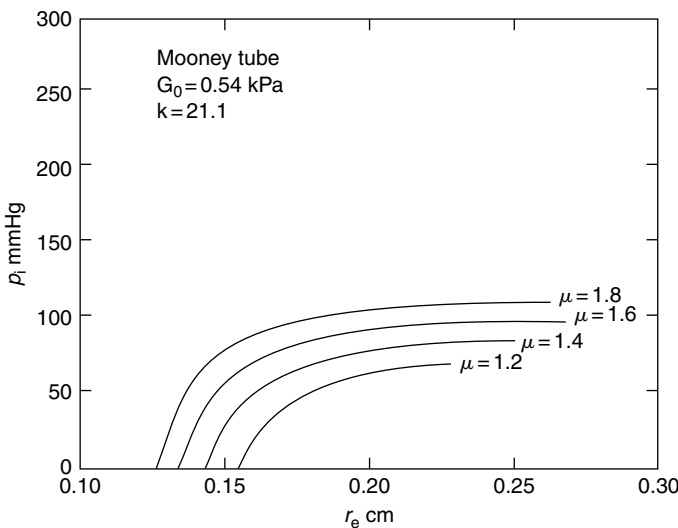
An alternative isotropic strain energy density function which can predict the appropriate type of stress stiffening for blood vessels is an exponential where the arguments is a polynomial of the strain invariants.


FIGURE 57.4 Pressure–radius curves for a Mooney–Rivlin tube with the approximate dimensions of the carotid.
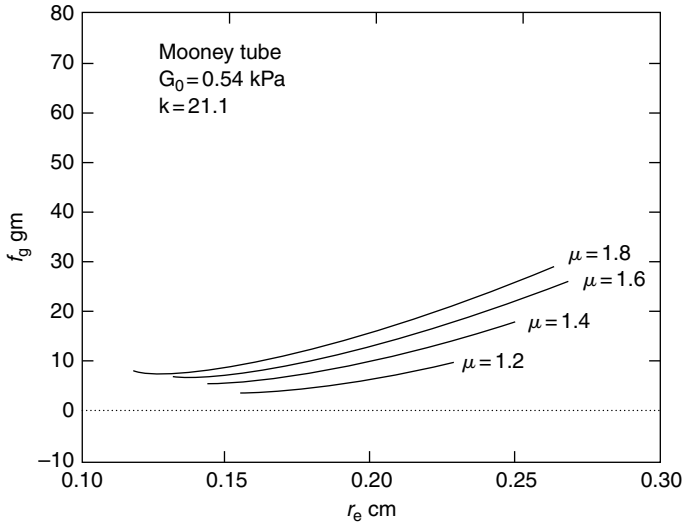

FIGURE 57.5 Longitudinal distending force as a function of radius for the Mooney–Rivlin tube.
FIGURE 57.6 Pressure–radius curves for tube with the approximate dimensions of the carotid calculated using an isotropic exponential strain energy density function.

The first-order form is given by

$$W^{\star} = \frac{G_0}{2k_1} \exp[k_1(I_1 - 3) + k_2(I_2 - 3)] \tag{57.42}$$

This requires the determination of only two independent elastic constants. The third, G_0, is introduced to facilitate scaling of the argument of the exponent (see Figure 57.6 and Figure 57.7). This exponential form is attractive for several reasons. It is a natural extension of the observation that biologic tissue stiffness is proportional to the load in simple elongation. This stress stiffening has been attributed to a statistical recruitment and alignment of tangled and disorganized long chains of proteins. The exponential forms resemble statistical distributions derived from these same arguments.
FIGURE 57.7 Longitudinal distending force as a function of radius for the isotropic tube.

57.6.2 Anisotropic Blood Vessels

Studies of the orthotropic behavior of blood vessels may employ polynomial or exponential strain energy density functions that include all strain terms or extension ratios. In particular, the strain energy density function can be of the form

$$W^\star = q_n(\lambda_r, \lambda_\theta, \lambda_z) \tag{57.43}$$

or

$$W^\star = e^{q_n(\lambda_r, \lambda_\theta, \lambda_z)} \tag{57.44}$$

where q_n is a polynomial of order n. Since the material is incompressible, the explicit dependence upon λ_r can be eliminated either by substituting $\lambda_r = \lambda_\theta^{-1}\lambda_z^{-1}$ or by assuming that the wall is thin and hence that the contribution of these terms is small. Figure 57.8 and Figure 57.9 illustrate how well the experimental data can be fitted to an exponential strain density function whose argument is a polynomial of order $n = 3$.

Care must be taken to formulate expressions that will lead to stresses that behave properly. For this reason it is convenient to formulate the strain energy density in terms of the Lagrangian strains

$$e_i = 1/2(\lambda_i^2 - 1) \tag{57.45}$$

and in this case we can consider polynomials of the lagrangian strains, $q_n(e_r, e_\theta, e_z)$.

Vaishnav et al. [16] proposed using a polynomial of the form

$$W^\star = \sum_{i=2}^{n} \sum_{j=0}^{i} a_{ij-i} e_\theta^{i-j} e_z^j \tag{57.46}$$

to approximate the behavior of the canine aorta. They found better correlation with order-three polynomials over order-two, but order-four polynomials did not warrant the addition work.
FIGURE 57.8 Pressure–radius curves for a fully orthotropic vessel calculated with an exponential strain energy density function.
FIGURE 57.9 Longitudinal distending force as a function of radius for the orthotropic vessel.

Later, Fung et al. [4] found very good correlation with an expression of the form

$$W - \frac{C}{2} \exp[a_1(e_\theta^2 - e_z^{\star 2}) + a_2(e_z^2 - e_z^{\star 2}) + 2a_4(e_\theta e_z - e_\theta^\star e_z^\star)] \tag{57.47}$$

for the canine carotid artery, where $e_\theta^\star$ and $e_z^\star$ are the strains in a reference configuration at *in situ* length and pressure. Why should this work? One answer appears to be related to residual stresses and strains.

When residual stresses are ignored, large-deformation analysis of thick-walled blood vessels predicts steep distributions in σ_θ and σ_z through the vessel wall, with the highest stresses at the interior. This prediction is considered significant because high tensions in the inner wall could inhibit vascularization and oxygen transport to vascular tissue.
FIGURE 57.10 Stress distributions through the wall at various pressures for the orthotropic vessel.

When residual stresses are considered, the stress distributions flatten considerably and become almost uniform at *in situ* length and pressure. Figure 57.10 shows the radial stress distributions computed for a vessel with $\beta = 1$ and $\beta = 1.11$. Takamizawa and Hayashi have even considered the case where the strain distribution is uniform *in situ* [9]. The physiologic implications are that vascular tissue is in a constant state of flux. New tissue is synthesized in a state of stress that allows it to redistribute the internal loads more uniformly. There probably is no stress-free reference state [7,8,17]. Continuous dissection of the tissue into smaller and smaller pieces would continue to relieve residual stresses and strains [10].

The Venous System

Artin A. Shoukas
Johns Hopkins University School of Medicine

Carl F. Rothe
Indiana University

The venous system not only serves as a conduit for the return of blood from the capillaries to the heart but also provides a dynamic, variable blood storage compartment that influences cardiac output. The systemic (noncardiopulmonary) venous system contains more than 75% of the blood volume of the entire systemic circulation. Although the heart is the source of energy for propelling blood throughout the circulation, filling of the right heart before the subsequent beat is primarily passive. The subsequent amount of blood ejected is exquisitely sensitive to the transmural filling pressure (e.g., a change of right heart filling pressure of 1 cm water can cause the cardiac output to change by about 50%).

Because the blood vessels are elastic and have smooth muscle in their walls, contraction or relaxation of the smooth muscle can quickly redistribute blood between the periphery and the heart to influence cardiac filling and thus cardiac output. Even though the right ventricle is not essential for life, its functioning acts to reduce the central venous pressure to facilitate venous return [1]. It largely determines the magnitude of the cardiac output by influencing the degree of filling of the left heart. Dynamic changes in venous tone, by redistributing blood volume, can thus, at rest, change cardiac output over a range of more than ±20%. The dimensions of the vasculature influence both blood flow — by way of their resistive properties — and contained blood volume — by way of their capacitive properties. The arteries have about 10 times the resistance of the veins, and the veins are more than 10 times as compliant as the arteries.

The conduit characteristics of the venous system primarily depend on the anatomy of the system. Valves in the veins of the limbs are crucial for reducing the pressure in dependent parts of the body. Even small movements from skeletal muscle activity tend to compress the veins and move blood toward the heart. A competent valve then blocks back flow, thus relieving the pressure when the movement stops. Even a few steps can reduce the transmural venous pressure in the ankle from as much as 100 mmHg to about 20 mmHg. Without this mechanism, transcapillary movement of fluid into the extravascular spaces results in edema. Varicose (swollen) veins and peripheral pooling of blood can result from damage to the venous valves. During exercise, the rhythmic contraction of the skeletal muscles, in conjunction with venous

valves, provides an important mechanism — the skeletal muscle pump — aiding the large increases in blood flow through the muscles without excessive increases in capillary pressure and blood pooling in the veins of the muscles. Without this mechanism, the increase in venous return leading to the dramatic increases in cardiac output would be greatly limited.

58.1 Definitions

58.1.1 Capacitance

Capacitance is a general term that relates the magnitude of contained volume to the transmural pressure across the vessel walls and is defined by the pressure–volume relationship. In living blood vessels, the pressure–volume relationship is complex and nonlinear. At transmural pressure near zero, there is a finite volume within the vessels (see definition of *unstressed volume*). If this volume is then removed from the vessels, there is only a small decrease in transmural pressure as the vessel collapses from a circular cross-section to an elliptical one. This is especially true for superficial or isolated venous vessels. However, for vessels which are tethered or embedded in tissue a negative pressure may result without appreciably changing the shape of the vessels. With increases in contained volume, the vessel becomes distended, and there is a concomitant increase in transmural pressure. The incremental change in volume to incremental change in transmural pressure is often relatively constant. At very high transmural pressures vessels become stiffer, and the incremental volume change to transmural pressure change is small. Because all blood vessels exhibit these nonlinearities, no single parameter can describe capacitance; instead the entire pressure-volume relationship must be considered.

58.1.2 Compliance

Vascular compliance (C) is defined as the slope of the pressure-volume relationship. It is the ratio of the change in incremental volume (ΔV) to a change in incremental transmural pressure (ΔP). Thus $C = \Delta V / \Delta P$. Because the pressure-volume relationship is nonlinear, the slope of the relationship is not constant over its full range of pressures, and so the compliance should be specified at a given pressure. Units of compliance are those of volume divided by pressure, usually reported in ml/mmHg. Values are typically normalized to wet tissue weight or to total body weight. When the compliance is normalized by the total contained blood volume, it is termed the *vascular distensibility* and represents the fractional change in volume $(\Delta V / V)$ per change in transmural pressure; $D = (\Delta V / V) \, \Delta P$, where V is the volume at control or at zero transmural pressure.

58.1.3 Unstressed Volume

Unstressed volume (V_0) is the volume in the vascular system when the transmural pressure is zero. It is a calculated volume obtained by extrapolating the relatively linear segment of the pressure-volume relationship over the normal operating range to zero transmural pressure. Many studies have shown that reflexes and drugs have quantitatively more influence on V_0 than on the compliance.

58.1.4 Stressed Volume

The *stressed volume* (V_s) is the volume of blood in the vascular system that must be removed to change the computed transmural pressure from its prevailing value to zero transmural pressure. It is computed as the product of the vascular compliance and transmural distending pressure: $V_s = C \times P$. The total contained blood volume at a specific pressure (P) is the sum of stressed and unstressed volume. The unstressed volume is then computed as the total blood volume minus the stressed volume. Because of the marked nonlinearity around zero transmural pressure and the required extrapolation, both V_0 and V_s are virtual volumes.

58.1.5 Capacity

Capacity refers to the amount of blood volume contained in the blood vessels at a specific distending pressure. It is the sum of the unstressed volume and the stressed volume, $V = V_0 + V_s$.

58.1.6 Mean Filling Pressure

If the inflow and outflow of an organ are suddenly stopped, and blood volume is redistributed so that all pressures within the vasculature are the same, this pressure is the *mean filling pressure* [2]. This pressure can be measured for the systemic or pulmonary circuits or the body as a whole. The arterial pressure often does not equal the venous pressure as flow is reduced to zero, because blood must move from the distended arterial vessels to the venous beds during the measurement maneuver, and flow may stop before equilibrium occurs. This is because smooth-muscle activity in the arterial vessels, rheological properties of blood, or high interstitial pressures act to impede the flow. Thus corrections must often be made [2,3]. The experimentally measured mean filling pressure provides a good estimate of P_v (the pressure in the minute venules), for estimating venous stressed volume.

58.1.7 Venous Resistance

Venous resistance (R) refers to the hindrance to blood flow through the venous vasculature caused by friction of the moving blood along the venous vascular wall. By definition it is the ratio of the pressure gradient between the entrance of the venous circulation, namely the capillaries, and the venous outflow divided by the venous flow rate. Thus

$$R = \frac{(P_c = P_{ra})}{F} \tag{58.1}$$

where R is the venous resistance, P_c is the capillary pressure, P_{ra} is the right atrial pressure, and F is the venous flow. As flow is decreased to zero, arterial closure may occur, leading to a positive perfusion pressure at zero flow. With partial collapse of veins, a Starling resistor like condition is present in which an increase in outlet pressure has no influence on flow until the outlet pressure is greater than the "waterfall" pressure.

58.1.8 Venous Inertance

Venous inertance (I_v) is the opposition to a change in flow rate related to the mass of the bolus of blood that is accelerated or decelerated. The inertance I_v for a cylindrical tube with constant cross-sectional area is $I_v = L\rho/A$, where L is the length of the vessel, ρ is the density of the blood, and A is the cross-sectional area [4].

58.2 Methods to Measure Venous Characteristics

Our knowledge of the nature and role of the capacitance characteristics of the venous system has been limited by the difficulty of measuring the various variables needed to compute parameter values. State-of-the-art equipment is often needed because of the low pressures and many disturbing factors present. Many of the techniques that have been used to measure venous capacitance require numerous assumptions that may not be correct or are currently impossible to evaluate [3].

58.2.1 Resistance

For the estimate of vascular resistance, the upstream to outflow pressure gradient across the tissues must be estimated along with a measure of flow. Pressures in large vessels are measured with a catheter connected to a pressure transducer, which typically involves measurement of minute changes in resistance elements attached to a stiff diaphragm which flexes proportionally to the pressure. For the veins in tissue, the

upstream pressure, just downstream from the capillaries, is much more difficult to measure because of the minute size ($\sim$15 μm) of the vessels. For this a servo-null micropipette technique may be used. A glass micropipette with a tip diameter of about 2 μm is filled with a 1 to 2 mol saline solution. When the pipette is inserted into a vein, the pressure tends to drive the lower conductance blood plasma into the pipette. The conductance is measured using an AC-driven bridge. A servosystem, driven by the imbalance signal, is used to develop a counter pressure to maintain the interface between the low-conductance filling solution and the plasma near the tip of the pipette. This counter pressure, which equals the intravascular pressure, is measured with a pressure transducer. Careful calibration is essential.

Another approach for estimating the upstream pressure in the veins is to measure the mean filling pressure of the organ (see above) and assume that this pressure is the upstream venous pressure. Because this venous pressure must be less than the capillary pressure and because most of the blood in an organ is in the small veins and venules, this assumption, though tenuous, is not unreasonable. To measure flow many approaches are available including electromagnetic, transit-time ultrasonic, or Doppler ultrasonic flowmeters. Usually the arterial inflow is measured with the assumption that the outflow is the same. Indicator dilution techniques are also used to estimate average flow. They are based on the principle that the reduction in concentration of infused indicator is inversely proportional to the rate of flow. Either a bolus injection or a continuous infusion may be used. Adequacy of mixing of indicator across the flow stream, lack of collateral flows, and adequately representative sampling must be considered [5].

58.2.2 Capacitance

For estimating the capacitance parameters of the veins, contained volume, rather than flow, and transmural pressure, rather than the longitudinal pressure gradient, must be measured. Pressures are measured as described above. For the desired pressure-volume relationship the total contained volume must be known.

Techniques used to measure total blood volume include *indicator dilution.* The ratio of the integral of indicator concentration time to that of concentration is used to compute the mean transit time (MIT) following the sudden injection of a bolus of indicator [3,5]. The active volume is the product of MTT and flow, with flow measured as outlined above. Scintigraphy provides an image of the distribution of radioactivity in tissues. A radioisotope, such as technicium 99 that is bound to red blood cells which in turn are contained within the vasculature, is injected and allowed to equilibrate. A camera, with many collimating channels sensitive to the emitted radiation, is placed over the tissue. The activity recorded is proportional to the volume of blood. Currently it is not possible to accurately calibrate the systems to provide measures of blood volume because of uncertain attenuation of radiation by the tissue and distance. Furthermore, delimiting a particular organ within the body and separating arterial and venous segments of the circulation are difficult.

58.2.3 Compliance

To estimate compliance, changes in volume are needed. This is generally easier than measuring the total blood volume. Using *plethysmography,* a rigid container is placed around the organ, and a servo system functions to change the fluid volume in the chamber to maintain the chamber pressure-constant. The consequent volume change is measured and assumed to be primarily venous, because most of the vascular volume is venous. With a tight system and careful technique, at the end of the experiment both inflow and outflow blood vessels can be occluded and then the contained blood washed out and measured to provide a measure of the total blood volume [6].

58.2.4 Gravimetric Techniques

Gravimetric techniques can be used to measure changes in blood volume. If the organ can be isolated and weighed continuously with the blood vessels intact, changes in volume can be measured in response to drugs or reflexes. With an important modification, this approach can be applied to an organ or the systemic circulation; the tissues are perfused at a constant rate, and the outflow is emptied at a constant pressure

into a reservoir. Because the reservoir is emptied at a constant rate for the perfusion, changes in reservoir volume reflect an opposite change in the perfused tissue blood volume [7]. To measure compliance, the outflow pressure is changed (2 to 5 mmHg) and the corresponding change in reservoir volume noted. With the inflow and outflow pressure held constant, the pressure gradients are assumed to be constant so that 100% of an outflow pressure change can be assumed to be transmitted to the primary capacitance vessels. Any reflex or drug-induced change in reservoir volume may be assumed to be inversely related to an active change in vascular volume [7–9]. If resistances are also changed by the reflex or drug, then corrections are needed and the interpretations are more complex.

58.2.5 Outflow Occlusion

If the outflow downstream from the venous catheter is suddenly occluded, the venous pressure increases, and its rate of increase is measured. The rate of inflow is also measured so that the compliance can be estimated as the ratio flow to rate of pressure rise: Compliance in ml/mmHg = (flow in ml/min)/(rate of venous pressure rise in mmHg/min). The method is predicated on the assumption that the inflow continues at a constant rate and that there is no pressure gradient between the pressure measuring point and the site of compliance for the first few seconds of occlusion when the rate of pressure rise is measured.

58.2.6 Integral of Inflow Minus Outflow

With this technique both inflow and outflow are measured and the difference integrated to provide the volume change during an experimental forcing. If there is a decrease in contained volume, the outflow will be transiently greater than the inflow. The volume change gives a measure of the response to drugs or reflexes. Following a change in venous pressure, the technique can be used to measure compliance. Accurate measures of flow are needed. Serious errors can result if the inflow is not measured but is only assumed to be constant during the experimental protocol. With all methods dependent on measured or controlled flow, small changes in zero offset, which is directly or indirectly integrated, leads to serious error after about 10 min, and so the methods are not useful for long-term or slow responses.

58.3 Typical Values

Cardiac output, the sine qua non of the cardiovascular system, averages about 100 ml/(min-kg). It is about 90 in humans, is over 110 ml/(min-kg) in dogs and cats, and is even higher on a body weight basis in small animals such as rats and mice. The mean arterial blood pressure in relaxed, resting, conscious mammals averages about 90 mmHg. The mean circulatory filling pressure averages about 7 mmHg, and the central venous pressure just outside the right heart about 2 mmHg. The blood volume of the body is about 75 ml/kg, but in humans it is about 10% less, and it is larger in small animals. It is difficult to measure accurately because the volume of distribution of the plasma is about 10% higher than that of the red blood cells.

Vascular compliance averages about 2 ml (mmHg-kg body weight). The majority is in the venules and veins. Arterial compliance is only about 0.05 ml/mmHg-kg. Skeletal muscle compliance is less than that of the body as a whole, whereas the vascular compliance of the liver is about 10 times that of other organs. The stressed volume is the product of compliance and mean filling pressure and so is about 15 ml/kg. By difference, the unstressed volume is about 60 ml/kg.

As flow is increased through a tissue, the contained volume increases even if the outflow pressure is held constant, because there is a finite pressure drop across the veins which is increased as flow increases. This increase in upstream distending pressure acts to increase the contained blood volume. The volume sensitivity to flow averages about 0.1 ml per 1 ml/min change in flow [10]. For the body as a whole, the sensitivity is about 0.25 ml per 1 ml/min with reflexes blocked, and with reflexes intact it averages about 0.4 ml/min^3. Using similar techniques, it appears that the passive compensatory volume redistribution

from the peripheral toward the heart during serious left heart failure is similar in magnitude to a reflex-engendered redistribution from activation of venous smooth muscle [6].

The high-pressure carotid sinus baroreceptor reflex system is capable of changing the venous capacitance [9]. Over the full operating range of the reflex it is capable of mobilizing up to 7.5 ml/kg of blood by primarily changing the unstressed vascular volume with little or no changes in venous compliance [7,8]. Although this represents only a 10% change in blood volume, it can cause nearly a 100% change in cardiac output. It is difficult to say with confidence what particular organ and/or tissue is contributing to this blood volume mobilization. Current evidence suggests that the splanchnic vascular bed contributes significantly to the capacitance change, but this also may vary between species [11].

Roland N. Pittman
Medical College of Virginia

59.1 Introduction

The microcirculation is comprised of blood vessels (arterioles, capillaries, and venules) with diameters of less than approximately 150 μm. The importance of the microcirculation is underscored by the fact that most of the hydrodynamic resistance of the circulatory system lies in the microvessels (especially in arterioles) and most of the exchange of nutrients and waste products occurs at the level of the smallest microvessels. The subjects of microcirculatory research are blood flow and molecular transport in microvessels, mechanical interactions and molecular exchange between these vessels and the surrounding tissue, and regulation of blood flow and pressure and molecular transport. Quantitative knowledge of microcirculatory mechanics and mass transport has been accumulated primarily in the past 30 years owing to significant innovations in methods and techniques to measure microcirculatory parameters and methods to analyze microcirculatory data. The development of these methods has required joint efforts

59-1

of physiologists and biomedical engineers. Key innovations include significant improvements in intravital microscopy, the dual-slit method (Wayland–Johnson) for measuring velocity in microvessels, the servo-null method (Wiederhielm–Intaglietta) for measuring pressure in microvessels, the recessed oxygen microelectrode (Whalen) for polarographic measurements of partial pressure of oxygen, and the microspectrophotometric method (Pittman–Duling) for measuring oxyhemoglobin saturation in microvessels. The single-capillary cannulation method (Landis–Michel) has provided a powerful tool for studies of transport of water and solutes through the capillary endothelium. In the last decade, new experimental techniques have appeared, many adapted from cell biology and modified for *in vivo* studies, that are having a tremendous impact on the field. Examples include confocal and multiphoton microscopy for better three-dimensional resolution of microvascular structures, methods of optical imaging using fluorescent labels (e.g., labeling blood cells for velocity measurements) and fluorescent dyes (e.g., calcium ion and nitric oxide sensitive dyes for measuring their dynamics in vascular smooth muscle, endothelium, and surrounding tissue cells *in vivo*), development of sensors (glass filaments, optical and magnetic tweezers) for measuring forces in the nanonewton range that are characteristic of cell–cell interactions, phosphorescence decay measurements as an indicator of oxygen tension, and methods of manipulating receptors on the surfaces of blood cells and endothelial cells. In addition to the dramatic developments in experimental techniques, quantitative knowledge and understanding of the microcirculation have been significantly enhanced by theoretical studies, perhaps having a larger impact than in other areas of physiology. Extensive theoretical work has been conducted on the mechanics of the red blood cell (RBC) and leukocyte; mechanics of blood flow in single microvessels and microvascular networks, oxygen (O_2), carbon dioxide (CO_2), and nitric oxide (NO) exchange between microvessels and surrounding tissue; and water and solute transport through capillary endothelium and the surrounding tissue [1,2]. These theoretical studies not only aid in the interpretation of experimental data, but in many cases also serve as a framework for quantitative testing of working hypotheses and as a guide in designing and conducting further experiments. The accumulated knowledge has led to significant progress in our understanding of mechanisms of regulation of blood flow and molecular exchange in the microcirculation in many organs and tissues under a variety of physiological and pathological conditions (e.g., hypoxia, hypertension, sickle cell anemia, diabetes, inflammation, hemorrhage, ischemia/reperfusion, sepsis, cancer). Discussions are under way to organize the enormous amount of information on the microcirculation in the form of a database or a network of databases encompassing anatomical and functional data, and conceptual (pathway) and computational models. This effort is referred to as the Microcirculation Physiome Project, a subset of the Physiome Project [3].

The goal of this chapter is to give an overview of the current status of research on the systemic microcirculation. Issues of pulmonary microcirculation are not discussed. Because of space limitations, it is not possible to recognize numerous important contributions to the field of microcirculatory mechanics and mass transport. In most cases we refer to recent reviews, when available, and journal articles where earlier references can be found. We discuss experimental and theoretical findings and point out gaps in our understanding of microcirculatory flow phenomena.

59.2 Mechanics of Microvascular Blood Flow

Vessel dimensions in the microcirculation are small enough so that the effects of the particulate nature of blood are significant [2]. Blood is a suspension of formed elements (red blood cells, white blood cells [leukocytes], and platelets) in plasma. Plasma is an aqueous solution of mostly proteins (albumin, globulins, and fibrinogen) and electrolytes. Under static conditions, human RBCs are biconcave discs with a diameter of approximately 7–9 μm. The main function of the RBC is delivery of O_2 to tissue. Most of the O_2 carried by the blood is chemically bound to hemoglobin inside the RBCs. The mammalian RBC is comprised of a viscoelastic membrane filled with a viscous fluid, concentrated hemoglobin solution. The membrane consists of the plasma membrane and underlying cytoskeleton. The membrane can undergo deformations without changing its surface area, which is nearly conserved locally. RBCs are so easily deformable that they can flow through small pores with a diameter of <3 μm. Leukocytes (grouped into

several categories: granulocytes, monocytes, lymphocytes, macrophages, and phagocytes) are spherical cells with a diameter of approximately 10–20 μm. They are stiffer than RBCs. The main function of these cells is immunologic, that is, protection of the body against microorganisms causing disease. In contrast to mammalian RBCs, leukocytes are nucleated and are endowed with an internal structural cytoskeleton. Leukocytes are capable of active ameboid motion, the property which allows their migration from the blood stream into the tissue. Platelets are disc-shaped blood elements with diameter of approximately 2–3 μm. Platelets play a key role in thrombogenic processes and blood coagulation. The normal volume fraction of RBCs (hematocrit) in humans is 40–45%. The total volume of RBCs in blood is much greater than the volume of leukocytes and platelets. Rheological properties of blood in arterioles and venules and larger vessels are determined primarily by RBCs; however, leukocytes play an important mechanical role in capillaries and small venules.

Blood plasma is a Newtonian fluid with viscosity of approximately 1.2 cP. The viscosity of whole blood in a rotational viscometer or a large-bore capillary viscometer exhibits shear-thinning behavior, that is, viscosity decreases when shear rate increases. At shear rates >100 s^{-1} and a hematocrit of 40%, typical viscosity values are 3–4 cP. The dominant mechanism of the non-Newtonian behavior is RBC aggregation and the secondary mechanism is RBC deformation under shear forces. The cross-sectional distribution of RBCs in vessels is nonuniform, with a core of concentrated RBC suspension and a cell-free or cell-depleted marginal layer, typically 2–5 μm thick, adjacent to the vessel wall. The nonuniform RBC distribution results in the **Fahraeus effect** (the microvessel hematocrit is smaller than the feed or discharge hematocrit) due to the fact that, on the average, RBCs move with a higher velocity than blood plasma, and the concomitant **Fahraeus–Lindqvist effect** (the **apparent viscosity** of blood is lower than the bulk viscosity measured with a rotational viscometer or a large-bore capillary viscometer at a high shear rate). The **apparent viscosity** of a fluid flowing in a cylindrical vessel of radius R and length L under the influence of a pressure difference ΔP is defined as

$$\eta_a = \frac{\pi \Delta P R^4}{8QL}$$

where Q is the volumetric flow rate. For a Newtonian fluid the apparent viscosity becomes the dynamic viscosity of the fluid and the above equation represents **Poiseuille's Law**. The apparent viscosity is a function of hematocrit, vessel radius, blood flow rate, and other parameters. In the microcirculation, blood flows through a complex branching network of arterioles, capillaries, and venules. Arterioles are typically 10–150 μm in diameter, capillaries are 4–8 μm, and venules are 10–200 μm. Now we will discuss vascular wall mechanics and blood flow in vessels of different sizes in more detail.

59.2.1 Mechanics of the Microvascular Wall

The wall of arterioles is comprised of the intima that contains a single layer of contiguous endothelial cells, the media that contains a single layer of smooth muscle cells in terminal and medium-size arterioles or several layers in the larger arterioles, and the adventitia that contains collagen fibers with occasional fibroblasts and mast cells. Fibers situated between the endothelium and the smooth muscle cells comprise the basement membrane. The single layer of smooth muscle cells terminates at the capillaries and reappears at the level of small venules; the capillary wall is devoid of smooth muscle cells. Venules typically have a larger diameter and smaller wall thickness-to-diameter ratio than arterioles of the corresponding branching order.

Most of our knowledge of the mechanics of the microvascular wall comes from *in vivo* or *in vitro* measurements of vessel diameter as a function of transmural pressure [4]. Development of isolated microvessel preparations has made it possible to precisely control the transmural pressure during experiments. In addition, these preparations allow one to separate the effects of metabolic factors and blood flow rate from the effect of pressure by controlling both the chemical environment and the flow rate through the vessel. Arterioles and venules exhibit vascular tone, that is, their diameter is maximal when smooth muscle is completely relaxed (inactivated). When the vascular smooth muscle is constricted, small arterioles may

even completely close their lumen to blood flow, presumably by buckling endothelial cells. Arterioles exhibit a **myogenic response** not observed in other blood vessels, with the exception of cerebral arteries: within a certain physiological pressure range the vessels constrict in response to elevation of transmural pressure and dilate in response to reduction of transmural pressure; in other words, in a certain range of pressures the slope of the pressure–diameter relationship is negative. Arterioles of different size exhibit different degrees of myogenic responsiveness. This effect has been documented in many tissues both *in vivo* and *in vitro* (in isolated arterioles) and has been shown to play an important role in regulation of blood flow and capillary pressure (see the section on Regulation of Blood Flow below).

The stress–strain relationship for a thin-walled microvessel can be derived from the experimentally obtained pressure–diameter relationship using the Law of Laplace. Stress in the vessel wall can be decomposed into passive and active components. The passive component corresponds to the state of complete vasodilation. The active component determines the vascular tone and the myogenic response. Steady-state stress–strain relationships are, generally, nonlinear. For arterioles, diameter variations of 50% or even 100% under physiological conditions are not unusual, so that finite deformations have to be considered in formulating the constitutive relationship for the wall (relationship between stress, strain, and their temporal derivatives). Pertinent to the question of microvascular mechanics is the mechanical interaction of a vessel with its environment, which consists of connective tissue, parenchymal cells, and extracellular fluid. There is ultrastructural evidence that blood vessels are tethered to the surrounding tissue, so that mechanical forces can be generated when the vessels constrict or dilate, or when the tissue is moving, for example, in contracting striated muscle, myocardium, or intestine. Little quantitative information is currently available about the magnitude of these forces, chiefly because of the difficulty of such measurements. Magnetic tweezers make it possible to probe the mechanics of the microvascular wall *in vivo* and its interaction with the surrounding tissue [5].

Under time-dependent conditions microvessels exhibit viscoelastic behavior. In response to a stepwise change in the transmural pressure, arterioles typically respond with a fast "passive" change in diameter followed by a slow "active" response with a characteristic time of the order of tens of seconds. For example, when the pressure is suddenly increased, the vessel diameter will quickly increase, with subsequent vasoconstriction that may result in a lower value of steady-state diameter than that prior to the increase in pressure. Therefore, to accurately describe the time-dependent vessel behavior, the constitutive relationship between stress and strain or pressure and diameter must also contain temporal derivatives of these variables. Theoretical analysis of the resulting nonlinear equations shows that such constitutive equations lead to predictions of spontaneous oscillations of vessel diameter (**vasomotion**) under certain conditions [6,7]. Theoretical analysis of Ca^{2+} oscillations in vascular smooth muscle cells also predicts spontaneous oscillations [8]. Vasomotion has been observed *in vivo* in various tissues and under various physiological conditions. Whether experimentally observed vasomotion and its effect on blood flow (flow motion) can be quantitatively described by the theoretical studies remains to be established. It should be noted that other mechanisms leading to spontaneous flow oscillations have been reported that are associated with blood rheology and not with vascular wall mechanics [9,10].

For most purposes, capillary compliance is not taken into account. However, in some situations, such as analysis of certain capillary water transport experiments or leukocyte motion in a capillary, this view is not adequate and capillary compliance has to be accounted for. Since the capillary wall is devoid of smooth muscle cells, much of this compliance is passive, and its magnitude is small. However, the presence of contractile proteins in the cytoskeleton of capillary endothelial cells and associated pericytes opens a possibility of active capillary constriction or dilation.

59.2.2 Capillary Blood Flow

Progress in this area is closely related to studies of mechanics of blood cells described elsewhere in this book. In narrow capillaries, RBCs flow in single file, separated by gaps of plasma. They deform and assume a parachute-like shape, generally non-axisymmetric, leaving a submicron plasma sleeve between the RBC and endothelium. In the smallest capillaries, their shape is sausage-like. The hemoglobin

solution inside an RBC is a Newtonian fluid. The constitutive relationship for the membrane is accurately expressed by the Evans–Skalak finite-deformations model; molecular-based models considering spectrin, actin, and other RBC cytoskeleton constituents have also been formulated [11]. The coupled mechanical problem of membrane and fluid motion has been extensively investigated using both analytical and numerical approaches [12]. An important result of the theoretical studies is the prediction of the apparent viscosity of blood. While these predictions are in good agreement with *in vitro* studies in glass tubes, they underestimate a few available *in vivo* capillary measurements of apparent viscosity. In addition, *in vivo* capillary hematocrit in some tissues is lower than predicted from *in vitro* studies with tubes of the same size. To explain the low values of hematocrit, RBC interactions with the endothelial glycocalyx have been implicated [13]. Recent direct measurements of microvascular resistance and theoretical analyses provide further evidence of the role of the glycocalyx [14,15].

The motion of leukocytes through blood capillaries has also been studied thoroughly in recent years. Because leukocytes are larger and stiffer than RBCs, under normal flow conditions an increase in capillary resistance caused by a single leukocyte may be orders of magnitude greater than that caused by a single RBC [16]. Under certain conditions, flow stoppage may occur caused by leukocyte plugging. After a period of ischemia, red blood cell and leukocyte plugging may prevent tissue reperfusion (ischemia-reperfusion injury) [17]. Chemical bonds between membrane-bound receptors and endothelial adhesion molecules play a crucial role in leukocyte–endothelium interactions. Methods of cell and molecular biology permit manipulation of the receptors and thus make it possible to study leukocyte microcirculatory mechanics at the molecular level. More generally, methods of cell and molecular biology open new and powerful ways to study cell micromechanics and cell–cell interactions.

59.2.3   Arteriolar and Venular Blood Flow

The cross-sectional distribution of RBCs in arterioles and venules is nonuniform. A concentrated suspension of RBCs forms a core surrounded by a cell-free or cell-depleted layer of plasma. This "lubrication" layer of lower viscosity fluid near the vessel wall results in lower values of the apparent viscosity of blood compared to its bulk viscosity, resulting in the Fahraeus–Lindqvist effect [2,18]. There is experimental evidence that velocity profiles of RBCs are generally symmetric in arterioles, except very close to vascular bifurcations, but may be asymmetric in venules; the profiles are close to parabolic in arterioles at normal flow rates, but are blunted in venules [19,20]. Moreover, flow in the venules may be stratified as the result of converging blood streams that do not mix rapidly. The key to understanding the pattern of arteriolar and venular blood flow is the mechanics of flow at vascular bifurcations, diverging for arteriolar flow and converging for venular flow [21]. An important question is under what physiological or pathological conditions does RBC aggregation affect arteriolar and venular velocity distribution and vascular resistance. Much is known about aggregation *in vitro*, but *in vivo* knowledge is incomplete [2,18,22,23].

Problems of leukocyte distribution in the microcirculation and their interaction with the microvascular endothelium have attracted considerable attention in recent years [17]. Leukocyte rolling along the walls of venules, but not arterioles, has been demonstrated. This effect results from differences in the microvascular endothelium, mainly attributed to the differential expression of adhesion molecules on the endothelial surface [24]. Platelet distribution in the lumen is important because of platelets' role in blood coagulation. Detailed studies of platelet distribution in arterioles and venules show that the cross-sectional distribution of these disk-shaped blood elements is dependent on the blood flow rate and vessel hematocrit [25]; molecular details of platelet–endothelium interactions are available [26]. Considerable progress has been made in computational modeling of leukocytes in microvessels and their interaction with red blood cells [27–29].

To conclude, many important features of blood flow through arterioles and venules are qualitatively known and understood; however, a rigorous theoretical description of flow as a suspension of discrete particles is not yet available. Such description is necessary for a quantitative understanding of the mechanisms of the nonuniform distribution of blood cells in microvessels.

59.2.4 Microvascular Networks: Structure and Hemodynamics

Microvascular networks in different organs and tissues differ in their appearance and structural organization. Methods have been developed to quantitatively describe network architectonics and hemodynamics [30]. The microvasculature is an adaptable structure capable of changing its structural and functional characteristics in response to various stimuli [31]. **Angiogenesis**, rarefaction, and microvascular remodeling are important examples of this adaptive behavior that play important physiological and pathophysiological roles. Methods of fractal analysis have been applied to interpret experimental data on angioarchitecture and blood flow distribution in the microcirculation; these methods explore the property of geometrical and flow similarity that exist at different scales in the network [32]. Microvascular hydraulic pressure varies systematically between consecutive branching orders, decreasing from the systemic values down to 20–25 mmHg in the capillaries and decreasing further by 10–15 mmHg in the venules. Mean microvascular blood flow rate in arterioles decreases toward the capillaries, in inverse proportion to the number of "parallel" vessels, and increases from capillaries through the venules. In addition to this longitudinal variation of blood flow and pressure among different branching orders, there are significant variations among vessels of the same branching order, referred to as flow heterogeneity. The heterogeneity of blood flow and RBC distribution in microvascular networks has been well-documented in a variety of organs and tissues. This phenomenon may have important implications for tissue exchange processes, so significant efforts have been devoted to the quantitative analysis of blood flow in microvascular networks. A mathematical model of blood flow in a network can be formulated as follows: First, network topology or vessel interconnections have to be specified. Second, the diameter and length of every vascular segment have to be known. Alternatively, vessel diameter can be specified as a function of transmural pressure and perhaps some other parameters; these relationships are discussed in the preceding section on wall mechanics. Third, the apparent viscosity of blood has to be specified as a function of vessel diameter, local hematocrit, and shear rate. Fourth, a relationship between RBC flow rates and bulk blood flow rates at diverging bifurcations has to be specified; this relationship is often referred to as the "bifurcation law." Finally, at the inlet vessel branches boundary conditions have to be specified: bulk flow rate as well as RBC flow rate or hematocrit; alternatively, pressure can be specified at both inlet and outlet branches. This set of generally nonlinear equations can be solved to yield pressure at each bifurcation, blood flow rate through each segment, and discharge or microvessel hematocrit in each segment. These equations also predict vessel diameters if vessel compliance is taken into account. The calculated variables can then be compared with experimental data. Such a detailed comparison was reported for rat mesentery [30]. The authors found a good agreement between theoretical and experimental data when histograms of parameter distributions were compared, but poor agreement, particularly for vessel hematocrit, when comparison was done on a vessel-by-vessel basis. In these calculations, the expression for apparent viscosity was taken from *in vitro* experiments. The agreement was improved when the apparent viscosity was increased substantially from its *in vitro* values, particularly in the smallest vessels. Thus, a working hypothesis was put forward that *in vivo* apparent viscosity in small vessels is higher than the corresponding *in vitro* viscosity in glass tubes. Recent experimental and theoretical studies support this hypothesis and attribute the difference to the effect of the endothelial glycocalyx and its associated macromolecules, which are often referred to, collectively, as the endothelial surface layer (ESL) [14]. The ESL appears to be exquisitely controlled, and it is affected by a variety of biochemical and mechanical factors [33,34].

59.3 Molecular Transport in the Microcirculation

59.3.1 Transport of Oxygen, Carbon Dioxide, and Nitric Oxide

One of the most important functions of the microcirculation is the delivery of O_2 to tissue and the removal of waste products, particularly of CO_2, from tissue. O_2 is required for aerobic intracellular respiration for the production of adenosine triphosphate (ATP). CO_2 is produced as a by-product of these biochemical reactions. Tissue metabolic rate can change drastically, for example, in aerobic muscle in the transition

from rest to exercise, which necessitates commensurate changes in blood flow and O_2 delivery. One of the major issues studied is how O_2 delivery is matched to O_2 demand under different physiological and pathological conditions. This question arises for short-term or long-term regulation of O_2 delivery in an individual organism, organ, or tissue, as well as in the evolutionary sense, in phylogeny. The hypothesis of symmorphosis, a fundamental balance between structure and function, has been formulated for the respiratory and cardiovascular systems and tested in a number of animal species [35].

In the smallest exchange vessels (capillaries and small arterioles and venules), O_2 molecules are released from hemoglobin inside RBCs, diffuse through the plasma, cross the endothelium, the extravascular space, and parenchymal cells until they reach mitochondria where they are utilized in the process of oxidative phosphorylation. The nonlinear relationship between hemoglobin saturation with O_2 and the local O_2 tension (PO_2) is described by the **oxyhemoglobin dissociation curve** (ODC). The theory of O_2 transport from capillaries to tissue was conceptually formulated by August Krogh in 1918 and it has dominated the thinking of physiologists for eight decades. The model he formulated considered a cylindrical tissue volume supplied by a single central capillary; this element was considered the building block for the entire tissue. A constant metabolic rate was assumed and PO_2 at the capillary–tissue interface was specified. The solution to the corresponding transport equation is the Krogh–Erlang equation describing the radial variation of O_2 tension in tissue. Over the years, the **Krogh Tissue Cylinder model** has been modified by many investigators to include transport processes in the capillary and PO_2-dependent consumption. However, in the past few years new conceptual models of O_2 transport have emerged. First, it was discovered experimentally and subsequently corroborated by theoretical analysis that capillaries are not the only source of oxygen, but arterioles (**precapillary O_2 transport**) and to a smaller extent venules (postcapillary O_2 transport), also participate in tissue oxygenation; in fact, a complex pattern of O_2 exchange may exist among arterioles, venules and adjacent capillary networks [36,37]. Second, theoretical analysis of intracapillary transport suggested that a significant part of the resistance to O_2 transport, on the order of 50%, is located within the capillary, primarily due to poor diffusive conductance of the plasma gaps between the erythrocytes. Third, the effect of **myoglobin-facilitated O_2 diffusion** in red muscle fibers and cardiac myocytes has been re-evaluated, however, its significance must await additional experimental studies. Fourth, geometric and hemodynamic heterogeneities in O_2 delivery have been quantified experimentally and modeled theoretically. Theoretical analyses of oxygen transport have been applied to a variety of tissues and organs [38–40]. One important emerging area of application of this knowledge is artificial oxygen carriers, hemoglobin-based and nonhemoglobin-based [41].

Transport of CO_2 is coupled to O_2 through the Bohr effect (effect of CO_2 tension on the blood O_2 content) and the Haldane effect (effect of PO_2 on the blood CO_2 content). Diffusion of CO_2 is faster than that of O_2 because CO_2 solubility in tissue is higher; theoretical studies predict that countercurrent exchange of CO_2 between arterioles and venules is of major importance so that equilibration of CO_2 tension with surrounding tissue should occur before capillaries are reached. Experiments are needed to test these theoretical predictions.

Nitric oxide (NO) is a diatomic gas that is enzymatically synthesized from L-arginine by several isoforms of NO synthase (NOS). The isoforms of NO synthase are divided into inducible NOS (iNOS or NOS2) and constitutive NOS (cNOS), based on their nondependent and dependent, respectively, control of activity from intracellular calcium/calmodulin. Constitutive NOS are further classified as neuronal NOS (nNOS or NOS1) and endothelial NOS (eNOS or NOS3). Nitric oxide plays an important role in both autocrine and paracrine manners in a myriad of physiological processes including regulation of blood pressure and blood flow, platelet aggregation and leukocyte adhesion. In smooth muscle cells, NO activates the enzyme soluble guanylate cyclase (sGC) that catalyzes the conversion of guanosine triphosphate (GTP) to cyclic guanosine monophosphate (cGMP), thus causing vasodilation [42]. Traditionally, eNOS has been considered the principal source of bioavailable microvascular NO under most physiological conditions. Evidence is mounting that nNOS expressed in nerve fibers, which innervate arterioles, together with nNOS positive mast cells are also major sources of NO [43]. NO produced by endothelial cells diffuses to vascular smooth muscle and to the flowing blood, where it rapidly reacts with hemoglobin in RBCs and free hemoglobin present in pathological conditions, such as sickle cell disease, or during administration of free

hemoglobin as a blood substitute. Other non-neuronal cell types, including cardiac and skeletal myocytes, also express nNOS. Direct measurements of NO concentration in the microcirculation with high spatial resolution have been performed with porphyrinic-based microsensors and optical dyes. Mathematical models of NO transport have been developed that describe the transport of NO synthesized by eNOS and nNOS in and around microvessels [44–50]. In addition to the mechanism of free diffusion of NO, another mechanism has been proposed and is under intense scrutiny whereby NO reacts with thiols in blood to form long-lived *S*-nitrosothiols (SNOs) with vasodilatory activity [51]. No theoretical work has been attempted to simulate this mechanism.

59.3.2   Transport of Solutes and Water

The movement of solute molecules across the capillary wall occurs primarily by two mechanisms: diffusion and solvent drag. Diffusion is the passive mechanism of transport that rapidly and efficiently transports small solutes over the small distances (tens of microns) between the blood supply (capillaries) and tissue cells. Solvent drag refers to the movement of solute that is entrained in the bulk flow of fluid across the capillary wall and is generally negligible, except in cases of large molecules with small diffusivities and high transcapillary fluid flow.

The capillary wall is composed of a single layer of endothelial cells about l μm thick. Lipid soluble substances (e.g., O_2) can diffuse across the entire wall surface, whereas water soluble substances are restricted to small aqueous pathways equivalent to cylindrical pores 8 to 9 nm in diameter (e.g., glucose in most capillaries; in capillaries with tight junctions and few fenestrations (brain, testes), glucose is predominantly transported). Total pore area is about 0.1% of the surface area of a capillary. The permeability of the capillary wall to a particular substance depends upon the relative size of the substance and the pore ("restricted" diffusion). The efficiency of diffusive exchange can be increased by increasing the number of perfused capillaries (e.g., heart and muscle tissue from rest to exercise), since this increases the surface area available for exchange and decreases the distances across which molecules must diffuse.

The actual pathways through which small solutes traverse the capillary wall appear to be in the form of clefts between adjacent endothelial cells. Rather than being open slits, these porous channels contain a matrix of small cylindrical fibers (primarily glycosaminoglycans) that occupy about 5% of the volume of these pathways. The permeability properties of the capillary endothelium are modulated by a number of factors, among which are plasma protein concentration and composition, rearrangement of the endothelial cell glycocalyx, calcium influx into the endothelial cell, and endothelial cell membrane potential. Many of the studies that have established our current understanding of the endothelial exchange barrier have been carried out on single perfused capillaries in the frog and in mammalian tissues [52,53]. There could be, in addition to the porous pathways, nonporous pathways that involve selective uptake of solutes and subsequent transcellular transport (of particular importance in endothelium barriers). In order to study such pathways, one must try to minimize the contributions to transcapillary transport from solvent drag.

The processes whereby water passes back and forth across the capillary wall are called filtration and absorption. The flow of water depends upon the relative magnitude of hydraulic and osmotic pressures across the capillary wall and is described quantitatively by the Kedem–Katchalsky equations (the particular form of the equations applied to capillary water transport is referred to as **Starling's Law**). Recently, the physical mechanism of Starling's Law has been re-assessed [54]. Overall, in the steady state there is an approximate balance between hydraulic and osmotic pressures which leads to a small net flow of water. Generally, more fluid is filtered than is reabsorbed; the overflow is carried back to the vascular system by the lymphatic circulation. The lymphatic network is composed of a large number of small vessels, the terminal branches of which are closed. Flap valves (similar to those in veins) ensure unidirectional flow of lymph back to the central circulation. The smallest (terminal) vessels are very permeable, even to proteins that occasionally leak from systemic capillaries. Lymph flow is determined by interstitial fluid pressure and the lymphatic "pump" (oneway flap valves and skeletal muscle contraction). Control of interstitial fluid protein concentration is one of the most important functions of the lymphatic system. If more net fluid is filtered than can be removed by the lymphatics, the volume of interstitial fluid increases.

This fluid accumulation is called edema. This circumstance is important clinically since solute exchange (e.g., O_2) decreases due to the increased diffusion distances produced when the accumulated fluid pushes the capillaries, tethered to the interstitial matrix, away from each other.

59.4 Regulation of Blood Flow

The cardiovascular system controls blood flow to individual organs (1) by maintaining arterial pressure within narrow limits and (2) by allowing each organ to adjust its vascular resistance to blood flow so that each receives an appropriate fraction of the cardiac output. There are three major mechanisms that control the function of the cardiovascular system: neural, humoral, and local [55]. The sympathetic nervous system and circulating hormones both provide overall vasoregulation, and thus coarse flow control, to all vascular beds. The local mechanisms provide finer regional control within a tissue, usually in response to local changes in tissue activity or local trauma. The three mechanisms can work independently of each other, but there are also interactions among them.

The classical view of blood flow control involved the action of vasomotor influences on a set of vessels called the "resistance vessels," generally arterioles and small arteries smaller than about 100 to 150 μm in diameter, which controlled flow to and within an organ [56]. The notion of "precapillary sphincters" that control flow in individual capillaries has been abandoned in favor of the current notion that the terminal arterioles control the flow in small capillary networks that branch off of these arterioles. In recent years, it has become clear that the resistance to blood flow is distributed over a wider range of vessel branching orders with diameters up to 500 μm. There are mechanisms to be discussed in Section 59.4.2 that are available for coordinating the actions of local control processes over wider regions.

59.4.1 Neurohumoral Regulation of Blood Flow

The role of neural influences on the vasculature varies greatly from organ to organ. Although all organs receive sympathetic innervation, regulation of blood flow in the cerebral and coronary vascular beds occurs mostly through intrinsic local (metabolic) mechanisms. The circulations in skeletal muscle, skin, and some other organs, however, are significantly affected by the sympathetic nerves. In general, the level of intrinsic myogenic activity and sympathetic discharge sets the state of vascular smooth muscle contraction (basal vascular tone) and hence vascular resistance in organs. This basal tone is modulated by circulating and local vasoactive influences, for example, endothelium-derived relaxing factor (EDRF), identified as nitric oxide, endothelium-derived hyperpolarizing factor (EDHF) [57], prostacyclin (PGI_2), endothelin, and vasoactive substances released from parenchymal cells.

59.4.2 Local Regulation of Blood Flow

In addition to neural and humoral mechanisms for regulating the function of the cardiovascular system, there are mechanisms intrinsic to the various tissues that can operate independently of neurohumoral influences. The site of local regulation is the microcirculation. Examples of local control processes are autoregulation of blood flow, reactive hyperemia, and active (or functional) hyperemia. The mechanisms of local regulation have been identified as (1) the myogenic mechanism based on the ability of vascular smooth muscle to actively contract in response to stretch; (2) the metabolic mechanism, based on a link between blood flow and tissue metabolism; (3) the flow-dependent mechanism, primarily based on the release of NO by endothelial cells in response to shear forces. The effects are coordinated and integrated in the microvascular network via chemical and electrical signals propagating through gap junctions. Experimental evidence and theoretical models are discussed in [55,56,58–60].

Cells have a continuous need for O_2 and also continuously produce metabolic wastes, some of which are vasoactive (usually vasodilators). Under normal conditions there is a balance between O_2 supply and demand, but imbalances give rise to adjustments in blood flow that bring supply back into register with demand. Consider exercising skeletal muscle as an example. With the onset of exercise, metabolite

production and O_2 requirements increase. The metabolites diffuse away from their sites of production and reach the vasculature. Vasodilation ensues, lowering resistance to blood flow. The resulting increase in blood flow increases the O_2 supply and finally a new steady state is achieved in which O_2 supply and demand are matched. This scenario operates for other tissues in which metabolic activity changes.

The following O_2-linked metabolites have been implicated as potential chemical mediators in the metabolic hypothesis: adenosine (from ATP hydrolysis: ATP $\rightarrow$ ADP $\rightarrow$ AMP $\rightarrow$ adenosine), H^+, and lactate (from lactic acid generated by glycolysis). Their levels are increased when there is a reduction in O_2 supply relative to demand (i.e., tissue hypoxia). The production of more CO_2 as a result of increased tissue activity (leading to increased oxidative metabolism) leads to vasodilation through increased H^+ concentration. Increased potassium ion and interstitial fluid osmolarity (i.e., more osmotically active particles) transiently cause vasodilation under physiological conditions associated with increased tissue activity.

It has also been established that the RBC itself could act as a mobile sensor for hypoxia [61]. The mechanism works as follows: Under conditions of low oxygen and pH, the RBC releases ATP, which binds to purinergic receptors on the endothelial cells. This leads to the production in the endothelial cells of the vasodilator NO. Since the most likely location for hypoxia would be in or near the venular network, the local vasodilatory response to NO is propagated to upstream vessels causing arteriolar vasodilation (see the following section on Coordination of Vasomotor Responses).

59.4.3 Coordination of Vasomotor Responses

Communication via gap junctions between the two active cell types in the blood vessel wall, smooth muscle, and endothelial cells plays an important role in coordinating the responses among resistance elements in the vascular network [55,56,62]. There is chemical and electrical coupling between the cells of the vessel wall, and this signal, in response to locally released vasoactive substances (e.g., from vessel wall, RBCs or parenchymal cells), can travel along a vessel in either direction with a length constant of about 2 mm. There are two immediate consequences of this communication. A localized vasodilatory stimulus of metabolic origin will be propagated to contiguous vessels, thereby lowering the resistance to blood flow in a larger region. In addition, this more generalized vasodilation should increase the homogeneity of blood flow in response to the localized metabolic event. The increase in blood flow produced as a result of this vasodilation will cause flow as well to increase at upstream sites. The increased shear stress on the endothelium as a result of the flow increase will lead to vasodilation of these larger upstream vessels. Thus, the neurohumoral and local responses are linked together in a complex control system that matches regional perfusion to the local metabolic needs.

59.4.4 Angiogenesis and Vascular Remodeling

In addition to short-term regulation of blood flow operating on the timescale of tens of seconds to minutes, there are mechanisms that operate on the scales of hours, days, and weeks that result in angiogenesis (capillary growth from the preexisting microvessels) and microvascular remodeling or adaptation (structural and geometric changes in the vascular wall) [31]. Stimuli for angiogenesis and microvascular remodeling could be hypoxia, injury, inflammation, or neoplasia. The processes of angiogenesis and vascular remodeling are complex and knowledge at the molecular, cellular, and tissue level is being accumulated at a fast rate. Briefly, it is understood that low cellular oxygen is sensed through a transcription factor HIF1 (Hypoxia-Inducible Factor) pathway, leading to activation of dozens of genes [63]. Among them is vascular endothelial growth factor (VEGF) — one of the most potent inducers of angiogenesis. VEGF is secreted by parenchymal and stromal cells and diffuses through the extracellular space. Once it reaches endothelial cells, it activates them causing hyperpermeability and expression of metalloproteinases (MMPs) that then participate in the proteolysis of the extracellular matrix. The activated endothelial cells migrate, proliferate, and differentiate, resulting in the formation of a capillary sprout. Subsequently, the endothelial cells

secrete platelet-derived growth factor (PDGF) that participates in recruiting stromal fibroblasts and progenitor cells to the new capillaries. When these cells reach the vessels, they differentiate into pericytes and smooth muscle cells, thus stabilizing the vessels. Many of these processes are poorly understood. At this point, quantitative computational approaches are particularly useful in gaining a better understanding of these processes; research in this area is rapidly evolving [60,64–66].

Defining Terms

Angiogenesis: The growth of new capillaries from the preexisting microvessels.

Apparent viscosity: The viscosity of a Newtonian fluid that would require the same pressure difference to produce the same blood flow rate through a circular vessel as the blood.

Fahraeus effect: Microvessel hematocrit is smaller than hematocrit in the feed or discharge reservoir.

Fahraeus–Lindqvist effect: Apparent viscosity of blood in a microvessel is smaller than the bulk viscosity measured with a rotational viscometer or a large-bore capillary viscometer.

Krogh tissue cylinder model: A cylindrical volume of tissue supplied by a central cylindrical capillary.

Myogenic response: Vasoconstriction in response to elevated transmural pressure and vasodilation in response to reduced transmural pressure.

Myoglobin-facilitated O_2 diffusion: An increase of O_2 diffusive flux as a result of myoglobin molecules acting as a carrier for O_2 molecules.

Oxyhemoglobin dissociation curve: The equilibrium relationship between hemoglobin saturation and O_2 tension.

Poiseuille's Law: The relationship between volumetric flow rate and pressure difference for steady flow of a Newtonian fluid in a long circular tube.

Precapillary O_2 transport: O_2 diffusion from arterioles to the surrounding tissue.

Starling's Law: The relationship between water flux through the endothelium and the difference between the hydraulic and osmotic transmural pressures.

Vasomotion: Spontaneous rhythmic variation of microvessel diameter.

Mechanics and Deformability of Hematocytes

Richard E. Waugh
University of Rochester Medical Center

Robert M. Hochmuth
Duke University

60.1 Introduction

The term hematocytes refers to the circulating cells of the blood. These are divided into two main classes: erythrocytes, or red cells, and leukocytes, or white cells. In addition to these there are specialized cell-like structures called platelets. The mechanical properties of these cells are of special interest because of their physiological role as circulating corpuscles in the flowing blood. The importance of the mechanical properties of these cells and their influence on blood flow is evident in a number of hematological pathologies. The properties of the two main types of hematocytes are distinctly different. The essential character of a red cell is that of an elastic bag enclosing a Newtonian fluid of comparatively low viscosity. The essential behavior of white cells is that of a highly viscous fluid drop with a more or less constant cortical (surface) tension. Under the action of a given force, red cells deform much more readily than white cells. In this chapter we focus on descriptions of the behavior of the two cell types separately, concentrating on the viscoelastic characteristics of the red cell membrane, and the fluid characteristics of the white cell cytosol.

60.2 Fundamentals

60.2.1 Stresses and Strains in Two Dimensions

The description of the mechanical deformation of the membrane is cast in terms of principal **force resultants** and **principal extension ratios** of the surface. The force resultants, like conventional three-dimensional strains, are generally expressed in terms of a tensorial quantity, the components of which depend on coordinate rotation. For the purposes of describing the constitutive behavior of the surface, it is convenient to express the surface resultants in terms of rotationally invariant quantities. These can be either the principal force resultants N_1 and N_2, or the isotropic resultant $\bar{N}$ and the maximum shear resultant N_s. The surface strain is also a tensorial quantity, but may be expressed in terms of the principal extension ratios of the surface λ_1 and λ_2. The rate of surface shear deformation is given by [Evans and Skalak, 1979]:

$$V_s = \left(\frac{\lambda_1}{\lambda_2}\right)^{1/2} \frac{d}{dt}\left(\frac{\lambda_1}{\lambda_2}\right)^{1/2} \tag{60.1}$$

The membrane deformation is calculated from observed macroscopic changes in cell geometry, usually with the use of simple geometric shapes to approximate the cell shape. The membrane force resultants are calculated from force balance relationships. For example, in the determination of the **area expansivity modulus** of the red cell membrane or the **cortical tension** in neutrophils, the force resultants in the plane of the membrane of the red cell or the cortex of the white cell are isotropic. In this case, as long as the membrane surface of the cell does not stick to the pipette, the membrane force resultant can be calculated from the law of Laplace:

$$\Delta P = 2\bar{N}\left(\frac{1}{R_p} - \frac{1}{R_c}\right) \tag{60.2}$$

where R_p is the radius of the pipette, R_c is the radius of the spherical portion of the cell outside the pipette, $\bar{N}$ is the isotropic force resultant (tension) in the membrane, and ΔP is the aspiration pressure in the pipette.

60.2.2 Basic Equations for Newtonian Fluid Flow

The constitutive relations for fluid flow in a sphere undergoing axisymmetric deformation can be written:

$$\sigma_{rr} = -p + 2\eta \frac{\partial V_r}{\partial r} \tag{60.3}$$

$$\sigma_{r\theta} = \eta\left[\frac{1}{r}\frac{\partial V_r}{\partial \theta} + r\frac{\partial}{\partial r}\left(\frac{V_\theta}{r}\right)\right] \tag{60.4}$$

where σ_{rr} and $\sigma_{r\theta}$ are components of the stress tensor, p is the hydrostatic pressure, r is the radial coordinate, θ is the angular coordinate in the direction of the axis of symmetry in spherical coordinates, and V_r and V_θ are components of the fluid velocity vector. These equations effectively define the material viscosity, η. In general, η may be a function of the strain rate. The second term in Equation 60.3 contains the radial strain rate $\dot{\varepsilon}_{rr}$ and the bracketed term in Equation 60.4 corresponds to $\dot{\varepsilon}_{r\theta}$. For the purposes of evaluating this dependence, it is convenient to define the mean shear rate $\dot{\gamma}_m$ averaged over the cell volume and duration of the deformation process t_e:

$$\dot{\gamma}_m = \left(\frac{3}{4}\frac{1}{t_e}\int_0^{t_e}\int_0^{R(t)}\int_0^{\pi}\frac{r^2}{R^3}\left(\dot{\varepsilon}_{ij}\dot{\varepsilon}_{ij}\right)\sin\theta\, d\theta\, dr\, dt\right)^{1/2} \tag{60.5}$$

where repeated indices indicate summation.

60.3 Red Cells

60.3.1 Size and Shape

The normal red cell is a biconcave disk at rest. The average human cell is approximately 7.7 μm in diameter and varies in thickness from $\sim$2.8 μm at the rim to $\sim$1.4 μm at the center [Fung et al., 1981]. However, red cells vary considerably in size even within a single individual. The mean surface area is $\sim$130 μm^2 and the mean volume is 98 μm^3 (Table 60.1), but the range of sizes within a population is Gausian distributed with standard deviations of $\sim$15.8 μm^2 for the area and $\sim$16.1 μm^3 for the volume [Fung et al., 1981]. Cells from different species vary enormously in size, and tables for different species have been tabulated elsewhere [Hawkey et al., 1991].

Red cell deformation takes place under two important constraints: fixed surface area and fixed volume. The constraint of fixed volume arises from the impermeability of the membrane to cations. Even though the membrane is highly permeable to water, the inability of salts to cross the membrane prevents significant water loss because of the requirement for colloidal osmotic equilibrium [Lew and Bookchin, 1986]. The constraint of fixed surface area arises from the large resistance of bilayer membranes to changes in area per molecule [Needham and Nunn, 1990]. These two constraints place strict limits on the kinds of deformations that the cell can undergo and the size of the aperture that the cell can negotiate. Thus, a major determinant of red cell deformability is its ratio of surface area to volume. One measure of this parameter is the *sphericity*, defined as the dimensionless ratio of the two-thirds power of the cell volume to the cell area times a constant that makes its maximum value 1.0:

$$S = \frac{4\pi}{(4\pi/3)^{2/3}} \cdot \frac{V^{2/3}}{A} \tag{60.6}$$

The mean value of sphericity of a normal population of cells was measured by interference microscopy to be 0.79 with a standard deviation (S.D.) of 0.05 at room temperature [Fung et al., 1981]. Similar values were obtained using micropipettes: mean = 0.81, S.D. = 0.02 [Waugh and Agre, 1988]. The membrane area increases with temperature, and the membrane volume decreases with temperature, so the sphericity at physiological temperature is expected to be somewhat smaller. Based on measurements of the thermal area expansivity of 0.12%/°C [Waugh and Evans, 1979], and a change in volume of −0.14%/°C [Waugh and Evans, 1979], the mean sphericity at 37°C is estimated to be 0.76 to 0.78 (see Table 60.1).

60.3.2 Red Cell Cytosol

The interior of a red cell is a concentrated solution of hemoglobin, the oxygen-carrying protein, and it behaves as a Newtonian fluid [Cokelet and Meiselman, 1968]. In a normal population of cells there is a distribution of hemoglobin concentrations in the range 29 to 39 g/dl. The viscosity of the cytosol depends

TABLE 60.1 Parameter Values for a Typical
Red Blood Cell (37°C)

Area	132 μm^2
Volume	96 μm^3
Sphericity	0.77
Membrane area modulus	400 mN/m
Membrane shear modulus	0.006 mN/m
Membrane viscosity	0.00036 mN sec/m
Membrane bending stiffness	0.2×10^{-18} J
Thermal area expansivity	0.12%/°C
$\dfrac{1}{V}\dfrac{dV}{dT}$	−0.14%/°C

TABLE 60.2 Viscosity of Red Cell Cytosol (37°C)

Hemoglobin concentration (g/l)	Measured viscosity[1] (mPa sec)	Best fit viscosity[2] (mPa sec)
290	4.1–5.0	4.2
310	5.2–6.6	5.3
330	6.6–9.2	6.7
350	8.5–13.0	8.9

on the hemoglobin concentration as well as temperature (see Table 60.2). Based on theoretical models [Ross and Minton, 1977], the temperature dependence of the cytosolic viscosity is expected to be the same as that of water, that is, the ratio of cytosolic viscosity at 37°C to the viscosity at 20°C is the same as the ratio of water viscosity at those same temperatures. In most cases, even in the most dense cells, the resistance to flow of the cytosol is small compared with the viscoelastic resistance of the membrane when membrane deformations are appreciable.

60.3.3 Membrane Area Dilation

The large resistance of the membrane to area dilation has been characterized in micromechanical experiments. The changes in surface area that can be produced in the membrane are small, and so they can be characterized in terms of a simple Hookean elastic relationship between the isotropic force resultant $\bar{N}$ and the fractional change in surface area $\alpha = A/A_o - 1$:

$$\bar{N} = K\alpha \tag{60.7}$$

The proportionality constant K is called the *area compressibility modulus* or the *area expansivity modulus*. Early estimates placed its value at room temperature at ∼450 mN/m [Evans and Waugh, 1977] and showed a dependence of the modulus on temperature, its value changing from ∼300 mN/m at 45°C to a value of ∼600 mN/m at 5°C [Waugh and Evans, 1979]. Subsequently it was shown that the measurement of this parameter using micropipettes is affected by extraneous electric fields, and the value at room temperature was corrected upward to ∼500 mN/m [Katnik and Waugh, 1990]. The values in Table 60.3 are based on this measurement, and the fractional change in the modulus with temperature is based on the original micropipette measurements [Waugh and Evans, 1979].

60.3.4 Membrane Shear Deformation

The shear deformations of the red cell surface can be large, and so a simple linear relationship between force and extension is not adequate for describing the membrane behavior. The large resistance of the membrane composite to area dilation led early investigators to postulate that the membrane maintained constant surface density during shear deformation, that is, that the surface was two-dimensionally incompressible. Most of what exists in the literature about the shear deformation of the red cell membrane is based on this assumption. In the mid-1990s, experimental evidence emerged that this assumption is an oversimplification of the true cellular behavior, and that deformation produces changes in the local surface

TABLE 60.3 Temperature Dependence of Viscoelastic Coefficients of the Red Cell Membrane

density of the membrane elastic network [Discher et al., 1994]. Nevertheless, the older simpler relationships provide a relatively simple description of the cell behavior that can be useful for many applications, and so the properties of the cell defined under that assumption are summarized here.

For a simple, two-dimensional, incompressible, hyperelastic material, the relationship between the membrane shear force resultant N_s and the material deformation is [Evans and Skalak, 1979]

$$N_s = \frac{\mu_m}{2} \left(\frac{\lambda_1}{\lambda_2} - \frac{\lambda_2}{\lambda_1} \right) + 2\eta_m V_s \tag{60.8}$$

where λ_1 and λ_2 are the principal extension ratios for the deformation and V_s is the rate of surface shear deformation (Equation 60.1). The *membrane shear modulus* μ_m and the *membrane viscosity* η_m are defined by this relationship. Values for these coefficients at different temperatures are given in Table 60.3.

60.3.5 Stress Relaxation and Strain Hardening

Subsequent to these original formulations, a number of refinements to these relationships have been proposed. Observations of persistent deformations after micropipette aspiration for extended periods of time formed the basis for the development of a model for long-term stress relaxation [Markle et al., 1983]. The characteristic times for these relaxations were on the order of 1 to 2 h, and they were thought to correlate with permanent rearrangements of the membrane elastic network.

Another type of stress relaxation is thought to occur over very short times (∼0.1 sec) after rapid deformation of the membrane either by micropipette [Chien et al., 1978] or in cell extension experiments (Waugh and Bisgrove, unpublished observations). This phenomenon is thought to be due to transient entanglements within the deforming network. Whether or not the phenomenon actually occurs remains controversial. The stresses relax rapidly, and it is difficult to account for inertial effects of the measuring system and to reliably assess the intrinsic cellular response.

Finally, there has been some evidence that the coefficient for shear elasticity may be a function of the surface extension, increasing with increasing deformation. This was first proposed by Fischer in an effort to resolve discrepancies between theoretical predictions and observed behavior of red cells undergoing dynamic deformations in fluid shear [Fischer et al., 1981]. Increasing elastic resistance with extension has also been proposed as an explanation for discrepancies between theoretical predictions based on a constant modulus and measurements of the length of a cell projection into a micropipette [Waugh and Marchesi, 1990]. However, due to the approximate nature of the mechanical analysis of cell deformation in shear flow, and the limits of optical resolution in micropipette experiments, the evidence for a dependence of the modulus on extension is not clear-cut, and this issue remains unresolved.

60.3.6 New Constitutive Relations for the Red Cell Membrane

The most modern picture of membrane deformation recognizes that the membrane is a composite of two layers with distinct mechanical behavior. The membrane bilayer, composed of phospholipids and integral membrane proteins, exhibits a large elastic resistance to area dilation but is fluid in surface shear. The membrane skeleton, composed of a network of structural proteins at the cytoplasmic surface of the bilayer, is locally compressible and exhibits an elastic resistance to surface shear. The assumption that the membrane skeleton is locally incompressible is no longer applied. This assumption had been challenged over the years on the basis of theoretical considerations, but only very recently has experimental evidence emerged that shows definitively that the membrane skeleton is compressible. This has led to a new constitutive model for membrane behavior [Mohandas and Evans, 1994]. The principal stress resultants in the membrane skeleton are related to the membrane deformation by:

$$N_1 = \mu_N \left(\frac{\lambda_1}{\lambda_2} - 1 \right) + K_N \left(\lambda_1 \lambda_2 - \frac{1}{(\lambda_1 \lambda_2)^n} \right) \tag{60.9}$$

and,

$$N_2 = \mu_N \left(\frac{\lambda_2}{\lambda_1} - 1 \right) + K_N \left(\lambda_1 \lambda_2 - \frac{1}{(\lambda_1 \lambda_2)^n} \right) \tag{60.10}$$

where μ_N and K_N are the shear and isotropic moduli of the membrane skeleton respectively, and n is a parameter to account for molecular crowding of the skeleton in compression. The original modulus based on the two-dimensionally incompressible case is related to these moduli by:

$$\mu_m \approx \frac{\mu_N K_N}{\mu_N + K_N} \tag{60.11}$$

Values for the coefficients determined from fluorescence measurements of skeletal density distributions during micropipette aspiration studies are $\mu_N \approx 0.01$ mN/m and $K_N \approx 0.02$ mN/m. The value for n is estimated to be $\sim$2 [Discher et al., 1994].

These new concepts for membrane constitutive behavior have yet to be thoroughly explored. The temperature dependence of these moduli is unknown, and the implications that such a model will have on interpretation of dynamic deformations of the membrane remain to be resolved.

60.3.7 Bending Elasticity

Even though the membrane is very thin, it has a high resistance to surface dilation. This property, coupled with the finite thickness of the membrane gives the membrane a small but finite resistance to bending. This resistance is characterized in terms of the **membrane bending modulus**. The bending resistance of biological membranes is inherently complex because of their lamellar structure. There is a local resistance to bending due to the inherent stiffness of the individual leaflets of the membrane bilayer. (Because the membrane skeleton is compressible, it is thought to contribute little if anything to the membrane bending stiffness.) In addition to this local stiffness, there is a **nonlocal bending resistance** due to the net compression and expansion of the adjacent leaflets resulting from the curvature change. The nonlocal contribution is complicated by the fact that the leaflets may be redistributed laterally within the membrane capsule to equalize the area per molecule within each leaflet. The situation is further complicated by the likely possibility that molecules may exchange between leaflets to alleviate curvature-induced dilation/compression. Thus, the bending stiffness measured by different approaches probably reflects contributions from both local and nonlocal mechanisms, and the measured values may differ because of different contributions from the two mechanisms. Estimates based on buckling instabilities during micropipette aspiration give a value of $\sim 0.18 \times 10^{-18}$ J [Evans, 1983]. Measurements based on

the mechanical formation of lipid tubes from the cell surface give a value of 0.2 to 0.25 $\times 10^{-18}$ J [Hwang and Waugh, 1997].

60.4 White Cells

Whereas red cells account for approximately 40% of the blood volume, white cells occupy less than 1% of the blood volume. Yet because white cells are less deformable, they can have a significant influence on blood flow, especially in the microvasculature. Unlike red cells, which are very similar to each other, as are platelets, there are several different kinds of white cells or *leukocytes*. Originally, leukocytes were classified into groups according to their appearance when viewed with the light microscope. Thus, there are *granulocytes*, *monocytes*, and *lymphocytes* [Alberts et al., 1989]. The granulocytes with their many internal granules are separated into *neutrophils*, *basophils*, and *eosinophils* according to the way each cell stains. The neutrophil, also called a *polymorphonuclear leukocyte* because of its segmented or "multilobed" nucleus, is the most common white cell in the blood (see Table 60.4). The lymphocytes, which constitute 20 to 40% of the white cells and which are further subdivided into *B lymphocytes* and *killer* and *helper T lymphocytes*, are the smallest of the white cells. The other types of leukocytes are found with much less frequency. Most of the geometric and mechanical studies of white cells reported below have focused on the neutrophil because it is the most common cell in the circulation, although the lymphocyte has also received attention.

60.4.1 Size and Shape

White cells at rest are spherical. The surfaces of white cells contain many folds, projections, and "microvilli" to provide the cells with sufficient membrane area to deform as they enter capillaries with diameters much smaller than the resting diameter of the cell. (Without the reservoir of membrane area in these folds, the constraints of constant volume and membrane area would make a spherical cell essentially undeformable.) The excess surface area of the neutrophil, when measured in a wet preparation, is slightly more than twice the apparent surface area of a smooth sphere with the same diameter [Evans and Yeung, 1989; Ting-Beall et al., 1993]. It is interesting to note that each type of white cell has its own unique surface topography, which allows one to readily determine if a cell is, for example, either a neutrophil or monocyte or lymphocyte [Hochmuth et al., 1995].

TABLE 60.4   Size and Appearance of White Cells in the Circulation

Granulocytes	Occurrence[1] (% of WBC's)	Cell volume[2] (μm^3)	Cell diameter[2] (μm)	Nucleus[3] % cell volume	Cortical tension (mN/m)
Neutrophils	50–70	300–310	8.2–8.4	21	0.024–0.035 [4]
Basophils	0–1	—			—
Eosinophils	1–3	—		18	—
Monocytes	1–5	400	9.1	26	0.06[5]
Lymphocytes	20–40	220	7.5	44	0.035[5]

[5] Preliminary data, Hochmuth, Zhelev and Ting-Beall.

The cell volumes listed in Table 60.4 were obtained with the light microscope, either by measuring the diameter of the spherical cell or by aspirating the cell into a small glass pipette with a known diameter and then measuring the resulting length of the cylindrically shaped cell. Other values for cell volume obtained using transmission electron microscopy are somewhat smaller, probably because of cell shrinkage due to fixation and drying prior to measurement [Schmid-Schönbein et al., 1980; Ting-Beall et al., 1995]. Although the absolute magnitude of the cell volume measured with the electron microscope may be erroneous, if it is assumed that all parts of the cell dehydrate equally when they are dried in preparation for viewing, then this approach can be used to determine the volume occupied by the nucleus (Table 60.4) and other organelles of various white cells. The volume occupied by the granules in the neutrophil and eosinophil (recall that both are granulocytes) is 15 and 23%, respectively, whereas the granular volume in monocytes and lymphocytes is less than a few percent.

60.4.2 Mechanical Behavior

The early observations of Bagge et al. [1977] led them to suggest that the neutrophil behaves as a simple viscoelastic solid with a Maxwell element (an elastic and viscous element in series) in parallel with an elastic element. This elastic element in the model was thought to pull the unstressed cell into its spherical shape. Subsequently, Evans and Kukan [1984] and Evans and Yeung [1989] showed that the cells flow continuously into a pipette, with no apparent approach to a static limit, when a constant suction pressure was applied. Thus, the cytoplasm of the neutrophil should be treated as a liquid rather than a solid, and its surface has a persistent *cortical tension* that causes the cell to assume a spherical shape.

60.4.3 Mechanical Behavior

Using a micropipette and a small suction pressure to aspirate a hemispherical projection from a cell body into the pipette, Evans and Yeung measured a value for the cortical tension of 0.035 mN/m. Needham and Hochmuth [1992] measured the cortical tension of individual cells that were driven down a tapered pipette in a series of equilibrium positions. In many cases the cortical tension increased as the cell moved further into the pipette, which means that the cell has an apparent area expansion modulus (Equation 60.7). They obtained an average value of 0.04 mN/m for the expansion modulus and an extrapolated value for the cortical tension (at zero area dilation) in the resting state of 0.024 mN/m. The importance of the actin cytoskeleton in maintaining cortical tension was demonstrated by Tsai et al. [1994]. Treatment of the cells with a drug that disrupts actin filament structure (CTB = cytochalasin B) resulted in a decrease in cortical tension from 0.027 to 0.022 mN/m at a CTB concentration of 3 μM and to 0.014 mN/m at 30 μM.

Preliminary measurements in one of our laboratories (RMH) indicate that the value for the cortical tension of a monocyte is about double that for a granulocyte, that is, 0.06 mN/m, and the value for a lymphocyte is about 0.035 mN/m.

60.4.4 Bending Rigidity

The existence of a cortical tension suggests that there is a cortex — a relatively thick layer of F-actin filaments and myosin — that is capable of exerting a finite tension at the surface. If such a layer exists, it would have a finite thickness and bending rigidity. Zhelev et al. [1994] aspirated the surface of neutrophils into pipettes with increasingly smaller diameters and determined that the surface had a bending modulus of about 1 to 2×10^{-18} J, which is 5 to 50 times the bending moduli for erythrocyte or lipid bilayer membranes. The thickness of the cortex should be smaller than the radius of smallest pipette used in this study, which was 0.24 μm.

60.4.5 Apparent Viscosity

Using their model of the neutrophil as a Newtonian liquid drop with a constant cortical tension and (as they showed) a negligible surface viscosity, Yeung and Evans [1989] analyzed the flow of neutrophils

into a micropipette and obtained a value for the **cytoplasmic viscosity** of about 200 Pa sec. In their experiments, the aspiration pressures were on the order of 10 to 1000 Pa. Similar experiments by Needham and Hochmuth [1990] using the same Newtonian model (with a negligible surface viscosity) but using higher aspiration pressures (ranging from 500 to 2000 Pa) gave an average value for the cytoplasmic viscosity of 135 Pa sec for 151 cells from five individuals. The apparent discrepancy between these two sets of experiments was resolved to a large extent by Tsai et al. [1993], who demonstrated that the neutrophil viscosity decreases with increasing rate of deformation. They proposed a model of the cytosol as a **power law fluid**:

$$\eta = \eta_c \left(\frac{\dot{\gamma}_m}{\dot{\gamma}_c} \right)^{-b} \tag{60.12}$$

where $b = 0.52$, $\dot{\gamma}_m$ is defined by Equation 60.5, and η_c is a characteristic viscosity of 130 Pa sec when the characteristic mean shear rate, $\dot{\gamma}_c$, is 1 sec^{-1}. These values are based on an approximate method for calculating the viscosity from measurements of the total time it takes for a cell to enter a micropipette. Because of different approximations used in the calculations, the values of viscosity reported by Tsai et al. [1993] tend to be somewhat smaller than those reported by Evans et al. or Hochmuth et al. Nevertheless, the shear rate dependence of the viscosity is the same, regardless of the method of calculation. Values for the viscosity are given in Table 60.5.

In addition to the dependence of the viscosity on shear rate, there is also evidence that it depends on the extent of deformation. In micropipette experiments the initial rate at which the cell enters the pipette is significantly faster than predicted, even when the shear rate dependence of the viscosity is taken into account. In a separate approach, the cytosolic viscosity was estimated from observation of the time course of the cell's return to a spherical geometry after expulsion from a micropipette. When the cellular deformations were large, a viscosity of 150 Pa sec was estimated [Tran-Son-Tay et al., 1991], but when the deformation was small, the estimated viscosity was only 60 Pa sec [Hochmuth et al., 1993]. Thus, it appears that the viscosity is smaller when the magnitude of the deformation is small, and increases as deformations become large.

An alternative attempt to account for the initial rapid entry of the cell into micropipettes involved the application of a **Maxwell fluid** model with a constant cortical tension. Dong et al. [1988] used this model to analyze both the shape recovery of neutrophils following small, complete deformations in pipettes and the small-deformation aspiration of neutrophils into pipettes. Another study by Dong et al. [1991], they used a finite-element, numerical approach and a Maxwell model with constant cortical tension to describe

TABLE 60.5 Viscous Parameters of White Blood Cells

	Range of viscosities (Pa sec)[1]		Characteristic	Shear rate
Cell type	Minimum	Maximum	viscosity (Pa sec)	dependence (b)

the continuous, finite-deformation flow of a neutrophil into a pipette. However, in order to fit the theory to the data for the increase in length of the cell in the pipette with time, Dong et al. [1991] had to steadily increase both the elastic and viscous coefficients in their finite-deformation Maxwell model. This shows that even a Maxwell model is not adequate for describing the rheological properties of the neutrophil.

Although it is clear that the essential behavior of the cell is fluid, the simple fluid drop model with a constant and uniform viscosity does not match the observed time course of cell deformation in detail. Many of these discrepancies have been resolved by Drury and Dembo, who developed a finite element analysis of a cell using a model having substantial cortical dissipation with shear thinning and a shear thinning cytoplasm [Drury and Dembo 2001]. Their model matches cellular behavior during micropipette aspiration over a wide range of pipette diameters and entry rates. Only the initial rapid entry phase of the deformation is not predicted. Thus, the fluid drop model including shear thinning and elevated viscosity at the cell cortex captures the essential behavior of the cell, and when it is applied consistently (that is, for similar rate and extent of deformation) it provides a sound basis for predicting cell behavior and comparing the behaviors of different types of cells.

Although the mechanical properties of the neutrophil have been studied extensively as discussed above, the other white cells have not been studied in depth. Preliminary unpublished results from one of our laboratories (RMH) indicate that monocytes are somewhat more viscous (from roughly 30% to a factor of two) than neutrophils under similar conditions in both recovery experiments and experiments in which the monocyte flows into a pipette. A lymphocyte, when aspirated into a small pipette so that its relatively large nucleus is deformed, behaves as an elastic body in that the projection length into the pipette increases linearly with the suction pressure. This elastic behavior appears to be due to the deformation of the nucleus, which has an apparent area elastic modulus of 2 mN/m. A lymphocyte recovers its shape somewhat more quickly than the neutrophil does, although this recovery process is driven both by the cortical tension and by the elastic nucleus. These preliminary results are discussed by Tran-Son-Tay et al. [1994]. Finally, the properties of a human myeloid leukemic cell line (HL60) thought to resemble immature neutrophils of the bone marrow have also been characterized, as shown in Table 60.5. The apparent cytoplasmic viscosity varies both as a function of the cell cycle and during maturation toward a more neutrophil-like cell. The characteristic viscosity ($\dot{\gamma}_c = 1 \sec^{-1}$) is 200 Pa sec for HL60 cells in the G1 stage of the cell cycle. This value increases to 275 Pa sec for cells in the S phase, but decreases with maturation, so that 7 days after induction the properties approach those of neutrophils (150 Pa sec) [Tsai et al., 1996a, b].

It is important to note in closing that the characteristics described above apply to passive leukocytes. It is the nature of these cells to respond to environmental stimulation and engage in active movements and shape transformations. **White cell activation** produces significant heterogeneous changes in cell properties. The cell projections that form as a result of stimulation (called pseudopodia) are extremely rigid, whereas other regions of the cell may retain the characteristics of a passive cell. In addition, the cell may produce large protrusive or contractile forces. The changes in cellular mechanical properties that result from cellular activation are complex and only beginning to be formulated in terms of mechanical models. One notable recent contribution to this field was made by Herant et al., who developed a two-phase model of the cell interior accounting for different properties of the cytoskeleton and the cytosol, and estimating possible effects of swelling and polymerization forces [Herant et al., 2003].

60.5   Summary

Constitutive equations that capture the essential features of the responses of red blood cells and passive leukocytes have been formulated, and material parameters characterizing the cellular behavior have been measured. The red cell response is dominated by the cell membrane which can be described as a hyper-viscoelastic, two-dimensional continuum. The passive white cell behaves like a highly viscous fluid drop, and its response to external forces is dominated by the large viscosity of the cytosol. Refinements of these constitutive models and extension of mechanical analysis to activated white cells is anticipated as the ultrastructural events that occur during cellular deformation are delineated in increasing detail.

Defining Terms

Area expansivity modulus: A measure of the resistance of a membrane to area dilation. It is the proportionality between the isotropic force resultant in the membrane and the corresponding fractional change in membrane area. (Units: 1 mN/m = 1 dyn/cm)

Cortical tension: Analogous to surface tension of a liquid drop, it is a persistent contractile force per unit length at the surface of a white blood cell. (Units: 1 mN/m = 1 dyn/cm)

Cytoplasmic viscosity: A measure of the resistance of the cytosol to flow. (Units: 1 Pa sec = 10 poise)

Force resultant: The stress in a membrane integrated over the membrane thickness. It is the two-dimensional analog of stress with units of force/length. (Units: 1 mN/m = 1 dyn/cm)

Maxwell fluid: A constitutive model in which the response of the material to applied stress includes both an elastic and viscous response in series. In response to a constant applied force, the material will respond elastically at first, then flow. At fixed deformation, the stresses in the material will relax to zero.

Membrane bending modulus: The intrinsic resistance of the membrane to changes in curvature. It is usually construed to exclude nonlocal contributions. It relates the moment resultants (force times length per unit length) in the membrane to the corresponding change in curvature (inverse length). (Units: 1 Nm = 1 J = 10^7 erg)

Membrane shear modulus: A measure of the elastic resistance of the membrane to surface shear deformation; that is, changes in the shape of the surface at constant surface area (Equation 60.8). (Units: 1 mN/m = 1 dyn/cm)

Membrane viscosity: A measure of the resistance of the membrane to surface shear flow, that is to the rate of surface shear deformation (Equation 60.8). (Units: 1 mN sec/m = 1 m Pa sec m = 1 dyn sec/cm = 1 surface poise)

Nonlocal bending resistance: A resistance to bending resulting from the differential expansion and compression of the two adjacent leaflets of a lipid bilayer. It is termed nonlocal because the leaflets can move laterally relative to one another to relieve local strains, such that the net resistance to bending depends on the integral of the change in curvature of the entire membrane capsule.

Power law fluid: A model to describe the dependence of the cytoplasmic viscosity on rate of deformation (Equation 60.12).

Principal extension ratios: The ratios of the deformed length and width of a rectangular material element (in principal coordinates) to the undeformed length and width.

Sphericity: A dimensionless ratio of the cell volume (to the 2/3 power) to the cell area. Its value ranges from near zero to one, the maximum value corresponding to a perfect sphere (Equation 60.6).

White cell activation: The response of a leukocyte to external stimuli that involves reorganization and polymerization of the cellular structures and is typically accompanied by changes in cell shape and cell movement.

Further Information

Basic information on the mechanical analysis of biomembrane deformation can be found in Evans and Skalak [1979], which also appeared as a book under the same title (CRC Press, Boca Raton, FL, 1980). A more recent work that focuses more closely on the structural basis of the membrane properties is Berk et al., chapter 15, pp. 423–454, in the book *Red Blood Cell Membranes: Structure, Function, Clinical Implications* edited by Peter Agre and John Parker, Marcel Dekker, New York, 1989. More detail about the membrane structure can be found in other chapters of that book.

Basic information about white blood cell biology can be found in the book by Alberts et al. [1989]. A more thorough review of white blood cell structure and response to stimulus can be found in two reviews by T.P. Stossel, one entitled, "The mechanical response of white blood cells," in the book, *Inflammation: Basic Principles and Clinical Correlates*, edited by J.I. Galin et al., Raven Press, New York, 1988, pp. 325–342, and the second entitled, "The molecular basis of white blood cell motility," in the book, *The Molecular Basis of Blood Diseases*, edited by G. Stamatoyannopoulos et al., W. B. Saunders, Philadelphia, 1994, pp. 541–562. The most recent advances in white cell rheology can be found in the book, *Cell Mechanics and Cellular Engineering*, edited by Van C. Mow et al., Springer Verlag, New York, 1994.

Mechanics of Tissue/Lymphatic Transport

Geert W. Schmid-Schönbein
Alan R. Hargens
University of California-San Diego

61.1 Introduction

Transport of fluid and metabolites from blood to tissue is critically important for maintaining the viability and function of cells within the body. Similarly, transport of fluid and waste products from tissue to the **lymphatic system** of vessels and nodes is also crucial to maintain tissue and organ health. Therefore, it is important to understand the mechanisms for transporting fluid containing micro- and macromolecules from blood to tissue and the drainage of this fluid into the lymphatic system. Because of the succinct nature of this chapter, readers are encouraged to consult more complete reviews of blood/tissue/lymphatic transport by Aukland and Reed [1993], Bert and Pearce [1984], Casley-Smith [1982], Curry [1984], Hargens [1986], Jain [1987], Lai-Fook [1986], Levick [1984], Reddy [1986], Schmid-Schönbein [1990], Schmid-Schönbein and Zweifach [1994], Staub [1988], Staub et al. [1987], Taylor and Granger [1984], Wei et al. [2003], Zweifach and Lipowsky [1984], and Zweifach and Silverberg [1985].

Most previous studies of blood/tissue/lymphatic transport have used isolated organs or whole animals under general anesthesia. Under these conditions, transport of fluid and metabolites is artificially low in comparison to animals that are actively moving. In some cases, investigators employed passive motion

61-1

by connecting an animal's limb to a motor in order to facilitate studies of blood to lymph transport and lymphatic flow. However, new methods and technology allow studies of physiologically active animals so that a better understanding of the importance of transport phenomena in moving tissues is now apparent, especially in skeletal muscle, skin, and subcutaneous tissue. Therefore, the major focus of this chapter emphasizes recent developments in the understanding of the mechanics of tissue/lymphatic transport.

The majority of the fluid that is filtered from the microcirculation into the interstitial space is carried out of the tissue via the lymphatic network. This unidirectional transport system originates with a set of blind channels in distal regions of the microcirculation. It carries a variety of interstitial molecules, proteins, metabolites, colloids, and even cells along channels deeply embedded in the tissue parenchyma toward a set of sequential lymph nodes and eventually back into the venous system via the right and left thoracic ducts. The lymphatics are the pathways for immune surveillance by the lymphocytes and thus, they are one of the important pathways of the immune system [Wei et al., 2003].

In the following sections, we describe basic transport and tissue morphology as related to lymph flow. We also present recent evidence for a two-valve system in lymphatics that offers an updated view of lymph transport.

61.2   Basic Concepts of Tissue/Lymphatic Transport

61.2.1   Transcapillary Filtration

Because lymph is formed from fluid filtered from the blood, an understanding of transcapillary exchange must be gained first. Usually pressure parameters favor filtration of fluid across the **capillary** wall to the **interstitium** (J_c) according to the Starling–Landis equation:

$$J_c = L_p A[(P_c - P_t) - \sigma_p(\pi_c - \pi_t)] \tag{61.1}$$

where J_c is the net transcapillary fluid transport, L_p is hydraulic conductivity of capillary wall, A is capillary surface area, P_c is capillary blood pressure, P_t is interstitial fluid pressure, σ_p is reflection coefficient for protein, π_c is capillary blood **colloid osmotic pressure**, and π_t is the interstitial fluid colloid osmotic pressure.

In many tissues, fluid transported out of the capillaries is passively drained by the initial lymphatic vessels so that:

$$J_c = J_l \tag{61.2}$$

where J_l is the lymph flow and pressure within the initial lymphatic vessels P_l depends on higher interstitial fluid pressure P_t for establishing lymph flow:

$$P_t \geq P_l \tag{61.3}$$

61.2.2   Starling Pressures and Edema Prevention

Hydrostatic and *colloid osmotic pressures* within the blood and interstitial fluid primarily govern transcapillary fluid shifts (Figure 61.1). Although input arterial pressure averages about 100 mmHg at heart level, capillary blood pressure P_c is significantly reduced due to resistance R, according to the Poiseuille's equation:

$$R = \frac{8\eta l}{\pi r^4} \tag{61.4}$$

where η is the blood viscosity, l is the vessel length between feed artery and capillary, and r is the radius.

Therefore, normally at the heart level, P_c is approximately 30 mmHg. However, during upright posture, P_c at foot level is about 90 mmHg and only about 25 mmHg at head level [Parazynski et al., 1991].
FIGURE 61.1 Starling pressures that regulate transcapillary fluid balance. Pressure parameters which determine direction and magnitude of transcapillary exchange include capillary blood pressure P_c, interstitial fluid pressure P_t (directed into capillary when positive or directed into tissue when negative), plasma colloidal osmotic pressure π_c, and interstitial fluid colloidal osmotic pressure π_t. Precapillary sphincters (P.S.) regulate P_c, capillary flow, and capillary surface area A. It is generally agreed that a hydrostatic pressure gradient ($P_t >$ lymph pressure P_l) drains off excess interstitial fluid under conditions of net filtration. Relative magnitudes of pressures are depicted by the size of arrows. (From Hargens A.R. 1986. In R. Skalak and S. Chien (Eds.), *Handbook of Bioengineering*, vol. 19, pp. 1–35, New York, McGraw-Hill. With permission.)

Differences in P_c between capillaries of the head and feet are due to gravitational variation of the blood pressure such that the pressure $p = \rho g h$. For this reason, volumes of transcapillary filtration and lymph flows are generally higher in tissues of the lower body as compared to those of the upper body. Moreover, one might expect much more sparse distribution of lymphatic vessels in upper body tissues. The brain has no lymphatics, but most other vascular tissues have lymphatics. In fact, tissues of the lower body of humans and other tall animals have efficient skeletal muscle pumps, prominent lymphatic systems, and noncompliant skin and fascial boundaries to prevent dependent **edema** [Hargens et al., 1987].

Other pressure parameters in the Starling–Landis equation such as P_t, π_c, and π_t are not as sensitive to changes in body posture as is P_c. Typical values for P_t range from -2 to 10 mmHg depending on the tissue or organ under investigation [Wiig, 1990]. However, during movement, P_t in skeletal muscle increases to 150 mmHg or higher [Murthy et al., 1994], providing a mechanism to promote lymphatic flow and venous return via the skeletal pump (Figure 61.2). Blood colloid osmotic pressure π_c usually ranges between 25 and 35 mmHg and is the other major force for retaining plasma within the vascular system and preventing edema. Interstitial π_t depends on the reflection coefficient of the capillary wall (σ_p ranges from 0.5 to 0.9 for different tissues) as well as washout of interstitial proteins during high filtration rates [Aukland and Reed, 1993]. Typically π_t ranges between 8 and 15 mmHg with higher values in upper body tissues compared to those in the lower body [Parazynski et al., 1991; Aukland and Reed, 1993]. Precapillary sphincter activity (see Figure 61.1) also decreases blood flow, decreases capillary filtration area A, and reduces P_c in dependent tissues of the body to help prevent edema during upright posture [Aratow et al., 1991].

61.2.3 Interstitial Fluid Transport

Interstitial flow of proteins and other macromolecules occurs by two mechanisms, diffusion and convection. During simple diffusion according to Fick's equation:

$$J_p = -D\frac{\partial c_p}{\partial x} \tag{61.5}$$
FIGURE 61.2 Simultaneous intramuscular pressure oscillations in the soleus (top panel) and the tibialis anterior (bottom panel) muscles during plantar- and dorsiflexion exercise. Soleus muscle is an integral part of the calf muscle pump. (From Murthy, G., Watenpaugh, D.E., Ballard, R.E. et al., 1994. *J. Appl. Physiol.* 76: 2742. With permission.)

where J_p is the one-dimensional protein flux, D is diffusion coefficient, and $\partial c_p/\partial x$ is the concentration gradient of protein through interstitial space.

For most macromolecules such as proteins, the diffusional transport is limited. It serves to disperse molecules, but it does not effectively serve to transport large molecules especially if their diffusion is restricted by interstitial matrix proteins, membrane barriers, or other structures that limit their free thermal motion. Instead, both experimental and theoretical evidence highlights the dependence of volume and solute flows on hydrostatic and osmotic pressure gradients [Hargens and Akeson, 1986; Hammel, 1994] and suggests that convective flow plays the dominating role in interstitial flow and transport of nutrients to tissue cells. For example, in the presence of osmotic or hydrostatic pressure gradients, protein transport J_p is coupled to fluid transport according to:

$$J_p = \bar{c}_p J_v \qquad (61.6)$$

where $\bar{c}_p$ is the average protein concentration and J_v is the volume flow of fluid.

Transport of interstitial fluid toward the lymphatics requires convective flow, since it needs to be focused on relatively few channels in the interstitium. Diffusion cannot serve such a purpose because diffusion merely disperses fluid and proteins. Lymph formation and flow greatly depend upon tissue movement or activity related to muscle contraction and tissue deformations. It is also generally agreed that formation of initial lymph depends solely on the composition of nearby interstitial fluid and pressure gradients across the interstitial/lymphatic boundary [Zweifach and Lipowsky, 1984; Hargens, 1986]. For this reason, lymph formation and flow can be quantified by measuring disappearance of isotope-labeled albumin from subcutaneous tissue or skeletal muscle [Reed et al., 1985].

61.2.4 Lymphatic Architecture

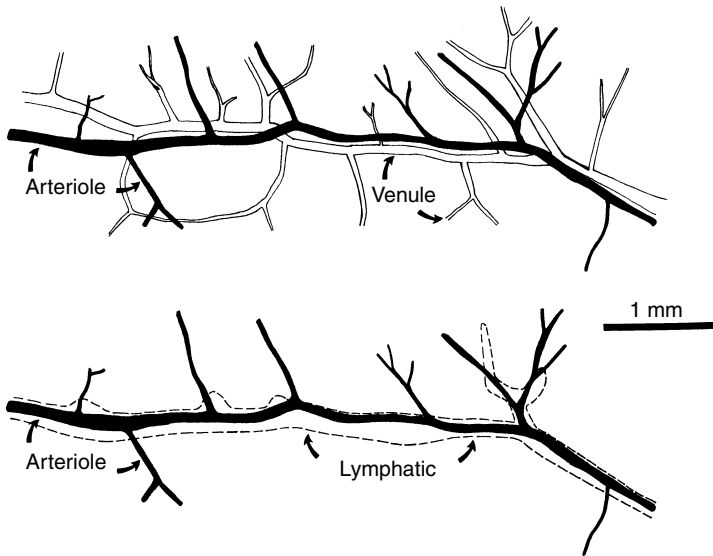
To understand lymph transport in engineering terms it is paramount that we develop a detailed picture of the lymphatic network topology and vessel morphology. This task is facilitated by a number of morphological and ultrastructural studies from past decades that give a general picture of the morphology


FIGURE 61.3 Tracing of a typical lymphatic channel (bottom panel) in rat spinotrapezius muscle after injection with a micropipette of a carbon contrast suspension. All lymphatics are of the initial type and are closely associated with the arcade arterioles. Few lymphatics follow the path of the arcade venules, or their side branches, the collecting venules or the transverse arterioles. (From Skalak et al., 1986. In A.R. Hargens (Ed.) *Tissue Nutrition and Viability*, pp. 243–262, Springer-Verlag, New York. With permission.)

and location of lymphatic vessels in different tissues. Lymphatics are studied by injections of macroscopic and microscopic contrast media and by light and electron microscopic sections. The display of the lymphatics is organ specific and there are many variations in lymphatic architecture [Schmid-Schönbein, 1990]. In this chapter, we will focus our discussion predominantly on skeletal muscle, intestine, and skin. However, the mechanisms outlined below may in part be also relevant to other tissues and organs.

In skeletal muscle, lymphatics are positioned in *immediate* proximity of the arterioles [Skalak et al., 1984]. The majority of feeder arteries in skeletal muscle and most, but not all, of the arcade arterioles are closely accompanied by a lymphatic vessel (Figure 61.3). Lymphatics can be traced along the entire length of the arcade arterioles, but they can be traced only over relatively short distances (less than about 50 μm) into the side branches of the arcades, the transverse (terminal) arterioles, which supply the blood into the capillary network. Systematic reconstructions of the lymphatics in skeletal muscle have yielded little evidence for lymphatic channels that enter into the capillary network per se [Skalak et al., 1984]. Thus, the network density of lymphatics is quite low compared to the high density of the capillary network in muscle, a characteristic feature of lymphatics in most organs [Skalak et al., 1986]. The close association between lymphatics and the vasculature is also present in skin [Ikomi and Schmid-Schönbein, 1995] and in other organs and may extend into the central vasculature. Recently, Saharinen et al. [2004] reviewed lymphatic vasculature development and molecular regulation in tumor metastasis and inflammation. It is apparent that current understandings of lymphatic growth factors and strategies to limit lymphatic vessel growth may allow manipulation of lymphatic growth in disease.

61.2.5 Lymphatic Morphology

Histological sections of the lymphatics permit the classification into two distinct subsets, *initial* lymphatics and *collecting* lymphatics. The initial lymphatics (sometimes also denoted as terminal or capillary lymphatics) form a set of blind endings in the tissue that feed into the collecting lymphatics, and that in turn, are the conduits into the lymph nodes. While both initial and collecting lymphatics are lined

by a highly attenuated endothelium, only the collecting lymphatics have smooth muscle in their media. In accordance, contractile lymphatics exhibit spontaneous narrowing of their lumen, while there is no evidence for contractility (in the sense of a smooth muscle contraction) in the initial lymphatics. Contractile lymphatics are capable of peristaltic smooth muscle contractions that, in conjunction with periodic opening and closing of intraluminal valves, permit unidirectional fluid transport. The lymphatic smooth muscle has adrenergic innervation [Ohhashi et al., 1982], it exhibits myogenic contraction [Hargens and Zweifach, 1977; Mizuno et al., 1997], and reacts to a variety of vasoactive stimuli [Ohhashi et al., 1978; Benoit, 1997], including signals that involve nitric oxide [Ohhashi and Takahashi, 1991; Bohlen and Lash, 1992; Yokoyama and Ohhashi, 1993]. None of these contractile features has been documented in initial lymphatics.

The lymphatic endothelium has a number of similarities with vascular endothelium. It forms a continuous lining and has typical cytoskeletal fibers such as microtubules, intermediate fibers, and actin in both fiber bundle form and matric form. There are numerous caveolae, Weibel-Palade bodies, but lymphatic endothelium has fewer interendothelial adhesion complexes and a discontinuous basement membrane. The residues of the basement membrane are attached to interstitial collagen via anchoring filaments [Leak and Burke, 1968] that provide relatively firm attachment of the endothelium to interstitial structures.

61.2.6 Lymphatic Network Display

One of the interesting aspects regarding lymphatic transport in skeletal muscle is the fact that all lymphatics *inside* the muscle parenchyma are of the noncontractile, *initial* type [Skalak et al., 1984]. *Collecting* lymphatics can only be observed outside the muscle fibers as conduits to adjacent lymph nodes. The fact that all lymphatics inside the tissue parenchyma are of the initial type is not unique to skeletal muscle, but has been demonstrated in other organs [Unthank and Bohlen, 1988; Yamanaka et al., 1995]. The initial lymphatics are positioned in the adventitia of the arcade arterioles surrounded by collagen fibers (Figure 61.4). Thus, the initial lymphatics are in immediate proximity to the arteriolar smooth muscle, and adjacent to myelinated nerves fibers and a set of mast cells that accompany the arterioles. The initial lymphatics are frequently sandwiched between arteriolar smooth muscle and their paired venules, and they in turn are embedded between the skeletal muscle fibers [Skalak et al., 1984]. The initial lymphatics are firmly attached to the adjacent basement membrane and collagen fibers via anchoring filaments [Leak and Burke, 1968]. The basement membrane of the lymphatic endothelium is discontinuous, especially at the interendothelial junctions, so that macromolecules and even cells and particles enter the initial lymphatics [Casley-Smith, 1962; Bach and Lewis, 1973; Strand and Persson, 1979; Bollinger et al., 1981; Ikomi et al., 1996].

The lumen cross section of initial lymphatics is highly irregular in contrast to the overall circular cross section of collecting lymphatics (Figure 61.4). Luminal cross sections of initial lymphatics are partially or completely collapsed and may frequently span around the arcade arteriole. In fact, we have documented cases in which the arcade arteriole is completely surrounded by an initial lymphatic channel, highlighting the fact that the activity of the lymphatics is closely linked to that of the arterioles [Ikomi and Schmid-Schönbein, 1995].

61.2.7 The Intraluminal (Secondary) Lymphatic Valves

Initial lymphatics in skeletal muscle have intraluminal valves that consist of bileaflets and a funnel structure [Mazzoni et al., 1987]. The leaflets are flexible structures and are opened and closed by a viscous pressure drop along the valve funnel. In closed position, these leaflets can support considerable pressures [Eisenhoffer et al., 1995; Ikomi et al., 1997]. This arrangement preserves normal valve function even in initial lymphatics with irregularly shaped lumen cross sections.
FIGURE 61.4 Histological cross sections of lymphatics (LYM) in rat skeletal muscle before (a) and after (b) contraction of the paired arcade arterioles (ART). The lymphatic channel is of the initial type with a single attenuated endothelial layer (curved arrows). Note, that in the dilated arteriole, the lymphatic is essentially compressed (a) while the lymphatic is expanded after arteriolar contraction (b) which is noticeable by the folded endothelial cells in the arteriolar lumen. In both cases, the lumen cross-sectional shape of the initial lymphatic channels is highly irregular. All lymphatics in skeletal muscle have these characteristic features. (From Skalak T.C., Schmid-Schönbein G.W., and Zweifach B.W. 1984. *Microvasc. Res.* 28: 95.)

61.2.8 The Primary Lymphatic Valves

The lymphatic endothelial cells are attenuated and have many of the morphological characteristics of vascular endothelium, including expression of P-selectin, von Willebrand factor [Di Nucci et al., 1996], and factor VIII [Schmid-Schönbein, 1990]. An important difference between vascular and lymphatic endothelium lies in the arrangement of the endothelial junctions. In the initial lymphatics, the endothelial cells lack tight junctions [Schneeberger and Lynch, 1984] and are frequently encountered in an overlapping but open position, so that proteins, large macromolecules, and even chylomicron particles can readily pass through the junctions [Casley-Smith, 1962, 1964; Leak, 1970]. Examination of the junctions with scanning electron microscopy shows that there exists a periodic *interdigitating* arrangement of endothelial extensions. Individual extensions are attached via anchoring filaments to the underlying basement membrane

(b)
FIGURE 61.4   Continued.

and connective tissue, but the two extensions of adjacent endothelial cells resting on top of each other are not attached by interendothelial adhesion complexes. Mild mechanical stretching of the initial lymphatics shows that the endothelial extensions can be separated in part from each other, indicating that the membranes of two neighboring lymphatic endothelial cells are not attached to each other, but are firmly attached to the underlying basement membrane [Castenholz, 1984]. Lymphatic endothelium does not exhibit continuous junctional complexes, and instead has a "streak and dot" like immunostaining pattern of VE-cadherin and associated intracellular proteins desmoplakin and plakoglobulin [Schmelz et al., 1994]. However the staining pattern is not uniform for all lymphatics, and in larger lymphatics a more continuous pattern is present. This highly specialized arrangement has been referred to as the *lymphatic endothelial microvalves* [Schmid-Schönbein, 1990] or primary lymphatic valves. They are "*primary*" because fluid from the interstitium must first pass across these valves before entering the lymphatic lumen and then pass across the intraluminal, that is, secondary, valves. Particles deposited into the interstitial space adjacent to initial lymphatics pass across the endothelium of the initial lymphatics. However once the particles are inside the initial lymphatic lumen, they cannot return back into the interstitial space unless the endothelium is injured. Indeed, the endothelial junctions of the initial lymphatics serve as a functional valve system [Trzewik et al., 2001].

61.2.9 Mechanics of Lymphatic Valves

In contrast to the central large valves in the heart that are closed by inertial fluid forces, the lymphatic valves are small and the fluid Reynolds number is almost zero. Thus, because no inertial forces are available to open and close these valves, unique valve morphology has evolved in these small valves. The valves form long funnel-shaped channels, which are inserted into the lymph conduits and attached at their base. The funnel is prevented from inversion by attachment via a buttress to the lymphatic wall. The valve wall structure consists of a collagen layer sandwiched between two endothelial layers, and the entire structure is quite deformable under mild physiological fluid pressures. The funnel structure allows a *viscous pressure gradient* that is sufficient to generate a pressure drop during forward fluid motion to open, and upon flow reversal to close the valves [Mazzoni et al., 1987]. The primary lymphatic valves also open as passive structures at the peripheral endothelial cell extensions. They require sites where they are free to bend into the lumen of the initial lymphatics and where they are *not* attached by anchoring filaments to the adjacent extracellular matrix [Mendoza et al., 2003].

61.2.10 Lymph Formation and Pump Mechanisms

One of the important questions fundamental to lymphology is: How do fluid and large particles in the interstitium find their way into initial lymphatics? In light of the relative sparse existence of initial lymphatics, a directed convective transport is required that can be provided by either a hydrostatic or a colloid osmotic pressure drop [Zweifach and Silberberg, 1979]. However, the exact mechanism of this unidirectional flow has remained an elusive target. Several proposals have been advanced and these are discussed in detail in Schmid-Schönbein [1990]. Briefly, a number of authors have postulated that there exists a constant pressure drop from the interstitium into the initial lymph, which may support a steady fluid flow into the lymphatics. Nevertheless, repeated measurements with different techniques have uniformly failed to provide supporting evidence for a *steady* pressure drop to transport fluid into the initial lymphatics [Zweifach and Prather, 1975; Clough and Smaje, 1978]. Under steady-state conditions, no steady pressure drop exists in the vicinity of the initial lymphatics in skeletal muscle within the resolution of the measurement technique (about 0.2 cm H_2O) [Skalak et al., 1984]. An order of magnitude estimate of the pressure drop expected at the relatively slow flow rates of the lymphatics shows, however, that the pressure drop from the interstitium may be significantly lower [Schmid-Schönbein, 1990]. Furthermore, the assumption of a *steady* pressure drop is not in agreement with the substantial evidence that lymph flow rate is enhanced under unsteady conditions (see below). Some investigators have postulated an osmotic pressure in the lymphatics to aspirate fluid into the initial lymphatics [Casley-Smith, 1972] due to ultrafiltration across the lymphatic endothelium, a mechanism referred to as "bootstrap effect" [Perl, 1975]. Critical tests of this hypothesis, such as the microinjection of hyperosmotic protein solutions, have not led to a uniformly accepted hypothesis for lymph formation involving an osmotic mechanism. Others have suggested a retrograde aspiration mechanism, such that the recoil in the collecting lymphatics serves to lower the pressure in the initial lymphatics upstream of the collecting lymphatics [Reddy, 1986; Reddy and Patel, 1995], or an electric charge difference across lymphatic endothelium [O'Morchoe et al., 1984].

61.2.11 Tissue Mechanical Motion and Lymphatic Pumping

An intriguing feature of lymphatic pressure is that lymphatic flow rates depend on tissue motion. In a resting tissue, the lymph flow rate is relatively small. However, different forms of tissue motion serve to enhance lymph flow. This was originally demonstrated for pulsatile pressures in the rabbit ear. Perfusion of the ear with steady pressure (even at the same mean pressure) stops lymph transport, while pulsatile pressures promote lymph transport [Parsons and McMaster, 1938]. In light of the paired arrangement of the arterioles and lymphatics, periodic expansion of the arterioles compresses adjacent lymphatics, and vice versa, a reduction of arteriolar diameter during the pressure reduction phase expands adjacent lymphatics [Skalak et al., 1984] (Figure 61.4). Vasomotion, associated with a slower contraction of the arterioles, but with a larger amplitude than pulsatile pressure, increases lymph formation

[Intaglietta and Gross, 1982; Colantuoni et al., 1984]. In addition, muscle contractions, simple walking [Olszewski and Engeset, 1980], respiration, intestinal peristalsis, skin compression [Ohhashi et al., 1991], and other tissue motions are associated with increased lymph flow rates. Periodic tissue motions are significantly more effective to enhance the lymph flow than elevation of the venous pressure [Ikomi et al., 1996), which is also associated with enhanced fluid filtration (Renkin et al., 1977].

A requirement for lymph fluid flow is the periodic expansion and compression of the initial lymphatics. Because initial lymphatics do not have their own smooth muscle, the expansion and compression of initial lymphatics depend on the motion of tissue in which they are embedded. In skeletal muscle, the strategic location of the initial lymphatics in the adventitia of the arterioles provides the milieu for expansion and compression via several mechanisms: arteriolar pressure pulsations or vasomotion, active or passive skeletal muscle contractions, or external muscle compression. Direct measurements of the cross-sectional area of the initial lymphatics during arteriolar contractions or during skeletal muscle shortening support this hypothesis [Skalak et al., 1984; Mazzoni et al., 1990] (Figure 61.5). The different lymph pump mechanisms are additive. Resting skeletal muscle has much lower lymph flow rates (provided largely by the arteriolar pressure pulsation and vasomotion) than skeletal muscle during exercise (produced by a combination of intramuscular pressure pulsations and skeletal muscle shortening) [Ballard et al., 1998].

Measurements of lymph flow rates in an afferent lymph vessel (diameter about 300 to 500 μm, proximal to the popliteal node) in the hind leg [Ikomi and Schmid-Schönbein, 1996] demonstrate that lymph fluid formation is influenced by passive or active motion of the surrounding tissue. Lymphatics in this tissue region drain muscle and skin of the hind leg, and the majority is of the *initial* type, whereas collecting lymphatics are detected outside the tissue parenchyma in the fascia proximal to the node. Without whole leg rotation, lymph flow remains at low but nonzero values. If the pulse pressure is stopped, lymph flow falls to values below detectable limits (less than about 10% of the values during pulse pressure). Introduction of whole leg passive movement causes strong, frequency-dependent lymph flow rates that increase linearly with the logarithm of frequency between 0.03 and 1.0 Hz (Figure 61.6). Elevation of venous pressure, which enhances fluid filtration from the vasculature and elevates the flow rates, does not significantly alter the dependency of lymph flow on periodic tissue motion [Ikomi et al., 1996].

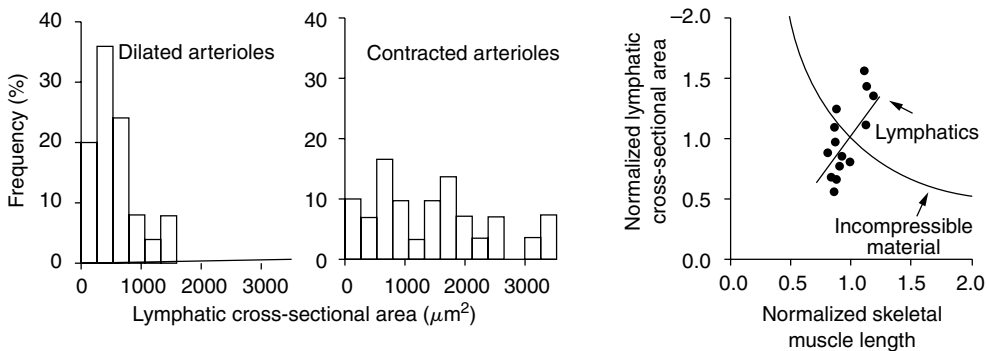
Similarly, application of passive tissue compression on the skin elevates lymph flow rate in a frequency-dependent manner. Lymph flow rates are determined to a significant degree by the *local* action of the lymph pump, because arrest of the heartbeat and reduction of the central blood pressure to zero does not


FIGURE 61.5 Histograms of initial lymphatic cross-sectional area in rat spinotrapezius muscle before (left) and after (middle) contraction of the paired arteriole with norepinephrine. Lymphatic cross-sectional area as a function of muscle length during active contraction or passive stretch (right). Cross-sectional area and muscle length are normalized with respect to the values *in vivo* in resting muscle. Note the expansion of the initial lymphatics with contraction of the arterioles or muscle stretch. (From Skalak T.C., Schmid-Schönbein G.W., and Zweifach B.W. 1984. *Microvasc. Res.* 28: 95; Mazzoni M.C., Skalak T.C., and Schmid-Schönbein G.W. 1990. *Am. J. Physiol.* 259: H1860.)

stop lymph flow. Instead, cardiac arrest reduces lymph flow rate only about 50% during continued leg motion or application of periodic shear stress to the skin for several hours [Ikomi and Schmid-Schönbein, 1996]. Periodic compression of the initial lymphatics also enhances proteins and lymphocyte counts in the lymphatics [Ikomi et al., 1996] (Figure 61.7). Thus either arteriolar smooth muscle or parenchymal skeletal muscle activity expands and compresses the initial lymphatics in skeletal muscle. These mechanisms serve to adjust lymph flow rates according to organ activity such that a resting skeletal muscle has a very low lymph flow rate. During normal daily activity or mild or strenuous exercise, lymph flow rates as well as protein and cell transport into the lymphatics increases [Olszewski et al., 1977].

61.2.12 A Lymph Pump Mechanism with Primary and Secondary Valves

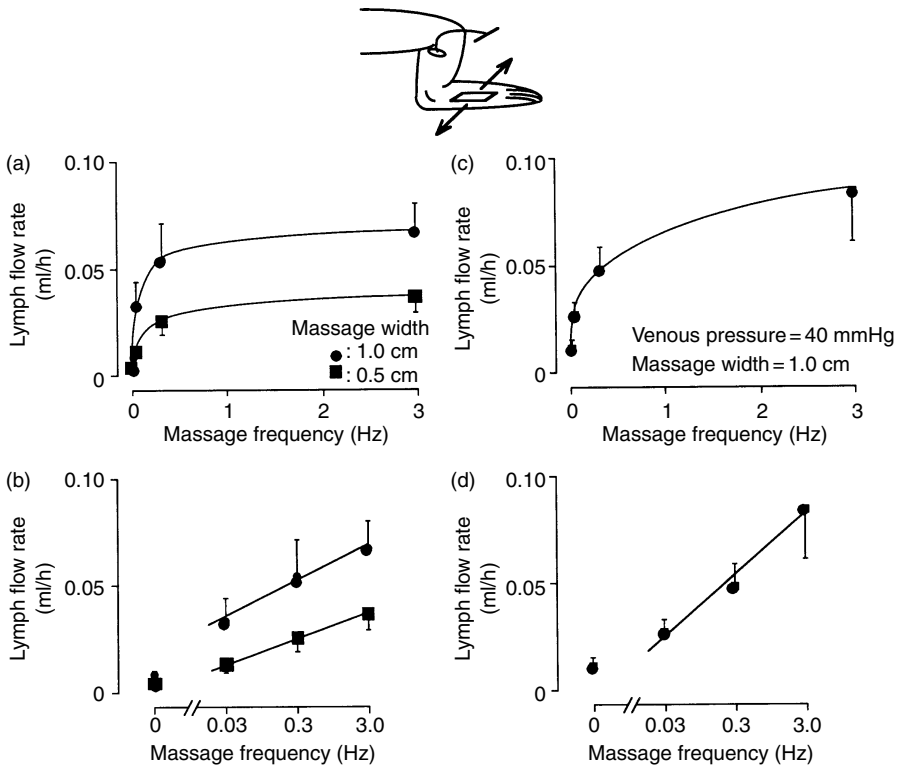
Regular expansion and compression of initial lymphatic channels require a set of valves to achieve unidirectional flow. Such valves open and close with each expansion and compression of the lymphatics to permit entry at the upstream end of the lymphatics and discharge downstream toward the lymph nodes. There is a cycle of valve opening and closing with every expansion and compression of the lymphatic channels. During expansion, the upstream primary lymphatics are open and permit entry of interstitial fluid. The secondary valves are closed to prevent retrograde flow along the lymphatic channels. During compression, the primary valves are closed, while the secondary valves are open to permit discharge along the lymphatic channels into the contractile lymphatics and toward the lymph nodes.


FIGURE 61.6 Lymph flow rates in a prenodal afferent lymphatic draining the hind leg as a function of the frequency of a periodic surface shear motion (massage) without (panels a, b) and with (panels c, d) elevation of the venous pressure by placement of a cuff. Zero frequency refers to a resting leg with a lymph flow rate, which depends on pulse pressure. The amplitudes of the tangential skin shear motion were 1 and 0.5 cm (panels a, b) and 1 cm in the presence of the elevated venous pressure (panels c, d). Note that the ordinates in panels c and d are larger than those in panels a and b. (From Ikomi F., Hunt J., Hanna G. et al. 1996. *J. Appl. Physiol.* 81: 2060.)
FIGURE 61.7 Lymph leukocyte count (left) and leukocyte flux (right) before and after application of periodic hind leg skin shear motion (massage) at a frequency of about 1 Hz and amplitude of 1 cm. The flux rates were computed from the product of lymph flow rates and the lymphocyte counts. *Statistically significant different from case without massage. (Adapted from Ikomi F., Hunt J., Hanna G. et al. 1996. *J. Appl. Physiol.* 81: 2060.)

Thus, we view lymphatic transport as having a robust mechanism that requires the presence of two-valve systems. In fact, all compartments that rely on a repeated cycle of expansion and compression require two-valve systems, the lymphangions along the contractile lymphatics, and even larger structures such as the ventricles of the heart, the blower in the fireplace, or even the shipping locks in the Panama Canal. None of these structures can provide unidirectional transport if one of the valves is removed, irrespective of whether it is located upstream or downstream [Schmid-Schönbein, 2003].

61.3 Conclusion

The lymphatic vessel is a unique transport system that is present even in primitive physiological systems. These vessels carry out a multitude of functions, many of which have yet to be discovered. Lymphatics have a two-valve system, a primary valve system at the level of the lymphatic endothelium and a secondary valve system in the lumen of the lymphatics, facilitating unidirectional transport toward the lymphatic nodes and thoracic duct. Details of lymphatic growth kinetics are subject to initial molecular analysis designed to identify key growth factors and their molecular control [Lohela et al., 2003; Saharinen et al., 2004]. A more detailed bioengineering analysis, especially at the molecular level [Jeltsch et al., 1997] is a fruitful area for future exploration.

Defining Terms

Capillary: The smallest blood vessel of the body that provides oxygen and other nutrients to nearby cells and tissues.

Colloid osmotic pressure: A negative pressure that depends on protein concentration (mainly of albumin and globulins) and prevents excess filtration across the capillary wall.

Edema: Excess fluid or swelling within a given tissue.

Interstitium: The space between cells of various tissues of the body. Normally fluid and proteins within this space are transported from the capillary to the initial lymphatic vessel.

Lymphatic System: The clear network of vessels which return excess fluid and proteins to the blood via the thoracic duct.

Modeling in Cellular Biomechanics

Alexander A. Spector
Johns Hopkins University

Roger Tran-Son-Tay
University of Florida

62.1 Introduction

Mechanical forces, stresses, strains, and velocities play a critical role in many important aspects of cell physiology, such as cell adhesion, motility, and signal transduction. The modeling of cell mechanics is a challenging task because of the interconnection of mechanical, electrical, and biochemical processes; involvement of different structural cellular components; and multiple timescales. It can involve nonlinear mechanics and thermodynamics, and because of its complexity, it is most likely that it will require the use of computational techniques. Typical steps in the development of a cell modeling include *constitutive relations* describing the state or evolution of the cell or its components, *mathematical solution or transformation* of the corresponding equations and boundary conditions, and *computational implementation* of the model.

Modeling is a powerful tool in the simulation of processes in cells dealing with different time and spatial scales, and in the mechanical characterization of cellular parameters. It is also effective in the interpretation and design of experiments, as well as in the prediction of new effects and phenomena. It is clear that modeling would play an increasing role in improving our understanding of the biological and physiological processes in cells, under both normal and pathological conditions.

In this chapter, we focus on several important features of the cell physiology where mechanical models have been developed. All the presented analyses are based on the cell constitutive relations, in which parameters are extracted from the experiments. We also discuss different forms of cell motility, including

rolling, crawling, swimming, and gliding. The topic of cell adhesion is presented in the context of cell rolling. Finally, we review various forms of mechanotransduction in cells. Some areas where mechanics also plays an important role, such as cell growth and division, are left for further reading in the recommended literature.

62.2 Mechanical Properties of the Cell

62.2.1 Constitutive Relations

The basis of cell modeling is the relationships that exist between the applied forces (stresses) and the corresponding cellular response in terms of strains or velocities. Under appropriate timescales, the cellular material can be considered elastic. In this case, the constitutive relations express the stresses in terms of strains (displacement gradients). If a cell undergoes a large deformation (e.g., in the micropipette aspiration experiment), the corresponding equation is nonlinear. If a cell composition and the applied external forces are such that cellular properties are direction-independent then the cell is considered isotropic. If the properties of a cell or its cytoskeleton are different depending on the direction (e.g., the cylindrical cochlear outer hair cell's composite membrane is softer in the longitudinal direction) then the cell is considered anisotropic. Cells that are naturally isotropic can acquire anisotropy as a result of a directional application of an external load (e.g., a reorganization of the cytoskeleton in endothelial cells in response to blood-flow shear stresses). If stresses or (and) strains relax during the process under consideration, or there is a significant frequency effect on the cellular response, models of viscoelastic materials are used. Maxwell and Voigt models describe, respectively, fluid-type and solid-type behavior. The standard linear solid model combines the properties of both, Maxwell and Voigt models, includes two relaxation times, and can describe both stress and strain relaxation. Recently, a more general viscoelastic model for cells has been proposed [Fabry et al., 2001]. The feature of this model is a power dependence of the viscoelastic moduli on the frequency with Voigt-type and Maxwell-type behavior for low and high frequencies, respectively. Purely elastic or viscoelastic models treat the cellular material as a single phase. While the cell has several components, its content can be treated as a two-phase medium where one phase is associated with the cytoskeleton and the other is related to the cytoplasm.

Long molecules that compose the cellular cytoskeleton can be treated from the standpoint of polymer mechanics where the response of the material to the application of a force is associated with changes in entropy (transition from disorder to more order). The cytoskeletal fibers are treated either as chains of segments that are completely free to move in three directions (freely joined chain model) or as flexible slender rods (worm-like chain model). The same approaches are applied to cellular components, such as the cytoskeleton, membrane, and nucleus. There is an important distinction in the models of relatively thin cellular membranes. They are considered either as shells with a certain stress distribution across the thickness or as intrinsically two-dimensional continua. In both cases, the mechanical parameters are split into two groups: moduli characterizing the in-plane properties and those characterizing the out-of-plane bending and twist of the membrane.

62.2.2 Interpretation of Experiments

There are several major techniques that are used to extract the mechanical properties of cells. The models and experiments are interconnected: the experiments provide parameters for the models and, in turn, the models are the basis for the interpretation of the experiments. One common technique is micropipette aspiration, where a pipette is sealed on the surface of a cell, negative pressure is applied inside the pipette, and a portion of the cell is aspirated into the pipette. The height of the aspirated portion is considered as an inverse measure of the cell stiffness. The same technique is used to observe the time response of the cell to the application of pressure, and in this case, the corresponding relaxation time is a measure of the cell's viscoelastic properties. The experiment with the micropipette aspiration of a red blood cell was interpreted by considering the cell membrane (including the cytoskeleton) as a nonlinear elastic half-space
FIGURE 62.1 Simulation of the micropipette aspiration of the red blood cell cytoskeletal network for different ratios, (a) and (b), of the aspiration length L to the radius of the pipette R_p; (c) shows the profiles of the network element density $\bar{\rho}$ along the z-axis of the pipette. (From Discher, D.E., Boal, D.H., and Boey, S.K. *Biophys. J.*, 75, 1584, 1998. With permission.)

characterized by two parameters, an area expansion modulus and a shear modulus. This approach was extended to include the viscoelasticity of the cell membrane. Earlier continuum thermodynamic models of the red blood cell membrane were summarized in the monograph by Evans and Skalak [1980]. Later, Discher et al. [1998] developed an analysis of the micropipette aspiration experiment by considering the red blood cell cytoskeleton as a polymer network. Each spectrin molecule was treated as a worm-like chain, and the state of the whole network inside the micropipette was determined by a Monte Carlo simulation (Figure 62.1).

White blood cells have also been extensively studied with the micropipette, and many models have been developed to describe the cell rheological properties [Tran-Son-Tay et al., 2004; Kan et al., 1999a].

Theret et al. [1988] analyzed the micropipette experiment with endothelial cell. The cell was interpreted as a linear elastic isotropic half-space, and the pipette was considered as an axisymmetric rigid punch. This approach was later extended to a viscoelastic material of the cell and to the model of the cell as a deformable layer. The solutions were obtained both analytically by using the Laplace transform and numerically by using the finite element method. Spector et al. [1998] analyzed the application of the micropipette to a cylindrical cochlear outer hair cell. The cell composite membrane (wall) was treated as an orthotropic elastic shell, and the corresponding problem was solved in terms of Fourier series. Recently, Hochmuth [2000] reviewed the micropipette technique applied to the analysis of the cellular properties.

Another technique widely used in the estimation of the properties of cells and their components is atomic force microscopy, where the sample is probed by a sharp tip located at the end of a cantilever of a prescribed stiffness, and the corresponding indentation is tracked with a laser. The force/indentation relationship is a characterization of the cell (cellular component) properties. A traditional interpretation of this experiment is based on Hertz theory of a frictionless contact of a rigid tip with an elastic isotropic half-space [Radmacher et al., 1996]. The finite thickness of the cell can be taken into account by considering an elastic layer adhered to a substrate. More details of cell geometry and rheology can be considered by using the finite element method.

Magnetocytometry is also a popular method of the characterization of the cell mechanical properties. In this method, a magnetic bead specifically coated to adhere to a targeted area is perturbed by a magnetic field. The properties of the cell are extracted by using the resulting (force or moment)/(displacement or rotation) of the bead. Wang and Ingber [1994] used this technique to analyze how the viscoelastic properties of the cytoskeleton of endothelial cells are controlled by cell shape and the cell's interaction with the extracellular matrix. In a recent study, Karcher et al. [2003] considered a bead under the action of a magnetic force on the surface of a cellular monolayer. On the basis of a linear viscoelastic model and finite element solutions, the authors found the force/displacement relationship for the bead. Van Vilet et al. [2003] have presented a broad review of the techniques used to probe living cells.

62.2.3 Properties of Cellular Components

The cell plasma membrane is critical for mechanotransduction and cellular metabolism, and its mechanical properties have been estimated by a number of experimental techniques. The major features of biomembranes are their fluidity, bending elasticity, and the local surface area preservation. Helfrich [1973] proposed and Evans [1974] established a thermodynamic basis for a strain energy function for such membranes. Recently, Steigmann [1999] derived the most general form of the model for a two-dimensional fluid with bending resistance. For a finer analysis, another mechanical characteristic of biomembranes, nonlocal bending, was introduced [Evans, 1980; Waugh and Hochmuth, 1987; Bo and Waugh, 1989]. This parameter comes from differential area expansions and compressions of two layers of the membrane that slip relative to each other. The proposed constitutive relations for biological membranes were applied to the interpretation of important experiments, such as pulling tethers and aspiration into the micropipette.

The mechanical properties of the nucleus, the stiffest component of the cell, are important for the overall cellular response. It is, probably, even more significant that forces transmitted from the cell surface and acting on the nucleus can alter gene expression and protein synthesis. Kan et al. (1999a) have modeled the nucleus as a viscous fluid and analyzed the effect of the nucleus on the leukocyte recovery. Guilak et al. [2000] have estimated the linear viscoelastic properties of nuclei of chondrocytes. Caille et al. [2002] used a model of nonlinear elastic material to estimate Young's modulus of endothelial cell nuclei. Recently, Dahl et al. [2004], by using the micropipette technique, have estimated the mechanical properties of the cell's nuclear envelope.

62.3 Cell Motility

62.3.1 Cell Rolling and Adhesion

Cell rolling can be described as a decrease in velocity of cells (occurring only with leukocytes) in preparation to adhere to an endothelial wall. It is an essential part of a larger process of the immune system which allows leukocytes to travel and bind to trauma-induced tissues. A factor that influences the effectiveness of rolling is cell velocity. As leukocyte velocity decreases (slow rolling), the chance for adhesion rises. Another contributing factor to this phenomenon is time. Leukocytes are viscoelastic bodies, which mean that they are susceptible to deformation when a given force is applied over a specific time. As this interval grows, the shape of the leukocyte changes even more, causing an increase in the contact area of the cell. As the contact area increases, so does its chance of adhesion.

As noted earlier, there is much evidence to support the statement that rolling is an absolute prerequisite to leukocyte adhesion. This is certainly true for muscle and skin tissue. However, this is not conclusive for all tissues. The liver, lung, and heart are examples where rolling may not be necessary for leukocyte recruitment. In the lung's alveolar capillaries and the liver's sinusoids, rolling is not observed because the vessel lumen or interstitial gap is extremely small, which allows for adhesion to occur straight from tethering.

The recent cell adhesion paradigm has been developed to emphasize the role of kinetics. Conceptualized by Bell [1978] and refined by several authors [Hammer and Lauffenburger, 1987; Dembo et al., 1988], the reaction kinetics approach integrates the adhesive interaction of the cells with the surface into the

adhesion mechanism. Several physicochemical properties can affect the adhesion of a cell, such as rates of reaction, affinity, mechanical elasticity, kinetic response to stress, and length of adhesion molecules.

Several models have been proposed for describing the interaction of the leukocyte with the endothelium cells. Mathematical models of cell rolling/adhesion can be classified into two classes based on equilibrium [Evans, 1985; Alon et al., 1995] and kinetics concepts [Dembo et al., 1988; Alon et al., 1998; Kan et al., 1999b]. The kinetics approach is more capable of handling the dynamics of cell adhesion and rolling. In this approach, formation and dissociation of bonds occur according to the reverse and forward rate constants.

Using this concept, Hammer and Lauffenburger [1987] studied the effect of external flow on cell adhesion. The cell is modeled as a solid sphere, and the receptors at the surface of the sphere are assumed to diffuse and to convect into the contact area. The main finding is that the adhesion parameters, such as the reverse and forward reaction rates and the receptor number, have a strong influence on the peeling of the cell from the substrate.

Dembo et al. [1988] developed a model based on the ideas of Evans [1985] and Bell [1978]. In this model, a piece of membrane is attached to the wall, and a pulling force is exerted on one end while the other end is held fixed. The cell membrane is modeled as a thin inextensible membrane. The model of Dembo et al. [1988] was subsequently extended via a probabilistic approach for the formation of bonds by Coezens-Roberts et al. [1990]. Other authors used the probabilistic approach and Monte Carlo simulation to study the adhesion process as reviewed by Zhu [2000]. Dembo's model has also been extended to account for the distribution of microvilli on the surface of the cell and to simulate the rolling and the adhesion of a cell on a surface under shear flow. Hammer and Apte [1992] modeled the cell as a microvilli-coated hard sphere covered with adhesive springs. The binding and breakage of bonds and the distribution of the receptors on the tips of the microvilli are computed using a probabilistic approach.

In order to take into account the cell deformability, which has shown to be necessary for calculating the magnitude of the adhesion force, Dong and Lei [2000] have modeled the cell as a liquid drop encapsulated into an elastic ring. They show how the deformability and the adhesion parameters affect the leukocyte and adhesion process in shear flow. However, only a small portion of the adhesion length is allowed to peel away from the vessel wall. This constraint is not physically sound, and a more sophisticated model was developed by N'Dri et al. [2003].

Chang et al. [2000] used computer simulation of cell adhesion to study the initial tethering and rolling process based on Bell's model, and constructed a state diagram for cell adhesion under viscous flows under an imposed shear rate of 100 sec^{-1}. This shear rate corresponds to the experimental value where rolling of the cell occurs. To create the state diagrams, the ratio V/V_{H} of rolling velocity V to the hydrodynamic velocity V_{H} (velocity of nonadherent cells translating near the wall) is computed as a function of the reverse reaction rate, k_{ro}, for a given value of r_0 as using the Bell equation

$$k_{\mathrm{r}} = k_{\mathrm{ro}} \exp \left(\frac{r_0 f}{k_{\mathrm{b}} T} \right) \tag{62.1}$$

where k_{ro} is the unstressed dissociation rate constant, $k_{\mathrm{b}} T$ the thermal energy, r_0 the reactive compliance, and f the bond force. From the graph of V/V_{H} vs. k_{ro}, the values of k_{ro} for a given value of r_0 are estimated. The estimated values are used to plot k_{ro} as a function of r_0 for a given ratio of V/V_{H}. From these curves, different dynamic states of adhesion can be identified. The first state, where cells move at a velocity greater than 95% of the hydrodynamic velocity V_{H}, is defined as no adhesion state. The second state, where $0 < V/V_{\mathrm{H}} < 0.5$, is considered as the rolling domain and consists of fast and transient adhesion regimes. The firm adhesion state, where $V/V_{\mathrm{H}} = 0.0$ for a given period of time, defines the final state. Figure 62.2 shows the computed values of k_{ro} as a function of r_0.

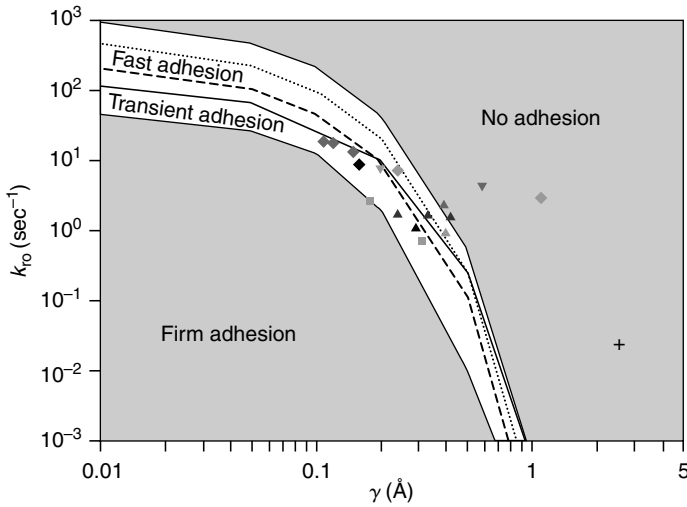
Adhesion occurs for high values of k_{ro} and low values of r_0, as indicated by the wide area between the no- and firm-adhesion zones in Figure 62.3. As r_0 increases, k_{ro} has to decrease in order for adhesion to take place. In the simulation (Figure 62.3), both association rate k_{f} and wall shear rate are kept constant. Varying k_{f} does not change the shape of the state diagram but shifts the location of the rolling envelope


FIGURE 62.2 State diagram for adhesion. Four different states are shown. The dotted curve represents velocity of 0.3 V_H and the dashed curve represents velocity of 0.1 V_H. (From Chang, K.C., Tees, D.F.J., and Hammer, D.A. *Proc. Natl Acad. Sci. USA*, 97, 11262, 2000. With permission.)
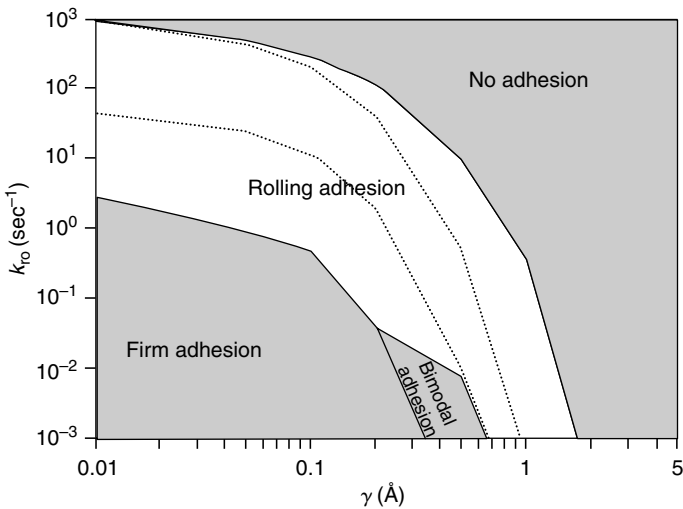

FIGURE 62.3 State of diagram for shear rate ranging from 30 to 400 sec^{-1}. The dotted curves indicate the boundaries of the rolling state at shear rate $G = 100$ sec^{-1}. The rolling adhesion area represents the region where rolling motion occurs over shear rate ranging from 30 to 400 sec^{-1}. In the bimodal-adhesion regime, cells display either firm adhesion or no adhesion, without rolling motion, as the applied shear rate is altered from 100 to 400 sec^{-1}. (From Chang, K.C., Tees, D.F.J., and Hammer, D.A. *Proc. Natl Acad. Sci. USA*, 97, 11262, 2000. With permission.)

in the k_{ro}–r_0 plane. The shear rate used in Chang et al. [2000] is in the range of the physiological flow for postcapillary venules and lies between 30 and 400 sec^{-1}. They found that as the shear rate increases, there is an abrupt change from firm adhesion to no adhesion without rolling motion. As r_0 increases, k_{ro} has to decrease in order for adhesion to take place. In the simulation, both association rate k_f and wall shear rate are kept constant. For values of r_0 less than 0.1 Å and high reverse rate constant values k_{ro}, the rolling velocity is independent of the spring constant.

Tees et al. [2002] used the approach described in Chang et al. [2000] to study the effect of particle size on the adhesion. They observed that an increase of the particle size raises the rolling velocity. This is consistent with the experimental finding of Shinde Patil et al. [2001]. In both studies, the Bell model is used to construct the state diagram but same results can be achieved using the spring model.

Using leukocytes, Alon et al. [1995] showed that the Bell equation and the spring model both fit the experimental data better than the linear relationship, suggesting an exponential dependence of k_r on F_b. Chen and Springer [1990] studied the principles that govern the formation of bonds between a cell moving freely over a substrate in shear flow and those governing the bond dissociation due to hydrodynamic forces, and found that bond formation is governed by shear rate whereas bond breakage is governed by shear stress. Their experimental data are well described by the Bell equation.

In the study of Smith et al. [1999], a high temporal and spatial resolution microscopy is used to reveal features that previous studies could not capture [Alon et al., 1995]. They found that the measured dissociation constants for neutrophil tethering events at 250 pN/bond are lower than the values predicted by the Bell and Hookean spring models. The plateau observed in the graph of the shear stress vs. the reaction rate k_r suggests that there is a force value above which the Bell and spring models are not valid. Since the model proposed so far considers the cell as a rigid body, whether the plateau is due to molecular, mechanical or cell deformation is not clear at this time.

Cell rolling and adhesion have been extensively studied over the years. However, it is clear that much further studies are needed. Table 62.1 summarizes some of the efforts reported in the literature.

62.3.2 Cell Crawling

The process of cell crawling consists of three major stages (1) extension of the leading edge, (2) establishing new adhesions in the front area and weakening of the exiting adhesions in the trailing area, and (3) pulling the back of the cell. Polymerization of the actin fibers in the protruded area of the crawling cell is considered the main mechanism of pushing the cell ahead. Thus, the modeling of the production of the pushing force is based on the polymerization/depolymerization analysis of actin fibers. There are two main approaches to the modeling of the polymerization-based active forces. In the first approach, the kinetics of a single fiber or array of fibers is considered. In the second, which is the continuum-type model, the fibers are treated as one phase of a two-phase reacting cytosol.

Peskin et al. [1993] have proposed the Brownian ratchet theory to describe the active force production. The main component of that theory was the interaction between a rigid protein and a diffusing object in front of it. If the object undergoes a Brownian motion, and the fiber undergoes polymerization, there are rates at which the polymer can push the object and overcome the external resistance. The problem was formulated in terms of a system of reaction-diffusion equations for the probabilities of the polymer to have certain number of monomers. Two limiting cases, fast diffusion and fast polymerization, were treated analytically that resulted in explicit force/velocity relationships. This theory was subsequently extended to elastic objects and to the transient attachment of the filament to the object. The correspondence of these models to recent experimental data is discussed in the article by Mogilner and Oster [2003].

Mogilner and Edelstein-Keshet [2002] modeled the protrusion of the leading edge of a cell by considering an array of actin fibers inclined with respect to the cell membrane. The authors have considered the main sequence of events associated with the actin dynamics, including polymerization of the barbed edge of the actin polymer and depolymerization at the protein pointed edge. The barbed edges assemble actin monomers with molecules of adenosine triphosphate (ATP) attached. The new barbed edges are activated by Arp2/3 complexes and they branch to start new actin filaments. The rate of polymerization is controlled by capping of the barbed edges. The problem reduced to a system of reaction-diffusion equations and was solved in the steady-state case. As a result of this solution, the force/velocity relationships corresponding to different regimes were obtained. Recently, Bindschadler et al. [2004] have constructed a comprehensive model of the actin cycle that can be used in various problems of cell motility. The authors took into account the major actin-binding protein regulating actin assembly and disassembly and solved the problem in a steady-state case.

TABLE 62.1   Overview of Some Fundamental Adhesion Kinetic Models

Kinetic model	Main assumptions/features	Major findings
Point attachment [Hammer and Lauffenberger, 1987]	Bonds are equally stressed in the contact area (flat) Binding and dissociation occur according to characteristic rate constants Receptors diffuse and convect into the binding area of contact	Adhesion occurrence depends on values of dimensionless quantities that characterize the interaction between the cell and the surface
Peeling [Dembo et al., 1988]	Clamped elastic membrane Bond stress and chemical rate constants are related to bond strain Bonds are linear springs fixed in the plane of the membrane Chemical reaction of bond formation and breakage is reversible Diffusion of adhesion molecules is negligible	Critical tension to overcome the tendency of the membrane to spread over the surface can be calculated Predictions of model depend whether the bonds are catch-bonds or slip-bonds If adhesion is mediated by catch-bonds, then no matter how much tension is applied, it is impossible to separate membrane and surface
Microvilli-coated hard sphere covered with adhesive springs [Hammer and Apte, 1992]	Combined point attachment model with peeling model Binding determined by a random statistical sampling of a probability distribution that describes the binding (or unbinding)	Model can describe rolling, transit attachment, and firm adhesion A critical adhesion modulator is the spring slippage (it relates the strain of a bond to its rate of breakage; the higher the slippage, the faster the breakage for the same strain)
Two-dimensional elastic ring [Dong et al., 1999]	Bond density related to the kinetics of bond formation Bonds are elastic springs Interaction between moving fluid and adherent cell	Shear forces acting on the entire cortical shell of the cell are transmitted on a relatively small "peeling zone" at the cell's trailing edge
Two-dimensional cell modeled as a liquid and a compound drop [N'Dri et al., 2003]	Cell deforms with nucleus inside Bonds are elastic springs Macro/micro model for cell deformation Kinetics model based on Dembo [1988]. Nano scale model for ligand-receptor Uniform flow at the inlet as in parallel-flow chamber assay	Results compare well with numerical and experimental results found in the literature for simple liquid drop Cell viscosity and surface tension affect Leukocyte rolling velocity Nucleus increases the bond lifetime and decreases leukocyte rolling velocity Cell with larger diameter rolls faster Uniform flow at the inlet as in parallel flow chamber assay

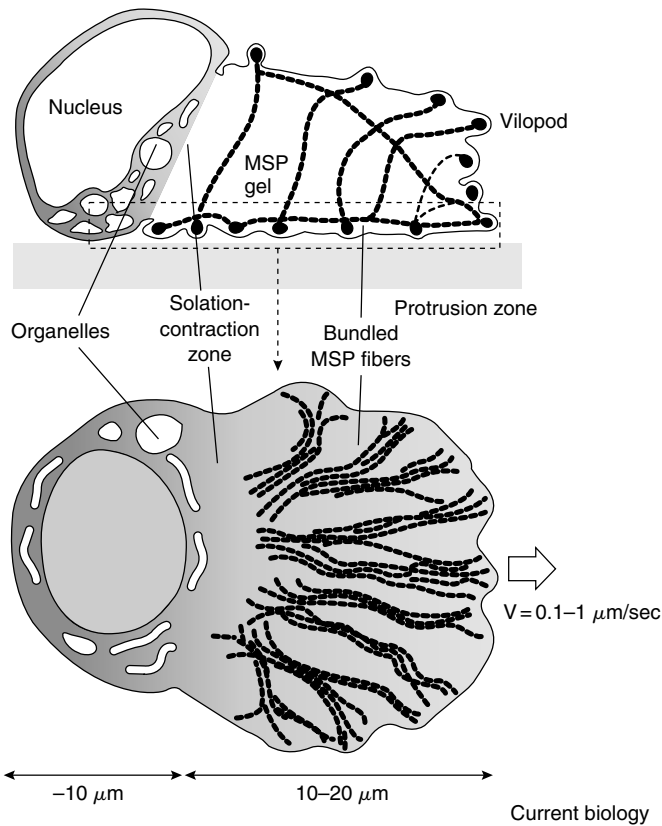
An alternative to the explicit analysis of actin fibers is a continuum approach where the cytoskeletal fibers are treated as one of two phases of the cytosol. Dembo and Harlow [1986] have proposed a general model of contractile biological polymer networks based on the analysis of reactive interpenetrating flow. In that model, the cytoplasm was viewed as a mixture of a contractile network of randomly oriented cytoskeletal filaments and an aqueous solution. Both phases were treated as homogeneous Newtonian fluids. Later, Alt and Dembo [1999] have applied a similar approach to the modeling of the motion of ameboid cells. The authors paid a special attention to the boundary conditions. They introduced three boundary surfaces: the area of contact between the cell and the substrate, the surface separating the cell


FIGURE 62.4 The model of locomotion of the nematode sperm cell. At the leading edge of the cell, the growing MSP filaments bundle into thick fibers that push the cell front out, and at the same time, store elastic energy. In the acidic environment at the rear part of the cell, the interfilament interactions weaken, the filaments unbundled and contract providing the contractile force to pull up the cell body. (From Mogilner, A. and Oster, G. *Curr. Biol.*, 13, R721, 2003. With permission.)

body and the lamellapodium, and the surface of the lamellapodium, and they specified particular boundary conditions along each of these surfaces. Numerical solution of the problem resulted in cellular responses in the form of waves along the direction of the cellular movement. Recently, a two-phase continuum model has been applied to two problems of motility of the active neutrophil. In the first problem, the neutrophil was stimulated with the chemoattractant fMLP and the generation of the pseudopod was modeled, and in the second, the cell moved inside the micropipette toward the same chemoattractant. Two models, a cytoskeletal swelling force and a polymerization force, were used for the active force production. A finite difference method in terms of the time variable and a Galerkin finite element treatment in terms of the special variables were used to obtain numerical solutions.

Bottino et al. [2002] used a version of the continuum two-phase method and studied the crawling of nematode sperm. This process is also driven by polymerization of another (not actin) protein, called the major sperm protein (MSP). The proposed model considers the major stages of crawling, including filament polymerization and generation of the force for the lamellapodial extension, storage of elastic energy, and finally the production of the contraction that pulls the rear of the cell. The total stresses consisted of two parts, the passive elastic stresses and active tensile stresses. In the acidic environment near the leading edge of the cell, the cytosol solates, and the elastic energy is released to push the cell forward. The solation was modeled by the removal of the active stresses. The solation rate was modeled by a pH gradient with lower pH at the rear part of the cell (Figure 62.4). The finite element method was used in the implementation of a two-dimensional version of the model.

62.3.3 Cell Swimming and Gliding

Most bacteria move by swimming for which they use helical flagella. In the bacteria with a left-handed helix (e.g., *Escherichia coli* and *Salmonella*), counterclockwise rotation generates a force pushing the cell forward. In contrast, clockwise rotation results in instability of the cell motion: the flagella fly apart, and the cell is not pushed in any particular direction. In the former case, the cell movement looks like smooth swimming, and in the latter case, the cell tumbles. In general, bacteria alternate between these two regimes of movement. The rotation of flagella is controlled by the molecular motor embedded in the bacterial membrane and driven by the transmembrane proton gradient. The movement of the bacterium can be changed by addition of chemoattractants, which results in suppression of tumbling and swimming toward a food source.

In contrast to bacterial swimming, many microorganisms, including myxobacteria, cyanobacteria, and flexobacteria, move via gliding. Nozzle-like structures were found in some of these bacteria. Slime is extruded through the nozzle pores, and this fact leads to a hypothesis that the bacterial sliding is driven by a slime-related propulsion mechanism. In earlier models of torque and switching in the bacterial flagellar motor, the motor consisted of two, rotating and stationary, parts. The rotating part had tilted positively and negatively charged strips along its surface. The stationary part of the motor included several channels conducting protons. Each channel had two binding sites, and therefore, could be in four states. The electrostatic energy of the interaction between the charges along the rotating part and protons bound to the channels was converted into the corresponding torque acting on the moving part. Further development and review of the models of this type can be found in Elston and Oster [1996].

CheY is one of the proteins controlling the motor in the flagella in chemotaxis. Phosphorylation of this protein results in tumbling of the bacterium. Mogilner et al. [2002] have modeled the process of switching of the bacterial molecular motor in response to binding CheY. The motor was assumed being in one of two states that correspond to the two directions of rotation of the flagella. The kinetic equations for the probabilities of the motor being in each state included a rate constant proportional to the concentration of CheY. In addition, the free energy profile with two minima that depend on the CheY concentration was introduced. As a result, the fraction of time that the motor rotates clockwise was found as a function of the CheY concentration. This function described by a sigmoidal curve was checked against experimental data and good agreement was found. Wolgemuth et al. [2002] have proposed a model of myxobacteria gliding. The authors assumed that the area inside the cell near the nozzle is filled with a polyelectrolyte gel that consists of cross-linked fibers. When the bacterium interacts with its liquid environment, the gel swells and releases from the nozzle. This results in the generation of a propulsive force pushing the bacterium forward. The authors showed that the extrusion of the gel through 50 nozzles produces a force sufficient to drive the bacterium through the viscous environment at the velocities observed in the experiment.

62.4 Mechano-, Mechanoelectrical, and Electromechanical Transduction

62.4.1 Mechanotransduction

Cells of all types are constantly exposed to external forces within their physiological environment. In mechanotransduction, cells convert the external mechanical signals into biochemical, morphological, biophysical, and the like responses. As an example, endothelial cells respond to shear stresses acting on the cell's membrane. Under physiological conditions, these stresses are associated with blood flow. In another example, the external stress (compression) causes mechanotransduction in chondrocytes, which is important, both for the functioning of natural cartilage and for design of artificial cartilage. Adhesion (traction) forces along the area of interaction of a cell with the extracellular matrix determine cell shape, which is critically important for cell's fate, including growth, division, and apoptosis (Chen et al., 1997, 2004, for review). Recently, Nelson et al. (2005) have found that cell growth is controlled by stress gradients in the cellular layer. General models that include biochemical aspect of signaling are complex; and their

philosophy is discussed in the article by Asthagiri and Lauffenburger [2000]. Here we concentrate on several biomechanical aspects of the problem. One of them is the remodeling of the cytoskeleton in endothelial cells resulting from the action of external shear stress.

Suciu et al. [1997] have modeled the process of a reorientation of the actin filaments in response to shear stress acting on the membrane of endothelial cells. The authors assumed that the filament angular drift velocity is proportional to the applied shear stress and reduced the problem to a system of integrodifferential equations in terms of the partial concentrations of actin filaments being in different states (free, attached to the membrane, etc.). The same mathematical approach was later used to model a reorganization of the actin filaments in endothelial cells subjected to a cyclic stretch (simulation of the effect of the circumferential cyclic stretch of blood vessel). The reorganization of the cytoskeleton results in overall changes in cellular mechanical properties. Thoumine et al. [1999] have analyzed such changes that occur during fibroblast spreading and they found a significant stiffening of the cell. Sato et al. [2000] have shown significant changes in the viscoelastic properties of endothelial cells as a result of the action of shear stresses.

One of the hypothesis of mechanotransduction is based on force transmission from the cell surface (cell membrane or adhesion sites) through the cytoskeleton to the nucleus, the ultimate site of biochemical signals where this pathway ends with alteration of gene expression and protein synthesis [Thomas et al., 2002]. The forces deforming the nucleus can have a severalfold effect: first, they can change the binding rates of the molecules involved in DNA synthesis and gene transcription; second, these forces can cause changes in DNA molecules and chromatin fibers; and third, they can affect transport on mRNA molecules through the nuclear pores. Jean et al. [2004, 2005], by using analytical and computational approaches, have analyzed the adhesion–cytoskeleton–nucleus mechanical pathway during the rounding of endothelial cells.

62.4.2 Mechanoelectrical Transduction, Mechanosensitive Channels, and Electromechanical Transduction

During mechanoelectrical transduction, the mechanical stimuli applied to the cell membrane result in (in-) activation of ionic currents through mechanosensitive channels. In eukaryotic cells, such channels are typically connected to the cell cytoskeleton. In several examples, stretch-activated channels modulate cell volume in cardiac ventricular myocytes, have a functional role in electrical and mechanical activity of smooth muscles, are involved in bone response to mechanical loading, produce a Ca^{++} influx that leads to waves of calcium-induced calcium release, and so on. One of the features of mechanosensitive channels is the sensing not only of the stimulus itself but also of its time history [Sachs and Morris, 1998]. The main technique of studying the physiology of mechanosensitive channels is the patch pipette, and it was found that a full opening of the channel requires several cmHg of pressure, or several thousandths of Newton per meter of the equivalent membrane force (resultant). In the modeling of mechanosensitive channels, the channel has several states, and the probability of the channel of being open is determined by free energy barriers that depend on the mechanical stimulus. Usually, this stimulus is represented by isotropic tension in the cell membrane, which, in the expression of free energy, is multiplied by a typical change in the area of the channel. Bett and Sachs [2000] have analyzed the mechanosensitive channels in the chick heart, and, to reflect the observed inactivation of ionic current, used a three — closed, open, and inactivated — state model of the channel. The authors have also proposed that inactivation consists of two stages: reorganization of the cytoskeleton and blocking action of an agent released by the cell. A quantitative description of this two-step process was based on a viscoelastic-type model that reflected the mechanical properties of the cortical layer underlying the channel. Auditory hair cells and vestibular cells receive mechanical stimuli and sense them via transducer channels located in the stereocilia bundle. The channels in hair cells receiving acoustic signal are extremely fast, typical time up to 10 μsec [Corey and Hudspeth, 1979], and there is recent evidence that they can provide an active amplification of the mechanical stimulus applied to the stereocilia. A theoretical interpretation of the behavior of these channels is based on gating-spring models that state that there is an elastic element (gating spring) whose tension determines the transition of the channel from a closed to an open state.

Electromechanical transduction, a novel form of signal transduction, was found in outer hair cells of the mammalian cochlea. The hearing process in vertebrates is associated only with the mechanoelectrical form of transduction via transducer channels in the stereocilia of a single type of sensory cells. However, mammals have a special arrangement with two types of sensory cells, inner and outer hair cells. The outer hair cells provide a positive feedback in the processing of sound via a unique form of motility, named electromotility, when unconstrained cells change their length and constrained cells generate active forces in response to changes in the cell membrane potential. Deformation of the cell causes displacement current in the cell membrane. These features constitute the direct and converse piezoelectric-type effects, and a nonlinear thermodynamically consistent piezoelectric model has been proposed to describe mechanics and electromotility of the outer hair cell [Spector, 2001; Spector and Jean, 2004].

63.1　Introduction

The inner ear is a transducer of mechanical force to appropriate neural excitation. The key element is the receptor cell, or hair cell, which has cilia on the apical surface and afferent (and sometimes efferent) neural synapses on the lateral walls and base. Generally for hair cells, mechanical displacement of the cilia in the forward direction toward the tallest cilia causes the generation of electrical impulses in the nerves, while backward displacement causes inhibition of spontaneous neural activity. Displacement in the lateral direction has no effect. For moderate frequencies of sinusoidal ciliary displacement (20 to 200 Hz), the neural impulses are in synchrony with the mechanical displacement, one impulse for each cycle of excitation. Such impulses are transmitted to the higher centers of the brain and can be perceived as sound. For lower frequencies, however, neural impulses in synchrony with the excitation are apparently confused with the spontaneous, random firing of the nerves. Consequently, there are three mechanical devices in the inner ear of vertebrates that provide perception in the different frequency ranges. At zero frequency, that is, linear acceleration, the otolith membrane provides a constant force acting on the cilia of hair cells. For low frequencies associated with rotation of the head, the semicircular canals provide the proper force on cilia. For frequencies in the hearing range, the cochlea provides the correct forcing of hair cell cilia. In nonmammalian vertebrates, the equivalent of the cochlea is a bent tube, and the upper frequency of hearing is around 7 kHz. For mammals, the upper frequency is considerably higher, 20 kHz for man but extending to almost 200 kHz for toothed whales and some bats. Other creatures, such as certain insects, can perceive high frequencies, but do not have a cochlea nor the frequency discrimination of vertebrates.

Auditory research is a broad field [Keidel and Neff, 1976]. The present article provides a brief guide of a restricted view, focusing on the transfer of the input sound pressure into correct stimulation of hair cell cilia in the cochlea. In a general sense, the mechanical functions of the semicircular canals and the otoliths are clear, as are the functions of the outer ear and middle ear; however, the cochlea continues to elude a reasonably complete explanation. Substantial progress in cochlear research has been made in the past decade, triggered by several key discoveries, and there is a high level of excitement among workers in the area. It is evident that the normal function of the cochlea requires a full integration of mechanical, electrical, and chemical effects on the milli-, micro-, and nanometer scales. Recent texts, which include details of the anatomy, are by Pickles [1988] and Gulick and coworkers [1989]. A summary of analysis and data related to the macromechanical aspect up to 1982 is given by Steele [1987], and more recent surveys specifically on the cochlea are by de Boer [1991], Dallos [1992], Hudspeth [1989], Ruggero [1993], and Nobili and colleagues [1998].

63.2   Anatomy

The cochlea is a coiled tube in the shape of a snail shell (Cochlea = Schnecke = Snail), with length about 35 mm and radius about 1 mm in man. There is not a large size difference across species: the length is 60 mm in elephant and 7 mm in mouse. There are two and one-half turns of the coil in man and dolphin, and five turns in guinea pig. Despite the correlation of coiling with hearing capability of land animals [West, 1985], no significant effect of the coiling on the mechanical response has yet been identified.

63.2.1   Components

The cochlea is filled with fluid and divided along its length by two partitions. The main partition is at the center of the cross-section and consists of three segments (1) on one side — the *bony shelf*, (or *primary spiral osseous lamina*), (2) in the middle, an elastic segment (*basilar membrane*) (shown in Figure 63.1) and (3) on the other side, a thick support (*spiral ligament*). The second partition is *Reissner's membrane*, attached at one side above the edge of the bony shelf and attached at the other side to the wall of the cochlea. *Scala media* is the region between Reissner's membrane and the basilar membrane, and is filled with *endolymphatic fluid.* This fluid has an ionic content similar to intracellular fluid, high in potassium and low in sodium, but with a resting positive electrical potential of around +80 mV. The electrical potential is supplied by the *stria vascularis* on the wall in scala media. The region above Reissner's membrane is *scala vestibuli*, and the region below the main partition is *scala tympani*. Scala vestibuli and scala tympani are connected at the apical end of the cochlea by an opening in the bony shelf, the *helicotrema*, and are filled with *perilymphatic fluid.* This fluid is similar to extracellular fluid, low in potassium and high in sodium with zero electrical potential. Distributed along the scala media side of the basilar membrane is the sensory epithelium, the *organ of Corti*. This contains one row of *inner hair cells* and three rows of *outer hair cells.* In humans, each row contains about 4000 cells. Each of the inner hair cells has about twenty afferent synapses; these are considered to be the primary receptors. In comparison, the outer hair cells are sparsely innervated but have both afferent (5%) and efferent (95%) synapses.

The basilar membrane is divided into two sections. Connected to the edge of the bony shelf, on the left in Figure 63.1, is the *arcuate zone*, consisting of a single layer of transverse fibers. Connected to the edge of the spiral ligament, on the right in Figure 63.1, is the *pectinate zone*, consisting of a double layer of transverse fibers in an amorphous ground substance. The *arches of Corti* form a truss over the arcuate zone, which consist of two rows of *pillar cells.* The foot of the inner pillar is attached at the point of connection of the bony shelf to the arcuate zone, while the foot of the outer pillar cell is attached at the common border of the arcuate zone and pectinate zone. The heads of the inner and outer pillars are connected and form the support point for the *reticular lamina*. The other edge of the reticular lamina is attached to the top of *Henson cells*, which have bases connected to the basilar membrane. The inner hair cells are attached on the bony shelf side of the inner pillars, while the three rows of outer hair cells are attached to
FIGURE 63.1 Finite element calculation for the deformation of the cochlear partition due to pressure on the basilar membrane (BM). Outer hair cell (OHC) stereocilia are sheared by the motion of the pillars of Corti and reticular lamina relative to the tectorial membrane (TM). The basilar membrane is supported on the left by the bony shelf and on the right by the spiral ligament. The inner hair cells (IHC) are the primary receptors, each with about 20 afferent synapses. The inner sulcus (IC) is a fluid region in contact with the cilia of the inner hair cells.

the recticular lamina. The region bounded by the inner pillar cells, the recticular lamina, the Henson cells, and the basilar membrane forms another fluid region. This fluid is considered to be perilymph, since it appears that ions can flow freely through the arcuate zone of the basilar membrane. The cilia of the hair cells protrude into the endolymph. Thus the outer hair cells are immersed in perilymph at 0 mV, have an intracellular potential of −70 mV, and have cilia at the upper surface immersed in endolymph at a potential of +80 mV. In some regions of the ears of some vertebrates [Freeman and Weiss, 1990], the cilia are free standing. However, mammals always have a *tectorial membrane*, originating near the edge of the bony shelf and overlying the rows of hair cells parallel to the recticular lamina. The tallest rows of cilia of the outer hair cells are attached to the tectorial membrane. Under the tectorial membrane and inside the inner hair cells is a fluid space, the *inner sulcus,* filled with endolymph. The cilia of the inner hair cells are not attached to the overlying tectorial membrane, so the motion of the fluid in the inner sulcus must provide the mechanical input to these primary receptor cells. Since the inner sulcus is found only in mammals, the fluid motion in this region generated by acoustic input may be crucial to high frequency discrimination capability.

With a few exceptions of specialization, the dimensions of all the components in the cross section of the mammalian cochlea change smoothly and slowly along the length, in a manner consistent with high stiffness at the base, or input end, and low stiffness at the apical end. For example, in the cat the basilar membrane width increases from 0.1 to 0.4 mm while the thickness decreases from 13 to 5 μm. The density of transverse fibers decreases more than the thickness, from about 6000 fibers per μm at the base to 500 per μm at the apex [Cabezudo, 1978].

63.2.2 Material Properties

Both perilymph and endolymph have the viscosity and density of water. The bone of the wall and the bony shelf appear to be similar to compact bone, with density approximately twice that of water. The remaining components of the cochlea are soft tissue with density near that of water. The stiffnesses of the components vary over a wide range, as indicated by the values of Young's modulus listed in Table 63.1. These values are taken directly or estimated from many sources, including the stiffness measurements in the cochlea by Békésy [1960], Gummer and coworkers [1981], Strelioff and Flock [1984], Miller [1985], Zwislocki and Cefaratti [1989], and Olson and Mountain [1994].

TABLE 63.1 Typical Values and Estimates for Young's Modulus E

Compact bone	20	GPa
Keratin	3	GPa
Basilar membrane fibers	1.9	GPa
Microtubules	1.2	GPa
Collagen	1	GPa
Reissner's membrane	60	MPa
Actin	50	MPa
Red blood cell, extended (assuming thickness = 10 nm)	45	MPa
Rubber, elastin	4	MPa
Basilar membrane ground substance	200	kPa
Tectorial membrane	30	kPa
Jell-O	3	kPa
Henson's cells	1	kPa

63.3 Passive Models

The anatomy of the cochlea is complex. By modeling, one attempts to isolate and understand the essential features. Following is an indication of proposition and controversy associated with a few such models.

63.3.1 Resonators

The ancient Greeks suggested that the ear consisted of a set of tuned resonant cavities. As each component in the cochlea was discovered subsequently, it was proposed to be the tuned resonator. The most well known resonance theory is Helmholtz's. According to this theory, the transverse fibers of the basilar membrane are under tension and respond like the strings of a piano. The short strings at the base respond to high frequencies and the long strings toward the apex respond to low frequencies. The important feature of the Helmholz theory is the *place principle*, according to which the receptor cells at a certain *place* along the cochlea are stimulated by a certain frequency. Thus the cochlea provides a real-time frequency separation (Fourier analysis) of any complex sound input. This aspect of the Helmholtz theory has since been validated, since each of the some 30,000 fibers exiting the cochlea in the auditory nerve is sharply tuned to a particular frequency. A basic difficulty with such a resonance theory is that sharp tuning requires small damping, which is associated with a long ringing after the excitation ceases. Yet, the cochlea is remarkable for combining sharp tuning with short time delay for the onset of reception and the same short time delay for the cessation of reception.

A particular problem with the Helmholtz theory arises from the equation for the resonant frequency for a string under tension:

$$f = \frac{1}{2b}\sqrt{\frac{T}{\rho h}} \tag{63.1}$$

in which T is the tensile force per unit width, ρ is the density, b is the length, and h is the thickness of the string. In man, the frequency range over which the cochlea operates is $f = 200$ to 20,000 Hz, a factor of 100, while the change in length b is only a factor of 5 and the thickness of the basilar membrane h varies the wrong way by a factor of 2 or so. Thus to produce the necessary range of frequency, the tension T would have to vary by a factor of about 800. In fact the spiral ligament, which would supply such tension, varies in area by a factor of only 10.

63.3.2 Traveling Waves

No theory anticipated the actual behavior found in the cochlea in 1928 by Békésy [1960]. He observed *traveling waves* moving along the cochlea from base toward apex which have a maximum amplitude at a

certain place. The place depends on the frequency, as in the Helmholz theory, but the amplitude envelope in not very localized. In Békésy's experimental models, and in subsequent mathematical and experimental models, the anatomy of the cochlea is greatly simplified. The coiling, Reissner's membrane, and the organ of Corti are all ignored, so the cochlea is treated as a straight tube with a single partition. (An exception is in Fuhrmann and colleagues [1986]). A gradient in the partition stiffness similar to that in the cochlea, gives beautiful traveling waves in both experimental and mathematical models.

63.3.3 One-Dimensional Model

A majority of work has been based on the assumption that the fluid motion is one-dimensional. With this simplification the governing equations are similar to those for an electrical transmission line and for the long wavelength response of an elastic tube containing fluid. The equation for the pressure p in a tube with constant cross-sectional area A and with constant frequency of excitation is:

$$\frac{\mathrm{d}^2 p}{\mathrm{d}x^2} + \frac{2\rho\omega^2}{AK}p = 0 \tag{63.2}$$

in which x is the distance along the tube, ρ is the density of the fluid, ω is the frequency in radians per second, and K is the generalized partition stiffness, equal to the net pressure divided by the displaced area of the cross-section. The factor of 2 accounts for fluid on both sides of the elastic partition. Often K is represented in the form of a single degree-of-freedom oscillator:

$$K = k + \mathrm{i}\omega d - m\omega^2 \tag{63.3}$$

in which k is the static stiffness, d is the damping, and m is the mass density:

$$m = \rho_P \frac{h}{b} \tag{63.4}$$

in which ρ_P is the density of the plate, h is the thickness, and b is the width. Often the mass is increased substantially to provide better curve fits. A good approximation is to treat the pectinate zone of the basilar membrane as transverse beams with simply supported edges, for which

$$k = \frac{10Eh^3 c_\mathrm{f}}{b^5} \tag{63.5}$$

in which E is the Young's modulus, and c_f is the volume fraction of fibers. Thus for the moderate changes in the geometry along the cochlea as in the cat, h decreasing by a factor of 2, c_f decreasing by a factor of 12, b increasing by a factor of 5, the stiffness k from Equation 63.4 decreases by five orders of magnitude, which is ample for the required frequency range. Thus it is the bending stiffness of the basilar membrane pectinate zone and not the tension which governs the frequency response of the cochlea. The solution of Equation 63.2 can be obtained by numerical or asymptotic (called WKB or CLG) methods. The result is traveling waves for which the amplitude of the basilar membrane displacement builds to a maximum and then rapidly diminishes. The parameters of K are adjusted to obtain agreement with measurements of the dynamic response in the cochlea. Often all the material of the organ of Corti is assumed to be rigidly attached to the basilar membrane so that h is relatively large and the effect of mass m is large. Then the maximum response is near the *in vacua* resonance of the partition given by

$$\omega^2 = \frac{b}{h}\frac{k}{\rho} \tag{63.6}$$

The following are objections to the 1-D model [Siebert, 1974] (1) The solutions of Equation 63.2 show wavelengths of response in the region of maximum amplitude that are small in comparison with the size

of the cross section, violating the basic assumption of 1-D fluid flow. (2) In the drained cochlea, Békésy [1960] observed no resonance of the partition, so there is no significant partition mass. The significant mass is entirely from the fluid and therefore Equation 63.6 is not correct. This is consistent with the observations of experimental models. (3) In model studies by Békésy [1960] and others, the localization of response is independent of the area A of the cross-section. Thus Equation 63.2 cannot govern the most interesting part of the response, the region near the maximum amplitude for a given frequency. (4) Mechanical and neural measurements in the cochlea show dispersion which is incompatible with the 1-D model [Lighthill, 1991]. (5) The 1-D model fails badly in comparison with experimental measurements in models for which the parameters of geometry, stiffness, viscosity, and density are known.

Nevertheless, the simplicity of Equation 63.2 and the analogy with the transmission line have made the 1-D model popular. We note that there is interest in utilizing the principles in an analog model built on a silicon chip, because of the high performance of the actual cochlea. Watts [1993] reports on the first model with an electrical analog of 2-D fluid in the scali. An interesting observation is that the transmission line hardware models are sensitive to failure of one component, while the 2-D model is not. In experimental models, Békésy found that a hole at one point in the membrane had little effect on the response at other points.

63.3.4 Two-Dimensional Model

The pioneering work with two-dimensional fluid motion was begun in 1931 by Ranke, as reported in Ranke [1950] and discussed by Siebert [1974]. Analysis of 2-D and 3-D fluid motion without the *a priori* assumption of long or short wavelengths and for physical values of all parameters is discussed by Steele [1987]. The first of two major benefits derived from the 2-D model is the allowance of short wavelength behavior, that is, the variation in fluid displacement and pressure in the duct height direction. Localized fluid motion near the elastic partition generally occurs near the point of maximum amplitude and the exact value of A becomes immaterial. The second major benefit of a 2-D model is the admission of a stiffness-dominated elastic partition (i.e., massless) which better approximates the physiological properties of the basilar membrane. The two benefits together address all the objections the 1-D model discussed previously.

Two-dimensional models start with the Navier-Stokes and continuity equations governing the fluid motion, and an anisotropic plate equation governing the elastic partition motion. The displacement potential φ for the incompressible and inviscid fluid must satisfy Laplace's equation:

$$\varphi_{,xx} + \varphi_{,zz} = 0 \tag{63.7}$$

where x is the distance along the partition and z the distance perpendicular to the partition, and the subscripts with commas denote partial derivatives. The averaged potential and the displacement of the partition are:

$$\bar{\varphi} = \frac{1}{H}\int_0^H \varphi \, dz \quad w = \varphi_z(x,0) \tag{63.8}$$

so Equation 63.7 yields the "macro" continuity condition (for constant H):

$$\bar{\varphi}_{,xx} - w = 0 \tag{63.9}$$

An approximate solution is

$$\bar{\varphi}(x,z,t) = F(x)\cosh[n(x)(z-H)]e^{i\omega t} \tag{63.10}$$

where F is an unknown amplitude function, n is the local wave number, H is the height of the duct, t is time, and ω is the frequency. This is an exact solution for constant properties and is a good approximation

when the properties vary slowly along the partition. The conditions at the plate fluid interface yield the dispersion relation:

$$n \tanh(nH) = \frac{2\rho\omega^2}{AK} H \tag{63.11}$$

The averaged value Equation 63.8 of the approximate potential Equation 63.10 is:

$$\bar{\tilde{\varphi}} = \frac{F \sinh nH}{nH} \tag{63.12}$$

so the continuity condition Equation 63.9 yields the equation:

$$\bar{\tilde{\varphi}}_{,xx} = n^2 \bar{\tilde{\varphi}} = 0 \tag{63.13}$$

For small values of the wave number n, the system Equation 63.11 and Equation 63.13 reduce to the 1-D problem Equation 63.2.

For physiological values of the parameters, the wave number for a given frequency is small at the stapes and becomes large (i.e., short wave lengths) toward the end of the duct. With this formulation, the form of the wave is not assumed. It is clear that for large n the WKB solution will give excellent approximation to the solution of Equation 63.13 in exponential form. So it is possible to integrate Equation 63.13 numerically for small n for which the solution is not exponential and match the solution with the WKB approximation. This provides a uniformly valid solution for the entire region of interest without an *a prior* assumption of the wave form.

For a physically realistic model, the mass of the membrane can be neglected and K written as:

$$K = k(1 + i\varepsilon) \tag{63.14}$$

in which k is the static stiffness. For many polymers, the material damping ε is nearly constant. If the damping comes from the viscous boundary layer of the fluid, then ε is approximated by

$$\varepsilon \approx n\sqrt{\frac{\mu}{2\rho\omega}} \tag{63.15}$$

in which μ is the viscosity. For water, ε is small with a value near 0.05 at the point of maximum amplitude. The actual duct is tapered, so $H = H(x)$ and additional terms must be added to Equation 63.13.

The best verification of the mathematical model and calculation procedure comes from comparison with measurements in experimental models for which the parameters are known. Zhou and coworkers [1994] provide the first life-sized experimental model, designed to be similar to the human cochlea, but with fluid viscosity 28 times that of water to facilitate optical imaging. Results are shown in Figure 63.2 and Figure 63.3. Equation 63.13 gives rough agreement with the measurements.

63.3.5 Three-Dimensional Model

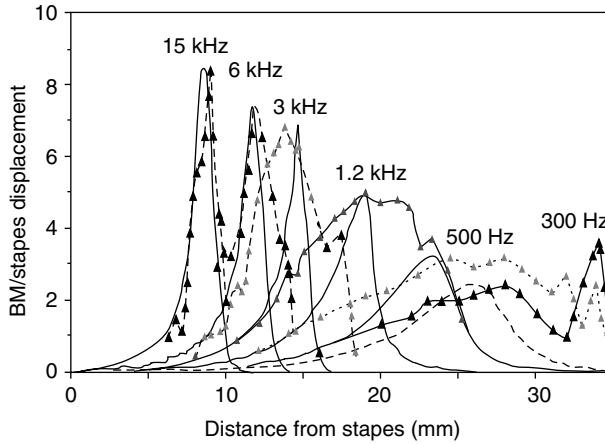
A further improvement in the agreement with experimental models can be obtained by adding the component of fluid motion in the direction across the membrane for a full 3-D model. The solution by direct numerical means is computationally intensive, and was first carried out by Raftenberg [1990], who reports a portion of his results for the fluid motion around the organ of Corti. Böhnke and colleagues [1996] use the finite element code ANSYS for the most accurate description to date of the structure of the organ of Corti. However, the fluid is not included and only a restricted segment of the cochlea considered. The fluid is also not included in the finite element calculations of Zhang and colleagues [1996]. A "large finite element method," which combines asymptotic and numerical methods for shell analysis, can be


FIGURE 63.2 Comparison of 3-D model calculations (solid curves) with experimental results of Zhou and co-workers [1994] (dashed curves) for the amplitude envelopes for different frequencies. This is a life-sized model, but with an isotropic BM and fluid viscosity 28 times that of water. The agreement is reasonable, except for the lower frequencies.
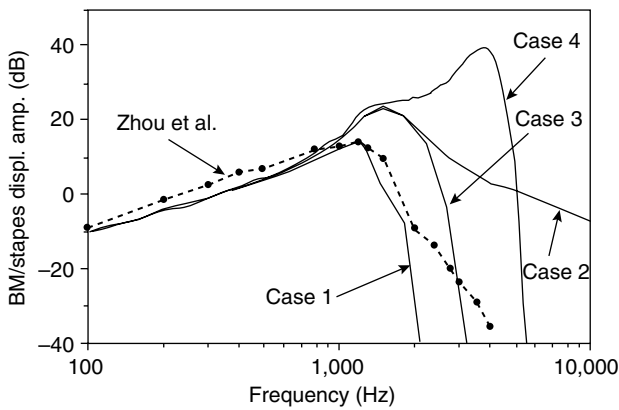

FIGURE 63.3 Comparison of 3-D model calculations with experimental results of Zhou and coworkers [1994] for amplitude at the place $x = 19$ mm as a function of frequency. The scales are logarithmic (20 dB is a factor of 10 in amplitude). Case 1 shows a direct comparison with the physical parameters of the experiment, with isotropic BM and viscosity 28 times that of water. Case 2 is computed for the viscosity reduced to that of water. Case 3 is computed for the BM made of transverse fibers. Case 4 shows the effect of active OHC feed-forward, with the pressure gain $\alpha = 0.21$ and feed-forward distance $\acute{y}x$ 25 μm. Thus lower viscosity, BM orthotropy, and active feed-forward all contribute to higher amplitude and increased localization of the response.

used for an efficient computation of all the structural detail as shown in Figure 63.1. Both the fluid and the details of the structure are considered with a simplified element description and simplified geometry by Kolston and Ashmore [1996], requiring some 10^5 degrees of freedom and hours of computing time (on a 66 MHz PC) for the linear solution for a single frequency. The asymptotic WKB solution, however, provides the basis for computing the 3-D fluid motion [Steele, 1987] and yields excellent agreement with older measurements of the basilar membrane motion in the real cochlea (with a computing time of 1 sec per frequency). The 2-D analysis Equation 63.13 can easily be extended to 3-D. The 3-D WKB calculations are compared with the measurements of the basilar membrane displacement in the experimental model of Zhou and coworkers [1994] in Figure 63.2 and Figure 63.3. As shown by Taber and Steele [1979], the 3-D

fluid motion has a significant effect on the pressure distribution. This is confirmed by the measurements by Olson [1998] for the pressure at different depths in the cochlea, that show a substantial increase near the partition.

63.4 The Active Process

Before around 1980, it was thought that the processing may have two levels. First the basilar membrane and fluid provide the correct place for a given frequency (a purely mechanical "first filter"). Subsequently, the micromechanics and electrochemistry in the organ of Corti, with possible neural interactions, perform a further sharpening (a physiologically vulnerable "second filter").

A hint that the two-filter concept had difficulties was in the measurements of Rhode [1971], who found significant nonlinear behavior of the basilar membrane in the region of the maximum amplitude at moderate amplitudes of tone intensity. Passive models cannot explain this, since the usual mechanical nonlinearities are significant only at very high intensities, that is, at the threshold of pain. Russell and Sellick [1977] made the first *in vivo* mammalian intracellular hair cell recordings and found that the cells are as sharply tuned as the nerve fibers. Subsequently, improved measurement techniques in several laboratories found that the basilar membrane is actually as sharply tuned as the hair cells and the nerve fibers. Thus the sharp tuning occurs at the basilar membrane. No passive cochlear model, even with physically unreasonable parameters, has yielded amplitude and phase response similar to such measurements. Measurements in a damaged or dead cochlea show a response similar to that of a passive model. Further evidence for an active process comes from Kemp [1978], who discovered that sound pulses into the ear caused echoes coming from the cochlea at delay times corresponding to the travel time to the place for the frequency and back. Spontaneous emission of sound energy from the cochlea has now been measured in the external ear canal in all vertebrates [Probst, 1990]. Some of the emissions can be related to the hearing disability of tinnitus (ringing in the ear). The conclusion drawn from these discoveries is that normal hearing involves an active process in which the energy of the input sound is greatly enhanced. A widely accepted concept is that spontaneous emission of sound energy occurs when the local amplifiers are not functioning properly and enter some sort of limit cycle [Zweig and Shera, 1995]. However, there remains doubt about the nature of this process [Allen and Neely (1992), Hudspeth (1989), Nobili and coworkers (1998)].

63.4.1 Outer Hair Cell Electromotility

Since the outer hair cells have sparse afferent innervation, they have long been suspected of serving a basic motor function, perhaps beating and driving the subtectorial membrane fluid. Nevertheless, it was surprising when Brownell and colleagues [1985] found that the outer hair cells have *electromotility*: the cell expands and contracts in an oscillating electric field, either extra- or intracellular. The electromotility exists at frequencies far higher than possible for normal contractile mechanisms [Ashmore, 1987]. The sensitivity is about 20 nm/mV (about 10^5 better than PZT-2, a widely used piezoelectric ceramic). It has not been determined if the electromotility can operate to the 200 kHz used by high frequency mammals. However, a calculation of the cell as a pressure vessel with a fixed charge in the wall [Jen and Steele, 1987] indicates that, despite the small diameter (10 μm), the viscosity of the intra- and extracellular fluid is not a limitation to the frequency response. In a continuation of the work reported by Hemmert and coworkers [1996], the force generation is found to continue to 80 kHz in the constrained cell. In contradiction, however, the same laboratory [Preyer and coworkers (1996)] finds that the intracellular voltage change due to displacement of the cilia drops off at a low frequency.

The motility appears to be due to a passive piezoelectric behavior of the cell plasma membrane [Kalinec and colleagues, 1992]. Iwasa and Chadwick [1992] measured the deformation of a cell under pressure loading and voltage clamping and computed the elastic properties of the wall, assuming isotropy. It appears that for agreement with both the pressure and axial stiffness measurements, the cell wall must be
FIGURE 63.4   Model of outer hair cell. The normal pumping of ions produces negative intracellular electrical potential. Displacement of the cilia in the excitatory direction causes an opening of the ion channels in the cilia. There is evidence that the channels are located at the point of closest proximity of the two cilia. The tip and lateral links are important to maintain the correct stiffness and position. The opening of the channels decreases the intracellular potential, causing a piezoelectric contraction of the cell and excitation of the neural synapses. This can be modeled by a constant flow rate pump, leak channel, and spring controlled gate. The mechanical effect of the flow on the gate is important. The inner hair cell also has cilia, no piezoelectric property, but about twenty afferent synapses.

orthotropic, similar to a filament reinforced pressure vessel with close to the optimum filament angle of 38° [Tolomeo and Steele, 1995]. Holley [1990] finds circumferential filaments of the cytoskeleton with an average nonzero angle of about 26°. Mechanical measurements of the cell wall by Tolomeo and coworkers [1996] directly confirm the orthotropic stiffness.

63.4.2 Hair Cell Gating Channels

In 1984, Pickles and colleagues discovered tip links connecting the cilia of the hair cell, as shown in Figure 63.4, that are necessary for the normal function of the cochlea. These links are about 6 nm in diameter and 200 nm long [Pickles, 1988]. Subsequent work by Hudspeth [1989] and Assad and Corey [1992] shows convincingly that there is a resting tension in the links. A displacement of the ciliary bundle in the excitatory direction causes an opening of ion channels in the cilia, which in turn decreases the intracellular potential. This depolarization causes neural excitation, and in the piezoelectric outer hair cells, a decrease of the cell length.

A purely mechanical analog model of the gating is in Steele [1992], in which the ion flow is replaced by viscous fluid flow and the intracellular pressure is analogous to the voltage. A constant flow-rate pump and leak channel at the base of the cell establish the steady-state condition of negative intracellular pressure, tension in the tip links, and a partially opened gate at the cilia through which there is an average magnitude of flow. The pressure drop of the flow through the gate has a nonlinear negative spring effect on the system. If the cilia are given a static displacement, the stiffness for small perturbation displacement is dependent on the amplitude of the initial displacement, as observed by Hudspeth [1989]. For oscillatory forcing of the cilia, the fluid analog shows that a gain in power is possible, as in an electrical or fluidic amplifier, and that a modest change in the parameters can lead to instability.

Thus it appears that amplification in the cochlea resides in the gating of the outer hair cell cilia, while the motility is due to passive piezoelectric properties of the cell wall. The flow through the gate has significant nonlinearity at small amplitudes of displacement of the cilia (10 nm). Sufficiently high amplitudes of displacement of the cilia will cause the tip links to buckle. We estimate that this will occur at around 70 dB sound pressure level, thereby turning off the active process for higher sound intensity.

There is evidence reported by Hackney and colleagues [1996] that the channels do not occur at either end of the tip links, but at the region of closest proximity of the cilia, as shown in Figure 63.4. Mechanical models such as in Furness and colleagues [1997], indicate that the channels at such a location can also be opened by force on the cilia. More elaborate models show that the stiffness of the tip links remains important to the mechanism.

There may be a connection between the gating channels and the discovery by Canlon and coworkers [1988]. They found that acoustic stimulation of the wall of the isolated outer hair cell caused a tonic (DC) expansion of the cell over a narrow frequency band, which is related to the place for the cell along the cochlea. Khanna and coworkers [1989] observe a similar tonic displacement of the whole organ of Corti.

63.5 Active Models

De Boer, [1991], Geisler [1993], and Hubbard [1993] discuss models in which the electromotility of the outer hair cells feeds energy into the basilar membrane. The partition stiffness K is expanded from Equation 35.3 into a transfer function, containing a number of parameters and delay times. These are classed as phenomenological models, for which the physiological basis of the parameters is not of primary concern. The displacement gain may be defined as the ratio of ciliary shearing displacement to cell expansion. For these models, the gain used is larger by orders of magnitude than the maximum found in laboratory measurements of isolated hair cells.

Another approach [Steele and colleagues (1993)], which is physiologically based, appears promising. The outer hair cells are inclined in the propagation direction. Thus the shearing of the cilia at the distance x causes a force from the hair cells acting on the basilar membrane at the distance $x + \Delta x$. This "feed-forward" law can be expressed in terms of the pressure as

$$p_{\text{ohc}}(x + \Delta x) = \alpha p(x) = \alpha[2p_{\text{f}}(x) + p_{\text{ohc}}(x)] \tag{63.16}$$

where p, the total pressure acting on the basilar membrane, consists of the effective pressure acting on the basilar membrane from the hair cells p_{ohc} and the pressure from the fluid p_{f}. The coefficient α is the force gain supplied by the outer hair cells. With this law, Equation 63.11 is replaced by:

$$(1 - e^{\text{in}\Delta x}) n \tanh nH = 2\frac{\rho\omega^2}{AK}H \tag{63.17}$$

from which the local wave number n must be computed numerically. Only two new parameters are needed, the gain α and the spacing Δx. With physiologically reasonable gain $\alpha = 0.18$ and spacing $\Delta x = 20\,\mu\text{m}$, the result is an increase of the response of the basilar membrane for higher frequencies by a factor of 10^2 in a narrow sector, apical to the passive peak. The simple feed-forward addition in Equation 63.17 enhances a narrow band of wave lengths without a closed control loop. At this time, it appears that much of the elaborate structure of the organ of Corti is for the purpose of such a "feed-forward." This approach is also found to work well for the 1-D model by Geisler and Sang [1995]. The results from the 3-D model for the effect of adding some feed-forward are shown in Figure 63.3. One defect of the current feed-forward results is that the shift of the maximum response point is about one octave, as seen in Figure 63.3, rather than one-half octave consistently shown in normal cochlear measurements of mechanical and neural response.

The significant nonlinear effect is the saturation of the active process at high amplitudes. This can be computed by letting the gain α be a function of the amplitude.

In the normal, active cochlea, it was first observed by Khanna and colleagues [1989] and subsequently by Gummer and colleagues [1996], that the tectorial membrane (TM in Figure 63.1) has a substantially higher amplitude than the basilar membrane. Presumably, the electromotile expansion of the outer hair cells encounters less resistance from the tectorial membrane than the basilar membrane. This shows the importance of getting the correct stiffness and geometry into a model.

63.6   Fluid Streaming

Békésy [1960] and many others have observed significant fluid streaming in the actual cochlea and in experimental models. Particularly for the high frequencies, it is tempting to seek a component of steady streaming as the significant mechanical stimulation of the inner hair cells [Lighthill, 1992]. Passive models indicated that such streaming occurs only at high sound intensity. Among the many open questions is whether or not the enhancement of amplitude provided by the feed-forward of energy by the outer hair cells and the mechanical nonlinearity at low amplitudes of displacement provided by the ciliary gating can trigger significant streaming. It is clear from the anatomy Figure 63.1, that the motion and corresponding pressure in the fluid of the inner sulcus is the primary source of excitation for the inner hair cells. The DC pressure associated with DC streaming would be an important effect.

63.7   Clinical Possibilities

A better understanding of the cochlear mechanisms would be of clinical value. Auditory pathology related to the inner ear is discussed by Pickles [1988] and Gulick and colleagues [1989]. The spontaneous and stimulated emissions from the cochlea raise the possibility of diagnosing local inner ear problems, which is being pursued at many centers around the world. The capability for more accurate, physically realistic modeling of the cochlea should assist in this process. A significant step is provided by Zweig and Shera [1995], who find that a random distribution of irregularities in the properties along the cochlea explains much of the emissions.

A patient with a completely nonfunctioning cochlea is referred to as having "nerve deafness." In fact, there is evidence that in many cases the nerves may be intact, while the receptor cells and organ of Corti are defective. For such patients, a goal is to restore hearing with cochlear electrode implants to stimulate the nerve endings directly. Significant progress has been made. However, despite electrode stimulation of nerves at the correct place along the cochlea for a high frequency, the perception of high frequency has not been achieved. So, although substantial advance in cochlear physiology has been made in the recent past, several such waves of progress may be needed to adequately understand the functioning of the cochlea.

Vestibular Mechanics

Wallace Grant
*Virginia Polytechnic Institute and
State University*

64.1 Introduction

The vestibular system is responsible for sensing motion and gravity and using this information for control of posture and body motion. This sense is also used to control eye position during head movement, allowing for a clear visual image. Vestibular function is rather inconspicuous, and for this reason it is frequently not recognized for its vital roll in maintaining balance and equilibrium, and in visual fixation with eye movements. It is truly a sixth sense, different from the five originally defined by Greek physicians.

The vestibular system is named for its position within the vestibule of the temporal bone of the skull. It is located in the inner ear along with the auditory sense. The vestibular system has both central and peripheral components. This chapter deals with the mechanical sensory function of the peripheral end organ and its ability to measure linear and angular inertial motion of the skull over the frequency ranges encountered in normal activities. The transduction process used to convert the mechanical signals into neural ones is also described.

64.2 Structure and Function

The vestibular system in each ear consists of the *otolith* and *saccule* (collectively by called the *otolithic organs*), which are the linear motion sensors, and the three *semicircular canals* (SCCs), which sense rotational motion. The SCCs are oriented in three nearly mutually perpendicular planes so that angular motion about any axis may be sensed. The otoliths and SCCs consist of membranous structures that are situated in hollowed-out sections and passageways in the vestibule of the temporal bone. This hollowed-out

64-1

section of the temporal bone is called the bony labyrinth and the membranous labyrinth, composed of cell lined soft tissue membrane, lies within this bony structure. The membranous labyrinth is filled with a fluid called *endolymph*, which is high in potassium, and the volume between the membranous and bony labyrinths is filled with a fluid called perilymph, which is similar to blood plasma.

The utricular otolith sits in the utricle and the saccular otolith is located within membranous saccule. Each of these organs is rigidly attached to the temporal bone of the skull with connective tissue. The three semicircular canals terminate on the utricle forming a complete circular fluid path and the membranous canals are also rigidly attached to the bony skull. This rigid attachment is vital to the roll of measuring inertial motion of the skull.

Each SCC has a bulge called the *ampulla* near one end, and inside the ampulla is the *cupula*, which is composed of saccharide gel, and forms a complete hermetic seal with the ampulla. The cupula sits on top of the *crista* which contains the sensory receptor cells called *hair cells*. These hair cells have small *stereocilia* (hairs) which extend into the cupula and sense its deformation. When the head is rotated the endolymph fluid, which fills the canal, tends to remain at rest due to its inertia, the relative flow of fluid in the canal deforms the cupula like a diaphragm and the hair cells transduce the deformation into nerve signals.

The otolithic organs are flat-layered structures covered above with endolymph. The top layer consists of calcium carbonate crystals called *otoconia* which are bound together by a saccharide gel. The middle layer consists of pure saccharide gel and the bottom layer consists of receptor hair cells which have stereocilia that extend into the gel layer. When the head is accelerated the dense otoconial crystals tend to remain at rest due to their inertia as the sensory layer tends to move away from the otoconial layer. This relative motion between the otoconial layer and the sensory layer deforms the gel layer. The hair cell stereocilia sense this deformation and the receptor cells transduce this deformation into nerve signals. When the head is tilted the weight acting on the otoconial layer also will deform the gel layer in shear and deflect the hair cell stereocilia. The hair cell stereocilia also have directional sensitivity which allows them to determine the direction of the acceleration acting in the plane of the otolith and saccule. The planes of the two organs are arranged perpendicular to each other so that linear acceleration in any direction can be sensed. These organs also respond to gravity and are used to measure head tilt. The *vestibular nerve*, which forms half of the *VIII cranial nerve*, innervates all of the receptor cells of the vestibular apparatus.

64.3 Otolith Distributed Parameter Model

The otoliths are an overdamped second-order system whose structure is shown in Figure 64.1a. In this model the otoconial layer is assumed to be rigid and nondeformable, the gel layer is a deformable layer of isotropic viscoelastic material, and the fluid endolymph is assumed to be Newtonian fluid. A small element of the layered structure with surface area dA is cut from the surface and a vertical view of this surface element, of width dx, is shown in Figure 64.1b. To evaluate the forces that are present, free body diagrams are constructed of each elemental layer of the small differential strip. See the nomenclature table for a description of all variables used in the following formulas (for derivation details see Grant et al., 1984 and 1991).

Otolith Variables

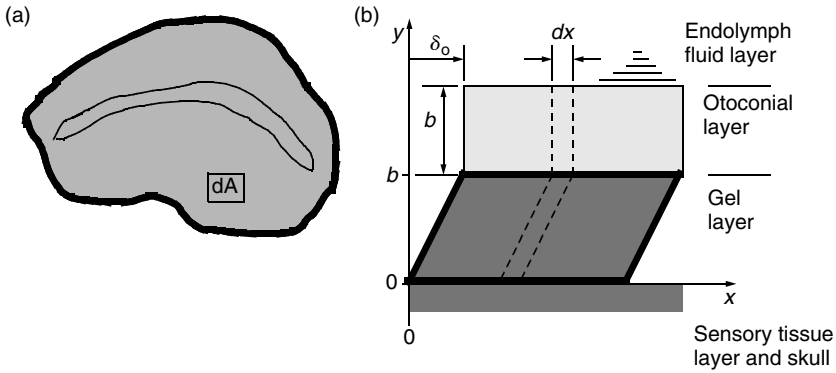
x	=	coordinate direction in the plane of the otoconial layer
y_g	=	coordinate direction normal to the plane of the otolith with origin at the gel base
y_f	=	coordinate direction normal to the plane of the otolith with origin at the fluid base
t	=	time
$u(y_f, t)$	=	velocity of the endolymph fluid measured with respect to the skull
$v(t)$	=	velocity of the otoconial layer measured with respect to the skull
$w(y_g, t)$	=	velocity of the gel layer measured with respect to the skull


FIGURE 64.1 Schematic of the otolith organ: (a) Top view showing the peripheral region with differential area dA where the model is developed, and the striolar area that makes a arch through the center of the otolith. (b) Cross section showing the layered structure where dx is the width of the differential area dA shown in the top view.

δ	=	displacement of the otoconial layer measured with respect to the skull
V_s	=	skull velocity in the x-direction measured with respect to an inertial reference frame
V	=	a characteristic velocity of the skull in the problem (e.g., magnitude of a step change)
ρ_o	=	density of the otoconial layer
ρ_f	=	density of the endolymph fluid
τ_g	=	gel shear stress in the x-direction
μ_g	=	viscosity of the gel material
μ_f	=	viscosity of the endolymph fluid
G	=	shear modulus of the gel material
b	=	gel layer and otoconial layer thickness (assumed equal)
g_x	=	gravity component in the x-direction

In the equation of motion for the endolymph fluid, the force $\tau_f dA$ acts on the fluid at the fluid–otoconial layer interface (Figure 64.2). This shear stress τ_f is responsible for driving the fluid flow. The linear Navier-Stokes equation for an incompressible fluid are used to describe this endolymph flow. Expressions for the pressure gradient, the flow velocity of the fluid measured with respect to an inertial reference frame, and the force due to gravity (body force) are substituted into the Navier-Stokes equation for flow in the x-direction yielding

$$\rho_f \frac{\partial u}{\partial t} = \mu_f \frac{\partial^2 u}{\partial y_f^2} \tag{64.1}$$

with boundary and initial conditions: $u(0, t) = v(t)$; $u(\infty, t) = 0$; and $u(y_f, 0) = 0$.

The gel layer is treated as a *Kelvin–Voight viscoelastic material* where the gel shear is acting in parallel. This viscoelastic material stress has both an elastic and viscous component acting in parallel. This viscoelastic material model was substituted into the momentum equation and the resulting gel layer equation of motion is

$$\rho_f \frac{\partial w}{\partial t} = G \int_0^t \left(\frac{\partial^2 w}{\partial y_f^2} \right) dt + \mu_f \frac{\partial^2 w}{\partial y_f^2} \tag{64.2}$$

with boundary and initial conditions: $w(b, t) = v(t)$; $w(0, t) = 0$; $w(y_g, 0) = 0$; and $\delta_g(y_g, 0) = 0$. The elastic term in the equation is written in terms of the integral of velocity with respect to time, instead of displacement, so the equation is in terms of a single dependent variable, the velocity.
FIGURE 64.2 The free-body diagrams of each layer of the otolith with the forces that act on each layer. The interfaces are coupled by shear stresses of equal magnitudes that act in opposite directions at each surface. The τ_g shear stress acts between the gel–otoconial layer and the τ_f acts between the fluid–otoconial layer. The forces acting at these interfaces are the product of shear stress τ and area dA. The B_x and W_x forces are the components of the buoyant and weight forces acting in the plane of the otoconial layer, respectively. See the nomenclature table for definitions of other variables. (a) *Endolymph fluid layer:* The spatial coordinate in the vertical direction is y_f and the velocity of the endolymph fluid is $u(y_f, t)$, a function of the fluid depth y_f and time t. (b) *Otoconial layer:* The otoconial layer with thickness b and at a height b above the gel layer vertical coordinate origin. The velocity of the otoconial layer is $v(t)$, which is a function of time only. (c) *Gel layer:* Gel layer of thickness b, vertical coordinate y_g, and horizontal coordinate δ_g the gel deflection. The gel deflection is a function of both y_g and time t. The velocity of the gel is $w(y_g, t)$, a function of y_g and t.

The otoconial layer equation was developed using Newton's second law of motion, equating the forces that act on the otoconial layer: fluid shear, gel shear, buoyant, and weight to the product of mass and inertial acceleration. The resulting otoconial layer equation is

$$\rho_o b \frac{\partial v}{\partial t} + (\rho_o - \rho_f)\left[\frac{\partial V_s}{\partial t} - g_x\right] = \mu_f \left(\left.\frac{\partial u}{\partial y_f}\right|_{y_f=0}\right) - G \int_0^t \left(\left.\frac{\partial w}{\partial y_g}\right|_{y_g=b}\right) dt + \mu_g \left(\left.\frac{\partial w}{\partial y_g}\right|_{y_g=b}\right)$$

(64.3)

with the following initial conditions $v(0) = 0$. The otoconial layer displacement can be calculated by integrating the velocity of this layer with respect to time

$$\delta = \int_0^t v \, dt \tag{64.4}$$

Displacement of the otoconial layer is the variable of importance, it is proportional to acceleration, and is the variable transduced into a neural signal.

64.4 Nondimensionalization of the Otolith Motion Equations

The equations of motion are then nondimensionalized to reduce the number of physical and dimensional parameters, and combine them into some useful nondimensional numbers. The following nondimensional variables, which are indicated by overbars, are introduced into the motion equations:

$$\bar{y}_f = \frac{y_f}{b} \quad \bar{y}_g = \frac{y_g}{b} \quad \bar{t} = \left(\frac{\mu_f}{\rho_o b^2}\right) t \quad \bar{u} = \frac{u}{V} \quad \bar{v} = \frac{v}{V} \quad \bar{w} = \frac{w}{V} \tag{64.5}$$

Several nondimensional parameters occur naturally as a part of the nondimensionalization process; these parameters are

$$R = \frac{\rho_f}{\rho_o} \quad \varepsilon = \frac{Gb^2\rho_o}{\mu_f^2} \quad M = \frac{\mu_g}{\mu_f} \quad \bar{g}_x = \left(\frac{\rho_o b^2}{V\mu_f}\right) g_x \tag{64.6}$$

These parameters represent the following: R is the density ratio and represents the system nondimentional mass, ε is a nondimensional elastic parameter and represents the system elasticity, M is the viscosity ratio and represents the system damping, and $\bar{g}_x$ is the nondimensional gravity.

The governing equations of motion in nondimensional form are then as follows:

$$\textit{Endolymph Fluid Layer} \qquad R\frac{\partial \bar{u}}{\partial \bar{t}} = \frac{\partial^2 \bar{u}}{\partial \bar{y}_f^2} \tag{64.7}$$

$$\textit{Boundary Conditions} \quad \bar{u}(0,\bar{t}) = \bar{v}(\bar{t}) \qquad \bar{u}(\infty,\bar{t}) = 0$$

$$\textit{Initial Conditions} \qquad \bar{u}(\bar{y}_f, 0) = 0$$

$$\textit{Otoconial Layer} \quad \frac{\partial \bar{v}}{\partial \bar{t}} + (1-R)\left[\frac{\partial \bar{V}_s}{\partial \bar{t}} - \bar{g}_x\right] = \left(\frac{\partial \bar{u}}{\partial \bar{y}_f}\bigg|_0\right) - \varepsilon \int_0^{\bar{t}} \left(\frac{\partial \bar{w}}{\partial \bar{y}_g}\bigg|_1\right) dt - M\left(\frac{\partial \bar{w}}{\partial \bar{y}_g}\bigg|_1\right) \tag{64.8}$$

$$\textit{Initial Condition} \quad \bar{v}(0) = 0$$

$$\textit{Gel Layer} \quad R\frac{\partial \bar{w}}{\partial \bar{t}} = \varepsilon \int_0^{\bar{t}} \left(\frac{\partial^2 \bar{w}}{\partial \bar{y}_g^2}\right) dt + M\left(\frac{\partial^2 \bar{w}}{\partial \bar{y}_g^2}\right) \tag{64.9}$$

$$\textit{Boundary Conditions} \quad \bar{w}(1,\bar{t}) = \bar{v}(\bar{t}) \qquad \bar{w}(0,\bar{t}) = 0$$

$$\textit{Initial Conditions} \qquad \bar{w}(\bar{y}_g, 0) = 0 \qquad \bar{\delta}_g(\bar{y}_g, 0) = 0$$

The nondimensional otoconial layer displacement becomes

$$\bar{\delta} = \left(\frac{V \rho_{o} b^2}{\mu_f} \right) \int_0^{\bar{t}} \bar{v} \, d\bar{t} \tag{64.10}$$

These equations can be solved numerically for the case of a step change in acceleration or velocity of the skull [Grant and Cotton, 1991]. Solutions for both step change in acceleration and velocity are shown in Figure 64.3.

64.5   Otolith Transfer Function

A transfer function of otoconial layer deflection re. (related to) skull acceleration can be obtained from the governing equations [Grant et al., 1994]. Starting with the nondimensional fluid and gel layer equations, taking the Laplace transform with respect to time and using the initial conditions, gives two ordinary differential equations. These equations can then be solved, using the boundary conditions. Taking the Laplace transform of the otoconial layer motion equation, combining with the two differential equation solutions, and integrating otoconial layer velocity to get deflection produces the transfer function for displacement re. acceleration

$$\frac{\bar{\delta}}{\bar{A}}(s) = \frac{(1 - R)}{s[s + \sqrt{Rs} + (\varepsilon/s + M)\sqrt{Rs/(\varepsilon/s + M)}\coth(\sqrt{Rs/(\varepsilon/s + M)})]} \tag{64.11}$$

s is the Laplace transform variable, and a general acceleration term A is defined as

$$\overline{A} = -\left(\frac{\partial \overline{V}_s}{\partial \bar{t}} - \bar{g}_x \right) \tag{64.12}$$

64.6   Otolith Frequency Response

This transfer function can now be studied in the frequency domain. It should be noted that these are linear partial differential equations and that the process of frequency domain analysis is appropriate. The range of values of $\varepsilon = 0.01$ to 0.2, $M = 5$ to 20, and $R = 0.75$ have been established [Grant and Cotton, 1991] in a numerical finite difference solution of the governing equations. Having established these values the frequency response can be completed.

In order to construct a magnitude and phase vs. frequency plot of the transfer function, the nondimensional time will be converted back to real time for use on the frequency axis. For the conversion to real time the following physical variables will be used: $\rho_o = 1350$ kg/m^3, $b = 15$ μm, and $\mu_f = 0.85$ mPa/sec. The general frequency response is shown in Figure 64.4. The flat response from DC up to the first corner frequency establishes this system as an accelerometer. This is the range of motion frequencies encountered in normal motion environments where this transducer is expected to function.

The range of flat response can be easily controlled with the two parameters and ε and M. It is interesting to note that both the elastic term and the system damping are controlled by the gel layer, thus an animal can easily control the system response by changing the parameters of this saccharide gel layer. The cross-linking of saccharide gels is extremely variable yielding vastly different elastic and viscous properties of the resulting structure. The density ratio R has the effect of changing the magnitude of the response, and the parameters ε and M control the dynamics of the response.

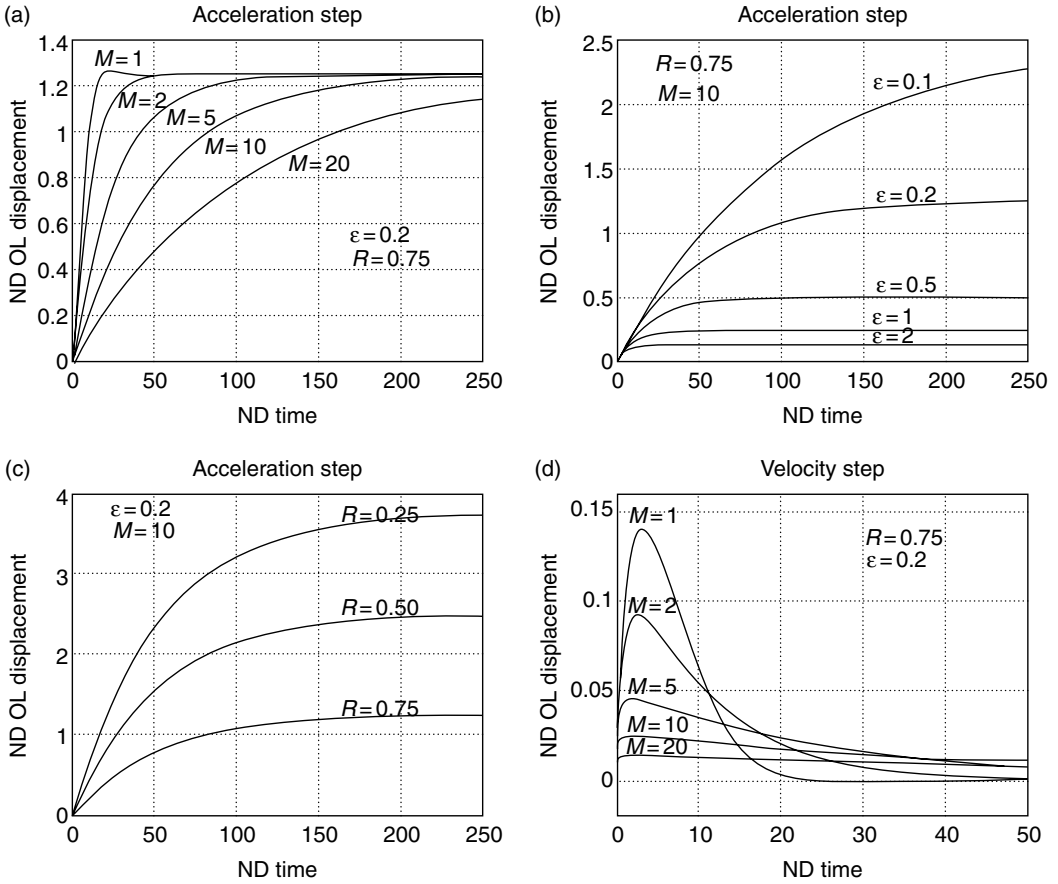
The otoconial layer transfer function can be compared to recent data from single fiber neural recording. The only discrepancy between the experimental data and theoretical model is a low-frequency phase lead and accompanying amplitude reduction. This has been observed in most experimental single-fiber recordings and has been attributed to the hair cell.


FIGURE 64.3 Solution of the otolith governing equations for the stimulus cases of a step change in acceleration and a step change in the velocity (impulse in acceleration). Scale label abbreviations used: ND = nondimensional, OL = otoconial layer. These solutions are shown for various values of the nondimensional elastic parameters ε, M, and R. In each case two of the nondimensional parameters were held constant and the remaining one was varied. These solutions reflect the general system behavior. The nondimensional time and displacement scales can be converted to real time and displacement for human physical variables as follows: nondimensional time of $1 = 0.36$ msec, and nondimensional displacement of $1 = 36\,\mu$m (human physical variables used: $b = 15\,\mu$m, $\mu_{\rm f} = 0.85$ mPa/sec, $\rho_{\rm f} = 1000$ kg/m^3, $\rho_{\rm o} = 1350$ kg/m^3, $G = 10$ Pa, $V = 0.1$ m/sec).

(a) Solution for a step change in acceleration for various values of the nondimensional system damping parameter M. The value of $M = 1$ shows a slight displacement overshoot. Note that as M is increased the displacement rise time is increased.

(b) Solution for a step change in acceleration of the head for various values of the nondimensional system elastic parameter ε. Note that as ε is increased the displacement magnitude decreases along with the rise time.

(c) Solution for a step change in acceleration of the head for various values of the nondimensional density ratio R. Since $R = \rho_f/\rho_o$, as it is increased the amplitude of displacement is decreases (the effect of increasing R is to lower the density of the otoconial layer). This parameter only changes the displacement amplitude with no effect on the dynamics.

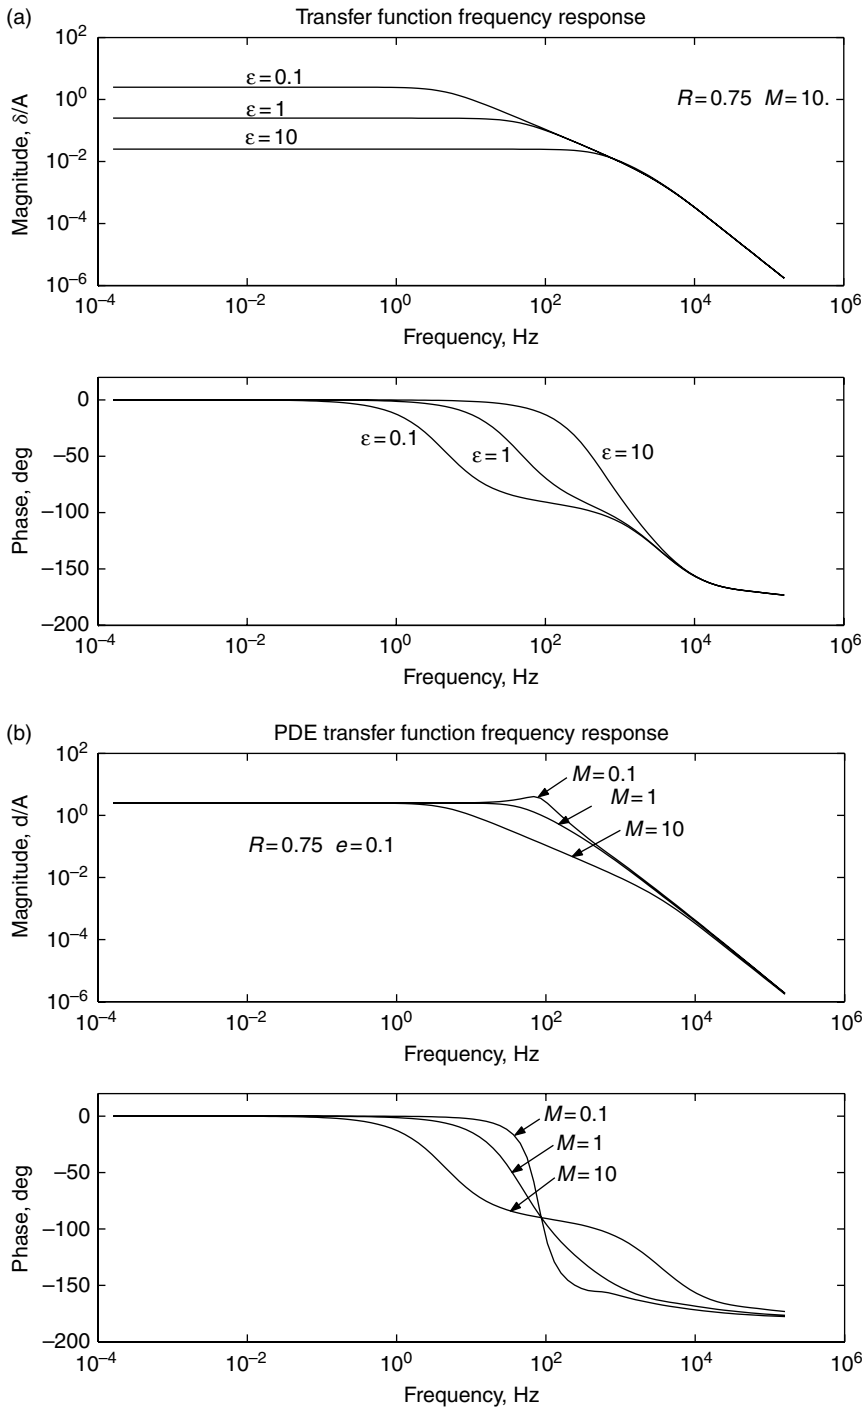
(d) Solution for a step change in velocity of the head (impulse in acceleration) for various values of the nondimensional damping parameter M. Note that as M is increased the amplitude peak is decreased and the settling time is increased. In this case the otoconial layer does not settle to a permanent fixed displacement, but returns to its equilibrium position. Again with $M = 1$ a slight overshoot on the return to equilibrium.


FIGURE 64.4 Frequency response of the utricular system shown using the transfer function of displacement re. acceleration. (a) Showing the effects of the nondimensional stiffness parameter term ε, while R and M are held constant. (b) Showing the effects of the nondimensional damping parameter term M, while R and ε are held constant. Note that the system is slightly underdamped when $M = 0.1$ as is denoted by the increase in magnitude at the corner frequency (slightly less than 10^2 Hz). This underdamped response is entirely possible since no restrictions were placed on the system during model formulation.
FIGURE 64.5 Schematic structure of the semicircular canal showing a cross section through the canal duct and utricle. Also shown in the upper right-hand corner is a cross section of the duct. R is the radius of curvature of the semicircular canal, a is the inside radius to the duct wall, and r is the spatial coordinate in the radial direction of the duct.

64.7 Semicircular Canal Distributed Parameter Model

The membranous SCC duct is modeled as a section of a rigid torus filled with an incompressible Newtonian fluid. The governing equations of motion for the fluid are developed from the Navier-Stokes equation. Refer to the nomenclature section for definition of all variables, and Figure 64.5 for a cross section of the SCC and membranous utricle sack.

Semicircular Canal Variables

$u(r,t)$	=	velocity of endolymph fluid measured with respect to the canal wall
r	=	radial coordinate of canal duct
a	=	inside radius of the canal duct
R	=	radius of curvature of semicircular canal
ρ_f	=	density of the endolymph fluid
μ_f	=	viscosity of the endolymph fluid
α	=	angular acceleration of the canal wall measured with respect to an inertial frame
ω	=	angular velocity of the canal wall measured with respect to an inertial frame
ϕ	=	angular displacement of the canal wall measured with respect to an inertial frame
Ω	=	magnitude of a step change of angular velocity of the head or canal wall
K	=	pressure–volume modulus of the cupula $= \Delta p / \Delta V$
Δp	=	differential pressure across the cupula
ΔV	=	volumetric displacement of endolymph fluid
β	=	angle subtended by the canal in radians ($\beta = \pi$ for a true semicircular canal)
λ_n	=	roots of $J_0(x) = 0$, where J_0 is Bessel's function of order 0 ($\lambda_1 = 2.405, \lambda_2 = 5.520, \ldots$)

We are interested in the flow of endolymph fluid with respect to the duct wall and this requires that the inertial motion of the duct wall $R\Omega$ be added to the fluid velocity u measured with respect to the duct wall.

The curvature of the duct can be shown to be negligible since $a \ll R$, and no secondary flow is induced, thus the curve duct can be treated as straight. Pressure gradients arise from two sources in the duct (1) presence of the utricle and (2) from the cupula. The cupula, when deflected, exerts a restoring force on the endolymph. The cupula can be modeled as a membrane with a linear pressure–volume modulus $K = \Delta p / \Delta V$, where Δp is the pressure difference across the cupula, which is produced by a volumetric displacement ΔV, where

$$\Delta V = 2\pi \int_0^t \int_0^a u(r, t) r \, dr \, dt \tag{64.13}$$

If the angle subtended by the membranous duct is denoted by β, the pressure gradient in the duct produced by the cupula is

$$\frac{\partial p}{\partial z} = \frac{K \Delta V}{\beta R} \tag{64.14}$$

The utricle pressure gradient can be approximated by [VanBuskirk, 1977]

$$\frac{\partial p}{\partial z} = \frac{2\pi - \beta}{\beta} \rho R \alpha \tag{64.15}$$

When this information is substituted into the Navier-Stokes equation the following governing equation for endolymph flow relative to the duct wall is obtained

$$\frac{\partial u}{\partial t} + \left(\frac{2\pi}{\beta}\right) R\alpha = -\frac{2\pi K}{\rho \beta R} \int_0^t \int_0^a u(r \, dr) dt + \frac{\mu_f}{\rho_f} \left[\frac{1}{r} \frac{\partial}{\partial r} \left(r \frac{\partial u}{\partial r} \right) \right] \tag{64.16}$$

This equation can be nondimensionalized using the following nondimensional variables denoted by overbars

$$\bar{r} = \frac{r}{a} \qquad \bar{t} = \left(\frac{\mu_f}{\rho_f a^2}\right) t \qquad \bar{u} = \frac{u}{R\Omega} \tag{64.17}$$

In terms of the nondimensional variables the governing equation for endolymph flow velocity becomes

$$\frac{\partial \bar{u}}{\partial \bar{t}} + \left(\frac{2\pi}{\beta}\right) \alpha(\bar{t}) = -\varepsilon \int_0^{\bar{t}} \int_0^1 (\bar{u}\bar{r}d\bar{r})dt + \frac{1}{r} \frac{\partial}{\partial \bar{r}} \left(\bar{r} \frac{\partial \bar{u}}{\partial \bar{r}} \right) \tag{64.18}$$

where the nondimensional parameter

$$\varepsilon = \frac{2K\pi a^6 \rho_f}{\beta R \mu_f^2} \tag{64.19}$$

which contains physical parameters for the system mass, stiffness, and damping. This ε parameter governs the response of the canals to angular acceleration. The boundary and initial conditions for this equation are a follows

$$\begin{array}{ll} \textit{Boundary conditions} & \bar{u}(1, \bar{t}) = 0 \qquad \dfrac{\partial \bar{u}}{\partial \bar{r}}(0, \bar{t}) = 0 \\[2mm] \textit{Initial condition} & \bar{u}(\bar{r}, 0) = 0 \end{array}$$

64.8 Semicircular Canal Frequency Response

To examine the frequency response of the SCC, a transfer function must be developed that relates the mean angular displacement of endolymph to head motion. The objective of this analysis is to see if the SCCs are angular acceleration, velocity, or displacement sensors. To achieve this, a relationship between α = angular acceleration, ω = angular velocity, and ϕ = angular displacement of the head, all measured

with respect to an inertial reference frame, is developed. This relationship in terms of the Laplace transform variable s is

$$\alpha(s) = s\omega(s) = s^2\phi(s) \tag{64.20}$$

To relate these to the mean angular displacement of endolymph, the volumetric displacement $\Delta V = \int_0^t(\int_0^a(u(r,t)2\pi r\,\mathrm{d}r))\mathrm{d}t$ is calculated from the distributed parameter solution and this is related to the mean angular displacement of the endolymph θ as

$$\theta = \frac{\Delta V}{\pi a^2 R} \tag{64.21}$$

Using the solution to the distributed parameter formulation for the SCC, for $\varepsilon \ll 1$, and for a step change in angular velocity of the canal wall Ω, the volumetric displacement becomes

$$\Delta V = \left(\frac{\pi\rho_f a^4}{8\mu_f}\right)\left(\frac{2\pi}{\beta}\right)R\Omega\sum_{n=1}^{\infty}\frac{1}{\lambda_n^4}\left(1 - \mathrm{e}^{-(\lambda_n^2\mu_f/a^2\rho_f)t}\right) \tag{64.22}$$

where λ_n represents the roots of the equation $J_0(x) = 0$, where J_0 is the Bessel function of zero order $(\lambda_1 = 2.405, \lambda_2 = 5.520, \ldots)$ [VanBuskirk et al., 1976; VanBuskirk and Grant, 1987].

A transfer function in terms of s can now be developed for frequency response analysis. This starts by developing an ordinary differential equation in θ for the system, using a moment sum about the SCC center, and developing terms for the inertia, damping, restoring moment created by the cupula incorporating ΔV. Using this relationship and Equation 64.20, the transfer function of mean angular displacement of endolymph θ re. ω the angular velocity of the canal wall (or head) is

$$\frac{\theta}{\omega}(s) = \left(\frac{\rho_f a^2}{8\mu_f}\right)\left(\frac{2\pi}{\beta}\right)\left(\frac{s}{(s + 1/\tau_L)(s + 1/\tau_S)}\right) \tag{64.23}$$

where the two time constants, one long (τ_L) and one short (τ_s) are given by:

$$\tau_S \cong \frac{a^2\rho_f}{\lambda_1^2\mu_f} \qquad \tau_L = \frac{8\mu_f\beta R}{K\pi a^4} \tag{64.24}$$

where $\tau_L \gg \tau_S$. Here the angular velocity of the head is used instead of the angular acceleration or angular displacement because, in the range of frequencies encountered by humans in normal motion, the canals are angular velocity sensors. This is easily seen if the other two transfer functions are plotted.

The utility of the above transfer function is apparent when used to generate the frequency response of the system. The values for the various parameters for humans are as follows: $a = 0.15$ mm, $R = 3.2$ mm, the dynamic viscosity of endolymph $\mu = 0.85$ mPa sec, $\rho_f = 1000$ kg/m^3, $\beta = 1.4\pi$, and $K = 3.4$ GPa/m^3. This produces values of the two time constants of $\tau_L = 20.8$ sec and $\tau_s = 0.00385$ sec. The frequency response of the system is shown in Figure 64.6. The range of frequencies from 0.01 to 30 Hz establishes the SCCs as angular velocity transducers of head motion. This range includes those encountered in everyday movement. Environments such a aircraft flight, automobile travel, and shipboard travel can produce frequencies outside the linear range for these transducers.

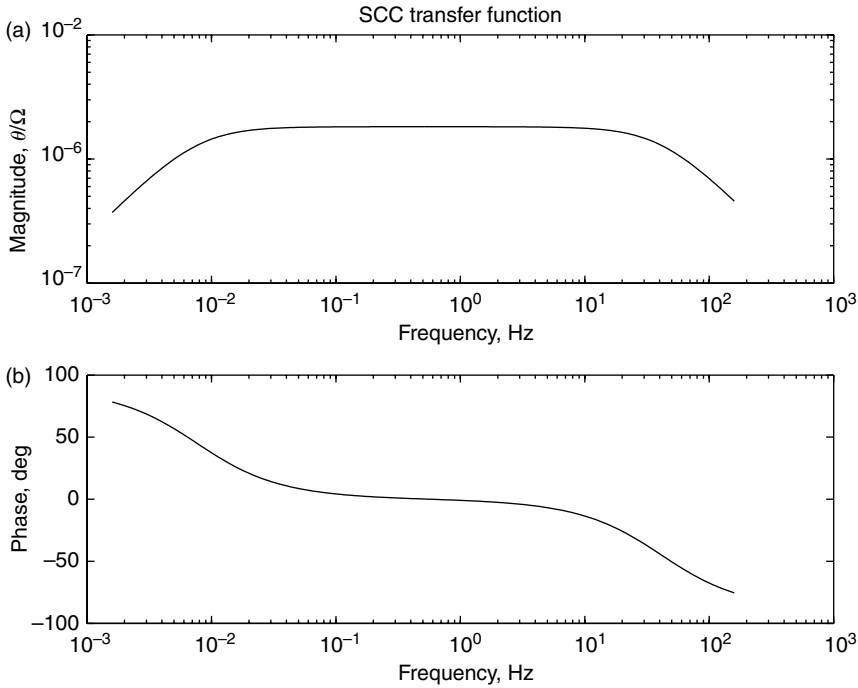
Rabbitt and Damino [1992] have modeled the flow of endolymph in the ampulla and its interaction with the cupula. This model indicates that the cupula adds a high frequency gain enhancement as well as phase lead over previous mechanical models. This is consistent with measurements of vestibular nerve recordings of gain and phase. Prior to this work, this gain and phase enhancement were thought to be of hair cell origin.


FIGURE 64.6 Frequency response of the human semicircular canals for the transfer function of mean angular displacement of endolymph fluid θ re. angular velocity of the head ω.

64.9 Hair Cell Structure and Transduction

As can be seen from the two frequency response diagrams for the otolith and SCC, the sensed variables, linear acceleration in the case of the otolith and angular velocity for the SCC, are transduced into a displacements. These displacements are cupula displacement for the SCC and otoconial layer displacement for the otolith. These displacements are then further transduced into neural signals by the hair cells in each sensory organ. The hair cells project small cilia or hairs, called *stereocilia*, from the apical surface of the cell body into the otolith gel layer and cupula (see Figure 64.7 and Figure 64.8). Figure 64.7 shows the geometry of a single stereocilium, which is cylindrical in shape and has a tapered base. Each stereocilium has an internal core of actin, which deforms when a force is applied to its top. Because of the tapered base, most of the deformation in a stereocilium is bending in this tapered section with a top force applied. Both bending and shear deformation take place throughout the entire stereocilia when they are deflected.

The stereocilia of a single hair cell form a bundle, with definite regular spacing in an hexagonal array when viewed form the top (see Figure 64.7). The height of each stereocilium in a bundle increases, in a stepwise fashion, to form an organ pipe arrangement. Stereocilia in a bundle are bound together by a set of links the run from stereocilia to stereocilia. These bundle links are what forms a bundle into a single functional unit. These links come in many types; however, there are two main structural types, *tip links* that run up at an angle from the tip of the stereocilia to its next taller neighbor, and *upper lateral links* that run horizontally in sets. The lateral links extend from one stereocilia to its six neighbors, forming six sets associated with each stereocilia.

A set is composed of a group of links that are spaced up and down the height of the stereocilia. The protein composition of these links is unknown, but each type of link is believed to have a different structure. The tip links are stiff and resist elongation more than the lateral links. The tallest cilia in the bundle is called a *kinocilium*, which is a true cilia with 9+2 tubule structure, different from the stereocilia, and it is linked to its neighboring stereocilia by a third type of link called a *stereocilia–kinocilium link.* Other link
FIGURE 64.7 Configuration of a vestibular hair cell bundle. (a) Stereocilia geometry of circular shaft with tapered base. These stereocilia are composed of actin surrounded by the cell membrane. (b) Bundle geometry for a typical vestibular stereocilia bundle, showing the staircase arrangement of increasing height of the stereocilia in the bundle. The tallest cilia in the bundle is different in structure from the stereocilia and is called a kinocilium, which has the 9+2 microtubule structure of a true cilium. The microtubule structure lacks the biochemical ability to be mobile and it appears to be present for structural rigidity only. (c) Lateral view of two stereocilia connected by tip and lateral links. (d) Top view of the stereocilia showing the locations of orientation of the tip links. (e) Top view of the stereocilia showing the locations and orientation of the lateral links.

structures have been identified in the bundle but will not be discussed here, as these are thought to be insignificant structural links. These interconnected stereocilia and kinocilium form a complete vestibular bundle.

Kinocilia are attached to the cupula and otoconial gel layer so that when these are deflected the kinocilia are also deflected pulling the entire hair cell bundle with it. When a hair cell bundle is deflected by a force applied to the kinocilium in a direction away from the bundle, the resulting deflection stretches the tip

(a)   (b)

Due to the fixation and drying for electron microscopy many artifacts are introduced in the bundle. (Photomicrographs taken by Dr. Ellengene Peterson, Ohio University, and used here with permission.)

links increasing their tension. In addition, lateral links are tensioned as well. The increased tension in a tip link increases the probability that an ion channel attached to the tip link will open. These ion channels are imbedded in the outer lipid bilayer of the hair cell and there is evidence that there are as many as two channels on each tip link. When tip link tension opens a channel, it allows free positive ions from the surrounding endolymph fluid to flow into the intercellular space of the hair cell. This influx of positive ions decreases the resting membrane potential of the cell. This starts the cascade of events that are associated with the depolarization of any sensory receptor cell, which ends with the release of neurotransmitter, and firing of the nerve that is in contact with the cell. In this fashion the mechanical deflection of the hair cell's bundle is converted into a neural signal. This process is termed *mechanotransduction*, and when linked with the extracellular structure of otoconial layer deflection and cupula deflection, the entire organ function becomes a complex inertial motion sensor of the head.

64.10 Hair Cell Mechanical Model

Mechanical deformation behavior of the hair cell bundles has been analyzed using finite element analysis (FEA). This analysis was done using a custom-written program that will accommodate any hair bundle configuration [Cotton and Grant, 2000]. The resulting model is a three-dimensional, distributed para-meter formulation which ramps up any applied force in incremental steps. Each force step considers the new, deformed geometry and recalculates displacements, link tensions, and internal force directions, until each of these values converges. This incremental ramp loading is a nonlinear computational process.
FIGURE 64.9 Circle plots of a bundle showing the tip link tensions in pN. These plots are topviews of the bundle where each stereocilia and kinocilium in the bundle is represented by a circle. The arrangement is to scale and represents the organization of cilia studied. The tip links are represented as solid lines connecting the circles. The number inside each circle represents the tension in the tip link attached to the top of that stereocilium which runs to the side of the next taller stereocilium. The shading is a relative designation of the tip link tension within that bundle, with dark indicating maximum tension. Stereocilia with an N designation indicates the absence of a tip link due to the absence of a taller stereocilium for attachment. The kinocilium is shown with a K in its circle. In the figure the bundle has a point loaded force applied at the top of the kinocilium. The magnitude of the applied force was adjusted to produce a bundle deflection of 50 nm. The force magnitude to produce the 50 nm deflection is 8 pN.

The model uses shear deformable beam elements for cilia. Tip links and lateral links are modeled as two-force members with linear spring-like behavior in tension. Lateral links can buckle and are not allowed to support compressive loads. Tip links are almost always in tension, they are treated similarly to lateral links and are not allowed to support a compressive load.

The program allows input specifications of material and geometric properties. Geometric properties include cilia and link diameters, tapering at the base of stereocilia, and cilia locations on the hair cell's apical surface. Material properties include elastic moduli for cilia and links, and the shear moduli for cilia.

In order to formulate a realistic bundle model, geometric data was gathered using light microscope and SEM photomicrographs. Material properties were determined from reference materials and using parametric studies. Figure 64.9 illustrates the pattern of tip link tensions generated in a bundle which is loaded with a force of sufficient magnitude to produce a 50-nm deflection, a typical large physiologic deflection (for details see Silber et al., 2004). In this figure, circles represent the configuration of stereocilia and kinocilium (K) on the apical surface of each hair cell (bundle viewed from top). The number inside each circle is the magnitude of tension in pN (peco Newtons) for the tip link attached to the top of that stereocilium; shading is scaled to this magnitude. The simulations shows that tensions are highest close to the kinocilium, and they drop steadily with distance from the kinocilium. Note also that higher tensions generally tend to occur in the middle columns of the bundle; peripheral columns have relatively low tensions, even those close to the kinocilium.

64.11 Concluding Remark

The mechanical signal of inertial head motion has been followed and quantified through the vestibular organs to neural signals that are generated in the receptor hair cells. As stated in the introduction, the central nervous system uses these signals for eye positioning during periods of motion and to coordinate muscular activity. The biggest problem for people who have lost their vestibular function is not being able to see during periods of body motion. Implantable artificial vestibules are being developed for future medical application.

Exercise Physiology

Arthur T. Johnson
Cathryn R. Dooly
University of Maryland

The study of exercise is important to medical and biological engineers. Cognizance of acute and chronic responses to exercise gives an understanding of the physiological stresses to which the body is subjected. To appreciate exercise responses requires a true systems approach to physiology, because during exercise all physiological responses become a highly integrated, total supportive mechanism for the performance of the physical stress of exercise. Unlike the study of pathology and disease, the study of exercise physiology leads to a wonderful understanding of the way the body is supposed to work while performing at its healthy best.

For exercise involving resistance, physiological and psychological adjustments begin even before the start of the exercise. The central nervous system (CNS) sizes up the task before it, assessing how much muscular force to apply and computing trial limb trajectories to accomplish the required movement. Heart rate may begin rising in anticipation of increased oxygen demands and respiration may also increase.

65.1 Muscle Energetics

Deep in muscle tissue, key components have been stored for this moment. Adenosine triphosphate (ATP), the fundamental energy source for muscle cells, is at maximal levels. Also stored are significant amounts of creatine phosphate and glycogen.

When the actinomyocin filaments of the muscles are caused to move in response to neural stimulation, ATP reserves are rapidly used, and ATP becomes adenosine diphosphate (ADP), a compound with much less energy density than ATP. Maximally contracting mammalian muscle uses approximately 1.7×10^{-5} mole of ATP per gram per second [White et al., 1959]. ATP stores in skeletal muscle tissue amount to 5×10^{-6} mole per gram of tissue, or enough to meet muscle energy demands for no more than 0.5 sec.

65-1

Initial replenishment of ATP occurs through the transfer of creatine phosphate (CP) into creatine. The resting muscle contains 4 to 6 times as much CP as it does ATP, but the total supply of high-energy phosphate cannot sustain muscle activity for more than a few seconds.

Glycogen is a polysaccharide present in muscle tissues in large amounts. When required, glycogen is decomposed into glucose and pyruvic acid, which, in turn, becomes lactic acid. These reactions form ATP and proceed without oxygen. They are thus called **anaerobic.**

When sufficient oxygen is available (aerobic conditions), either in muscle tissue or elsewhere, these processes are reversed. ATP is reformed from ADP and AMP (adenosine monophosphate), CP is reformed from creatine and phosphate (P), and glycogen is reformed from glucose or lactic acid. Energy for these processes is derived from the complete oxidation of carbohydrates, fatty acids, or amino acids to form carbon dioxide and water. These reactions can be summarized by the following equations:

Anaerobic:

$$\text{ATP} \leftrightarrow \text{ADP} + \text{P} + \text{free energy} \tag{65.1}$$

$$\text{CP} + \text{ADP} \leftrightarrow \text{creatine} + \text{ATP} \tag{65.2}$$

$$\text{glycogen or glucose} + \text{P} + \text{ADP} \rightarrow \text{lactate} + \text{ATP} \tag{65.3}$$

Aerobic:

$$\text{Glycogen or fatty acids} + \text{P} + \text{ADP} + \text{O}_2 \rightarrow \text{CO}_2 + \text{H}_2\text{O} + \text{ATP} \tag{65.4}$$

All conditions:

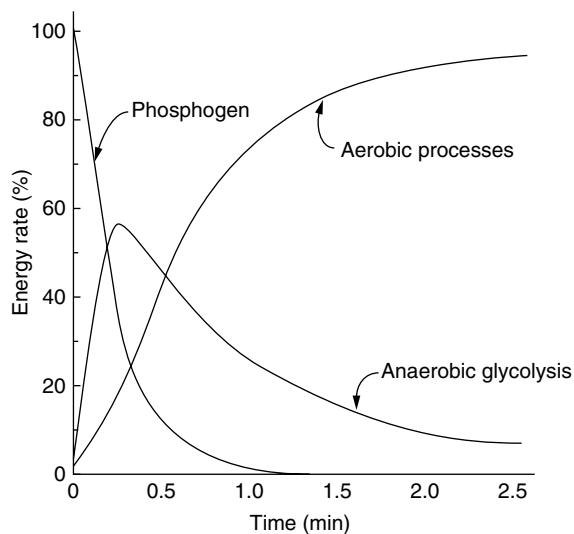
$$2\text{ADP} \leftrightarrow \text{ATP} + \text{AMP} \tag{65.5}$$
The most intense levels of exercise occur anaerobically [Molé, 1983] and can be maintained for only a minute or two (Figure 65.1).


FIGURE 65.1 Muscle energy sources at the beginning of exercise. (Redrawn from Molé, 1983. In A.A. Bove and D.T. Lowenthal [Eds.], *Exercise Medicine*, pp. 43–88. New York, Academic Press. With permission.)

65.2 Cardiovascular Adjustments

Mechanoreceptors in the muscles, tendons, and joints send information to the CNS that the muscles have begun movement, and this information is used by the CNS to increase heart rate via the sympathetic autonomic nervous system. Cardiac output, the rate of blood pumped by the heart, is the product of heart rate and stroke volume (amount of blood pumped per heart beat). Heart rate increases nearly exponentially at the beginning of exercise with a time constant of about 30 s. Stroke volume does not change immediately but lags a bit until the cardiac output completes the loop back to the heart.

During rest a large volume of blood is stored in the veins, especially in the extremities. When exercise begins, this blood is transferred from the venous side of the heart to the arterial side. Attempting to push extra blood flow through the resistance of the arteries causes a rise in both systolic (during heart ventricular contraction) and diastolic (during the pause between contractions) blood pressures. The increased blood pressures are sensed by baroreceptors located in the aortic arch and carotid sinus (Figure 65.2).

As a consequence, small muscles encircling the entrance to the arterioles (small arteries) are caused to relax by the CNS. Since, by Poiseuille's Law:

$$R = \frac{8L\mu}{\pi r^4} \tag{65.6}$$

where

R = resistance of a tube, N·sec/m^5
L = length of the tube, m
μ = viscosity of the fluid, kg/(m·sec) or N·sec/m^2
r = radius of the tube lumen, m

increasing the arteriole radius by 19% will decrease its resistance to one-half. Thus, systolic pressure returns to its resting value, and diastolic pressure may actually fall. Increased blood pressures are called *afterload* on the heart.

To meet the oxygen demand of the muscles, blood is redistributed from tissues and organs not directly involved with exercise performance. Thus, blood flows to the gastrointestinal tract and kidneys are reduced, whereas blood flows to skeletal muscle, cardiac muscle, and skin are increased.

The heart is actually two pumping systems operated in series. The left heart pumps blood throughout the systemic blood vessels. The right heart pumps blood throughout the pulmonary system. Blood pressures in the systemic vessels are higher than blood pressures in the pulmonary system.

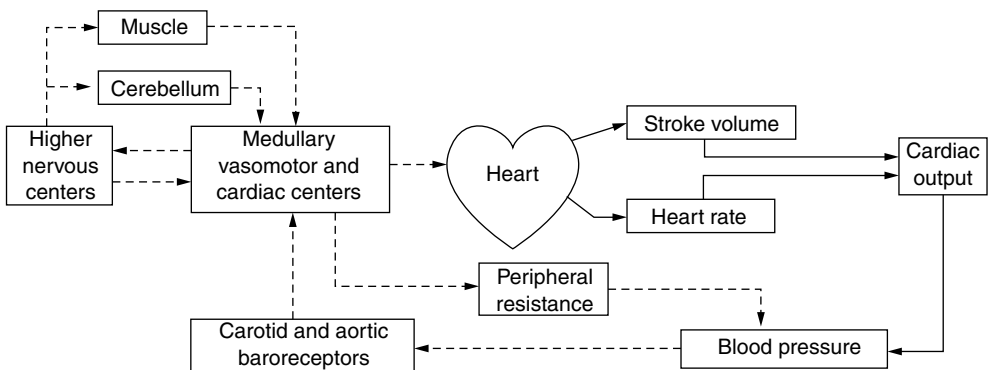
Two chambers comprise each heart. The atrium is like an assist device that produces some suction and collects blood from the veins. Its main purpose is to deliver blood to the ventricle, which is the more


FIGURE 65.2 General scheme for blood pressure regulation. Dashed lines indicate neural communication, and solid lines indicate direct mechanical effect.

powerful chamber that develops blood pressure. The myocardium (heart muscle) of the left ventricle is larger and stronger than the myocardium of the right ventricle. With two hearts and four chambers in series, there could be a problem matching flow rates from each of them. If not properly matched, blood could easily accumulate downstream from the most powerful chamber and upstream from the weakest chamber.

Myocardial tissue exerts a more forceful contraction if it is stretched before contraction begins. This property (known as *Starling's law of the heart*) serves to equalize the flows between the two hearts by causing a more powerful ejection from the heart in which more blood accumulates during diastole. The amount of initial stretching of the cardiac muscle is known as *preload.*

65.3 Maximum Oxygen Uptake

The heart has been considered to be the limiting factor for delivery of oxygen to the tissues. As long as oxygen delivery is sufficient to meet demands of the working muscles, exercise is considered to be aerobic. If oxygen delivery is insufficient, anaerobic metabolism continues to supply muscular energy needs, but lactic acid accumulates in the blood. To remove lactic acid and reform glucose requires the presence of oxygen, which must usually be delayed until exercise ceases or exercise level is reduced.

Fitness of an individual is characterized is characterized by a mostly reproducible measurable quantity known as maximal oxygen uptake ($V_{O_{2max}}$) that indicates a person's capacity for aerobic energy transfer and the ability to sustain high-intensity exercise for longer than 4 or 5 min (Figure 65.3). The more fit, the higher is$V_{O_{2max}}$. Typical values are 2.5 l/min for young male nonathletes, 5.0 l/min for well-trained male athletes; women have $V_{O_{2max}}$ values about 70 to 80% as large as males. Maximal oxygen uptake declines with age steadily at 1% per year.

Exercise levels higher than those that result in $V_{O_{2max}}$ can be sustained for various lengths of time. The accumulated difference between the oxygen equivalent of work and $V_{O_{2max}}$ is called the **oxygen deficit** incurred by an individual (Figure 65.4). There is a maximum oxygen deficit that cannot be exceeded by an individual. Once this maximum deficit has been reached, the person must cease exercise.

The amount of oxygen used to repay the oxygen deficit is called the **excess postexercise oxygen consumption** (EPOC). EPOC is always larger than the oxygen deficit because (1) elevated body temperature immediately following exercise increases bodily metabolism in general, which requires more than resting levels of oxygen to service, (2) increased blood epinephrine levels increase general bodily metabolism, (3) increased respiratory and cardiac muscle activity requires oxygen, (4) refilling of body oxygen stores requires excess oxygen, and (5) there is some thermal inefficiency in replenishing muscle chemical stores. Considering only lactic acid oxygen debt, the total amount of oxygen required to return the body to its normal resting state is about twice the oxygen debt; the efficiency of anaerobic metabolism is about 50% of aerobic metabolism.

65.4 Respiratory Responses

Respiratory also increases when exercise begins, except that the time constant for respiratory response is about 45 sec instead of 30 sec for cardiac responses (Table 65.1). Control of respiration (Figure 65.5) appears to begin with chemoreceptors located in the aortic arch, in the carotid bodies (in the neck), and in the ventral medula (in the brain). These receptors are sensitive to oxygen, carbon dioxide, and acidity levels but are most sensitive to carbon dioxide and acidity. Thus, the function of the respiratory system appears to be remove excess carbon dioxide and, secondarily, to supply oxygen. Perhaps this is because excess CO_2 has narcotic effects, but insufficient oxygen does not produce severe reactions until oxygen levels in the inhaled air fall to one-half of normal. There is no well-established evidence that respiration limits oxygen delivery to the tissues in normal individuals.

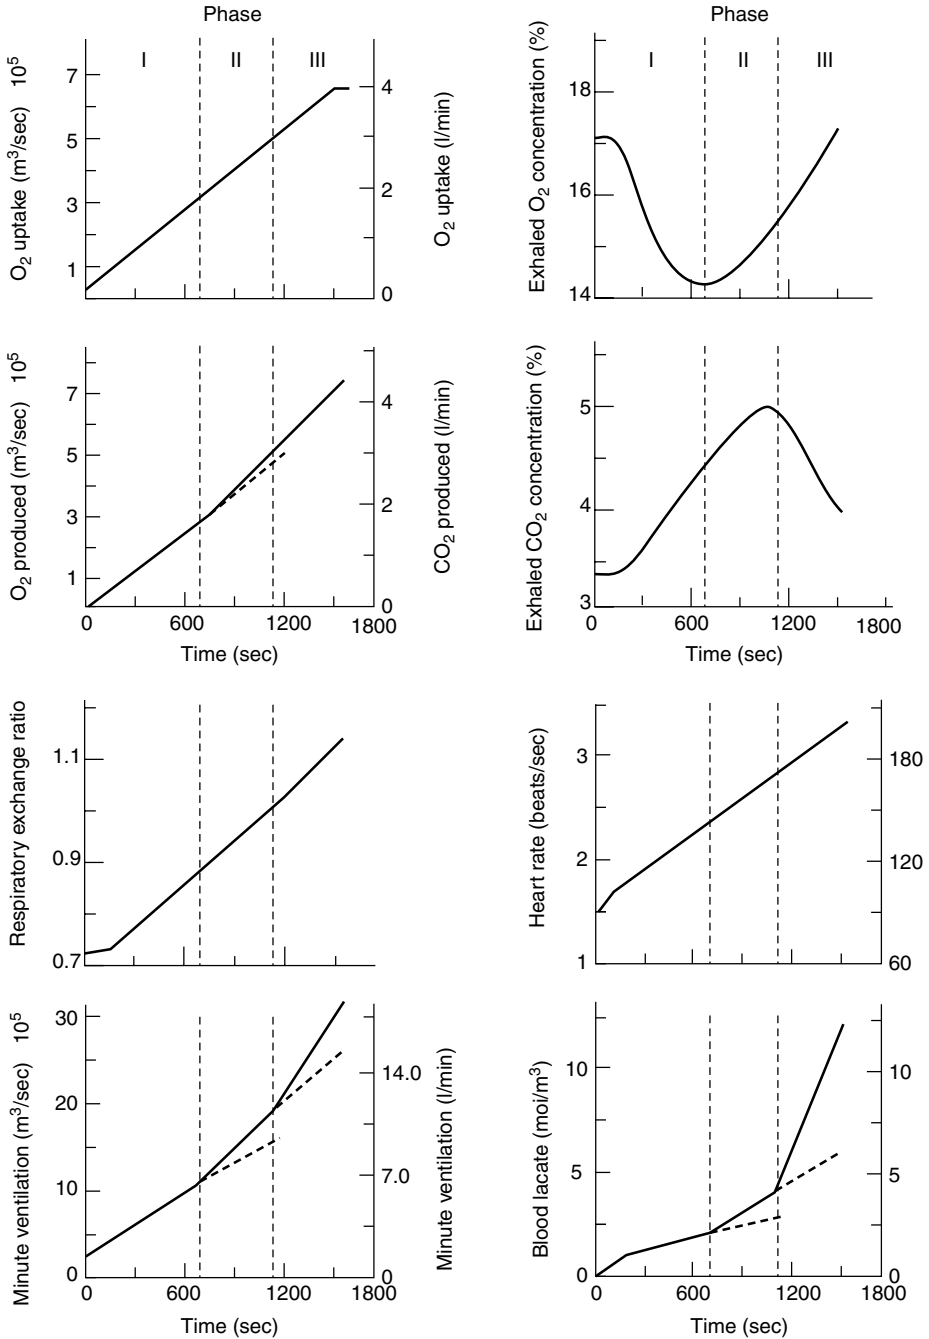
Oxygen is conveyed by convection in the upper airways and by diffusion in the lower airways to the alveoli (lower reaches of the lung where gas exchange with the blood occurs). Oxygen must diffuse from


FIGURE 65.3 Concurrent typical changes in blood and respiratory parameters during exercise progressing from rest to maximum. (Adapted and redrawn from Skinner, J.S. and McLellan, T.H. 1980, by permission of the American Alliance for Health, Physical Education, Recreation and Dance.)

the alveoli, through the extremely thin alveolocapillary membrane into solution in the blood. Oxygen diffuses further into red blood cells where it is bound chemically to hemoglobin molecules. The order of each of these processes is reversed in the working muscles where the concentration gradient of oxygen is in the opposite direction. Complete equilibration of oxygen between alveolar air and pulmonary blood
FIGURE 65.4 Oxygen uptake at the beginning of constant-load exercise increases gradually, accumulating an oxygen deficit that must be repaid at the end of exercise.

TABLE 65.1 Comparison of Response Time Constants for Three Major Systems of the Body

System	Dominant time constant, sec
Heart	30
Respiratory system	45
Oxygen uptake	49
Thermal system	3600

requires about 0.75 sec. Carbon dioxide requires somewhat less, about 0.50 sec. Thus, alveolar air more closely reflects levels of blood carbon dioxide than oxygen.

Both respiration rate and tidal volume (the amount of air moved per breath) increase with exercise, but above the anaerobic threshold the tidal volume no longer increases (remains at about 2 to 2.5 l). From that point, increases in ventilation require greater increases in respiration rate. A similar limitation occurs for stroke volume in the heart (limited to about 120 ml).

The work of respiration, representing only about 1 to 2% of the body's oxygen consumption at rest, increases to 8 to 10% or more of the body's oxygen consumption during exercise. Contributing greatly to this is the work to overcome resistance to movement of air, lung tissue, and chest wall tissue. Turbulent airflow in the upper airways (those nearest and including the mouth and nose) contributes a great deal of pressure drop. The lower airways are not as rigid as the upper airways and are influenced by the stretching and contraction of the lung surrounding them. High exhalation pressures external to the airways coupled with low static pressures inside (due to high flow rates inside) tend to close these airways somewhat and limit exhalation airflow rates. Resistance of these airways becomes very high, and the respiratory system appears like a flow source, but only during extreme exhalation.

65.5 Optimization

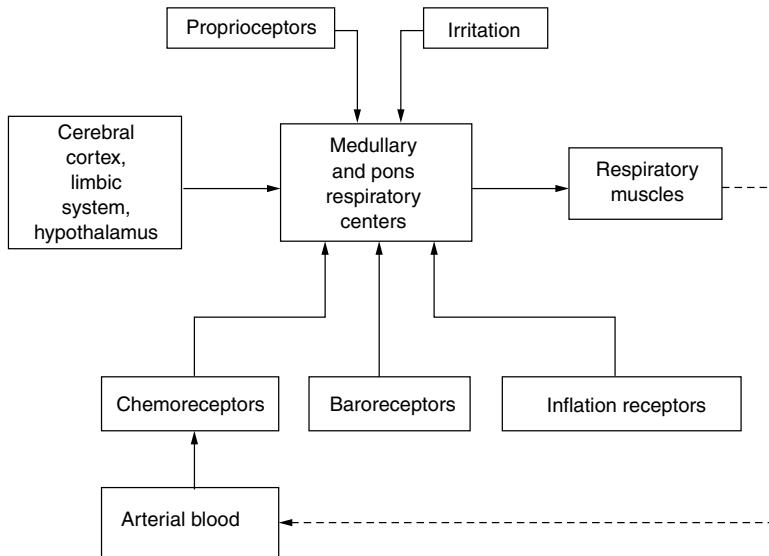
Energy demands during exercise are so great that optimal courses of action are followed for many physiological responses (Table 65.2). Walking occurs most naturally at a pace that represents the smallest energy expenditure; the transition from walking to running occurs when running expends less energy than walking; ejection of blood from the left ventricle appears to be optimized to minimize energy expenditure; respiratory rate, breathing waveforms, the ratio of inhalation time to exhalation time, airways resistance, tidal volume, and other respiratory parameters all appear to be regulated to minimize energy expenditure [Johnson, 1993].


FIGURE 65.5   General scheme of respiratory control.

65.6   Thermal Response

When exercise extends for a long enough time, heat begins to build up in the body. In order for heat accumulation to become important, exercise must be performed at a relatively low rate. Otherwise, performance time would not be long enough for significant amounts of heat to be stored.

Muscular activities are at most 20–25% efficient, and, in general, the smaller the muscle, the less efficient it is. Heat results from the other 75–80% of the energy supplied to the muscle.

Thermal challenges are met in several ways. Blood sent to the limbs and blood returning from the limbs are normally conveyed by arteries and veins in close proximity deep inside the limb. This tends to conserve heat by countercurrent heat exchange between the arteries and veins. Thermal stress causes blood to return via surface veins rather than deep veins. Skin surface temperature increases and heat loss by convection and radiation also increases. In addition, vasodilation of cutaneous blood vessels augments surface heat loss but puts an additional burden on the heart to deliver added blood to the skin as well as the muscles. Heart rate increases as body temperature rises.

Sweating begins. Different areas of the body begin sweating earlier than others, but soon the whole body is involved. If sweat evaporation occurs on the skin surface, then the full cooling power of evaporating sweat (670 W·h/kg) is felt. If the sweat is absorbed by clothing, then the full benefit of sweat evaporation is not realized at the skin. If the sweat falls from the skin, no benefit accrues.

Sweating for a long time causes loss of plasma volume (plasma shift), resulting in some hemoconcentration (2% or more). This increased concentration increases blood viscosity, and cardiac work becomes greater.

65.7   Applications

Knowledge of exercise physiology imparts to the medical or biological engineer the ability to design devices to be used with or by humans or animals, or to borrow ideas from human physiology to apply to other situations. There is need for engineers to design the many pieces of equipment used by sports and health enthusiasts, to modify prostheses or devices for the handicapped to allow for performance of greater than light levels of work and exercise, to alleviate physiological stresses caused by personal protective equipment and other occupational ergonometric gear, to design human-powered machines

TABLE 65.2   Summary of Exercise Responses for a Normal Young Male

	Rest	Light exercise	Moderate exercise	Heavy exercise	Maximal exercise
Oxygen uptake (l/min)	0.30	0.60	2.2	3.0	3.2
Maximal oxygen uptake (%)	10	20	70	95	100

that are compatible with the capabilities of the operators, and to invent systems to establish and maintain locally benign surroundings in otherwise harsh environments. Recipients of these efforts include athletes, the handicapped, laborers, firefighters, space explorers, military personnel, farmers, power-plant workers, and many others. The study of exercise physiology, especially in the language used by medical and biological engineers, can result in benefits to almost all of us.

Defining Terms

Anaerobic threshold: The transition between exercise levels that can be sustained through nearly complete aerobic metabolism and those that rely on at least partially anaerobic metabolism. Above the

anaerobic threshold, blood lactate increases and the relationship between ventilation and oxygen uptake becomes nonlinear.

Excess postexercise oxygen consumption (EPOC):   The difference between resting oxygen consumption and the accumulated rate of oxygen consumption following exercise termination.

Maximum oxygen consumption: The maximum rate of oxygen use during exercise. The amount of maximum oxygen consumption is determined by age, sex, and physical condition.

Oxygen deficit: The accumulated difference between actual oxygen consumption at the beginning of exercise and the rate of oxygen consumption that would exist if oxygen consumption rose immediately to its steady-state level corresponding to exercise level.

Factors Affecting Mechanical Work in Humans

Ben F. Hurley
Arthur T. Johnson
University of Maryland

High technology has entered our diversions and leisure activities. Sports, exercise, and training are no longer just physical activities but include machines and techniques attuned to individual capabilities and needs. This chapter considers several factors related to exercise and training that help in understanding human performance.

   Physiological work performance is determined by energy transformation that begins with the process of photosynthesis and ends with the production of biological work (Figure 66.1). Energy in the form of nuclear transformations is converted to radiant energy, which then transforms the energy from carbon dioxide and water into oxygen and glucose through photosynthesis. In plants, the glucose can also be converted to fats and proteins. Upon ingesting plants or other animals that eat plants, humans convert this energy through cellular respiration (the reverse of photosynthesis) to chemical energy in the form of adenosine triphosphate (ATP). The endergonic reactions (energy absorbed from the surroundings) that produce ATP are followed by exergonic reactions (energy released to surroundings) that release energy through the breakdown of ATP to produce chemical and mechanical work in the human body. The steps involved in the synthesis and breakdown of carbohydrates, fats, and proteins produce chemical work and provide energy for the mechanical work produced from muscular contractions. The purpose of this chapter is to provide a brief summary of some factors that can affect mechanical work in humans.

66.1 Exercise Biomechanics

66.1.1 Equilibrium

Anybody, including the human body, remains in stable equilibrium if the vectorial sum of all forces and torques acting on the body is zero. An unbalanced force results in linear acceleration, and an unbalanced
FIGURE 66.1 Schematic of energy transformations leading to muscular mechanical work.

TABLE 66.1 Fraction of Body Weights for Various Parts of the Body

Body part	Fraction
Head and neck	0.07
Trunk	0.43
Upper arms	0.07
Forearms and hands	0.06
Thighs	0.23
Lower legs and feet	0.14
	1.00

torque results in rotational acceleration. Static equilibrium requires that:

$$\sum F = 0 \tag{66.1}$$

$$\sum T = 0 \tag{66.2}$$

where F is vectorial forces, N, and T is vectorial torques, N m.

Some sport activities, such as wrestling, weight lifting, and fencing, require stability, whereas other activities, including running, jumping, and diving, cannot be performed unless there is managed instability. Shifting body position allows for proper control. The mass of the body is distributed as in Table 66.1, and the center of mass is located at approximately 56% of a person's height and midway from side-to-side and front-to-back. The center of mass can be made to shift by extending the limbs or by bending the torso.

66.1.2 Muscular Movement

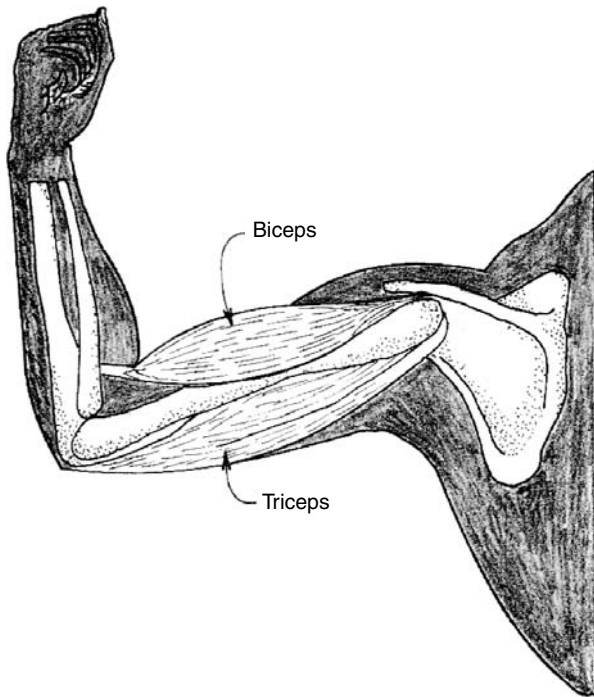
Mechanical movement results from contraction of muscles that are attached at each end to bones that can move relative to each other. The arrangement of this combination is commonly known as a class 3
FIGURE 66.2   A class 3 lever is arranged with the applied force interposed between the fulcrum and the load. Most skeletal muscles are arranged in this fashion.


FIGURE 66.3   The biceps muscle of the arm is arranged as a class 3 lever. The load is located at the hand and the fulcrum at the elbow.

lever (Figure 66.2), where one joint acts as the fulcrum (Figure 66.3), the other bone acts as the load, and the muscle provides the force interposed between fulcrum and load. This arrangement requires that the muscle force be greater than the load, sometimes by a very large amount, but the distance through which the muscle moves is made very small. These characteristics match muscle capabilities well (muscles can produce 7×10^5 N/m^2, but cannot move far). Since the distance is made smaller, the speed of shortening of the contracting muscle is also slower than it would be if the arrangement between the force and the load were different:

$$\frac{S_L}{S_M} = \frac{d_L}{d_M} \tag{66.3}$$

where S is speed, m/sec; d is distance from fulcrum, m; and L, M denotes load and muscle.
FIGURE 66.4   Force and power output of a muscle as a function of velocity. (Adapted and used with permission from Milsum, 1966.)

66.1.3 Muscular Efficiency

Efficiency relates external, or physical, work produced to the total chemical energy consumed:

$$\eta = \frac{\text{External work produced}}{\text{Chemical energy consumed}} \qquad (66.4)$$

Muscular efficiencies range from close to zero to about 20 to 25%. The larger numbers would be obtained for leg exercises that involve lifting body weight. In carpentry and foundry work, where both arms and legs are used, average mechanical efficiency is approximately 10% [Johnson, 1991]. For finer movements that require exquisite control, small muscles are often arranged in antagonistic fashion, that is, the final movement is produced as a result of the difference between two or more muscles working against each other. In this case, efficiencies approach zero. Isometric muscular contraction, where a force is produced but no movement results, has an efficiency of zero [Johnson et al. 2002].

   Muscles generally are able to exert the greatest force when the velocity of muscle contraction is zero. Power produced by this muscle would be zero. When the velocity of muscle contraction is about 8 m/sec the force produced by the muscle becomes zero, and the power produced by this muscle again becomes zero. Somewhere in between the above conditions stated, the power produced and the efficiency become the maximum (Figure 66.4).

   The isometric length–tension relationship of a muscle shows that the maximum force developed by a muscle is exerted at its resting length (the length of a slightly stretched muscle attached by its tendons to the skeleton) and decreases to zero at twice its resting length. Maximum force also decreases to zero at the shortest possible muscular length. Since muscular contractile force depends on the length of the muscle and length changes during contraction, muscular efficiency is always changing (Figure 66.5).

   Negative (eccentric) work is produced by a muscle when it maintains a force against an external force tending to stretch the muscle. An example of negative work is found as the action of the leg muscle during a descent of a flight of stairs. Since the body is being lowered, external work is less than zero. The muscles are using physiological energy to control the descent and prevent the body from accumulating kinetic energy as it descends.
FIGURE 66.5 The gross efficiency for hand cranking or bicycling is a function of the rate of work. (From Goldman, R.F., 1978. Computer models in manual materials handling. In Drury, C.G. (Ed.), *Safety in Manual Materials Handling*, National Institute for Occupational Safety and Health (NIOSH), Cincinnati, Ohio, pp. 110–116.)

Muscular efficiencies for walking downhill approach 120% [McMahon, 1984]. Since heat produced by the muscle is the difference between 100% and the percent efficiency, heat produced by muscles walking downhill is about 220% of their energy expenditure. Energy expenditure of muscles undergoing negative work is about one-sixth that of a muscle doing positive work [Johnson, 1991], so a leg muscle going uphill produces about twice as much heat as a leg muscle going downhill.

66.1.4 Locomotion

The act of locomotion involves both positive and negative work. There are four successive stages of a walking stride. In the first stage, both feet are on the ground, with one foot ahead of the other. The trailing foot pushes forward, and the front foot is pushing backward. In the second stage, the trailing foot leaves the ground and the front foot applies a braking force. The center of mass of the body begins to lift over the front foot. In the third stage, the trailing foot is brought forward and the supporting foot applies a vertical force. The body center of mass is at its highest point above the supporting foot. In the last stage, the body's center of mass is lowered and the trailing foot provides an acceleration force.

This alteration of the raising and lowering of the body center of mass, along with the pushing and braking provided by the feet, makes walking a low-efficiency maneuver. Walking has been likened to alternatively applying the brakes and accelerator while driving a car. Just as the fuel efficiency of the car would suffer from this mode of propulsion, so the energy efficiency of walking suffers from the way walking is performed.

There is an optimum speed of walking. Faster than this speed, additional muscular energy is required to propel the body forward. Moving slower than the optimal speed requires additional muscular energy to retard leg movement. Thus, the optimal speed is related to the rate at which the leg can swing forward. Simple analysis of the leg as a physical pendulum shows that the optimal walking speed is related to leg length:

$$S \propto \sqrt{L} \tag{66.5}$$
FIGURE 66.6 Power required for walking, running, and cycling by an adult male. Curves for walking and running interact at about 2.3 m/sec and show that walking is more efficient below the intersection and running is more efficient above. (Redrawn with permission from Alexander, 1984.)

Unlike walking, there is a stage of running during which both feet leave the ground. The center of mass of the body does not rise and fall as much during running as during walking, so the efficiency for running can be greater than for walking.

At a speed of about 2.5 m/sec, running appears to be more energy efficient than walking, and the transition is usually made between these forms of locomotion (Figure 66.6). Unlike walking, there does not appear to be a functional relationship between speed and leg length, so running power expenditure is linearly related to speed alone.

Why would anyone want to propel the extra weight of a bicycle in addition to body weight? On the surface it would appear that cycling would cost more energy than running or walking. However, the center of mass of the body does not move vertically as long as the cyclist sits on the seat. Without the positive and negative work associated with walking or running, cycling is a much more efficient form of locomotion than the other two (Figure 66.6), and the cost of moving the additional weight of the bicycle can easily be supplied.

Many sports or leisure activities have a biomechanical basis. Understanding of the underlying biomechanical processes can lead to improved performance. Yet, there are limits to performance that cause frustrations for competitive athletes. Hence, additional factors are sometimes employed to expand these limits. A brief discussion of some of these factors is given here.

66.1.5 Effects of Age

It is well established that the maximal capacity to exercise declines with age. However, many factors that change with age also affect maximal capacity to exercise. Examples of these factors include a gain in body fat, a decrease in lean body mass, onset of disease, and a decline in the level of physical activity. For this reason, it is difficult to determine exactly how much of the loss in capacity to exercise with age can really be attributed solely to the effects of aging. Nevertheless, the decline in cardiovascular or aerobic capacity with advanced aging is substantial. Aerobic capacity is assessed by measuring the maximal amount of oxygen that can be utilized during exercise and is known as V_{O_2max}. Pollock et al. [1997] reported more than a 30% decline in V_{O_2max} per decade of aging in a 20-year longitudinal study in those who did not maintain high levels of physical activity as they aged. This age-related decline was reduced substantially (~5 to 8% per decade) when exercise training was maintained throughout aging. Thus, there is no doubt

that maximal work capacity declines with advancing age. Although regular exercise (training) appears to reduce this decline substantially, it cannot completely prevent the detrimental effects of age on aerobic capacity.

Muscular strength (maximal force production) is maintained for a much longer time period throughout aging. Knee extensor strength, for example, does not become significantly reduced in men until they reach their 60s [Lynch et al., 1999]. These losses then occur at a rate of ~12 to 14% per decade. Loss of muscle mass occurs at a rate of ~6% per decade [Lynch et al., 1999]. There is some uncertainty about the magnitude of muscle power (product of force and velocity) loss with age [Martin et al., 2000], but it is believed to occur at a faster rate than strength [Skeleton et al., 1994]. There is also a loss of ~8% per decade in force per unit of muscle mass (muscle quality) [Lynch et al., 1999], indicating that the loss of strength is more than can be accounted for by strength alone.

66.1.6 Effects of Exercise Training

For the purpose of this review, exercise training will be divided into two training modalities, aerobic exercise training and strength training. Aerobic exercise training consists of regular muscular activities that use large amounts of oxygen to produce energy and include exercises such as walking, jogging, swimming, and cycling. Strength training (ST) refers to the type of regular muscular activity that cause muscles to contract (e.g., isotonic or so-called concentric exercise) or attempt to contract (e.g., isometric or eccentric exercise) against resistance. Hence, this type of training is often called resistance or resistive training and it can be performed with weight plates, machines, or by just using one's body weight for resistance, such as is done with certain kinds of calisthenics.

66.1.6.1 Aerobic Exercise Training

Many compensatory reactions allow the body to adapt to minor stresses, such as mild aerobic exercise, so that homeostasis (equilibrium) can be maintained. For example, the increased energy demands of aerobic exercise stimulate an increase in heart rate, respiration, blood flow, and many other cardiovascular and metabolic reactions that allow the body to maintain homeostasis. As the intensity of exercise increases it becomes more difficult for compensatory mechanisms to maintain homeostasis. After exceeding about 80% of an untrained person's maximal exercise capacity homeostasis can no longer be maintained for more than a few minutes before exhaustion results.

Regular aerobic exercise (training) elevates the threshold level so that a single exercise session can be performed before disturbing and eventually losing homeostasis. It does this by elevating the maximal physiological capacity for homeostasis so that the same intensity of aerobic exercise may no longer disrupt homeostasis because it is a lower percentage of maximal capacity. In addition, training produces specific adaptations during submaximal exercise that permit greater and longer amounts of work before losing homeostasis [Hurley and Hagberg, 1998]. A good example of this is when blood lactate rises with increased intensity of exercise. Prior to training, blood lactate concentration rises substantially when the intensity of exercise exceeds about 75% of maximal oxygen consumption (V_{O_2max}).

Following training, the same intensity of exercise results in a lower concentration of blood lactate, so exercise can now be performed at a higher fraction of the untrained V_{O_2max} before blood lactate reaches the same level as before training. This adaptation is so profound that blood lactate levels are often only slightly above resting values after training when performing submaximal exercise (e.g., <65% of V_{O_2max}). Thus, exercise training allows an individual to perform a much greater amount of work during exercise before homeostasis is disturbed to the point at which muscular exhaustion results.

66.1.6.2 Strength Training

Muscular strength declines with age [Lindle et al., 1997; Lynch et al., 1999; Roth et al., 2001], disease [Singh, 2002], and as a consequence of the administration of some medications [Singh, 2002] and can be increased substantially in a relatively short time period with ST [Hurley and Roth, 2000; Hurley and Kostek, 2001]. Muscle power can also be increased with ST, but the magnitude of increase depends on the

movement velocity of training during the muscle-shortening phase of exercise. Typical training modalities of ∼2 sec during the shortening phase and ∼4 sec during the muscle-lengthening phase of movement result in ∼30% increase in strength [Lemmer et al., 2000] and ∼25% increase in power [Jozsi et al., 1999]. However, increases of almost 100% have been reported when fast-velocity training has been incorporated [Fielding et al., 2002]. Our group has reported increases in muscle mass of ∼12% with ST, within the first couple of months of training, based on measurements made by magnetic resonance imaging of the entire volume of the muscle being trained [Ivey et al., 2000]. The amount of force per unit of muscle volume also increases substantially with ST [Tracey et al., 1999]. We have shown that ∼3 decades of age-related strength loss and two decades of age-related muscle mass loss can be recovered/reversed within the first couple of months of ST [Ivey et al., 2000; Lemmer et al., 2000].

66.1.7 Effects of Gender

Cardiovascular fitness and muscular strength are substantially higher in men compared to women. The aerobic capacity in men is about 40 to 50% higher than women. In addition, upper body strength is ∼100% higher and lower body strength is ∼50% higher in men [Lynch et al., 1999]. However, these differences are diminished substantially when body composition is taken into consideration. For example, when $V_{O_2 max}$ is expressed with reference to body mass (ml/kg of body weight/min) this difference narrows to ∼20% and to ∼10% when differences in muscle mass are taken into consideration. Differences in muscular strength between men and women are also narrowed when normalized for fat free mass [Lynch et al., 1999]. There does not appear to be any significant difference in responses to training between men and women when expressed on a relative basis (% change), but men appear to have greater muscle mass gains than women in response to ST when expressed in absolute terms [Ivey et al., 2000].

66.1.8 Effects of Genetics

We have observed great inter-individual variability in both the loss of muscle strength and mass with age, known as sarcopenia [Lindle et al., 1997; Lynch et al., 1999], as well as the gain in muscle strength and muscle mass with exercise training [Ivey et al., 2000; Lemmer et al., 2000]. For example, in a large number of ST studies performed in our laboratory, the increases in strength for individual subjects range from <5 to >100% and muscle mass changes range from no appreciable change to >25% increase. These ST-induced changes in strength and muscle mass are also highly variable in both young and older men and women. In this context, after only nine weeks of a highly standardized quadriceps ST program in a healthy and homogeneous group of young (20–30 yrs) and older (65–75 yrs) men and women, knee extension strength gains ranged from 9 to 45 kg in the young group and from 2 to 39 kg in the older group [Ivey et al., 2000]. These strength changes amounted to a 10–51% increase in the young group and a 5–59% increase in the older group. In this same study, the increases in MRI measured quadriceps muscle volume ranged from 19 to 344 cm^3 in the older subjects and 60 to 481 cm^3 in the young subjects. On a relative basis these increases ranged from <1 to 20% of the initial muscle volume of these subjects, further demonstrating the wide range of inter-individual changes in the trained muscle mass resulting from this highly standardized, short-term ST intervention. Others have observed similar large variations in strength and muscle mass changes with training [Buchner et al., 1993]. Collectively, these data strongly support the notion that genetic factors are involved in determining muscle strength and muscle mass responses to strength training.

The hypothesis that genetic factors may influence muscular strength is also supported by data from both animals [Biesiadecki et al., 1998] and humans [Reed et al., 1991]. Biesiadecki et al. [1998] observed a 1.5–5.2 fold divergence between the muscular strength of male rat strains with the lowest- and highest-strength levels, and Reed et al. [1991] observed significant genetic effects for absolute grip strength normalized for body weight in 127 identical and 130 fraternal twin pairs. Heredity accounted for 65% of the variance in grip strength, even after adjusting for the effects of weight, height, and age. Furthermore, Seeman et al. [1996] reported that genetic factors accounted for 60–80% of the inter-individual differences

in lean body mass. More recently, Huygens et al. [2004] reported heritability of skeletal muscle mass of up to 90%. In addition, Thomis et al. [1998] found evidence for a significant role of heredity in strength responses to strength training. These responses were independent of the influence of genetic factors on baseline strength values. These data provide strong support that genetic factors may influence sarcopenia (i.e., alterations in strength and muscle mass with age) and strength and muscle mass response to strength training. However, none of these studies assessed the effects of specific candidate genes or candidate gene variations (polymorphisms) on strength or muscle mass response to training.

The heritability of muscle mass and strength indicate that specific genes contribute to differences in muscle phenotype. More importantly, specific polymorphisms could at least partly explain the inter-individual variability in sarcopenia and muscle response to ST. We recently explored the relationship of gene polymorphisms to muscle phenotypes in genes thought to have a plausible physiological connection to changes in strength and muscle mass. We identified several candidate gene polymorphisms that were associated with changes in strength or muscle mass with either age or ST. These included genes that code for ciliary neurotrophic factor, insulin-like growth factors I and II, growth and differentiation factor 8 (myostatin), Vitamin D, and androgen receptors. At the time of this writing, studies are ongoing to assess the role of these genes in determining the extent to which strength and muscle mass respond to aging and ST. Based on the substantial heritability of muscle phenotype, future research will likely find other gene variants that help explain the inter-individual variability in both sarcopenia and muscle adaptation in response to both aerobic and strength training. This information is likely to provide a basis for individualizing exercise prescriptions for the prevention and treatment of sarcopenia and help explain why some people make substantial adaptations to training, whereas others do not. Moreover, it will provide specific explanations from a mechanistic perspective as to how genetics can influence mechanical and biological work in humans.

VII

Rehabilitation Engineering

Charles J. Robinson
Clarkson University and the Syracuse VA Medical Center

ENGINEERING ADVANCES HAVE RESULTED in enormous strides in the field of rehabilitation. Individuals with reduced or no vision can be given "sight"; those with severe or complete hearing loss can "hear" by being provided with a sense of their surroundings; those unable to talk can be aided to "speak" again; and those without full control of a limb (or with the limb missing) can, by artificial means, "walk" or regain other movement functions. But the present level of available functional restoration for seeing, hearing, speaking, and moving still pales in comparison to the capabilities of individuals without disability. As is readily apparent from the content of many of the chapters in this handbook, the human sensory and motor (movement) systems are marvelously engineered, both within a given system and integrated across systems. The rehabilitation engineer thus faces a daunting task in trying to design augmentative or replacement systems when one or more of these systems is impaired.

Rehabilitation engineering had its origins in the need to provide assistance to individuals who were injured in World War II. Rehabilitation engineering can be defined in a number of ways. Perhaps the most encompassing (and the one adopted here) is that proposed by Reswick [1982] — Rehabilitation engineering is the application of science and technology to ameliorate the handicaps of individuals with disabilities. With this definition, any device, technique, or concept used in rehabilitation that has a technological basis falls under the purview of rehabilitation engineering. This contrasts with the much narrower view that is held by some that rehabilitation engineering is only the design and production phase of a broader field called Assistive Technology. Lest one consider this distinction trivial, consider that the U.S. Congress has mandated that rehabilitation engineering and technology services be provided by all states; and an argument has ensued among various groups of practitioners about who can legally provide such services because of the various interpretations of what rehabilitation engineering is.

There is a core body of knowledge that defines each of the traditional engineering disciplines. Biomedical engineering is less precisely defined; but, in general, a biomedical engineer must be proficient in a traditional engineering discipline and have a working knowledge of things biological or medical. The rehabilitation engineer is a biomedical engineer who must not only be technically proficient as an engineer and know biology and medicine, but must also integrate artistic, social, financial, psychological, and physiological considerations to develop or analyze a device, technique, or concept that meets the needs of the population the engineer is serving. In general, rehabilitation engineers deal with musculo-skeletal or sensory disabilities. They often have a strong background in biomechanics. Most work in a multidisciplinary team setting.

Rehabilitation engineering deals with many aspects of rehabilitation including applied, scientific, clinical, technical, and theoretical. Various topics include, but are not limited to, assistive devices and other aids for those with disability, sensory augmentation and substitution systems, functional electrical stimulation (for motor control and sensory-neural prostheses), orthotics and prosthetics, myoelectric devices and techniques, transducers (including electrodes), signal processing, hardware, software, robotics, systems approaches, technology assessment, postural stability, wheelchair seating systems, gait analysis, biomechanics, biomaterials, control systems (both biological and external), ergonomics, human performance, and functional assessment [Robinson, 1993].

In this section of the handbook, we focus only on applications of rehabilitation engineering. The concepts of rehabilitation engineering, rehabilitation science, and rehabilitation technology are outlined in Chapter 67. Chapter 69 discusses the importance of personal mobility and various wheeled modes of transportation (wheelchairs, scooters, cars, vans, and public conveyances). Chapter 70 looks at other non-wheeled ways to enhance mobility and physical performance. Chapter 71 covers techniques available to augment sensory impairments or to provide a substitute to input sensory information. Conversely, Chapter 72 looks at the output side.

For the purposes of this handbook, many topics that partially fall under the rubric of rehabilitation engineering are covered elsewhere. These include chapters on Electrical Stimulation (Durand), Hard

Tissue Replacement — Long-Bone Repair and Joints (Goel), Biomechanics (Schneck), Musculoskeletal Soft Tissue Mechanics (Lieber), Analysis of Gait (Davis), Sports Biomechanics/Kinesiology (Johnson), Biodynamics (Diggs), Cochlear Mechanics (Steele), Measurement of Neuromuscular Performance Capabilities (Smith), Human Factors Applications in Rehabilitation Engineering (Strauss and Gunderson), Electrical Stimulators (Peckham), Prostheses and Artificial Organs (Galletti), Nerve Guidance Channels (Valentini), and Tracheal, Laryngeal, and Esophageal Replacement Devices (Shimizu).

Rehabilitation engineering can be described as an engineering systems discipline. Imagine being the design engineer on a project that has an unknown, highly nonlinear plant, with coefficients whose variations in time appear to follow no known or solvable model, where time (yours and your client's) and funding are severely limited, where no known solution has been developed (or if it has, will need modification for nearly every client so no economy of scale exists). Further, there will be severe impedance mismatches between available appliances and your client's needs. Or, the low residual channel capacity of one of your client's senses will require enormous signal compression to get a signal with any appreciable information content through it. Welcome to the world of the rehabilitation engineer!!

Rehabilitation Engineering, Science, and Technology

Charles J. Robinson
Clarkson University and the
Syracuse VA Medical Center

67.1 Introduction

Rehabilitation engineering requires a multidisciplinary effort. To put rehabilitation engineering into its proper context, we need to review some of the other disciplines with which rehabilitation engineers must be familiar. Robinson [1993] has reviewed or put forth the following working definitions and discussions: *Rehabilitation is the (re)integration of an individual with a* **disability** *into society.* This can be done either by enhancing existing capabilities or by providing alternative means to perform various functions or to substitute for specific sensations.

Rehabilitation engineering is the "*application* of science and technology to ameliorate the handicaps of individuals with disabilities" [Reswick, 1982]. In actual practice, many individuals who say that they practice "rehabilitation engineering" are not engineers by training. While this leads to controversies from practitioners with traditional engineering degrees, it also has the *de facto* benefit of greatly widening the scope of what is encompassed by the term "rehabilitation engineering."

Rehabilitation medicine is a clinical *practice* that focuses on the physical aspects of functional recovery, but that also considers medical, neurological and psychological factors. *Physical therapy, occupational*

67-1

therapy, and *rehabilitation counseling* are professions in their own right. On the sensory-motor side, other medical and therapeutical specialties practice rehabilitation in vision, audition, and speech.

Rehabilitation technology (or *assistive technology*) narrowly defined is the selection, design, or manufacture of augmentative or assistive devices that are appropriate for the individual with a disability. Such devices are selected based on the specific disability, the function to be augmented or restored, the user's wishes, the clinician's preferences, cost, and the environment in which the device will be used.

Rehabilitation science is the *development* of a body of knowledge, gleaned from rigorous basic and clinical research, that describes how a disability alters specific physiological functions or anatomical structures, and that details the underlying principles by which residual function or capacity can be measured and used to restore function of individuals with disabilities.

67.2   Rehabilitation Concepts

Effective rehabilitation engineers must be well versed in all of the areas described above since they generally work in a team setting, in collaboration with physical and occupational therapists, orthopedic surgeons, physical medicine specialists and/or neurologists. Some rehabilitation engineers are interested in certain activities that we do in the course of a normal day that could be summarized as **activities of daily living** (ADL). These include eating, toileting, combing hair, brushing teeth, reading, etc. Other engineers focus on *mobility* and the limitations to mobility. Mobility can be personal (e.g., within a home or office) or public (automobile, public transportation, accessibility questions in buildings). Mobility also includes the ability to move functionally through the environment. Thus, the question of mobility is not limited to that of getting from place to place, but also includes such questions as whether one can reach an object in a particular setting or whether a paralyzed urinary bladder can be made functional again. Barriers that limit mobility are also studied. For instance, an ill-fitted wheelchair cushion or support system will most assuredly limit mobility by reducing the time that an individual can spend in a wheelchair before he or she must vacate it to avoid serious and difficult-to-heal pressure sores. Other groups of rehabilitation engineers deal with *sensory disabilities*, such as sight or hearing, or with *communications disorders*, both in the production side (e.g., the nonvocal) or in the comprehension side. For any given client, a rehabilitation engineer might have all of these concerns to consider (i.e., ADLs, mobility, sensory and communication dysfunctions).

A key concept in physical or sensory rehabilitation is that of **residual function or residual capacity.** Such a concept implies that the function or sense can be quantified, that the performance range of that function or sense is known in a nonimpaired population, and that the use of residual capacity by a disabled individual should be encouraged. These measures of human performance can be made subjectively by clinicians or objectively by some rather clever computerized test devices.

A rehabilitation engineer asks three key questions: Can a diminished function or sense be successfully augmented? Is there a substitute way to return the function or to restore a sense? And is the solution appropriate and cost-effective? These questions give rise to two important rehabilitation concepts: orthotics and prosthetics. An **orthosis** is an appliance that aids an existing function. A **prosthesis** provides a substitute.

An artificial limb is a *prosthesis,* as is a wheelchair. An ankle brace is an *orthosis.* So are eyeglasses. In fact, eyeglasses might well be the consumate rehabilitation device. They are inexpensive, have little social stigma, and are almost completely unobtrusive to the user. They have let many millions of individuals with correctable vision problems lead productive lives. But in essence, a pair of eyeglasses is an optical device, governed by traditional equations of physical optics. Eyeglasses can be made out of simple glass (from a raw material as abundant as the sands of the earth!) or complex plastics such as those that are ultraviolet sensitive. They can be ground by hand or by sophisticated computer-controlled optical grinders. Thus, crude technology can restore functional vision. Increasing the technical content of the eyeglasses (either by material or manufacturing method) in most cases will not increase the amount of function restored, but it might make the glasses cheaper, lighter and more prone to be used.

67.3   Engineering Concepts in Sensory Rehabilitation

Of the five traditional senses, vision and hearing most define the interactions that permit us to be human. These two senses are the main input channel through which data with high information content can flow. We read; we listen to speech or music; we view art. A loss of one or the other of these senses (or both) can have a devastating impact on the individual affected. Rehabilitation engineers attempt to restore the functions of these senses either through augmentation or via sensory substitution systems. Eyeglasses and hearing aids are examples of augmentative devices that can be used if some residual capacity remains. A major area of rehabilitation engineering research deals with *sensory substitution systems* [Kaczmarek, Chapter 72].

The visual system has the capability to detect a single photon of light, yet also has a dynamic range that can respond to intensities many orders of magnitude greater. It can work with high contrast items and with those of almost no contrast, and across the visible spectrum of colors. Millions of parallel data channels form the optic nerve that comes from an eye; each channel transmits an asynchronous and quasi-random (in time) stream of binary pulses. While the temporal coding on any one of these channels is not fast (on the order of 200 bits/sec or less), the capacity of the human brain to parallel process the entire image is faster than any supercomputer yet built.

If sight is lost, how can it be replaced? A simple pair of eyeglasses will not work, since either the sensor (the retina), the communication channel (the optic nerve and all of its relays to the brain), or one or more essential central processors (the occipital part of the cerebral cortex for initial processing; the parietal and other cortical areas for information extraction) has been damaged. For replacement within the system, one must determine where the visual system has failed and whether a stage of the system can be artificially bypassed. If one uses another sensory modality (e.g., touch or hearing) as an alternate input channel, one must determine whether there is sufficient bandwidth in that channel and whether the higher-order processing hierarchy is plastic enough to process information coming via a different route.

While the above discussion might seem just philosophical, it is more than that. We normally read printed text with our eyes. We recognize words from their (visual) letter combinations. We comprehend what we read via a mysterious processing in the parietal and temporal parts of the cerebral cortex. Could we perhaps read and comprehend this text or other forms of writing through our fingertips with an appropriate interface? The answer surprisingly is yes! And, the adaptation actually goes back to one of the earliest applications of coding theory — that of the development of Braille. Braille condenses all text characters to a raised matrix of 2 by 3 dots (2^6 combinations), with certain combinations reserved as indicators for the next character (such as a number indicator) or for special contractions. Trained readers of Braille can read over 250 words per minute of grade 2 Braille (as fast as most sighted readers can read printed text!). Thus, the Braille code is in essence a rehabilitation engineering concept where an alternate sensory channel is used as a substitute and where a recoding scheme has been employed.

Rehabilitation engineers and their colleagues have designed other ways to read text. To replace the retina as a sensor element, a modern high resolution, high sensitivity, fast imaging sensor (CCD, etc.) is employed to capture a visual image of the text. One method, used by various page scanning devices, converts the scanned image to text by using optical character recognition schemes, and then outputs the text as speech via text-to-speech algorithms. This machine essentially recites the text, much as a sighted helper might do when reading aloud to the blind individual. The user of the device is thus freed of the absolute need for a helper. Such *independence* is often the goal of rehabilitation.

Perhaps the most interesting method presents an image of the scanned data directly to the visual cortex or retina via an array of implantable electrodes that are used to electrically activate nearby cortical or retinal structures. The visual cortex and retina are laid out in a topographic fashion such that there is an orderly mapping of the signal from different parts of the visual field to the retina, and from the retina to corresponding parts of the occipital cortex. The goal of stimulation is to mimic the neural activity that would have been evoked had the signal come through normal channels. And, such stimulation does produce the sensation of light. Since the "image" stays within the visual system, the rehabilitation solution is said to be **modality-specific.** However, substantial problems dealing with biocompatibility and image

processing and reduction remain in the design of the electrode arrays and processors that serve to interface the electronics and neurological tissue.

Deafness is another manifestation of a loss of a communication channel, this time for the sense of hearing. Totally deaf individuals use vision as a substitute input channel when communicating via sign language (also a substitute code), and can sign at information rates that match or exceed that of verbal communication. Hearing aids are now commercially available that can adaptively filter out background noise (a predictable signal) while amplifying speech (unpredictable) using autoregressive, moving average (ARMA) signal processing. With the recent advent of powerful digital signal processing chips, true digital hearing aids are now available. Previous analog aids, or digitally programable analog aids, provided a set of tunable filters and amplifiers to cover the low, mid and high frequency ranges of the hearing spectrum. But the digital aids can be specifically and easily tailored (i.e., programmed) to compensate for the specific losses of each individual client across the frequency continuum of hearing, and still provide automatic gain control and one or more user-selectable settings that have been adjusted to perform optimally in differing noise environments.

An exciting development is occurring outside the field of rehabilitation that will have a profound impact on the ability of the deaf to comprehend speech. Electronics companies are now beginning to market universal translation aids for travellers, where a phrase spoken in one language is captured, parsed, translated, and restated (either spoken or displayed) in another language. The deaf would simply require that the visual display be in the language that they use for writing.

Deafness is often brought on (or occurs congenitally) by damage to the cochlea. The cochlea normally transduces variations in sound pressure intensity at a given frequency into patterns of neural discharge. This neural code is then carried by the auditory (eighth cranial) nerve to the brainstem where it is preprocessed and relayed to auditory cortex for initial processing and on to the parietal and other cortical areas for information extraction. Similar to the case for the visual system, the cochlea, auditory nerve, auditory cortex and all relays in between maintain a topological map, this time based on tone frequency (tonotopic). If deafness is solely due to cochlear damage (as is often the case) and if the auditory nerve is still intact, a cochlear implant can often be substituted for the regular transducer array (the cochlea) while still sending the signal through the normal auditory channel (to maintain modality-specificity).

At first glance, the design of a cochlear prosthesis to restore hearing appears daunting. The hearing range of a healthy young individual is 20 to 16,000 Hz. The transducing structure, the cochlea, has 3,500 inner and 12,000 outer hair cells, each best activated by a specific frequency that causes a localized mechanical resonance in the basilar membrane of the cochlea. Deflection of a hair cell causes the cell to fire an all-or-none (i.e., pulsatile) neuronal discharge, whose rate of repetition depends to a first approximation on the amplitude of the stimulus. The outputs of these hair cells have an orderly convergence on the 30,000 to 40,000 fibers that make up the auditory portion of the eighth cranial nerve. These afferent fibers in turn go to brainstem neurons that process and relay the signals on to higher brain centers [Klinke, 1983]. For many causes of deafness, the hair cells are destroyed, but the eighth nerve remains intact. Thus, if one could elicit activity in a specific output fiber by means other than the hair cell motion, perhaps some sense of hearing could be restored. The geometry of the cochlea helps in this regard as different portions of the nerve are closer to different parts of the cochlea.

Electrical stimulation is now used in the cochlear implant to bypass hair cell transduction mechanisms [Loeb, 1985; Clark et al., 1990]. These sophisticated devices have required that complex signal processing, electronic and packaging problems be solved. One current cochlear implant has 22 stimulus sites along the scala tympani of the cochlea. Those sites provide excitation to the peripheral processes of the cells of the eighth cranial nerve, which are splayed out along the length of the scala. The electrode assembly itself has 22 ring electrodes spaced along its length and some additional guard rings between the active electrodes and the receiver to aid in securing the very flexible electrode assembly after it is snaked into the cochlea's very small (a few mm) round window (a surgeon related to me that positioning the electrode was akin to pushing a piece of cooked spaghetti through a small hole at the end of a long tunnel). The electrode is attached to a receiver that is inlaid into a slot milled out of the temporal bone. The receiver

contains circuitry that can select any electrode ring to be a source and any other electrode to be a sink for the stimulating current, and that can rapidly sequence between various pairs of electrodes. The receiver is powered and controlled by a radiofrequency link with an external transmitter, whose alignment is maintained by means of a permanent magnet imbedded in the receiver.

A digital signal processor stores information about a specific user and his or her optimal electrode locations for specific frequency bands. The object is to determine what pair of electrodes best produces the subjective perception of a certain pitch *in the implanted individual*, and then to associate a particular filter with that pair via the controller. An enormous amount of compression occurs in taking the frequency range necessary for speech comprehension and reducing it to a few discrete channels. At present, the optimum compression algorithm is unknown, and much fundamental research is being carried out in speech processing, compression and recognition. But, what is amazing is that a number of totally deaf individuals can relearn to comprehend speech exceptionally well without speech-reading through the use of these implants. Other individuals find that the implant aids in speech-reading. For some only an awareness of environmental sounds is apparent; and for another group, the implant appears to have had little effect. But, if you could (as I have been able to) finally converse in unaided speech with an individual who had been rendered totally blind and deaf by a traumatic brain injury, you begin to appreciate the power of rehabilitation engineering.

67.4 Engineering Concepts in Motor Rehabilitation

Limitations in mobility can severely restrict the quality of life of an individual so affected. A wheelchair is a prime example of a prosthesis that can restore personal mobility to those who cannot walk. Given the proper environment (fairly level floors, roads, etc.), modern wheelchairs can be highly efficient. In fact, the fastest times in one of man's greatest tests of endurance, the Boston Marathon, are achieved by the wheelchair racers. Although they do gain the advantage of being able to roll, they still must climb the same hills, and do so with only one-fifth of the muscle power available to an able-bodied marathoner.

While a wheelchair user could certainly go down a set of steps (not recommended), climbing steps in a normal manual or electric wheelchair is a virtual impossibility. Ramps or lifts are engineered to provide accessibility in these cases, or special climbing wheelchairs can be purchased. Wheelchairs also do not work well on surfaces with high rolling resistance or viscous coefficients (e.g., mud, rough terrain, etc.), so alternate mobility aids must be found if access to these areas is to be provided to the physically disabled. Hand-controlled cars, vans, tractors and even airplanes are now driven by wheelchair users. The design of appropriate control modifications falls to the rehabilitation engineer.

Loss of a limb can greatly impair functional activity. The engineering aspects of artificial limb design increase in complexity as the amount of residual limb decreases, especially if one or more joints are lost. As an example, a person with a mid-calf amputation could use a simple wooden stump to extend the leg, and could ambulate reasonably well. But such a leg is not cosmetically appealing and completely ignores any substitution for ankle function.

Immediately following World War II, the United States government began the first concerted effort to foster better engineering design for artificial limbs. Dynamically lockable knee joints were designed for artificial limbs for above-knee amputees. In the ensuing years, energy-storing artificial ankles have been designed, some with prosthetic feet so realistic that beach thongs could be worn with them! Artificial hands, wrists and elbows were designed for upper limb amputees. Careful design of the actuating cable system also provided for a sense of hand grip force, so that the user had some feedback and did not need to rely on vision alone for guidance.

Perhaps the most transparent (to the user) artificial arms are the ones that use electrical activity generated by the muscles remaining in the stump to control the actions of the elbow, wrist and hand [Stein et al., 1988]. This electrical activity is known as myoelectricity, and is produced as the muscle contraction spreads through the muscle. Note that these muscles, if intact, would have controlled at least

one of these joints (e.g., the biceps and triceps for the elbow). Thus, a high level of modality-specificity is maintained since the functional element is substituted only at the last stage. All of the batteries, sensor electrodes, amplifiers, motor actuators and controllers (generally analog) reside entirely within these myoelectric arms. An individual trained in the use of a myoelectric arm can perform some impressive tasks with this arm. Current engineering research efforts involve the control of simultaneous multi-joint movements (rather than the single joint movement now available) and the provision for sensory feedback from the end effector of the artificial arm to the skin of the stump via electrical means.

67.5   Engineering Concepts in Communications Disorders

Speech is a uniquely human means of interpersonal communication. Problems that affect speech can occur at the initial transducer (the larynx) or at other areas of the vocal tract. They can be of neurological (due to cortical, brainstem or peripheral nerve damage), structural, and/or cognitive origin. A person might only be able to make a halting attempt at talking, or might not have sufficient control of other motor skills to type or write.

If only the larynx is involved, an externally applied artificial larynx can be used to generate a resonant column of air that can be modulated by other elements in the vocal tract. If other motor skills are intact, typing can be used to generate text, which in turn can be spoken via text-to-speech devices described above. And the rate of typing (either whole words or via coding) might be fast enough so that reasonable speech rates could be achieved.

The rehabilitation engineer often becomes involved in the design or specification of augmentative communication aids for individuals who do not have good muscle control, either for speech or for limb movement. A whole industry has developed around the design of symbol or letter boards, where the user can point out (often painstakingly) letters, words or concepts. Some of these boards now have speech output. Linguistics and information theory have been combined in the invention of acceleration techniques intended to speed up the communication process. These include alternative language representation systems based on semantic (iconic), alphanumeric, or other codes; and prediction systems, which provide choices based on previously selected letters or words. A general review of these aids can be found in Chapter 73, while Goodenough-Trepagnier [1994] edited a good publication dealing with human factors and cognative requirements.

Some individuals can produce speech, but it is dysarthric and very hard to understand. Yet the utterance does contain information. Can this limited information be used to figure out what the individual wanted to say, and then voice it by artificial means? Research labs are now employing neural network theory to determine which pauses in an utterance are due to content (i.e., between a word or sentence) and those due to unwanted halts in speech production.

67.6   Appropriate Technology

Rehabilitation engineering lies at the interface of a wide variety of technical, biological and other concerns. A user might (and often does) put aside a technically sophisticated rehabilitation device in favor of a simpler device that is cheaper, and easier to use and maintain. The cosmetic appearance of the device (or cosmesis) sometimes becomes the overriding factor in acceptance or rejection of a device. A key design factor often lies in the use of the **appropriate technology** to accomplish the task adequately given the extent of the resources available to solve the problem and the residual capacity of the client. Adequacy can be verified by determining that increasing the technical content of the solution results in disproportionately diminishing gains or escalating costs. Thus, a rehabilitation engineer must be able to distinguish applications where high technology is required from those where such technology results in an incremental gain in cost, durability, acceptance and other factors. Further, appropriateness will greatly depend on location. What is

appropriate to a client near a major medical center in a highly developed country might not be appropriate to one in a rural setting or in a developing country.

This is not to say that rehabilitation engineers should shun advances in technology. In fact, a fair proportion of rehabilitation engineers work in a research setting where state-of-the-art technology is being applied to the needs of the disabled. However, it is often difficult to transfer complex technology from a laboratory to disabled consumers not directly associated with that laboratory. Such devices are often designed for use only in a structured environment, are difficult to repair properly in the field, and often require a high level of user interaction or sophistication.

Technology transfer in the rehabilitation arena is difficult, due to the limited and fragmented market. Advances in rehabilitation engineering are often piggybacked onto advances in commercial electronics. For instance, the exciting developments in text-to-speech and speech-to-text devices mentioned above are being driven by the commercial marketplace, and not by the rehabilitation arena. But such developments will be welcomed by rehabilitation engineers no less.

67.7   The Future of Engineering in Rehabilitation

The traditional engineering disciplines permeate many aspects of rehabilitation. Signal processing, control and information theory, materials design, computers are all in widespread use from an electrical engineering perspective. Neural networks, microfabrication, fuzzy logic, virtual reality, image processing and other emerging electrical and computer engineering tools are increasingly being applied. Mechanical engineering principles are used in biomechanical studies, gait and motion analysis, prosthetic fitting, seat cushion and back support design, and the design of artificial joints. Materials and metalurgical engineers provide input on newer biocompatable materials. Chemical engineers are developing implantable sensors. Industrial engineers are increasingly studying rehabilitative ergonomics.

The challenge to rehabilitation engineers is to find advances in *any* field, engineering or otherwise, that will aid their clients who have a disability.

Defining Terms

Note: All terms with * have been proposed by the National Center for Medical Rehabilitation and Research (NCMRR) of the US National Institutes of Health (NIH).

Activities of daily living (ADL):   Personal activities that are done by almost everyone in the course of a normal day including eating, toileting, combing hair, brushing teeth, reading, etc. ADLs are distinguished from hobbies and from work-related activities (e.g., typing).

Appropriate technology: the technology that will accomplish a task adequately given the resources available. Adequacy can be verified by determining that increasing the technological content of the solution results in diminishing gains or increasing costs.

*Disability: Inability or limitation in performing tasks, activities, and roles to levels expected within physical and social contexts.

*Functional limitation: Restriction or lack of ability to perform an action in the manner or within the range consistent with the purpose of an organ or organ system.

*Impairment: Loss or abnormality of cognitive, emotional, physiological, or anatomical structure or function, including all losses or abnormalities, not just those attributed to the initial pathophysiology.

Modality-specific: A task that is specific to a single sense or movement pattern.

Orthosis: A modality-specific appliance that aids the performance of a function or movement by augmenting or assisting the residual capabilities of that function or movement. An orthopaedic brace is an orthosis.

*Pathophysiology: Interruption or interference with normal physiological and developmental processes or structures.

Prosthesis: an appliance that substitutes for the loss of a particular function, generally by involving a different modality as an input and/or output channel. An artificial limb, a sensory substitution system, or an augmentative communication aid are prosthetic devices.

Residual function or residual capacity: Residual function is a measure of the ability to carry out one or more general tasks using the methods normally used. Residual capacity is a measure of the ability to carry out these tasks using any means of performance. These residual measures are generally more subjective than other more quantifiable measures such as residual strength.

*** Societal limitation:** Restriction, attributable to social policy or barriers (structural or attitudinal), which limits fulfillment of roles, or denies access to services or opportunities that are associated with full participation in society.

Orthopedic Prosthetics and Orthotics in Rehabilitation

Marilyn Lord
Alan Turner-Smith
King's College Hospital-London

An *orthopedic prosthesis* is an internal or external device that *replaces* lost parts or functions of the **neuroskeletomotor system**. In contrast, a *orthopedic orthosis* is a device that *augments* a function of the skeletomotor system by controlling motion or altering the shape of body tissue. For example, an artificial leg or hand is a prosthesis, whereas a calliper (or brace) is an orthosis. This chapter addresses only orthoses and external orthopedic prostheses; internal orthopedic prostheses, such as artificial joints, are a subject on their own.

When a human limb is lost through disease or trauma, the integrity of the body is compromised in so many ways that an engineer may well feel daunted by the design requirements for a prosthetic replacement. Consider the losses from a lower limb amputation. Gone is the structural support for the upper body in standing, along with the complex joint articulations and muscular motor system involved in walking. Lost also is the multimode sensory feedback, from *inter alia* pressure sensors on the sole of the foot, length and force sensors in the muscles, and position sensors in the joints, which closed the control loop around the skeletomotor system. The body also has lost a significant percentage of its weight and is now asymmetrical and unbalanced.

We must first ask if it is desirable to attempt to replace all these losses with like-for-like components. If so, we need to strive to make a bionic limb of similar weight embodying anthropomorphic articulations with

68-1

equally powerful motors and distributed sensors connected back into the wearer's residual neuromuscular system. Or, is it better to accept the losses and redefine the optimal functioning of the new unit of person-plus-technology? In many cases, it may be concluded that a wheelchair is the optimal solution for lower limb loss. Even if engineering could provide the bionic solution, which it certainly cannot at present despite huge inroads made into aspects of these demands, there remain additional problems inherent to prosthetic replacements to consider. Of these, the unnatural mechanical interface between the external environment and the human body is one of the most difficult. Notable, in place of weight bearing through the structures of the foot that are well adapted for this purpose, load must now be transferred to the skeletal structures via intimate contact between the surface of residual limb and prosthesis; the exact distribution of load becomes critical. To circumvent these problems, an alternative direct **transcutaneous** fixation to the bone has been attempted in limited experimental trials, but this brings its own problems of materials **biocompatability** and prevention of infection ingress around the opening through the skin. Orthotic devices are classified by acronyms that describe the joint which they cross. Thus an AFO is an ankle-foot orthosis, a CO is a cervical orthosis (neck brace or collar), and a TLSO is a thoracolumbosacral orthosis (spinal brace or jacket). The main categories are braces for the cervix (neck), upper limb, trunk, lower limb, and foot. Orthoses are generally simpler devices than prostheses, but because orthoses are constrained by the existing body shape and function, they can present an equally demanding design challenge. Certainly the interaction with body function is more critical, and successful application demands an in-depth appreciation of both residual function and the probable reaction to external interference. External orthotics are often classified as structural or functional, the former implying a static nature to hold an unstable joint and the latter a flexible or articulated system to promote the correct alignment of the joints during dynamic functioning. An alternative orthotic approach utilizes functional electrical stimulation (FES) of the patient's own muscles to generate appropriate forces for joint motion; this is dealt with in Chapter 70.

68.1 Fundamentals

Designers of orthotic and prosthetic devices are aware of the three cardinal considerations — function, structure, and **cosmesis**.

For requirements of function, we must be very clear about the objectives of treatment. This requires first an understanding of the clinical condition. **Functional prescription** is now a preferred route for the medical practitioner to specify the requirements, leaving the implementation of this instruction to the prosthetist, orthotist, or rehabilitation technologist. The benefits of this distinction between client specification and final hardware will be obvious to design engineers. Indeed, the influence of design procedures on the supply process is a contribution from engineering that is being appreciated more and more.

The second requirement for function is the knowledge of the biomechanics that underlies both the dysfunction in the patient and the function of proposed device to be coupled to the patient. Kinematics, dynamics, energy considerations, and control all enter into this understanding of function. Structure is the means of carrying the function, and finally both need to be embodied into a design that is cosmetically acceptable. Some of the fundamental issues in these concepts are discussed here.

To function well, the device needs an effective coupling to the human body. To this end, there is often some part that is molded to the contours of the wearer. Achieving a satisfactory mechanical interface of a molded component depends primarily on the shape. The internal dimensions of such components are not made an exact match to the external dimensions of the limb segment, but by a process of **rectification**, the shape is adjusted to relieve areas of skin with low load tolerance. The Shapes are also evolved to achieve appropriate load distribution for stability of coupling between prosthetic socket and limb or, in orthotic design, a system of usually three forces that generates a moment to stabilize a collapsing joint (Figure 68.1). Alignment is a second factor influencing the interface loading. For lower limb prostheses particularly, the alignment of the molded socket to the remainder of the structural components also will be critical in determining the moments and forces transmitted to the interface when the foot is flat on the ground. The same is true for lower limb orthoses, where the net action of the ground reaction forces and consequent
FIGURE 68.1 Three-force system required in an orthosis to control a valgus hindfoot due to weakness in the hindfoot supinators.

moments around the natural joints are highly dependent on the alignment taken up by the combination of orthosis and shoe. Adjustability may be important, particularly for children or progressive medical conditions. Functional components that enable desirable motions are largely straightforward engineering mechanisms such as hinges or dampers, although the specific design requirements for their dynamic performance may be quite complex because of the biomechanics of the body. An example of the design of knee joints is expanded below. These motions may be driven from external power sources but more often are passive or body-powered mechanisms. In orthoses where relatively small angular motions are needed, these may be provided by material flexibility rather than mechanisms.

The structural requirements for lower-limb prosthetics have been laid down at a consensus meeting [1978] bases on biomechanical measurement of forces in a gait laboratory, referred to as the *Philadelphia standards* and soon to be incorporated into an ISO standard (ISO 13404,5; ISO 10328). Not only are the load level and life critical, but so is the mode of failure. Sudden failure of an ankle bolt resulting in disengagement of an artificial foot is not only potentially life-threatening to an elderly amputee who falls and breaks a hip but also can be quite traumatic to unsuspecting witnesses of the apparent event of autoamputation. Design and choice of materials should ensure a controlled slow yielding, not brittle fracture. A further consideration is the ability of the complete structure to absorb shock loading, either the repeated small shocks of walking at the heel strike or rather more major shocks during sports activities or falls. This minimizes the shock transmitted through the skin to the skeleton, known to cause both skin lesions and joint degeneration. Finally, the consideration of hygiene must not be overlooked; the user must be able to clean the orthosis or prosthesis adequately without compromising its structure or function.

Added to the two elements of structure and function, the third element of *cosmesis* completes the trilogy. Appearance can be of great psychological importance to the user, and technology has its contribution here, too. As examples, special effects familiar in science fiction films also can be harnessed to provide realistic cosmetic covers for hand or foot prostheses. Borrowing from advanced manufacturing technology, optical shape scanning linked to three-dimensional (3D) computer-aided design, and **CNC machining** can be pressed into service to generate customized shapes to match a contralateral remaining limb. Up-to-date materials and component design each contribute to minimize the "orthopedic appliance" image of the devices (Figure 68.2). In providing cosmesis, the views of the user must remain paramount. The wearer
FIGURE 68.2   The ARGO reciprocating-gait orthosis, normally worn under the clothing, with structural components produced from 3D CAD. (Courtesy of Hugh Steeper, Ltd., U.K.)

will often choose an attractive functional design in preference to a life like design that is not felt to be part of his or her body.

Upper limb prostheses are often seen as a more interesting engineering challenge than lower limb, offering the possibilities for active motor/control systems and complex articulations. However, the market is an order of magnitude smaller and cost/benefit less easy to prove — after all, it is possible to function fairly well with one arm, but try walking with one leg. At the simplest end, an arm for a below-elbow amputee might comprise a socket with a terminal device offering a pincer grip (hand or hook) that can be operated through a Bowden cable by shrugging the shoulders. Such body-powered prostheses may appear crude, but they are often favored by the wearer because of a sense of position and force feedback from the cable, and they do not need a power supply. Another, more elegant method of harnessing body power is to take a muscle made redundant by an amputation and tether its tendon through an artificially fashioned loop of skin: the cable can then be hooked through the loop [Childress, 1989].

Externally powered devices have been attempted using various power sources with degrees of success. Pneumatic power in the form of a gas cylinder is cheap and light, but recharging is a problem that exercised the ingenuity of early suppliers: where supplies were not readily available, even schemes to involve the local fire services with recharging were costed. Also, contemplate the prospect of bringing a loaded table fork toward your face carried on the end of a position-controlled arm powered with spongy, low-pressure pneumatic actuators, and you will appreciate another aspect of difficulties with this source. Nevertheless, gas-powered grip on a hand can be a good solution. Early skirmishes with stiffer hydraulic servos were largely unsuccessful because of power supply and actuator weight and oil leakage. Electric actuation, heavy and slow at first, has gradually improved to establish its premier position. Input control to these powered devices can be from surface electromyography or by mechanical movement of, for example, the shoulder or an ectromelic limb. Feedback can be presented as skin pressure, movement of a sensor over the skin, or electric stimulation. Control strategies range from position control around a single joint or group of related joints through combined position and force control for hand grip to computer-assisted coordination of entire activities such as feeding.

The physical designs in prosthetic and orthotic devices has changed substantially over the past decade. One could propose that this is solely the introduction of new materials. The sockets of artificial limbs have always been fashioned to suit the individual patient, historically by carving wood, shaping leather, or beating sheet metal. Following the introduction of thermosetting fiber-reinforced plastics hand-shaped over a plaster cast of the limb residuum, substitution of thermoforming plastics that could be automatically vacuum-formed made a leap forward to give light, rapidly made, and cosmetically improved solutions. Polypropylene is the favored material in this application. The same materials permitted the new concept of custom-molded orthoses. Carbon fiber composites substituted for metal have certainly improved the performance of structural components such as limb shanks. But some of the progress owes much to innovative thinking. The flex foot is a fine example, where a traditional anthropomorphic design with imitation ankle joint and metatarsal break is completely abandoned and a functional design adopted to optimize energy storage and return. This is based on two leaf springs made from Kevlar, joined together at the ankle with one splaying down toward the toes to form the forefoot spring and the other rearward to form the heel spring (Figure 68.3). Apart from the gains for the disabled athletes for whom the foot was designed — and these are so remarkable that there is little point in competing now without this foot — clients across all age groups have benefited from the adaptability to rough ground and shock-absorption capability.

68.2 Applications

68.2.1 Computer-Aided Engineering in Customized Component Design

Computer-aided engineering has found a fertile ground for exploitation in the process of design of customized components to match to body shape. A good example is in sockets for artificial limbs. What prosthetists particularly seek is the ability to produce a well-fitting socket during the course of a single

FIGURE 68.3   The flex foot.

patient consultation. Traditional craft methods of casting the residual limb in plaster of paris, pouring a positive mold, manual rectification, and then socket fabrication over the **rectified** cast takes too long.

By using advanced technology, residual limb shapes can be captured in a computer, rectified by computer algorithms, and CNC machined to produce the rectified cast in under an hour so that with the addition of vacuum-formed machinery to pull a socket rapidly over the cast, the socket can be ready for trial fitting in one session. There are added advantages too, in that the shape is now stored in digital form in the computer and can be reproduced or adjusted whenever and wherever desired. Although such systems are still in an early stage of introduction, many practicing prosthetists in the United States have now had hands-on experience of this technology, and a major evaluation by the Veterans Administration has been undertaken [Houston et al., 1992].

Initially, much of the engineering development work went into the hardware components, a difficult brief in view of the low cost target for a custom product. Requirements are considerably different from those of standard engineering, for example, relaxation in the accuracies required (millimeters, not microns); a need to measure limb or trunk parts that are encumbered by the attached body, which may resist being orientated conveniently in a machine and which will certainly distort with the lightest pressure; and a need to reproduce fairly bulky items with strength to be used as a sacrificial mold. Instrumentation for body shape scanning has been developed using methods of silhouettes, Moiré fringes, contact probes measuring contours of plaster casts, and light triangulation. Almost universally the molds are turned by "milling on a spit" [Duncan and Mair, 1983], using an adapted lathe with a milling head to spiral down a large cylindrical plug of material such as plaster of paris mix. Rehabilitation engineers watch with great interest, some with envy, the developments in rapid prototyping manufacture, which is so successful in reducing the cycle time for one-off developments elsewhere in industry, but alas the costs of techniques such as stereolithography are as yet beyond economic feasibility for our area.

Much emphasis also has been placed on the graphics and algorithms needed to achieve rectification. Opinions vary as to what extent the computer should simply provide a more elegant tool for the prosthetist to exercise his or her traditional skills using 3D modeling and on-screen sculpting as a direct replacement for manual plaster rectification or to what extent the computer system should take over the bulk of the
FIGURE 68.4   A rectification requirement defined over the tibia of lower limb stump using the Shapemaker application for computer-aided socket design.
FIGURE 68.5   Adjusting a socket contour with reference to 3D graphics and cross-sectional profiles in the UCL CASD system. (Reproduced from Reynolds, D.P. and Lord, M. 1992. *Med. Biol. Eng. Comput.* 30: 419. With permission.)

process by an expert systems approach. Systems currently available tend to do a little of each. A series of rectification maps can be held as templates, each storing the appropriate relief or buildup to be applied over a particular anatomic area of the limb. Thus the map might provide for a ridge to be added down the front of the shin of a lower limb model so that the eventual socket will not press against the vulnerable bony prominence of the tibia (Figure 68.4). Positioning of the discrete regions to match individual anatomy might typically be anchored to one or more anatomic features indicated by the prosthetist. The prosthetist is also able to free-form sculpt a particular region by pulling the surface interactively with reference to graphic representation (Figure 68.5); this is particularly useful where the patient has some unusual feature not provided for in the templates.

As part of this general development, finite-element analysis has been employed to model the soft tissue distortion occurring during limb loading and to look at the influence of severity of rectification in the

resultant distribution of interface stress [Reynolds and Lord, 1992] (Figure 68.6). In engineering terms, this modeling is somewhat unusual and decidedly nonlinear. For a start, the tissues are highly deformable but nearly incompressible, which raises problems of a suitable Poisson ratio to apply in the modeling. Values of $n = 0.3$ to $n = 0.49$ have been proposed, based on experimental matching of stress-strain curves from indentation of limb tissue in vivo. In reality, though, compression (defined as a loss of volume) may be noted in a limb segment under localized external pressure due to loss of mass as first the blood is rapidly evacuated and then interstitial fluids are more slowly squeezed out. Also, it is difficult to define the boundaries of the limb segment at the proximal end, still attached to the body, where **soft tissues** can easily bulge up and out. This makes accurate experimental determination of the stress-strain curves for the tissue matrix difficult. A nonlinear model with interface elements allowing slip to occur between skin and socket at the limit of static friction may need to be considered, since the frictional conditions at the interface will determine the balance between shear and direct stresses in supporting body weight against the sloping sidewalls. Although excessive shear at the skin surface is considered particularly damaging, higher pressures would be required in its complete absence.

In a similar vein, computer-aided design (CAD) techniques are also finding application in the design of bespoke orthopedic footwear, using CAD techniques from the volume fashion trade modified to suit the one-off nature of bespoke work. This again requires the generation of a customized mold, or shoe last, for each foot, in addition to the design of patterns for the shoe uppers [Lord et al., 1991]. The philosophy of design of shoe lasts is quite different from that of sockets, because last shapes have considerable and fundamental differences from foot shapes. In this instance, a library of reference last shapes is held, and a suitable one is selected both to match the client's foot shape and to fulfill the shoemaking needs for the particular style and type of shoe. The schematic of the process followed in development of the Shoemaster system is shown in Figure 68.7.

Design of shoe inserts is another related application, with systems to capture, manipulate, and reproduce underfoot contours now in commercial use. An example is the Ampfit system, where the foot is placed on
FIGURE 68.6 Finite-element analysis employed to determine the sensitivity of interface pressure to socket shape rectification: (a) limb and socket; (b) elements in layers representing idealized geometry of bone, soft tissue, and socket liner; (c) rectification map of radial differences between the external free shape of the limb and the internal dimensions of socket; and (d) FE predictions of direct pressure. a platform to which preshaped arch supports or other wedges or domes may first be attached. A matrix of round-ended cylinders is then forced up by gas pressure through both platform and supports, supporting the foot over most of the area with an even load distribution. The shape is captured from the cylinder locations and fed into a computer, where rectification can be made similar to that described for prosthetic sockets. A benchtop CNC machine then routs the shoe inserts from specially provided blanks while the client waits.

68.2.2   Examples of Innovative Component Design

68.2.2.1   An Intelligent Prosthetic Knee

The control of an artificial lower limb turns out to be most problematic during the swing phase, during which the foot is lifted off the ground to be guided into contact ahead of the walker. A prosthetic lower limb needs to be significantly lighter than its normal counterpart because the muscular power is not present to control it. Two technological advances have helped. First, carbon fiber construction has reduced the mass of the lower limb, and second, pneumatic or hydraulically controlled damping mechanisms for the knee joint have enabled adjustment of the swing phase to suit an individual's pattern of walking.

Swing-phase control of the knee should operate in three areas:

1. Resistance to flexion at late stance during toe-off controls any tendency to excessive heel rise at early swing
2. Assistance to extension after midswing ensures that the limb is fully extended and ready for heel strike
3. Resistance before a terminal impact at the end of the extension swing dampens out the inertial forces to allow a smooth transition from flexed to extended knee position
FIGURE 68.8 Pneumatic cylinder action in a swing phase controller. (Reprinted with permission from S. Zahedi, The Results of the Field Trial of the Endolite Intelligent Prosthesis, Internal publication, Chas. A. Blatchford & Sons, U.K.)

In conventional limbs, parameters of these controls are determined by fixed components (springs, bleed valves) that are set to optimum for an individual's normal gait at one particular speed, for example, the pneumatic controller in Figure 68.8. If the amputee subsequently walks more slowly, the limb will tend to lead, while if the amputee walks more quickly, the limb will tend to fall behind; the usual compensatory actions are, respectively, an unnatural tilting of the pelvis to delay heel contact or abnormal kicking through of the leg.

In a recent advance, intelligence is built into the swing-phase controller to adjust automatically for cadence variations (Figure 68.9). A 4-bit microprocessor is used to adjust a needle valve, via a linear stepper motor, according to duration of the preceding swing phase [Zahedi, 1995]. The unit is programmed by the prosthetist to provide optimal damping for the particular amputee's swing phase at slow, normal, and fast walking paces. Thereafter, the appropriate damping is automatically selected for any intermediate speed.

68.2.3 A Hierarchically Controlled Prosthetic Hand

Control of the intact hand is hierarchical. It starts with the owner's intention, and an action plan is formulated based on knowledge of the environment and the object to be manipulated. For gross movements, the numerous articulations rely on "preprogrammed" coordination from the central nervous system. Fine control leans heavily on local feedback from force and position sensors in the joints and tactile information about loading and slip at the skin. In contrast, conventional prostheses depend on the conscious command of all levels of control and so can be slow and tiring to use.

Current technology is able to provide both the computing power and transducers required to recreate some of a normal hand's sophisticated proprioceptive control. A concept of extended physiologic proprioception (EPP) was introduced for control of gross arm movement [Simpson and Kenworthy, 1973] whereby the central nervous system is retrained through residual proprioception to coordinate gross actions applying to the geometry of the new extended limb. This idea can be applied to initiate gross hand movements while delegating fine control to an intelligent controller.

Developments by Chappell and Kyberd [1991] and others provide a fine example of the possibilities. A suitable mechanical configuration is shown in Figure 68.10. Four 12-V dc electric motors with gearboxes control, respectively, thumb adduction, thumb flexion, forefinger flexion, and flexion of digits 3, 4, and 5. Digits 3, 4, and 5 are linked together by a double-swingletree mechanism that allows all three to be driven together. When one digit touches an object the other two can continue to close until they also touch or reach their limit of travel. The movement of the digits allows one of several basic postures:

- *Three-point chuck:* Precision grip with digits 1, 2, and 3 (thumb set to oppose the midline between digits 2 and 3); digits 4 and 5 give additional support

FIGURE 68.10 The Southampton hand prosthesis with four degrees of freedom in a power grip. An optical/acoustic sensor is mounted on the thumb. (Reprinted from Chappell, P.H. and Kyberd, P.J. 1991. *J. Biomed. Eng.* 13: 363, Figure 1.)

- *Two-point grip:* Precision grip with digits 1 and 2 (thumb set to oppose forefinger); digits 3, 4, and 5 fully flexed and not used or fully extended
- *Fist:* As two-point grip but with thumb fully extended to allow large objects to be grasped
- *Small Fist:* As fist but with thumb flexed and abducted to oppose side of digit 2
- *Side, or key:* Digits 2 to 5 half fully flexed with thumb opposing side of second digit
- *Flat hand:* Digits 2 to 5 fully extended with thumb abducted and flexed, parked beside digit 2

The controller coordinates the transition between these positions and ensures that trajectories do not tangle. Feedback to the controller is provided by several devices. Potentiometers detect the angles of flexion of the digits; touch sensors detect pressure on the palmer surfaces of the digits; and a combined contact force (Hall effect) and slip sensor (from acoustic frequency output of force sensor) is mounted at the fingertips. The latter detects movement of an object and so controls grip strength appropriate to the task — whether holding a hammer or an egg [Kyberd and Chappell, 1993].

The whole hand may be operated by electromyographic signals from two antagonistic muscles in the supporting forearm stump, picked up at the skin surface. In response to tension in one muscle, the hand opens progressively and then closes to grip with an automatic reflex. The second muscle controls the mode of operation as the hand moves between the states of touch, hold, squeeze, and release.

68.2.4 A Self-Aligning Orthotic Knee Joint

Knee orthosis are often supplied to resist knee flexion during standing and gait at an otherwise collapsing joint. The rigid locking mechanisms on these devices are manually released to allow knee flexion during sitting. Fitting is complicated by the difficulty of attaching the orthosis with its joint accurately aligned to that of the knee. The simple diagram in Figure 68.11 shows how misplacement of a simple hinged orthosis with a notional fixed knee axis would cause the cuffs on the thigh and calf to press into the soft tissues of the limb (known as pistoning).
FIGURE 68.11 The problem caused by misplacement of a single-axis orthotic joint (a) is overcome by an orthosis (b) with a self-aligning axis. (The Laser system, courtesy of Hugh Steeper, Ltd., U.K.)

The human knee does not have a fixed axis, though, but is better represented as a polycentric joint. In a sagittal (side) view, it is easy to conceptualize the origin of these kinematics from the anatomy of the cruciate ligaments running crisscross across the joint, which together with the base of the femur and the head of the tibia form a classic four-bar linkage. The polycentric nature of the motion can therefore be mimicked by a similar geometry of linkage on the orthosis.

The problem of alignment still remains, however, and precision location of attachment points is not possible when gripping through soft tissues. In one attempt to overcome this specific problem, the knee mechanism has been designed with not one but two axes (Figure 68.11). The center of rotation is then free to self-align. This complexity of the joint while still maintaining the ability to fixate the knee and meeting low weight requirements is only achieved by meticulous design in composite materials.

68.3 Summary

The field of prosthetics and orthotics is one where at present traditional craft methods sit alongside the application of high technology. Gradually, advanced technology is creeping into most areas, bringing vast improvements in hardware performance specifications and aesthetics. This is, however, an area where the clinical skills of the prosthetist and orthotist will always be required in specification and fitting and where many of the products have customized components. The successful applications of technology are those which assist the professional to exercise his or her judgment, providing him or her with good tools and means to realize a functional specification.

Since the demand for these devices is thankfully low, their design and manufacture are small scale in terms of volume. This taxes the skills of most engineers, both to design the product at reasonable up-front costs and to manufacture it economically in low volume. For bespoke components, we are moving from a base of craft manufacture through an era when modularization was exploited to allow small-batch production toward the use of CAD. In the latter, the engineering design effort is then embodied in the CAD system, leaving the prosthetist or orthotist to incorporate clinical design for each individual component.

Specific examples of current applications have been described. These can only represent a small part of the design effort that is put into prosthetics and orthotics on a continuing basis, making advances in materials and electronics in particular available.

We are also aware that in the space available, it has not been possible to include a discussion of the very innovative work that is being done in intermediate technology for the third world, for which the International Society of Prosthetics and Orthotics (address below) currently has a special working group.

Defining Terms

Biocompatability: Compatibility with living tissue, for example, in consideration of toxicity, degradability, and mechanical interfacing.

CNC machining: Use of a computer numerically controlled machine.

Cosmesis: Aesthetics of appearance.

Ectromelia: Congenital gross shortening of the long bones of a limb.

Functional prescription: A doctor's prescription for supply of a device written in terms of its function as opposed to embodiment.

Neuroskeletomotor system: The skeletal frame of the body with the muscles, peripheral nerves, and central nervous system of the spine and brain, which together participate in movement and stabilization of the body.

Rectified, rectification: Adjustment of a model of body shape to achieve a desirable load distribution in a custom-molded prosthesis or orthosis.

Soft tissues: Skin, fat, connective tissues, and muscles which, along with the hard tissues of bone, teeth, etc. and the fluids, make up the human body.

Transcutaneous: Passing through the skin.

Wheeled Mobility: Wheelchairs and Personal Transportation

Rory A. Cooper
University of Pittsburgh

69.1 Introduction

Centuries ago, people with disabilities who survived for an extended period of time were transported on hammocks slung between poles which were carried by others. This was the preferred means of transportation of the upper class and thus carried no stigma. Later the wheelbarrow was developed and soon became a common mode of transportation for people with disabilities. Because wheelbarrows were used to transport materials, during this period in history, people with disabilities were looked upon as outcasts from society. During the renaissance, the French court popularized the first wheelchairs. Wheelchairs were overstuffed arm chairs with wheels placed upon them. This enabled movement, with assistance, indoors. Later the wooden wheelchair with wicker matting was developed. This type of chair remained the standard until the 1930s. Franklin D. Roosevelt was not satisfied with the wooden wheelchair and had many common metal kitchen chairs modified with wheels. In the 1930s a young mining engineer, named Everest experienced an accident that left him mobility impaired. He worked with a fellow engineer Jennings to

develop steel wheelchairs. Within a few years, they formed a company Everest & Jennings to manufacture wheelchairs. Following World War II, medical advances saved the lives of many veterans with spinal cord injuries or lower limb amputations, who would have otherwise died. Veterans medical centers issued these veterans steel framed wheelchairs with 18 inch seat widths. These wheelchairs were designed to provide the veteran some mobility within the hospital and home, and not to optimize ergonomic variables. Just as among the ambulatory population, mobility among people with disabilities varies. Mobility is more of a functional limitation than a disability related condition. Powered mobility can have tremendous positive psycho-social effects on an individual. Power wheelchairs provide greater independence to thousands of people with severe mobility impairments.

Power wheelchairs began in the 1940s as standard cross-brace folding manual wheelchairs adapted with automobile starter motors and an automobile battery. The cross-braced wheelchair remained the standard for a number of years. When the rigid power wheelchair frame was developed, space became available under the seat for electronic controls, respirators, communication systems, and reclining devices. By the mid-1970s, wheelchairs had evolved to the point where people had acquired a significant level of mobility.

A personal automobile has a profound effect on a persons' mobility and ability to participate in society. A wheelchair is suitable for short distances, and for many situations where an unimpaired person would walk. Modifications to vehicles may be as simple as a lever attached to the brake and accelerator pedals or as complex as a complete joystick controlled fly-by-wire system. Modifications to other components of the vehicle may be required to provide wheelchair access. An automobile may not be appropriate for some people who travel distances too long to be convenient with a wheelchair, but not long enough to warrant an adapted automobile. Micro-cars, enlarged wheelchairs which travel at bicycle speeds, are convenient for many people who wish only to travel to the local grocery store or post office. Micro-cars are also useful for people who like to travel along bicycle paths or drive short distances off-road.

69.2   Categories of Wheelchairs

There are two basic classes of wheelchairs: manually powered and externally powered. For practical purposes, externally powered wheelchairs are electrically powered wheelchairs. There are approximately 200,000 wheelchairs sold annually within the United States of which about 20,000 are powered wheelchairs. Most wheelchairs are purchased by third-party-payers (e.g., insurance companies, government agencies). This requires the market to be responsive to wheelchairs user's needs, prescriber expertise and experience, third-party-payer purchase criteria, and competition from other manufacturers. Despite the complicated interaction between these components, and the regulation of products by several government agencies, a variety of wheelchairs and options are available.

Depot wheelchairs are intended for institutional use where several people may use the same wheelchair. Generally, these wheelchairs are inappropriate for active people who use wheelchairs for personal mobility. Depot wheelchairs are designed to be inexpensive, accommodate large variations in body size, to be low maintenance, and often to be attendant propelled. They are heavy and their performance is limited. A typical depot wheelchair will have swing away footrests, removable armrests, a single cross-brace frame and solid tires.

People who have impairment of an arm and one or both lower extremities may benefit from a one-arm drive wheelchair that uses a linkage connecting the rear wheels. This allows the user to push upon the pushrim of one wheel and to propel both wheels. To effectively turn the wheelchair, the user must have the ability to disengage the drive mechanism.

Some people have weakness of the upper and lower extremities and can gain maximal benefit from wheelchair propulsion by combining the use of their arms and legs or by using only their legs. The design and selection of a foot-drive wheelchair depends greatly upon how the user can take greatest advantage of their motor abilities.

Indoor spaces are more limited and one is often required to get close to furnishings and fixtures to use them properly. Indoor wheelchairs often use rear casters because of the manueverability of these designs.

However, rear caster designs make the wheelchair less stable in lateral directions. Indoor wheelchairs typically have short wheelbases.

All wheelchairs are not propelled by the person sitting in the wheelchair. In many hospitals and long-term care facilities, wheelchairs are propelled by attendants. Attendant propelled wheelchair designs must consider the rider and the attendant as users. The rider must be transported safely and comfortably. The attendant must be able to operate and easily maneuver safely and with minimum physical strain.

Active users often prefer highly maneuverable and responsive wheelchairs which fit their physical and psychosocial character. The ultralight wheelchair evolved from the desire of wheelchair users to develop functional ergonomic designs for wheelchairs. Ultralight wheelchairs are made of such materials as aluminum, alloy steel, titanium, or composites. The design of ultralight wheelchairs allows a number of features to be customized by the user or be specified for manufacture. The most common features of all are the light weight, the high quality of materials used in their construction, and their functional design. Many people can benefit from ultralight wheelchair designs.

The desire to achieve better performance has led wheelchair users, inventors, and manufacturers to constantly develop specialized wheelchairs for sports. There is no real typical sports wheelchair as the design depends heavily on the sport. Basketball and tennis wheelchairs are often thought to typify sports wheelchair design. However, racing, field events or shooting wheelchairs have little in common with the former.

Some wheelchairs are made to change configuration from reclining to sitting, and from sitting to standing. Most stand-up wheelchairs cannot be driven in the stand-up setting in order to insure safe and stable operation. Standing gives the user the ability to reach cabinet and counter spaces otherwise inaccessible. Standing has the additional advantage of providing therapeutic benefits, that is, hemodynamic improvements, and amelioration of osteoporosis.

Stairs and other obstacles persist despite the progress made in universal design. Stair-climbing wheelchairs are electrically powered wheelchairs designed to ascend and descend stairs safely under the occupant's control. Stair-climbing wheelchairs are quite complicated, and often reconfigure themselves while climbing stairs. The additional power required to climb stairs often reduces the range of the wheelchair when compared to standard power wheelchairs.

69.3   Wheelchair Structure and Component Design

Several factors must be considered when designing a wheelchair frame: what are the intended uses, what are the abilities of the user, what are the resources available, and what are the existing products available. These factors determine if and how the frame will be designed and built. Successful designs of wheelchairs can only be accomplished with continuous input from and interaction with wheelchair users. The durability, aesthetics, function, ride comfort, and cost of the frame are dependent on the materials for construction, the frame geometry, and fabrication methods. One of the issues that makes wheelchair design more complicated is the fact that many users are dependent upon wheeled mobility everyday, nearly all day.

69.3.1   Materials

Most wheelchairs are made of either aluminum or steel. Some chairs are made of titanium or advanced composite materials, primarily carbon fiber, and in the future composite frames will probably begin to become more available. All of these materials have their strengths and weaknesses.

Common aluminum wheelchairs are Tungsten Inert Gas (TIG) welded (i.e., electrically welded together in a cloud of inert gas). They are sometimes bolted together using lugs. Most aluminum wheelchair frames are constructed of round drawn 6061 aluminum tubing. This is one of the least expensive and most versatile of the heat treatable aluminum alloys. It has most of the desirable qualities of aluminum, has good mechanical properties and high corrosion resistance. It can be fabricated using most standard techniques.

Most steel wheelchairs are made of mild steel (1040 or 1060) or chromium-molybdenum alloy (4130 or 4140) seamless tubing commonly called chro-moly. Mild steel is very inexpensive and easy to work with. It is wildly available, and performs well for many applications. However, it has a low strength to weight ratio compared to other materials. Chro-moly is widely used because of its weldability, ease of fabrication, mild hardenability, and high fatigueability. Commonly wheelchairs are made of tubing 0.028 to 0.035 in. in wall thickness but diameters vary depending on the expected loads between 0.25 and 1.25 in.

More and more of the high-end wheelchairs are made of titanium. Titanium is a lightweight, strong, nonferrous metal. Titanium wheelchair frames are TIG welded. Titanium is the most exotic of the metals used in production wheelchairs and the most expensive. Titanium requires special tooling and skill to be machined and welded. It has very good mechanical properties and high corrosion resistance. It is resilient to wear and abrasion. Titanium is used because of its availability, appearance, corrosion resistance, very good strength and light weight. A drawback of titanium, besides cost, is that titanium once worn or if flawed may break rapidly (i.e., it has a tendency towards brittle fractures).

Advanced composites have been in use in aerospace and industrial applications for a number of years. These materials include Kevlar, carbon fiber, and polyester limestone composite. These materials are now making the transition to wheelchair design. Kevlar is an organic fiber which is yellow in color and soft to the touch. It is extremely strong and tough. It is one of the lightest structural fabrics on today's market. Kevlar is highly resistant to impact, but its compression strength is poor. Carbon fibers are made by changing the molecular structure of rayon fibers by extreme stretching and heating. Carbon fiber is very stiff (high modulus of elasticity), very strong (high tensile strength) and has very low density (weight for a given volume). Composites come as cloth or yarn. Composite cloth is woven into bidirectional or unidirectional cloth. Unidirectional weaves can add strength along a particular direction. Composites must be bound together by resin or epoxy. Generally, polyester resins or various specialty epoxies (e.g., Safe-T-Poxy) are used. To achieve greatest strength a minimum amount of epoxy must be used while wetting all of the fibers. This is often achieved through a process called bagging. To increase the strength and stiffness of structural components a foam (e.g., styrofoam, urethane or PVC) core is used. The strengthening occurs because of the separation of the cloth layers (it now becomes more like a tube than a flat sheet). Polyester limestone composites have been used widely in industrial high voltage electrical component enclosures. A blend of polyester and limestone are used to form a mixture which can be molded under pressure and heated to form a stiff and durable finished product. Polyester limestone composites have high impact strength, and hold tolerances well, but have substantially lower strength to weight ratios than other composites. Their primary advantage is cost, polyester limestone composites are very inexpensive and readily available. Composites can be molded into elaborate shapes which opens a multitude of possibilities for wheelchair design.

69.3.2 Frame Design

Presently all common wheelchair frames center around tubular construction. The tubing can either be welded together, or bolted together using lugs. There are two basic common frame styles: box frame and the cantilever frame. The box frame is named such because of its rectangular shape, and that tubes outline the edges of the "box." Box frames can be very strong and very durable. A cantilever frame is named so because the front and rear wheels, when viewing the chair from the side, appear to be connected by only one tube; this is similar to having the front wheels attached to a cantilever beam fixed at the rear wheels. Both frame types require cross bracing to provide adequate strength and stiffness.

The box frame provides great strength and rigidity. If designed and constructed properly the frame only deflects minimally during normal loading, and most of the suspension is provided by the seat cushion, the wheels and the wheel mounting hardware. Many manufacturers do not triangulate their box frame designs to allow some flexibility. The cantilever frame is based upon a few basic principles (1) the frame can act as a suspension, (2) there are fewer tubes and they are closer to the body which may make the chair less conspicuous, and (3) there are fewer parts and fewer welds which makes the frame easier to construct.

69.3.3 Wheels and Casters

Casters can be as small as 2 in. in diameter or as large as 12 in. in diameter for wheelchairs designed for daily use. Casters are either pneumatic, semi-pneumatic, or solid (polyurethane). Pneumatic casters offer a smoother ride at the cost of increased maintenance, whereas polyurethane casters are very durable. Semi-pneumatic tires offer a compromise. Most active users prefer 5 in. polyurethane casters or 8 in. pneumatic casters for daily use. An 8-in. caster offers a better ride comfort at the expense of foot clearance. Caster foot clearance is maximized with a 2-in. "Roller Blade" caster often used for court sports (e.g., basketball, tennis, and racquetball). Rear wheels come in three common sizes 22, 24, and 26 in. They come in two styles: spoked and MAG. MAG wheels are typically made of plastic and are die cast. MAG wheels require minimal maintenance, and wear well. However, spoked wheels are substantially lighter, more responsive, and are generally preferred by active manual wheelchair users. Rear tires can be two types; pneumatic or puncture proof. Pneumatic tires can either use a separate tube and tire or a combined tube and tire (sew-up). Commonly, a belted rubber tire with a Butyl tube (65 psi) is used. However, those desiring higher performance prefer sew-up tires or Kevlar belted tires with high pressure tubes (180 psi). Puncture proof tires are heavier, provide less suspension, and are less lively than pneumatic tires.

The chair must be designed to optimize the interaction of the wheels with the ground. Four critical performance factors need to be considered (1) Caster Flutter, (2) Caster Float, (3) Tracking, and (4) Alignment. Caster flutter is the shimmy (rapid vibration of the front wheels) that may occur on some surfaces above certain speeds. When one of the casters does not touch the floor when on level ground, the wheelchair has caster float. Caster float decreases the stability and performance of the wheelchair. A manual wheelchair uses rear wheel steering via differential propulsion torque. Tracking is the tendency of the wheelchair/rider to maintain its course once control has been relinquished. Tracking is important, as the rider propels the handrims periodically (about every second) and if the chair does not track well it will drift from its course between pushes and force the rider to correct heading. This will waste valuable energy and reduce control over the chair. Alignment generally refers to the orientation of the rear wheels with respect to one another. Typically, it is desirable to have the rear wheels parallel to one another without any difference between the distance across the two rear wheels at the front and back. Misalignment on the order of 1/8 in. can cause a noticeable increase in the effort required to propel the wheelchair.

69.4 Ergonomics of Wheelchair Propulsion

The most important area of wheelchair design and prescription is determining the proper interaction between the wheelchair and the user. This can lead to reducing the risk of developing repetitive strain injury while maximizing mobility. Cardiovascular fitness can be improved through exercise which requires a properly fitted wheelchair.

69.4.1 Kinematics

Kinematic data by itself does not provide sufficient information for the clinician to implement appropriate rehabilitation intervention strategies or for the engineer to incorporate this information into wheelchair design changes. Kinematic data are commonly collected at 60 Hz, which is the maximum frequency of many videotape-based systems. Kinematic data analysis shows that experienced wheelchair users contact the pushrim behind top-dead-center and push to nearly 90° in front of top-dead-center. This is significantly longer than non-wheelchair users. Lengthening the stroke permits lowering the propulsion moment and may place less stress on the users' joints.

An important aspect of the evaluation, and possible retraining of wheelchair users is to determine the optimal stroke kinetics and kinematics [2]. However, there is typically some degree of variation from one stroke to another. Wheelchair propulsion kinematic data are typically cyclic (i.e., a person repeats or nearly repeats his/her arm motions over several strokes). Each marker of the kinematic model (e.g., shoulder, elbow, wrist, knuckle) of each subject generates an x and y set of data which is periodic. The frequencies

of the x and y data are dependent upon the anthropometry of the individual, the construction of the wheelchair, and the speed of propulsion. The periodic nature of the kinematic data for wheelchair propulsion can be exploited to develop a characteristic stroke from a set of kinematic data (with the rear hub of the wheelchair chosen as the origin) including several strokes.

69.4.2 Kinetics

The SMART[wheel] was developed to measure the pushrim forces required for evaluating net joint forces and moments to allow the clinician and researcher to study the level of stress experienced by the joint structures during wheelchair propulsion. The SMART[wheel] uses a standard wheelchair wheel fitted with three beams 120° apart and each has two full strain gage bridges. The strain gage bridges are each interfaced through an instrumentation amplifier to a micro-controller which transmits the data through a mercury slip-ring to the serial port of a computer. Kinetics of wheelchair propulsion are affected by speed of propulsion, injury level, user experience, and wheelchair type and fit. Van Der Woude et al. have reported on an ergometer which detected torque by way of a force transducer located in the wheel center and attached to what is referred to as the "wheel/hand rim construction" [7]. The ergometer was adjusted for each subject's anthropometric measurements. Data were sampled at 100 Hz for 7.5 sec periods with a digital filter cut-off frequency of 10 Hz. Mean and peak torque increased with mean velocity, a maximum mean peak torque of 31 N-m occurred at 1.27 m/sec. Torque curves of inexperienced subjects showed an initial negative deflection and a dip in the rising portion of the curve. Torque curves were reported to be in agreement with results of previous investigations [8–10].

Brauer and Hertig [12] measured the static torque produced on push-rims which were rigidly restrained by springs and mounted independent of the tires and rims of the wheelchair. The spring system was adjustable for the subject's strength. The wheels were locked in a fixed position. Torque was measured using slide-wire resistors coupled to the differential movements between the push-rim and wheels and recorded using a strip chart recorder. Subjects were asked to grasp the push-rim at six different test positions (−10, 0, 10, 20, 30, and 40 degrees relative to vertical) and to use maximal effort to turn both wheels forward. Male subjects (combined ambulatory and wheelchair users) produced torques of 27.9 to 46.6 N-m and female subjects produced torques of 17.1 to 32.1 N-m [12]. Grip location, handedness, grip strength, and how well the test wheelchair fit the anthropometric measurements of the individual affected the torque generated. Problems encountered were slipperiness of the push-rims due to a polished finish and limited contact due to the small diameter of the push-rim tubing (12.7 mm or 1/2 in). The use of one wheelchair for all subjects presented the problem of variations due to inappropriate fit for some individuals.

Brubaker, Ross, and McLaurin [13] examined the effect of horizontal and vertical seat position (relative to the wheel position) on the generation of static push-rim force. Force was measured using a test platform with a movable seat and strain gauged beams to which the push-rims were mounted. Pushing and pulling forces were recorded using a strip chart recorder. Static force was measured for four grip positions (−30, 0, 30, and 60 degrees) with various seat positions. Push-rim force ranged from approximately 500 to 750 N and varied considerably with seat position and rim position [13].

69.4.3 Net Joint Forces and Moments

Net joint forces and moments acting at the wrist, elbow and shoulder during wheelchair propulsion provide scientists and clinicians with information related to the level of stress borne by the joint structure. Joint moments and forces are calculated using limb segment and joint models, anthropometric data, kinetic data, and kinematic data. Joint moments data shows that forces at each joint vary among subjects in terms of peak forces, where they occur during the propulsion phase, and how quickly they develop. Peak net joint moments occur at different joint angles for different subjects, and conditions (e.g., speed, resistance). Convention for joint angles is that 180 degrees at the elbow represents full extension; while at the wrist, this is the hand in the neutral position (flexion less than 180 degrees and extension greater

than 180 degrees). Joint angles at the shoulder are determined between the arm and the trunk, with zero measured at the point where the trunk and arm are aligned. Wheelchair users show maximum net shoulder moment between 20° and 40° of extension. Some wheelchair users also show a rapid rise in the elbow extensor moment at the beginning of the stroke with the elbow at about 120°. This moment value begins to decrease between 150° and 170°. At the wrist, the peak moments occur between 190° and 220°. Net joint moments and force models need to account for hand center of pressure, inaccuracies in anthropometric data, and joint models related to clinical variables.

69.5   Power Wheelchair Electrical Systems

Some people are impaired to an extent that they would have no mobility without a power wheelchair. However, some people may have limited upper body mobility and may have the ability to propel a manual wheelchair for short distances. These people may liken using a power wheelchair to admitting defeat. However, a power wheelchair may provide greater mobility. In such cases it may be best to suggest a power wheelchair for longer excursions, and a manual wheelchair for in home and recreational use.

69.5.1   User Interface

Power wheelchairs are often used in conjunction with a number of other adaptive devices. For people with severe mobility impairments, power wheelchairs may be used with communication devices, computer access devices, respirators, and reclining seating systems. The integration of the users' multiple needs must also be considered when designing or prescribing a power wheelchair.

The joystick is the most common control interface between the user and the wheelchair. Joysticks produce voltage signals proportional to displacement, force, or switch closures. Displacement joysticks are most popular. Displacement joysticks may use either potentiometers, variable inductors (coils) or optical sensors to convert displacement to voltage. Inductive joysticks are most common as they wear well and they can be made quite sensitive. Joysticks can be modified to be used for chin, foot, elbow, tongue or shoulder control. Typically, short throw joysticks are used for these applications. Force sensing joysticks use three basic transducers: simple springs and dampeners on a displacement joystick, cantilever beams with strain gages, and fluid with pressure sensors. Force sensing joysticks which rely on passive dampeners or fluid pressure generally require the user to have a range of motion within normal values for displacement joysticks users. Beam-based force sensing joysticks require negligible motion, and hence may be used for people with limited motion abilities.

People who exhibit intention or spastic tremor or with multiple sclerosis may require special control considerations. Signal processing techniques are often required to grant the user greater control over the wheelchair. Typically, signal averaging or a low pass filter with a cut-off frequency of below 5 Hz is used. The signal processing is typically incorporated into the controller.

Some people lack the fine motor control to effectively use a joystick. An alternative for these people is to use a switch control or a head position control. A switch control simply uses either a set of switches or a single switch and a coded input, that is, Morse code or some other simple switch code. The input of the user is latched by the controller and the wheelchair performs the task commanded by the user. The user may latch the chair to repeatedly perform a task a specified number of times, for example, continue straight until commanded to do otherwise. Switch control is quite functional, but it is generally slower than joystick control. Switch inputs can be generated in many ways. Typically, low pressure switches are used. The input can come from a sip-and-puff mechanism which works off of a pressure transducer. A switch contact is detected when the pressure exceeds or drops below a threshold. The pressure sensor may be configured to react to pressure generated by the user blowing into or sipping from an input or by the user simply interrupting the flow in or out of a tube. Sip-and-puff may also be used as a combination of proportional and switch control. For example, the user can put the control in the "read speed" mode

and then the proportional voltage output from the pressure transducer will be latched as the user-desired speed.

Simple switches of various sizes can be used to control the chair using many parts of the body. Switches may be mounted on the armrests or a lap tray for hand or arm activation, on the footrest(s) for foot activation, or on a head rest for head activation. The motion of the head can also be used for proportional control by using ultrasonic sensors. Ultrasonic sensors can be mounted in an array about the headrest. The signal produced by the ultrasonic sensors is related to the position of the head. Hence, motion of the head can be used to create a proportional control signal. Ultrasonic head control and switch control can be combined to give some users greater mastery over their power wheelchair. Switches can be used to select the controller mode, whereas the ultrasonic sensors give a proportional input signal.

A critical consideration when selecting or designing a user interface is that the ability of the user to accurately control the interface is heavily dependent upon the stability of the user within the wheelchair. Often custom seating and postural support systems are required for a user interface to be truly effective. The placement of the user interface is also critical to its efficacy as a functional control device.

69.5.2   Integrated Controls

People with severe physical impairments may only be able to effectively manipulate a single input device. Integrated controls are used to facilitate using a single input device (e.g., joystick, head switches, voice recognition system) to control multiple actuators (e.g., power wheelchair, environmental control unit, manipulator). This provides the user with greater control over the environment. The M3S-Multiple Master Multiple Slave bus is designed to provide simple, reliable access to a variety of assistive devices. Assistive devices include input devices, actuators, and end-effectors. M3S is based on the Computer Area Network (CAN) standard.

A wide range of organizations provide assistive devices which offer the opportunity of functioning in a more independent manner. However, many of these devices and systems are developed without coordination resulting in incompatible products. Clinicians and users often desire to combine products from various sources to achieve maximal independence. The result is to have several devices with their own input devices and overlapping functions. Integrated controls provide access to various end-effectors with a single input device. The M3S provides an electronic communication protocol so that the system operates properly.

M3S is an interface specification with a basic hardware architecture, a bus communication protocol, and a configuration method. The M3S standard incorporates CAN plus two additional lines for greater security (i.e., 7 wire bus, 2 power lines, 2 CAN lines, safety lines, 1 shield, and 1 harness line). The system can be configured to each individual's needs. An M3S system consists of a microcontroller in each device and a control and configuration module (CCM). The CCM insures proper signal processing, system configuration, and safety monitoring. The CCM is linked to a display (e.g., visual, auditory, tactile) which allows the user to select and operate each end-effector. Any M3S compatible device can communicate with another M3S compatible device. M3S is an International Organization of Standards (ISO) open system communication implementation.

69.5.3   Power System

To implement a motor controller, a servo-amplifier is required to convert signal level power (volts at milliamps) to motor power (volts at amps). Typically, a design requirement for series, shunt, and brushless motor drives is to control torque and speed, and hence, power. Voltage control can often be used to control speed for both shunt and series motors. Series motors require feedback to achieve accurate control.

Either a linear servo-amplifier or a chopper can be used. Linear servo amplifiers are not generally used with power wheelchairs primarily because of their lower efficiency than chopper circuits. A motor can be thought of as a filter to a chopper circuit, in this case, the switching unit can be used as part of a speed and current control loop. The torque ripple and noise associated with phase control drives can be avoided by

the use of high switching frequencies. The response of the speed control loop is likewise improved with increasing switching frequency.

Motor torque is proportional to the armature current in shunt motors and to the square of the current in series motors. The conduction loss of the motor and servo-amplifier are both proportional to the current squared. Optimal efficiency is achieved by minimizing the form factor (I_{rms}/I_{mean}). This can be done by increasing the switching frequency to reduce the amplitude of the ripple. Benefits of increased efficiency are increased brush life, gear life, and lower probability of field permanent magnet demagnetization.

Switching or chopper drives are classified as either unidirectional or bi-directional. They are further divided by whether they use dynamic braking. Typically, power wheelchairs use bi-directional drives without dynamic braking. However, scooters may use unidirectional drives. The average voltage delivered to the motor from a switching drive is controlled by varying the duty cycle of the input waveform. There are two common methods of achieving this goal (1) fixed pulse width, variable repetition rate, and (2) pulse-width modulation (PWM). Power wheelchair servo-amplifiers typically employ PWM.

Pulse width modulation at a fixed frequency has no minimum on-time restriction. Therefore, current peaking and torque ripple can be minimized. For analysis, a d.c. motor can be modeled as a RL circuit, resistor and inductor, or in series with a voltage source. If the motor current is assumed continuous, then the minimum and maximum motor current can be represented by the following equation:

$$I_{min} = \frac{e^{-(R/L)t_{off}}\left(1 - e^{-(R/L)t_{on}}\right)}{1 - e^{-(R/L)(t_{on} - t_{off})}}\frac{V_s}{R} - \frac{V_{gen}}{R}$$

$$I_{max} = \frac{1 - e^{-(R/L)t_{on}}}{1 - e^{-(R/L)(t_{on} - t_{off})}}\frac{V_s}{R} - \frac{V_{gen}}{R}$$

Two basic design principles are used when designing switching servo-amplifiers (1) I_{max} should be limited to five times the rated current of the motor to ensure that demagnetization does not occur, (2) the ripple, $(I_{max} - I_{min})/I_{avg}$, should be minimized to improve the form factor, and reduce the conduction loss in the switching devices. To achieve low ripple, either the inductance has to be large or the switching frequency has to be high. Permalloy powder cores can be used to reduce core loss at frequencies above a few kilohertz. However, this comes at the cost of the electrical time constant of the motor, degrading the motor response time. Hence, raising the switching frequency is most desirable. A power MOSFET has the ability to switch rapidly without the use of load-shaping components.

There are several motor types that may be suitable for use with power wheelchairs. Most current designs use permanent magnet direct current motors. These motors provide high torque, high starting torque and are simplest to control. Permanent magnet direct current motors can either be controlled in what are commonly called current mode or voltage mode. These modes developed out of designs based upon controlling torque and speed, respectively.

Alternating current motors can be designed to be highly efficient and can be controlled with modern power circuitry. Because of the development and wide spread dissemination of switching direct current converters, it is quite feasible to use alternating current motors with a battery supply. To date, alternating current motors have only been used in research on power wheelchairs. The output of the motor is controlled by varying the phase or the frequency.

The battery energy storage system is recognized as one of the most significant limiting factors in powered wheelchair performance. Battery life and capacity are important. If battery life can be improved, the powered wheelchair user will have longer, reliable performance from his/her battery. An increase in battery capacity will allow powered wheelchair users to travel greater distances with batteries that weigh and measure the same as existing wheelchair batteries. Most importantly, increases in battery capacity will enable the use of smaller and lighter batteries. Because batteries account for such a large proportion of both the weight and volume of current powered wheelchair systems, wheelchair manufacturers must base much of their design around the battery package.

TABLE 69.1 Standard Power Wheelchair Battery
Group Sizes

Group number	Length	Width	Height
U1	7–3/4	5–3/16	7–5/16
22NF	9–7/16	5–1/2	8–15/16
24	10–1/4	6–13/16	8–7/8
27	12–1/16	6–13/16	8–7/8

Note: Units are in inches.

Power wheelchairs typically incorporate 24 V d.c. energy systems. The energy for the wheelchair is provided by two, deep cycle lead-acid batteries connected in series. Either wet cell or gel cell batteries are used. Wet cell batteries also cost about one-half as much as gel cell batteries. Gel cells may be required for transport by commercial air carriers.

Battery technology for wheelchair users remains unchanged despite the call for improvements by power wheelchair users. This may be in part due to the relatively low number of units purchased, about 500,000 per annum, when compared to automotive applications with about 6.6 million per annum by a single manufacturer. Wheelchair batteries are typically rated at 12 V and 30 to 90 ampere-h capacity at room temperature. A power wheelchair draws about 10 A during use. The range of the power wheelchair is directly proportional to the ampere-hour rating for the operating temperature.

Batteries are grouped by size. Group size is indicated by a standard number. The group size defines the dimensions of the battery as shown in Table 69.1. The ampere-hour rating defines the battery's capacity.

It is important that the appropriate charger be used with each battery set. Many battery chargers automatically reduce the amount of current delivered to the battery as the battery reaches full charge. This helps to prevent damage to the battery from boiling. The rate at which wet and gel cell batteries charge is significantly different. Some chargers are capable of operating with both types of batteries. Many require setting the charger for the appropriate battery type. Most wheelchair batteries connected in series are charged simultaneously with a 24 V battery charger.

69.5.4 Electromagnetic Compatibility

Powered wheelchairs have been reported to exhibit unintended movement. Wheelchair manufacturers and the US Food and Drug Administration Center for Devices and Radiological Health (FDA-CDRH) have examined the susceptibility of powered wheelchairs and scooters to interference from radio and microwave transmissions. These devices are tested at frequencies ranging from 26 MHz to 1 GHz, which is common for transmissions (e.g., radio, TV, microwave, telephones, mobile radios). Power wheelchairs incorporate complex electronics and microcontrollers which are sensitive to electromagnetic (EM) radiation, electrostatic discharge (ESD), and other energy sources.

Electric powered wheelchairs may be susceptible to electromagnetic interference (EMI) present in the ambient environment. Some level of EMI immunity is necessary to ensure the safety of power wheelchair users. Electromagnetic compatibility (EMC) is the term used to describe how devices and systems behave in an electromagnetic environment. Because of the complexity of power wheelchairs and scooters, and the interaction with an electromagnetic environment, susceptibility to interference cannot be calculated or estimated reliably. A significant number of people attach accessories (e.g., car stereos, computers, communication systems) to their power wheelchairs which also share the batteries. This may increase the susceptibility of other system components to EMI. A number of companies make electric powered devices designed to operate on power wheelchairs to provide postural support, pressure relief, environmental control, and motor vehicle operation. These devices may alter the EMI compatibility of power wheelchairs as provided by the original equipment manufacturer (OEM). Wheelchairs and accessories can be made to function properly within EM environments through testing.

Field strengths have been measured at 20 V/m from a 15 W hand held cellular telephone, and 8 V/m from a 1 W hand held cellular telephone [2]. The FDA-CDRH has tested power wheelchairs and scooters in a Gigahertz Transverse Electromagnetic (GTEM) cell, and in an anechoic chamber with exposure strengths from 3 to 40 V/m. The US FDA requires that a warning sticker be placed on each power wheelchair or scooter indicating the risk due to EMI.

Two tests are commonly performed on chairs: brake release and variation in wheel speed. The device(s) used for measuring wheel speed and brake release must not significantly alter the field. The brakes shall not release or the wheels are not to move with a wheel torque equivalent to a 1:6 slope with a 100 kg rider when the wheelchair is exposed to EM radiation. Non-electrical contact methods (e.g., audio sensing, optical sensing) of measuring brake release or wheelchair movement are preferable. Nominal wheel speed may drift over the length of the test. This drift is primarily due to drop in battery charge over the test interval. Wheel speed must be recorded without EM interference between test intervals. The percentage change in wheel speed during exposure to EM interference shall be referenced to the nominal wheel speed for that test interval. The variation in absolute forward speed, $(v_{emR} + v_{emL})/2$, is to be within 30% of the nominal forward speed, $(v_{nomR} + v_{nomL})/2$. The differential speed between the two wheels should be within 30% of each other, $2 \cdot (v_{emR} - v_{emL})/(v_{nomR} + v_{nomL})$. The test frequency must be held long enough to accommodate the slowest time constant (time required to reach 63% of maximum or minimum) of parameters related to wheelchair driving behavior. Currently two seconds is used by the FDA-CDRH test laboratory.

69.6 Personal Transportation

Special adaptive equipment requirements increase with the degree of impairment and desired degree of independence in areas such as personal care, mobility, leisure, personal transportation, and employment. People are concerned that they receive the proper equipment for them to safely operate their vehicle. Access and egress equipment have the greatest maintenance requirements. Other devices such as hand controls, steering equipment, securement mechanisms, and interior controls require less maintenance. Most users of adaptive driving equipment are satisfied with the performance of such equipment. Most frequent equipment problems are minor and are repaired by consumers themselves.

Physical functional abilities such as range of motion, manual muscle strength, sensation, grip strength, pinch strength, fine motor dexterity, and hand-eye coordination all may be related to driving potential. Driving characteristics must also be evaluated when determining an individual's potential to safely operate a motor vehicle. Throttle force, brake force, steering force, brake reaction time, and steering reaction time are all factors which influence an individual's driving potential.

69.6.1 Vehicle Selection

While it is often a difficult task to find an automobile which meets the specific needs of a particular wheelchair user, currently, no automobile meets the needs of all wheelchair users. Automotive consumers with disabilities are also concerned about ease of entry, stowage space for the wheelchair, and seat positioning. Reduced size, increasingly sloping windshields, lower roofs, and higher sills of new cars make selecting a new vehicle difficult for wheelchair users. The ability to load the wheelchair into a vehicle is essential. Some individuals with sufficient strength and a suitable vehicle are able to stow their wheelchairs inside the vehicle without the use of assistive devices. Many people must rely on an external loading device. The selection of the appropriate vehicle should be based upon the client's physical abilities and social needs.

An approach some people have used to overcome the problems associated with a smaller car is to use a car-top wheelchair carrying device. These devices lift the wheelchair to the top of the car, fold, and stow it. They have been designed to work with four door sedans, light trucks, and compact automobiles.

TABLE 69.2 Typical Ranges of
Accessibility Dimensions for
Sedans

Wheelbase	93–108
Door height	33–47
Door width	41–47
Headroom	36–39
Max. Space behind seat	9–19
Min. Space behind seat	4–9
Seat-to-ground distance	18–22
Width of door opening	38–51

Note: Units in inches.

There are several critical dimensions to an automobile when determining wheelchair accessibility. The wheelbase of the automobile is often used by auto manufacturers to determine vehicle size (e.g., full-size, mid-size, compact). Typical ranges for passenger vehicles are presented in Table 69.2.

69.6.2 Lift Mechanisms

Many wheelchair users who cannot transfer into a passenger vehicle seat or prefer a larger vehicle, drive vans equipped with wheelchair lifts. Platform lifts may use a lifting track, a parallelogram lifting linkage, or a rotary lift. Lift devices are either electromechanically or electrohydraulically powered. The platform often folds into the side doorway of the van. Crane lifts, also called swing-out lifts, have a platform which elevates and folds or rotates into the van. Lifts may either be semi-automatic or automatic. In many cases semi-automatic lifts require the user to initiate various stages (e.g., unlocking door, door opening, lowering lift) of the lifting process. Automatic lifts are designed to perform all lift functions. They usually have an outside key operated control box, or an interior radio controlled control box.

Some lifts use electrohydraulic actuators to lift and fold, with valves and gravity used to lower the lift. Crane lifts may swing out from a post at the front or rear of the side door. Interlocking mechanisms are available with some lifts to prevent the lift from being operated while the door is closed. The Society of Automotive Engineers (SAE) has developed guidelines for the testing of wheelchair lift devices for entry and exit from a personal vehicle. The standards are intended to set an acceptable level of reliability and performance for van lifts.

69.6.3 Wheelchair Restraint Mechanisms

Securement systems are used to temporarily attach wheelchairs to vehicles during transport. Many wheelchair users can operate a motor vehicle from their wheelchair, but are unable to transfer into a vehicle seat. Auto safety standards have reduced the number of U.S. automobile accident fatalities despite an increase in the number of vehicles. The crash pulse determines the severity of the collision of the test sled, and hence, simulates real-world conditions. Securement systems are tested with a surrogate wheelchair at 30 miles per h (48 +2/−0 km per h) with a 20g deceleration. Wheelchairs must be safely restrained when experiencing an impact of this magnitude and no part of the wheelchair shall protrude into the occupant space where it might cause injury.

Proper use of lap and shoulder belts is critical to protecting passengers in automobiles seats. A similar level of crash protection is required for individuals who remain in their wheelchairs during transportation. Wheelchairs are flexible, higher than a standard automobile seat, and not fixed to the vehicle. The passenger is restrained using a harness of at least one belt to provide pelvic restraint and two shoulder or torso belts that restrain both shoulders. A head support may also be used to prevent rearward motion of the head during impact or rebound. A three point restraint is the combination of a lap belt and a shoulder belt (e.g., pelvic torso restraint, lap-sash restraint, lap-shoulder restraint).

The relationship between injury criteria and the mechanics of restraint systems are important to insure the safety of wheelchair users in motor vehicles. Hip and head deflection are often used criteria for determining potential injury. The automotive industry has invested considerable effort for research and development to protect vehicle passengers. Research is not nearly extensive for the passenger who remains seated in a wheelchair while traveling. Many wheelchair and occupant restraint systems copy the designs used for standard automobile seats. However, this type of design may not be appropriate.

Crash tests have shown that for 10 or 20 g impacts of 100 msec duration, people may sustain injuries despite being restrained. When shoulder belts mounted 60 in. above the floor were used to restrain a 50th percentile male dummy, it was found that the torso was well controlled, and head and chest excursions were limited. When shoulder belts were anchored 36 in. above the floor they were ineffective in controlling torso movement. Kinematic results and head injury criteria (HIC) can be used to estimate the extent of injury sustained by a human passenger. A HIC of 1000 or greater indicates a serious or fatal head injury. Generally, a HIC value approaching or exceeding 1000 is indicative of head impact with some portion of the vehicle interior. The open space typically surrounding a wheelchair user in a public bus precludes impact with the buses' interior. High HIC values may occur when the torso is effectively restrained and there is a high degree of neck flexion. If the chin strikes the chest then there may be an impact great enough to cause head injury.

69.6.4 Hand Controls

Hand-controls are available for automatic and manual transmission vehicles. However, hand-controls for manual transmission automobiles must be custom made. There are also portable hand-controls, and long-term hand controls. Portable hand-controls are designed to easily attach to most common automobiles with a minimal number of tools. Hand-controls are available for either left or right hand control.

Many hand controls are attached to the steering column. Hand-controls either clamp to the steering column or are attached to a bracket which is bolted to the steering column or dash, typically where the steering column bolts to the dash. Installation of the hand-controls should not interfere with driver safety features (e.g., air bags, collapsible steering columns). The push rods of the hand-control either clamp directly to the pedals or the levers connected to them.

Most systems activate the brakes by having the driver push forward on a lever with a hand grip. This allows the driver to push against the back of the seat, creating substantial force, and braces the driver in the event of a collision. The throttle, or gas pedal, is operated in a number of ways. Some systems use a twist knob or motorcycle type throttle. Other systems actuate the throttle by pulling on the brake throttle lever. Another method is to rotate the throttle-brake lever downwards (i.e., pull the lever towards the thigh at a right angle to the brake application to operate the throttle). It is common to have the same vehicle driven by multiple people which may require the vehicle to be safely operated with hand-controls, and the OEM foot controls. Care must be taken to insure that the lever and brackets of the hand-controls do not restrict the driving motions of foot control drivers.

Many people have the motor control necessary to operate a motor vehicle, but they do not have the strength required to operate manual hand-controls. Automatic or Fly-By-Wire hand-controls use external actuators (e.g., air motors, servo mechanisms, hydraulic motors) to reduce the force required to operate various vehicle primary controls. Power steering, power brakes, six-way power seats, and power adjustable steering columns can be purchased as factory options on many vehicles.

Six-way power seats are used to provide greater postural support and positioning than standard automotive seats. They can be controlled by a few switches to move fore-aft, incline-recline, and superior-inferior. This allows the user to position the seat for easy entry and exit, and for optimal driving comfort. Power adjustable steering columns also make vehicles more accessible. By using a few buttons, the steering column can be tilted upwards or downwards allowing positioning for entry/exist into the vehicle, and for optimal driving control.

Custom devices are available for people who require more than the OEM options for power assistance. Microprocessor and electronic technology have dramatically changed how motor vehicles are designed.

Many functions of an automobile are controlled electronically or with electromechanical-electrohydraulic controls. This change in vehicle design has made a wide variety of options available for people who require advanced vehicle controls. Many automobiles use electronic fuel injection. Electronic fuel injection systems convert the position of the accelerator pedal to a serial digital signal which is used by a microcontroller to inject the optimal fuel-air mixture into the automobile at the proper time during the piston stroke. The electronic signal for the accelerator position can be provided by another control device (e.g., joystick, slide-bar).

Externally Powered and Controlled Orthoses and Prostheses

Dejan B. Popović
University of Belgrade and Aalborg University

Rehabilitation of humans with sensory–motor disability requires effective assistive systems that would allow their fast and maximal reintegration into the normal life. The cost-benefit functions that humans with disability likely appreciate and optimize comprise elements, such as (1) the quality of life measured by reintegration into the social and work environments; (2) reliability of the assistive system; (3) energy rate and cost with respect to the one used for accomplishing the same task with alternative methods; (4) disruption of normal activities when employing the assistive system; (5) cosmetics; (6) maintenance; and (7) cost. The same elements are considered, but, in a different order by the developers of the rehabilitation technology, practitioners of physical medicine, and rehabilitation and health-care providers.

Here we present technical aspects of the available externally powered orthoses and prostheses that interface directly or indirectly with the human neuro-musculo-skeletal system. We elaborate here two methods for the restoration of movements in humans with paralysis: functional activation of paralyzed muscles termed functional electrical stimulation (FES) or functional neuromuscular stimulation (FNS or NMS), and parallel application of FES and a mechanical orthosis called hybrid assistive system (HAS). We also describe externally controlled and powered leg and arm/hand prostheses.

70.1 Neural Prostheses Based on FES

Assistive systems that apply FES to restore sensory or motor function are called neural prostheses. A **neural prosthesis** (NP) could improve sensory or motor function in subjects after cerebro-vascular accident (CVA), spinal cord injury (SCI), and some other diseases of the central nervous (CNS) [1]. A motor NP applies electrical stimulation to artificially generate muscle contractions required for executing of a functional task in subjects who have lost voluntary control because of a disease or injury. The basic phenomena of the FES are the contraction of a muscle due to the direct stimulation of motorneurons, and reflexive responses due to the activation of sensory pathways and CNS. A NP sends a burst of short electric pulses (pulse duration: 0 to 250 μsec, pulse amplitude: 10 to 150 mA) to generate a function. The key element for achieving functional movement is the appropriate sequencing of bursts of electrical pulses. To achieve a smooth contraction of the extremity the burst of pulses has to have a frequency of about 20 pulses/sec. If less than 20 pulses/sec are induced into the motor nerve the muscle generates a series of twitches, instead of a fused smooth contraction of the muscle. In order to generate stronger force (tetanic contraction) higher frequencies (e.g., 30 to 50 pulses/sec) need to be applied. The higher the stimulation, the more the fatigue that will be developed in the stimulated muscle. Other types of stimulation (e.g., intermittent stimulation, use of doublets or *n*-plets) could improve the force vs. fatigue ratio. If the motor nerve is missing, then the muscle becomes denervated and it cannot generate functional force by means of NP. Recently, new methods were suggested that claim to be applicable for stimulation of denervated muscles [2,3]. The motor nerves can be stimulated using monophasic and biphasic current or voltage pulses. The monophasic pulses are used only with the surface electrodes because they lead to unbalanced charge delivery to the tissues, potentially causing the damage. Most NPs implement monophasic compensated current or voltage pulses.

The motor nerves can be stimulated using either surface (transcutaneous), percutaneous, or implanted electrodes. The transcutaneous stimulation is performed with self-adhesive or nonadhesive electrodes that are placed on the subject's skin in the vicinity of the motor point of the muscle that needs to be stimulated. Recently, new technology that uses electrode arrays positioned on the skin instead of single-filed electrodes was suggested [4]. This electrode array allows variation of the stimulation effects without moving of the electrode (e.g., simultaneous control of agonist and antagonistic muscles resulting with the variable stiffness of the joint, in parallel with the strong activation of the prime movers needed for the desired movement, and dynamic adaptation to the change of the position of the muscle vs. electrode during the movement) [5].

The alternative to surface electrodes is the implantable electrodes. One type of electrodes are wire electrodes that are applied percutaneously, that is, the electrode connects to the stimulator outside of the body, while the stimulation point is close to the motor point (inside the body). Another option is fully implantable electrodes that are sutured to the fascia placed close to the entry point of the motor nerve (epimysial electrodes). More recently, cuff electrodes have been introduced as the NP interface to the tissues. The cuff electrode allows selective stimulation of specific nerve fascicles. Implanted electrodes compared to surface electrodes guarantee higher stimulation selectivity with much less electrical charge applied, both being desired characteristics of NPs. The technology that was introduced few years ago use miniature implantable stimulator that communicates with the external unit via radio-frequency electromagnetic field. The current version of the small implants called Bion comprises the rechargeable battery that is charged when not used and is discharged during operation [6–8].

70.1.1 Restoration of Hand Functions

During the last 50 years several NPs for grasping have been designed and tested; yet, only few were brought to the market [9–11]. An important recent finding is that NPs have therapeutic effects if applied appropriately and timely [12]. The proof of the long-term therapeutic effect of NPs could be the milestone for the health-care providers to change their attitude and start paying for this important rehabilitation modality.

The neural prosthesis for grasping is most frequently used to help tetraplegic subjects to restore or hemiplegic patients to promote the recovery of the grasping function. Among tetraplegic subjects, the patients who benefit the most have a complete C5/C6 spinal lesion. Typically, these patients have preserved proximal upper limb muscles allowing them to perform limited reaching and manipulation, while their wrist and finger movements are greatly compromised. In hemiplegic subjects one arm is often fully functional, while the other arm is paretic or paralyzed because of the CVA. Hemiplegic subjects feel unpleasant stimulation because the sensory mechanisms are intact. One can decrease the unpleasant sensation by applying stimulation at higher frequency (e.g., 50 pulses/sec). The unpleasant sensation can also be decreased by using the pulses with the exponential rising edge.

The NP for grasping restores the two most frequently used grasp types: the palmar and the lateral grasp. The palmar grasp provides the opposition of the palm and the thumb; hence, allows holding bigger and heavier objects such as cans and bottles. The lateral grasp provides the opposition of the flexed index finger and the thumb and it is used to hold thinner objects such as keys, paper, etc. Finger flexion is performed by stimulating the *Flexor Digitorum Superficialis m.* and the *Flexor Digitorum Profundus m.* Finger extension is obtained by stimulating the *Extensor Communis Digitorum m.* Stimulation of the thumb's Thenar muscle or the median nerve produces thumb flexion. The FES can also be applied to generate elbow extension by stimulating the *Triceps Brachii m.* Such elbow extension in combination with the voluntary *Biceps Brachii m.* contraction can be used to augment the reaching. The FES could be used to stimulate elbow flexion (*Biceps Brachii m.*), or even the shoulder muscles to provide upper arm movements, yet these systems have not been developed into practical devices.

The NPs for grasping can be classified upon the source of control signals that trigger or regulate the stimulation pattern to the following groups: shoulder control [13], voice control [14,15], respiratory control [16], joystick control [13], position transducers [18,19], and trigger [11,20]. The classification can also be made upon the interface between the stimulator and the tissues to the following groups : one or two channel surface electrode systems [17–20], multichannel surface stimulation system [11,15,17], multichannel percutaneous systems with intramuscular electrodes [10,13,14,16], and fully implanted systems [10].

The first grasping system used to provide prehension and release [21] used a splint with a spring for closure and electrical stimulation of the thumb extensor for release. Rudel et al. [22] suggested the use of a simple two-channel stimulation system and a position transducer (sliding potentiometer). The shift of the potentiometer generated by the user controlled the opening and closing of the hand. This technique was used for the therapy of hemiplegic patients and as an orthosis for tetraplegic patients.

The approach taken at Ben Gurion University, Israel [15] used a voice controlled multichannel surface electrode system. Up to 12 bipolar stimulation channels, and a splint were used to control elbow, wrist, and hand functions. Daily mounting and fitting of the system were complex; but the experience lead to the commercial device called Handmaster NMS1 [23]. The Handmaster is a NP for grasping with three surface-stimulation channels. One stimulation channel is used to stimulate the finger extensors, the second for finger flexors, and the third generates the thumb opposition. The Handmaster is controlled with a push-button switch that triggers the hand opening and closing functions. One of the major advantages of the Handmaster in comparison with other surface stimulation systems is that it is easy to don and doff. The second feature is that Handmaster stabilizes the wrist being important for effective grasping, yet also limiting from some movements (e.g., supination and pronation).

Prochazka [18] introduced an assistive system that enhances tenodesis grasp that was controlled by a wrist flexion and extension. This, so called Bionic glove comprised three channels of stimulation to interface the paralyzed sensory–motor systems. The self-adhering surface electrodes, with the metal pin contacting the flexible garment, were positioned over the prime movers contributing to finger flexors, finger extensors, and thumb opposition/flexion. The wrist joint angle sensor triggered the "close the hand" pattern once the wrist extension was bigger than the selected threshold and vice versa, that is, the "open the hand" stimulation pattern was triggered once the sensor measured the wrist flexion bigger than the preset threshold. Clinical evaluation of the Bionic glove [24] indicated that the 6 months of use of the

FIGURE 70.1   Handmaster NMS1 (NESS, Israel) grasping device for tetraplegic and hemiplegic patients (left). Actigrip CS (Neurodan A/S, Denmark) is the surface functional electrical therapy system (right). (See text for details.)

Bionic glove was beneficial for tetraplegic patients both therapeutically and as an orthosis, yet, the overall acceptance rate remained insufficient.

Recently, an assistive system called Actigrip CS® (Figure 70.1, right panel) was brought to the market by the company Neurodan A/S, Denmark [11]. This device follows the development of the system introduced as the Belgrade Grasping-Reaching System (BGS®) [17]. The BGS had four stimulation channels, three of which were used to control the hand, while the fourth channel was used to control the elbow extension (stimulation of the *triceps brachii m.*) allowing a tetraplegic subject to reach objects that he/she was not able to do without of the NP. The grasping function was controlled by a push button switch that triggered the hand opening and closing. The grasping was separated into three phases: prehension that forms the correct aperture; relaxation that allows the hand to get in good contact with the object; and closing the hand by opposing either the palm and the thumb, or the side of the index finger and the thumb. The releasing function included two stages, opening of the hand and resting. The reaching function was controlled by implementing the synergy typical for able-bodied humans between the shoulder flexion/extension and elbow flexion/extension.

The Actigrip CS uses four channels of stimulation to control the hand functions. The novelty is the use of the life-like control: the use of triphasic pattern of agonist and antagonistic muscles and use of parallel stimulation of agonist and antagonistic muscles to control the joint stiffness [5]. Clinical studies with the Actigrip CS in poststroke humans suggested excellent recovery compared with the recovery following the conventional therapy.

The ETHZ-ParaCare NP was designed to improve grasping and walking functions in SCI and stroke patients [25]. This surface NP is fully programmable. The system has four stimulation channels, and can be interfaced with many sensors or sensory systems. The ETHZ-ParaCare neural prosthesis for grasping provides both palmar and lateral grasps. The system can be controlled with proportional EMG (electromyography), discrete EMG, push button, and sliding resistor control strategies [25–27].

The group at the Institute for Biokybernetik, Karlsruhe, Germany, suggested the use of EMG recordings from the muscle that is stimulated [28]. The aim of this device was to enhance grasping using weak muscles. It was possible to use retained recordings from the volar side of the forearm to trigger on and off the stimulation of the same muscle groups. In this case, it was essential to eliminate the stimulation artifact and the evoked potential caused by the stimulus in order to eliminate positive feedback effects,

which could generate a tetanic contraction that could not be turned off. Sennels et al. (1997) [29] have further developed this approach. In order to implement EMG control the NP has to include electrodes positioned over the muscle that can be voluntarily controlled [30]. The electrodes should be connected to low-noise, high-impedance, high common mode rejection ratio preamplifier. The output from the preamplifier should be fed to a blanking device in order to eliminate the stimulation artifact. The obtained integrated signal can be used as a trigger (switch), or as an input to a state machine. If the EMG recordings are to be used only as a trigger, a comparator that is connected to the reference voltage at the second input can achieve effective operation [30]. A state control relying on a multi-threshold detection could be used to allow the user to vary the strength of the grasp or select other modalities of grasping.

The alternatives to surface electrodes are implantable electrodes or fully implantable systems. In the early 1980s the FES group in Sendai developed a microcomputer-controlled NP for grasping by means of implanted electrodes [31]. The system comprised several intramuscular electrodes that were positioned by the hypodermal needles. These external parts comprised the NEC PC-98LT personal computer, and an external microcontroller-based stimulator. The stimulation patterns were "cloned" from the muscle activities recorded during voluntary grasping movements of able-bodied subjects. The stimulation sequences were triggered with a push button or a pneumatic pressure sensor. The subsequent version of the same system had 30 stimulation channels. This system demonstrated that post-SCI subjects with complete C4–C6 spinal cord lesion could achieve both reaching and grasping functions. Since 1994, in collaboration with NEC Inc. the Sendai FES team has developed a fully implantable 16-channel electric stimulator NEC FESMate. Two hundred of these stimulators were manufactured [32]. The operation of the NEC FESMate system is similar to the earlier Sendai stimulator.

The Freehand system (NeuroControl Co, Cleveland, OH, USA) (Figure 70.2) has eight implanted epimysial stimulation electrodes and an implanted stimulator [33]. The stimulation electrodes are used to generate flexion and extension of the fingers and the thumb in C5 and C6 SCI subjects in order to provide them with lateral (key pinch) or palmar grasp. The stimulation sequences that are used to generate both palmar and lateral grasps are individually tuned and are preprogrammed in the form of a "muscle contraction map." The hand closure and the hand opening are commanded using a position sensor that is placed on the shoulder of the subject's opposite arm. The position sensor monitors two axes of shoulder motion, protraction/retraction and elevation/depression. Typically, the protraction/retraction motion of the shoulder is used as a proportional signal for hand opening and closing. The shoulder elevation/depression motion is used to generate logic commands that are used to establish a zero level for the protraction/retraction command and to "freeze" the stimulation levels until the next logic command is issued. An additional switch is also provided to allow a user to choose between palmar and lateral grasp strategies. The shoulder position sensor and the controller are not implanted. Besides this sensor configuration, the Freehand system also allows one to use either external or implanted transducer mounted on ipsilateral wrist. This transducer measures the dorsal/volar flexion of the wrist and uses this motion to control hand opening and closing in a way similar to the shoulder position sensor [34,35]. The output of the shoulder or the wrist sensor is sent to an external control unit that generates an appropriate stimulation sequence for each stimulation electrode. This sequence is then sent via an inductive link to an implanted stimulator that generates the stimulation trains for each implanted stimulation electrode. More than 250 tetraplegic subjects have received the Freehand neural prosthesis at more than a dozen sites around the world. The subjects have demonstrated the ability to grasp and release objects and performing of typical daily activities more independently when using the neural prosthesis compared with no NP.

The idea of controlling the whole arm and assist manipulation in humans lacking shoulder and elbow control is getting more attention recently by the research team at the Case Western Reserve University (CWRU) in Cleveland, OH [36–39]. The system was designed to combine a fully implantable grasping system with some additional channels to control elbow extension, flexion, and shoulder movements. The control of reaching, unlike the control in the BGS NP, measures the position of the arm in space and for certain arm positions automatically triggers stimulation of the *triceps brachii m.*

Scott et al. [40] suggested the use of EMG recordings from sternocleidomastoid (SCM) muscles to control a FES system for hand control of tetraplegic individuals. Surface electrodes were applied over the

Implantable components of the freehand system
FIGURE 70.2 Freehand fully implantable grasping system (Neurocontrol, Cleveland, OH). The system comprises 8 epimysial electrodes for interfacing the muscles. The device is driven and controlled by an external unit that transmits energy and control signals to the implantable unit.

SCM muscles to record the EMG. The control could be described as a three-state machine (1) Strong flexion of the ipsilateral SCM opens the hand, (2) weaker flexion closes the hand, and (3) no flexion (below a selected threshold) locks the grasp. This is to say that three levels of EMG recordings trigger the controller to activate the following programs (1) increase the stimulation of the muscles that are contributing to the opening of the hand, (2) increase the stimulation of the muscles that are contributing to the closing of the hand, and (3) keep the activation of the muscles at the selected level. The control has been implemented using a fully implantable Freehand® grasping system. The use of SCM muscles could be of specific importance for bilateral application of commercial open-loop FES systems to improve hand grasp since the contralateral shoulder could be used for the control of the respective hand.

The development of implantable cuff electrodes to be used for sensing contact, slippage, and pressure [41–43] opened a new prospective in controlling grasping devices; and the Center for Sensory Motor Interactions in Aalborg, Denmark was pursuing a series of experiments combining their sensing technique with the fully implantable CWRU system.

70.1.2 Restoration of Standing and Walking

The application of NP to the restoration of gait was first investigated systematically in Ljubljana, Slovenia [44]. Currently, NP for gait rehabilitation is used in a clinical setting in several rehabilitation centers [45–51], and there is a growing trend for the design of devices for home use (see Figure 70.3).

Current surface NP systems use various numbers of stimulation channels. The simplest one, from a technical point, is a single channel stimulation system. This system is only suitable for hemiplegic

FIGURE 70.3 A complete paraplegic subject walking assisted with the Parastep I (Sigmedics, Chicago, IL). The walking assist comprises six channels that stimulate hip and knee extensors and withdrawal reflex bilaterally. Patient is wearing an ankle–foot orthosis and uses the rolling walker instrumented with the switches for control of stepping.
FIGURE 70.4 The components of the prototype of the Actigait system. The Actigait is an implantable foot-drop preventor for poststroke hemiplegic patients. The picture shows the cuff electrode that selectively stimulates the peroneal nerve connected to the implantable two-channel stimulator (left side of the image). The right side of the image shows the external unit with the cooper winding (transmitting antenna).

patients, and a limited group of incomplete paraplegic patients. These individuals can perform limited ambulation with assistance of the upper extremities without NP. The NP in these humans is used to activate a single muscle group. The first demonstrated application of this technique was in hemiplegic patients [52] following the patent and research of Liberson [53]. The stimulation was applied to ankle dorsiflexors so the "foot-drop" can be eliminated. Several versions of foot-drop stimulators with the shoe trigger-switch were developed and tested with various levels of success [54–56]. A commercial system was designed by Stein et al. [57] integrating a single-channel stimulator and a tilt sensor that replaced the foot trigger-switch. Single- and dual-channel correcting foot-drop is now a regular clinical treatment in some rehabilitation institution [58].

A version of the foot-drop stimulator that is being introduced is called Actigait, and it was brought to the market by the company Neurodan A/S, DK. The Actigait uses a cuff electrode to selectively stimulate peroneal nerve; thereby, effectively controlling the foot-drop and assisting the paretic limb during the swing. The heel switch or, potentially, the implantable sensor that records activity from a sensory nerve innervating the lateral side of the foot [59] triggers the dorsiflexion by means of a multichannel cuff electrode (see Figure 70.4).

A multichannel NP with a minimum of four stimulation channels is required for ambulation of a patient with a complete motor lesion of lower extremities and preserved balance and upper body motor control [44]. Appropriate bilateral stimulation of the quadriceps muscles locks the knees during standing. Stimulating the common peroneal nerve on the ipsilateral side, while switching off the quadriceps stimulation on that side, produces a withdrawal of that leg. This withdrawal (flexion) combined with an adequate movement of the upper body and use of the upper extremities for propulsion and support allow ground clearance. This withdrawal is considered as the swinging of the leg. Hand or foot switches can provide the flexion–extension alternation needed for a slow forward or backward progression. Sufficient arm strength must be available to provide balance in parallel bars, rolling walker, or crutches. These systems evolved

into a commercial six-channel assistive system called Parastep-1R (Sigmedics, Chicago, IL) approved for home usage by the Food and Drugs Administration (FAD) in 1994.

Multichannel percutaneous systems for gait restoration, with many channels, were suggested [60–62]. The main advantage of these systems is the plausibility to selectively activate many muscle groups. The implantable system also activates deep muscles that are not accessible by surface stimulation. A preprogrammed stimulation pattern that is a replica of the EMG pattern typical for humans with no motor disorders is delivered to muscles controlling the ankle, knee, and hip joints as well as to some trunk muscles. The experience of the Cleveland research team suggested that 48 channels are required for a complete paraplegic patient to achieve an acceptable and effective walking pattern. More recently the Cleveland group changed their stimulation strategy and are suggesting limited external bracing to operate in parallel to the electrical stimulation. Fine-wire intramuscular electrodes are cathodes positioned close to the motor point within selected muscles. Knee extensors (rectus femoris, vastus medialis, vastus lateralis, vastus intermedius), hip flexors (sartorius, tensor fasciae latae, gracilis, iliopsoas), hip extensors (semimembranosus, gluteus maximus), hip abductors (gluteus medius), ankle dorsiflexors (tibialis anterior, peroneus longus), ankle plantar flexors (gastrocnemius lateralis and medialis, plantaris and soleus), and paraspinal muscles are selected for activation. A surface electrode is used as a common anode. Interleaved pulses are delivered with a multichannel, battery-operated, portable stimulator. The hand controller allows the selection of gait activity. These systems were limited to the clinical environment. The application was investigated in complete spinal cord lesions and in stroke patients. The same strategy and selection criteria for implantation were used for both stroke and SCI patients. Recent developments use the CWRU system with eight channels per leg to be activated and improved control.

A multichannel totally implanted FES system [51] was proposed and tested in few subjects. This system uses a 16-channel implantable stimulator and attached to the epineurium electrodes. Femoral and gluteal nerves were stimulated for hip and knee extension. The so-called round-about stimulation was applied in which four electrodes were located around the nerve and stimulated intermittently. This stimulation method reduces muscle fatigue.

The development of the stimulation technology is giving new hopes. Two new techniques are especially important (1) application of remotely controlled wireless micro-stimulators [63,64], and (2) so-called stimulator for all seasons [65]. There are several attempts to design effective wireless stimulator that are believed to be capable of selectively stimulating fascicles [66,67]. Using the technology of cochlear implants is finding its way for standing and walking restoration [68].

Some essentials limit effectiveness of FES based NPs: muscle fatigue caused by nonphysiological activation of sensory-motor systems, reduced muscle forces compared with the forces in naturally controlled muscles, modified reflex activities, spasticity, etc. From the engineering point of view the further development of NPs has to address the following issues: the interface between a FES system and neuromuscular structures in the organism, biocompatibility of the FES system, and overall practicality. The least resolved solution in FES based motor NPs is automatic control (see Chapter 15 of this book).

70.1.3 Hybrid Assistive Systems for Walking

The combination of FES and external skeleton for restoring motor functions in humans with sensory-motor disability is called hybrid assistive system (HAS) [69–71]. Several HAS designs have been proposed that combine relatively simple rigid mechanical structures for passive stabilization of lower limbs during stance phase and FES systems. These systems combine use of a **reciprocating gait orthosis** with multichannel stimulation, the use of an ankle–foot orthosis or an extended ankle–foot orthosis with a knee cage or the use of a **self-fitting modular orthosis** [72–78]. Each trend in the design of HAS implies different applications as well as specific hardware and control problems. On the basis of accumulated experience, the following features can serve as criteria for a closer description of various HAS designs (1) partial mechanical support, (2) parallel operation of the biological and mechanical system, (3) sequential operation of the biological and the mechanical system. The partial mechanical support refers to the use of braces to assist FES only at specific events within a walking cycle [75]. The advanced version of

powered orthoses to be used with FES is being developed by Goldfarb and colleagues [76]. Control of joints in mechanical orthosis is becoming again a target of research and development mainly because of new technological tools [77,78].

70.2 Active Prostheses

The role of active prosthesis is to extend the function provided by a "nonexternally" powered and controlled artificial organ (see Chapter 137 of previous edition), hence to improve the over all performance of motor function, ultimately providing better quality of life.

70.2.1 Externally Controlled Transfemoral Prostheses

Effective restoration of walking and standing of handicapped humans is an important element to improve the quality of life. Artificial legs of different kinds have been in use for a long time, but in many cases they are inadequate for the needs of amputees, specifically for high transfemoral (above the knee) amputees (e.g., hip disarticulation), bilateral amputees, and highly active patients (e.g., subjects involved in sport).

Modern technology has led to greatly improved design of transtibial (below the knee) prostheses (TTP). Below-knee amputees perform many normal locomotor activities, and participate in many sports requiring running, jumping, and other jerky movements [79]. The biggest progress was made using readily available and easy-to-work-with plastic and graphite alloys for building the artificial skeletal portion of the shank and foot [80]. TTP are light, easy to assemble, and over-all very reliable. TTP provide good support and excellent energy absorption leading to reduced impacts and jerks; yet, allowing storing of the energy that helps in the push-off phase in the gait cycle. Existing TTP, although without ankle joints, duplicate closely the dynamics of the normal foot–ankle complex during swing and stance phases of the step cycle.

The same technology has been introduced into the design of transfemoral prostheses (TFP). The requirements for a TFP were stated by Wagner and Catranis [81]. The prosthesis must support the body weight of the amputee like the normal limb during the stance phase of level walking, on slopes and on soft or rough terrain. This implies that the prosthesis provides "stability" during weight bearing: that is, it prevents sudden or uncontrolled flexion of the knee during weight bearing. The second requirement is that the body is supported such that undesirable socket/stump interface pressures and gait abnormalities due to painful socket/stump contact are prevented. The analysis of biomechanical factors that influence the shaping, fitting, and alignment of the socket is a problem in itself. If the fitting has been accomplished, allowing the amputee to manipulate and control the prosthesis in an active and comfortable manner, the socket and stump can be treated as one single body. The third requirement, which is somewhat controversial, is that the prosthesis should duplicate as nearly as possible the kinematics and dynamics of normal gait. The amputee should walk with a normal-looking gait over a useful range of speeds associated with typical activities for normal persons of similar age. The latter requirement has received attention in recent years and fully integrated systems, so-called self-contained active TFPs are being incorporated into modern rehabilitation. The self-contained principle implies that the artificial leg contains the energy source, actuator, controller, and sensors.

The externally controlled knee is a recent development that provides some solutions that fulfill the said requirements. Two microprocessor controlled pneumatic knee prosthesis using the Kobe technology [82] are available: the Endolite Intelligent Prosthesis (Blatchford and Sons, London, UK) and the Seattle Limb Systems Power Knee (Seattle Limb Systems, Seattle, WA). Intelligent Prosthesis was first developed in 1993 and an improved version was further introduced in 1995 (Intelligent Prosthesis Plus) and 1998 (Adaptive Prosthesis) [83].

The Adaptive Prosthesis uses two microprocessor-controlled motor valves to control a hybrid hydraulic and pneumatic system. The hydraulic system controls stance, flexion, and terminal impact. The pneumatic portion of the system control both swing phase and knee extension. The Adaptive Prosthesis also offers a

FIGURE 70.5 The C-leg. The C-leg is a transfemoral prosthesis that incorporates intelligent knee mechanism allowing controlled swing and stance phases of the gait cycle.

voluntary locking mechanism for extended standing and a stumble control that responds to prevent knee buckling. The Adaptive Prosthesis has batteries that power the system for several months and a software design that prevents memory loss during battery replacement [83–85].

The C-leg® produced by Otto Bock was introduced in 1997. The C-leg® comprises the microprocessor-controlled knee with both hydraulic stance and swing phase control [86]. It has force sensors in the shin that use heel, toe, and axial loading data to determine stance phase stability. A knee-angle sensor provides data for control of swing phase, angle, velocity, and direction of the moment created by the knee. Sensor technology adapts to movement by measuring angles and moments 50 times per second. The unit transfers information to the hydraulic valve allowing reaction to changing conditions. This mechanism results in an individual's gait that resembles natural walking on many different types of terrain. The C-leg® uses a rechargeable battery that lasts 25 to 30 h. When the battery drains of power, the knee goes into safety mode [86]. The company claims that C-leg® immediately adapts to different walking speeds and provides knee stability (see Figure 70.5).

The application of prostheses starts to be more complex when subjects are to walk stairs, slope, and uneven terrain. Walking downstairs and down the slope requires the controlled flexion of the knee joint, and the flexion is totally dependent on the environmental conditions. James et al. [87] introduced a microcomputer control of the hydraulic system effecting stiffness in both flexion and extension from free to lock states. C-leg from Otto Bock, Germany is the first microprocessor-controlled knee joint which incorporates some of these features. Electronic sensors supply basic data for stance-phase stability and stance-phase control. This is the closest approximation to natural gait where subjects no longer have to think about walking. Walking upstairs and up slopes requires a powered knee joint, which is still not commercially available and has not been developed even for experimental purposes to the satisfaction of researchers, clinical, and over all potential users. Powered transfemoral prostheses have been suggested [88,89] but the technology and control have not been adequate.

There are two groups of patients who will benefit greatly from the powered leg: patients with hip disarticulation and bilateral amputees. In both cases, amputees are not able to generate movement of the

thigh that is required to drive the underpowered system; hence, the externally powered knee joint will compensate for lack of power by the user.

70.2.2 Powered Hand and Arm Prostheses

The power for active hand and arm prostheses can come form the body (Body-powered Prosthesis), or from external sources (Externally-powered prosthesis) [90–97]. Gross body movement controls a body-powered prosthesis. The movement of the shoulder, upper arm, or chest is captured by a harness system, which is attached to a cable that is connected to a terminal device (hook or hand). For some levels of amputation or deficiency, an elbow system can be added to provide the amputee additional function. An amputee must possess at least one or more of the following gross body movements: glenohumeral flexion, scapular abduction or adduction, shoulder depression and elevation, and chest expansion in order to control body-powered prosthesis. In addition, sufficient residual limb length and sufficient musculature must exist.

There are two types of controls for body-powered hands and hooks, voluntary opening and voluntary closing: voluntary opening gives the subject grasping control even when he/she is relaxed. The tradeoff for this is limited grip force, often less than 30 N. Voluntary closing allows the subject to have substantially greater grip force, often over 150 N, but does not allow the subject to relax without losing grasp.

Many amputees who wear a body-powered prosthesis develop increased control due to a phenomenon called extended proprioception [90]. Extended proprioception gives the wearer feedback as to the position of the terminal device. The subject will know whether the hook is open or closed by the extent of pressure the harness is exerting on his or her shoulder area without having to visually inspect the operation. Many amputees do not like the cosmetic appearance of the hook and control cables and they request a "natural-like" part of the body replacement.

Externally powered prostheses use electrical power to provide function. The electrical power is applied via motors located in the terminal device (hand or hook), wrist, and elbow. The grip force of the hand can be in excess of 100 N. Command signals are generated either by voluntary contraction of muscles, so-called **myoelectric control**, or by using switches of different kinds. For applications that are more complex, both the command signals are used for different operations (e.g., control of several degrees of freedom).

Myoelectric control is a very popular command method [95]. It relies on the ability of the amputee to generate voluntary contraction of a muscle that he or she would normally use for the same function before the disability, or some other synergistic muscle at his/her subconscious level. Muscle contraction can be registered by recording of the electrical activity of muscles (Electromyogram — EMG). Electrodes that contact the skin capture EMG signal. The EMG can be recorded accurately if the appropriate technology is used. EMG has to be carefully extracted from "electrical noise." Many individuals prefer this type of control because it only requires the wearer to contract his muscles. This eliminates the need for a tight, often uncomfortable control harness. Another advantage of a myoelectric prosthesis is that because it does not require a control cable or harness, a cosmetic skin can be applied in either latex or silicone, greatly enhancing the cosmetic restoration.

An example of the profound designs is the Utah Arm 2 for the transhumeral amputees (see Figure 70.6) [92]. The Utah arm and hand system for transhumeral amputees allows sensitive control of elbow, hand, and wrist (optional) using only EMG signals from two muscles. The exclusive myoelectric system eliminates cables, letting the amputee move the arm and hand slowly or quickly in any position, ultimately leading to a more natural response with less effort. The Utah Arm, combined with its high performance hand control, supplies the wearer with superior cosmetic appearance. Smooth exterior hand covers provide natural look. For rugged tasks, the hand can be changed to another hand or terminal device. The optional electrically driven wrist joint allows hand pronation and supination. Proportional or on–off myoelectric controls are both available based on the subject's request and abilities.

The ServoPro, an exclusive feature of the Utah Arm, is designed for amputees with shoulder disarticulation, interscapulothoracic, or brachial plexus injuries. The ServoPro eliminates the electrodes normally
FIGURE 70.6   The Utah arm is a self-contained battery powered artificial arm–hand complex. The system comprises myoelectric control of the elbow, wrist, and grasping movements.

required to operate the Utah Arm. The system may be the only option, which can provide functional control of both elbow and hand. The ServoPro is based on a harness, but instead of cables, electronic components are pushed and pulled to generate command signals that will control the electrically powered prosthesis. The ServoPro requires much smaller excursion of movement and less effort compared with body-powered cables in equivalent mechanical systems. The servo control is accurate and it uses feedback from sensors in the elbow and hand.

Hybrid prosthesis utilizes a body-powered elbow and a myoelectrically controlled terminal device — hook or hand. Most important ability provided to the patient is to simultaneously control elbow flexion and extension while opening or closing the electric hand/hook or while rotating the wrist. The other prosthetic options generally require the wearer to control one function at a time (flex the elbow, lock the elbow, open or close the terminal device). The hybrid prosthesis weighs less and is less expensive than a similar prosthesis with an electrically powered elbow and hand. An example is the Ergo arm from Otto Bock that uses the new elbow system that can be unlocked or locked in any position, even under loads up to 250 N. A slight pull on the cable lowers the forearm gradually. Releasing the cable immediately locks the elbow in that position. For normal locking or unlocking, the cable has to be pulled stronger. The elbow is designed to support myoelectric hand. When the prosthetic arm is extended, the system stores the energy to facilitate flexion. The arm swings smoothly while walking. Subject-adjustable counterbalance makes the arm feel lighter, even with an electric wrist and terminal device.

Otto Bock Sensor Hand provides secure grasps of various objects. The system frees the user from constant watch on the objects in the hand since the automatic grasping feature senses when an object is about to slip and makes necessary adjustments. The Flexi-Grip function gives the amputee a natural look and flexible grip. The hand is controlled by volitional contraction of muscles that are touching the socket.

The electrodes are built into the socket. This hand is used with the passive wrist rotation with ratchet mechanism or optional friction wrist. The Sensor Hand senses the change in the center of gravity and readjusts its grip automatically. The hand closes at maximum speed and grips an object with the least amount of force. When the contact of fingers and the object are sensed, the control changes to grip-force control and increases the force to its maximum. Two programs can be executed, namely, (1) controlling the opening speed by the strength of the muscle signal (contraction) in addition to controlling the closing speed based on a decrease in muscle tension and (2) controlling both speed by the strength of the muscle contraction.

The current commercial hand prostheses have extremely limited performance compared with the able-bodied arm and hand. The Southampton Artificial Hand has been in existence for several decades and is based upon the original hypothesis for the development of a hierarchically controlled myoelectric prosthesis. The mechanics of the Southampton hand has undergone several stages; however, the main hypothesis remains the same. Vast quantities of information are utilized to form a stable and comfortable grip in able-bodied humans. The grip is constantly adjusted to prevent the slip, deforming or crushing of the object and incorrect orientation (e.g., spilling the content of a container). In all systems described above the grasping force is preselected based on experience, and rarely voluntarily adjusted based on visual feedback. The philosophy behind the development of the Southampton hand is to come with the adaptive, mechanical structure that uses sensors and intelligent control to generate optimum grip. The basis of the control is a finite state of modeling and use of synergistic model of movement of fingers and the thumb. The hand has five functioning digits and four degrees of freedom. The index finger acts independently from the other three fingers, which move in tandem. The other two degrees of freedom are in the thumb. Slip transducers are built in the pads of the fingers.

Defining Terms

Artificial reflex control: A sensory-driven control algorithm based on knowledge representation (production rule based system).

Externally controlled assistive system: Assistive system for restoration of motor functions with automatic control.

Externally powered assistive system: Assistive system for restoration of motor functions that uses external power to control muscles of drive actuators.

Hybrid assistive systems: Combination of a functional electrical stimulation and a mechanical orthosis.

Myoelectric (EMG) control: Use of voluntary generated myoelectric activity as control signals for an externally controlled and powered assistive system.

Neural Prosthesis — Assistive systems for replacing or augmenting sensory–motor funcion Functional electrical stimulation or **Functional neuromuscular stimulation**:   Patterned electrical stimulation of neuromuscular structures dedicated to restore motor functions.

Reciprocating gait orthosis: A walking and standing assistive system with a reciprocating mechanism for hip joints, which extends the contralateral hip when the ipsilateral hip is flexed.

Self-fitting modular orthosis: A modular, self-fitting, mechanical orthosis with a soft interface between human body and the orthosis.

Transfemoral prosthesis: Artificial leg for amputes with the amputation between the knee and hip joint (transfemur).

Transtibial prosthesis: Artificial leg for amputes with the amputation between the ankle and the knee joints (transtibia)

Sensory Augmentation and Substitution

Kurt A. Kaczmarek
University of Wisconsin-Madison

This chapter will consider methods and devices used to present visual, auditory, and tactual (touch) information to persons with sensory deficits. **Sensory augmentation systems** such as eyeglasses and hearing aids enhance the existing capabilities of a functional human sensory system. **Sensory substitution** is the use of one human sense to receive information normally received by another sense. Braille and speech synthesizers are examples of systems that substitute touch and hearing, respectively, for information that is normally visual (printed or displayed text).

   The following three sections will provide theory and examples for aiding the visual, auditory, and tactual systems. Because capitalizing on an *existing* sensory capability is usually superior to substitution, each section will consider first augmentation and then substitution, as shown below:

Human Sensory Systems

Visual	Auditory	Tactual
Visual augmentation	Auditory augmentation	Tactual augmentation
Tactual vision substitution	Visual auditory substitution	Tactual substitution
Auditory vision substitution	Tactual auditory substitution	

71.1   Visual System

With a large number of receptive channels, the human visual system processes information in a parallel fashion. A single glimpse acquires a wealth of information; the field of view for two eyes is 180 degrees horizontally and 120 vertically [Mehr and Shindell, 1990]. The spatial resolution in the central (foveal) part of the visual field is approximately 0.5–1.0 min of arc [Shlaer, 1937], although Vernier acuity, the specialized task of detecting a misalignment of two lines placed end to end, is much finer, approximately 2 sec of arc [Stigmar, 1970]. Low-contrast presentations substantially reduce visual acuity.

The former resolution figure is the basis for the standard method of testing visual acuity, the Snellen chart. Letters are considered to be "readable" if they subtend approximately 5 min of arc and have details one-fifth this size. Snellen's 1862 method of reporting visual performance is still used today. The ratio 20/40, for instance, indicates that a test was conducted at 20 ft and that the letters that were recognizable at that distance would subtend 5 min of arc of 40 ft (the distance at which a normally sighted, or "20/20," subject could read them). Although the standard testing distance is 20, 10 and even 5 ft may be used, under certain conditions, for more severe visual impairments [Fonda, 1981].

Of the approximately 6 to 11.4 million people in the United States who have visual impairments, 90% have some useful vision [NIDRR, 1993]. In the United States, *severe visual impairment* is defined to be 20/70 vision in the better eye with best refractive correction (see below). Legal blindness means that the best corrected acuity is 20/200 or that the field of view is very narrow (<20 degrees). People over 65 years of age account for 46% of the legally blind and 68% of the severely visually impaired. For those with some useful vision, a number of useful techniques and devices for visual augmentation can allow performance of many everyday activities.

71.1.1   Visual Augmentation

People with certain eye disorders see better with higher- or lower-than-normal light levels; an **illuminance** from 100 to 4000 lux may promote comfortable reading [Fonda, 1981]. Ideal illumination is diffuse and directed from the side at a 45-degree angle to prevent glare. The surrounding room is preferably 20% to 50% darker than the object of interest.

Refractive errors cause difficulties in focusing on an object at a given distance from the eye [Mountcastle, 1980]. Myopia (near-sightedness), hyperopia (far-sightedness), astigmatism (focus depth that varies with radial orientation), and presbyopia (loss of ability to adjust focus, manifested as far-sightedness) are the most common vision defects. These normally can be corrected with appropriate eyeglasses or contact lenses and are rarely the cause of a disability.

Magnification is the most useful form of image processing for vision defects that do not respond to refractive correction. The simplest form of image magnification is getting closer; halving the distance to an object doubles its size. Magnifications up to 20 times are possible with minimal loss of field of view. At very close range, eyeglasses or a loupe may be required to maintain focus [Fonda, 1981]. Hand or stand magnifiers held 18–40 cm (not critical) from the eye create a virtual image that increases rapidly in size as the object-to-lens distance approaches the focal length of the lens. Lenses are rated in diopters ($D = 1/f$, where f is the focal length of the lens in centimeters). The useful range is approximately 4–20 D; more powerful lenses are generally held close to the eye as a loupe, as just mentioned, to enhance field of view. For distance viewing, magnification of 2–10 times can be achieved with hand-held telescopes at the expense of a reduced field of view.

Closed-circuit television (CCTV) systems magnify print and small objects up to 60 times, with higher effective magnifications possible by close viewing. Users with vision as poor as 1/400 (20/8000) may be able to read ordinary print with CCTV [Fonda, 1981]. Some recent units are portable and contain black/white image reversal and contrast enhancement features.

Electrical (or, more recently, magnetic) stimulation of the visual cortex produces perceived spots of light called *phosphenes.* Some attempts, summarized in Webster et al. [1985], have been made to map these sensations and display identifiable patterns, but the phosphenes often do not correspond spatially

with the specific location on the visual cortex. Although the risk and cost of this technique do not yet justify the minimal "vision" obtained, future use cannot be ruled out.

71.1.2 Tactual Vision Substitution

With sufficient training, people without useful vision can acquire sufficient information via the tactile sense for many activities of daily living, such as walking independently and reading. The traditional long cane, for example, allows navigation by transmitting surface profile, roughness, and elasticity to the hand. Interestingly, these features are *perceived* to originate at the tip of the cane, not the hand where they are transduced; this is a simple example of **distal attribution** [Loomis, 1992]. Simple electronic aids such as the hand-held Mowat sonar sensor provide a tactile indication of range to the nearest object.

Braille reading material substitutes raised-dot patterns on 2.3-mm centers for visual letters, enabling reading rates up to 30 to 40 words per minute (wpm). Contracted Braille uses symbols for common words and affixes, enabling reading at up to 200 wpm (125 wpm is more typical).

More sophisticated instrumentation also capitalizes on the spatial capabilities of the tactile sense. The Optacon (*opt*ical-to-*tac*tile *con*verter) by TeleSensory, Inc. (Mountain View, Calif.) converts the outline of printed letters recorded by a small, hand-held camera to enlarged **vibrotactile** letter outlines on the user's fingerpad. The camera's field of view is divided into 100 or 144 pixels (depending on the model), and the reflected light intensity at each pixel determines whether a corresponding vibrating pin on the fingertip is active or not. Ordinary printed text can be read at 28 (typical) or 90 (exceptional) wpm.

Spatial orientation and recognition of objects beyond the reach of a hand or long cane are the objective of experimental systems that convert an image from a television-type camera to a matrix of **electrotactile** or vibrotactile stimulators on the abdomen, forehead, or fingertip. With training, the user can interpret the patterns of tingling or buzzing pints to identify simple, high-contrast objects in front of the camera, as well as experience visual phenomena such as looming, perspective, parallax, and distal attribution [Bach-y-Rita, 1972; Collins, 1985].

Access to graphic or spatial information that cannot be converted into text is virtually impossible for blind computer users. Several prototype devices have been built to display computer graphics to the fingers via vibrating or stationary pins. A fingertip-scanned display tablet with embedded electrodes, under development in our laboratory [Kaczmarek et al., 1997], eliminates all moving parts; ongoing tests will determine if the spatial performance and reliability are adequate.

71.1.3 Auditory Vision Substitution

Electronic speech synthesizers allow access to electronic forms of text storage and manipulation. Until the arrival of graphic user interfaces such as those in the Apple Macintosh® and Microsoft Windows® computer operating systems, information displayed on computer screens was largely text-based. A number of products appeared that converted the screen information to speech at rates of up to 500 wpm, thereby giving blind computer users rapid access to the information revolution. Fortunately, much of the displayed information in graphic operating systems is not essentially pictorial; the dozen or so common graphic features (e.g., icons, scroll bars, buttons) can be converted to a limited set of words, which can then be spoken. Because of the way information is stored in these systems, however, the screen-to-text conversion process is much more complex, and the use of essentially spatial control features such as the mouse await true spatial display methods [Boyd et al., 1990].

Automated optical character recognition (OCR) combined with speech synthesis grants access to the most common printed materials (letters, office memorandums, bills), which are seldom available in Braille or narrated-tape format. First popularized in the Kurzweil reading machine, this marriage of technologies is combined with a complex set of lexical, phonetic, and syntactic rules to produce understandable speech from a wide variety of, but not all, print styles.

Mobility of blind individuals is complicated, especially in unfamiliar territory, by hazards that cannot be easily sensed with a long cane, such as overhanging tree limbs. A few devices have appeared that

convert the output of sonar-like ultrasonic ranging sensors to discriminable audio displays. For example, the Wormald Sonicguide uses interaural intensity differences to indicate the azimuth of an object and frequency to indicate distance [Cook, 1982]; subtle information such as texture can sometimes also be discriminated.

71.2 Auditory System

The human auditory system processes information primarily serially; having at best two receptive channels, spatial information must be built up by integration over time. This later capability, however, is profound. Out of a full orchestra, a seasoned conductor can pinpoint an errant violinist by sound alone.

Human hearing is sensitive to sound frequencies from approximately 16 to 20,000 Hz and is most sensitive at 1000 Hz. At this frequency, a threshold root-mean-square pressure of 20 Pa (200 μbar) can be perceived by normally hearing young adults under laboratory conditions. **Sound pressure level** (SPL) is measured in decibels relative to this threshold. Some approximate benchmarks for sound intensity are a whisper at 1 m (30 dB), normal conversion at 1 m (60 dB), and a subway train at 6 m (90 dB). Sounds increasing from 100 to 140 dB become uncomfortable and painful, and short exposures to a 160-dB level can cause permanent hearing impairment, while continuous exposure to sound levels over 90 dB can cause slow, cumulative damage [Sataloff et al., 1980].

Because hearing sensitivity falls off drastically at lower frequencies, clinical audiometric testing uses somewhat different scales. With the DIN/ANSI reference threshold of 6.5 dB SPL at 1 kHz, the threshold rises to 24.5 dB at 250 Hz and 45.5 dB at 125 Hz [Sataloff et al., 1980]. Hearing loss is then specified in decibels relative to the reference threshold, rather than the SPL directly, so that a normal audiogram would have a flat threshold curve at approximately 0 dB.

71.2.1 Auditory Augmentation

Loss of speech comprehension, and hence interpersonal communication, bears the greatest effect on daily life and is the main reason people seek medical attention for hearing impairment. Functional impairment begins with 21- to 35-dB loss in average sensitivity, causing difficulty in understanding faint speech [Smeltzer, 1993]. Losses of 36–50 dB and 51–70 dB cause problems with normal and loud speech. Losses greater than 90 dB are termed *profound* or *extreme* and cannot be remedied with any kind of hearing aid; these individuals require auditory substitution rather than augmentation.

Hearing loss can be caused by conduction defects in the middle ear (tympanic membrane and ossicles) or by sensorineural defects in the inner ear (cochlear transduction mechanisms and auditory nerve). Conduction problems often can be corrected medically or surgically. If not, hearing aids are often of benefit because the hearing threshold is elevated uniformly over all frequencies, causing little distortion of the signal. Sensorineural impairments differentially affect different frequencies and also cause other forms of distortion that cannot be helped by amplification or filtering. The dynamic range is also reduced, because while loud sounds (>100 dB) are often still perceived as loud, slightly softer sounds are lost. Looked at from this perspective, it is easy to understand why the amplification and automatic gain control of conventional hearing aids do not succeed in presenting the 30-dB or so dynamic range of speech to persons with 70 + dB of sensorineural impairment.

Most hearing aids perform three basic functions (1) Amplification compensates for the reduced sensitivity of the damaged ear. (2) Frequency-domain filtering compensates for hearing loss that is not spectrally uniform. For example, most sensorineural loss disproportionately affects frequencies over 1 kHz or so, so high-frequency preemphasis may be indicated. (3) Automatic gain control (ACG) compresses the amplitude range of desired sounds to the dynamic range of the damaged ear. Typical AGC systems respond to loud transients in 2–5 msec (attack time) and reduce their effect in 100–300 msec (recovery time).

Sophisticated multiband AGC systems have attempted to normalize the ear's amplitude/frequency response, with the goal of preserving intact the usual intensity relationships among speech elements. However, recent research has shown that only certain speech features are important for intelligibility

[Moore, 1990]. The fundamental frequency (due to vocal cord vibration), the first and second formants (the spectral peaks of speech that characterize different vowels), and place of articulation are crucial to speech recognition. In contrast, the overall speech envelope (the contour connecting the individual peaks in the pressure wave) is not very important; articulation information is carried in second-formant and high-frequency spectral information and is not well-represented in the envelope [Van Tasell, 1993]. Therefore, the primary design goal for hearing aids should be to preserve and make audible the individual spectral components of speech (formants and high-frequency consonant information).

The cochlear implant could properly be termed an auditory augmentation device because it utilizes the higher neural centers normally used for audition. Simply stated, the implant replaces the function of the (damaged) inner ear by electrically stimulating the auditory nerve in response to sound collected by an external microphone. Although the auditory percepts produced are extremely distorted and noiselike due to the inadequate coding strategy, many users gain sufficient information to improve their lipreading and speech-production skills. The introductory chapter in this section provides a detailed discussion of this technology.

71.2.2 Visual Auditory Substitution

Lipreading is the most natural form of auditory substitution, requiring no instrumentation and no training on the part of the speaker. However, only about one-third to one-half of the 36 or so phonemes (primary sounds of human speech) can be reliably discriminated by this method. The result is that 30% to 50% of the words used in conversational English look just like, or very similar to, other words (homophenes) [Becker, 1972]. Therefore, word pairs such as buried/married must be discriminated by grammar, syntax, and context.

Lipreading does not provide information on voice fundamental frequency or formants. With an appropriate hearing aid, any residual hearing (less than 90-dB loss) often can supply some of this missing information, improving lipreading accuracy. For the profoundly deaf, technological devices are available to supply some or all of the information. For example, the Upton eyeglasses, an example of a cued-speech device, provide discrete visual signals for certain speech sounds such as fricatives (letters like *f* of *s*, containing primarily high-frequency information) that cannot be readily identified by sight.

Fingerspelling, a transliteration of English alphabet into hand symbols, can convey everyday words at up to 2 syllables per second, limited by the rate of manual symbol production [Reed et al., 1990]. American Sign Language uses a variety of upper body movements to convey words and concepts rather than just individual letters, at the same effective rate as ordinary speech, 4 to 5 syllables per second.

Closed captioning encodes the full text of spoken words on television shows and transmits the data in a nonvisible part of the video signal (the vertical blanking interval). Since July of 1993, all new television sets sold in the United States with screens larger than 33 cm diagonal have been required to have built-in decoders that can optionally display the encoded text on the screen. Over 1000 h per week of programming is closed captioned [National Captioning Institute, 1994].

Automatic speech-recognition technology may soon be capable of translating ordinary spoken discourse accurately into visually displayed text, at least in quiet environments; this may eventually be a major boon for the profoundly hearing impaired. Presently, such systems must be carefully trained on individual speakers and/or must have a limited vocabulary [Ramesh et al., 1992]. Because there is much commercial interest in speech command of computers and vehicle subsystems, this field is advancing rapidly.

71.2.3 Tactual Auditory Substitution

Tadoma is a method of communication used by a few people in the deaf-blind community and is of theoretical importance for the development of tactual auditory substitution devices. While sign language requires training by both sender and receiver, in Tadoma, the sender speaks normally. The trained receiver places his or her hands on the face and neck of the sender to monitor lip and jaw movements, airflow at the lips, and vibration of the neck [Reed et al., 1992]. Experienced users achieve 80% keyword recognition

of everyday speech at a rate of 3 syllables per second. Using no instrumentation, this the highest speech communication rate recorded for any tactual-only communication system.

Alternatively, tactile vocoders perform a frequency analysis of incoming sounds, similarly to the ear's cochlea [Békésy, 1955], and adjust the stimulation intensity of typically 8 to 32 tactile stimulators (vibrotactile or electrotactile) to present a linear spectral display to the user's abdominal or forehead skin. Several investigators [Saunders et al., 1981; Blamey and Clark, 1985; Brooks and Frost, 1986; Boothroyd and Hnath-Chisolm, 1988] have developed laboratory and commercial vocoders. Although vocoder users cannot recognize speech as well as Tadoma users, research has shown that vocoders can provide enough "auditory" feedback to improve the speech clarity of deaf children and to improve auditory discrimination and comprehension in some older patients [Szeto and Riso, 1990] and aid in discrimination of phonemes by lipreading [Hughes, 1989; Rakowski et al., 1989]. An excellent review of earlier vocoders appears in Reed et al. [1982]. The most useful information provided by vocoders appears to be the second-formant frequency (important for distinguishing vowels) and position of the high-frequency plosive and fricative sounds that often delineate syllables [Bernstein et al., 1991].

71.3 Tactual System

Humans receive and combine two types of perceptual information when touching and manipulating objects. *Kinesthetic* information describes the relative positions and movements of body parts as well as muscular effort. Muscle and skin receptors are primarily responsible for kinesthesis; joint receptors serve primarily as protective limit switches [Rabischong, 1981]. Tactile information describes spatial pressure patterns on the skin given a fixed body position. Everyday touch perception combines tactile and kinesthetic information; this combination is called **tactual** or **haptic perception**. Loomis and Lederman [1986] provide an excellent review of these perceptual mechanisms.

Geldard [1960] and Sherrick [1973] lamented that as a communication channel, the tactile sense is often considered inferior to sight and hearing. However, the tactile system possess some of the same spatial and temporal attributes as both of the "primary" senses [Bach-y-Rita, 1972]. With over 10,000 parallel channels (receptors) [Collins and Saunders, 1970], the tactile system is capable of processing a great deal of information if it is properly presented.

The human kinesthetic and tactile senses are very robust and, in the case of tactile, very redundant. This is fortunate, considering their necessity for the simplest of tasks. Control of movement depends on kinesthetic information; tremors and involuntary movements can result from disruption of this feedback control system. Surgically repaired fingers may not have tactile sensation for a long period or at all, depending on the severity of nerve injuries; it is known that insensate digits are rarely used by patients [Tubiana, 1988]. Insensate fingers and toes (due to advanced Hansen's disease or diabetes) are often injured inadvertently, sometimes requiring amputation. Anyone who has had a finger numbed by cold realizes that it can be next to useless, even if the range of motion is normal.

The normal sensitivity to touch varies markedly over the body surface. The threshold forces in dynes for men (women) are lips, 9 (5); fingertips, 62 (25); belly 62 (7); and sole of foot, 343 (79) [Weinstein, 1968]. The fingertip threshold corresponds to 10-μm indentation. Sensitivity to vibration is much higher and is frequency-and area-dependent [Verillo, 1985]. A 5-cm^2 patch of skin on the palm vibrating at 250 Hz can be felt at 0.16-μm amplitude; smaller areas and lower frequencies require more displacement. The minimal separation for two nonvibrating points to be distinguished is 2–3 mm on the fingertips, 17 mm on the forehead, and 30–50 mm on many other locations. However, size and localization judgments are considerably better than these standard figures might suggest [Vierck and Jones, 1969].

71.3.1 Tactual Augmentation

Although we do not often think about it, kinesthetic information is reflected to the user in many types of human-controlled tools and machines, and lack of this feedback can make control difficult. For example, an automobile with power steering always includes some degree of "road feel" to allow the driver to

respond reflexively to minor bumps and irregularities without relying on vision. Remote-control robots (telerobots) used underwater or in chemical- or radiation-contaminated environments are slow and cumbersome to operate, partly because most do not provide force feedback to the operator; such feedback enhances task performance [Hannaford and Wood, 1992].

Tactile display of spatial patterns on the skin uses three main types of transducers [Kaczmarek et al., 1991; Kaczmarek and Bach-y-Rita, 1995]. **Static tactile** displays use solenoids, shape-memory alloy actuators, and scanned air or water jets to indent the skin. Vibrotactile displays encode stimulation intensity as the amplitude of a vibrating skin displacement (10–500 Hz); both solenoids and piezoelectric transducers have been used. *Electrotactile* stimulation uses 1–100 mm^2-area surface electrodes and careful waveform control to electrically stimulate the afferent nerves responsible for touch, producing a vibrating or tingling sensation.

Tactile rehabilitation has received minimal attention in the literature or medical community. One research device sensed pressure information normally received by the fingertips and displayed it on the forehead using electrotactile stimulation [Collins and Madey, 1974]. Subjects were able to estimate surface roughness and hardness and detect edges and corners with only one sensor per fingertip. Phillips [1988] reviews prototype tactile feedback systems that use the intact tactile sense to convey hand and foot pressure and elbow angle to users of powered prosthetic limbs, often with the result of more precise control of these devices.

Slightly more attention has been given to tactile augmentation in special environments. Astronauts, for example, wear pressurized gloves that greatly diminish tactile sensation, complicating extravehicular repair and maintenance tasks. Efforts to improve the situation range from mobile tactile pins in the fingertips to electrotactile stimulation on the abdomen of the information gathered from fingertip sensors [Bach-y-Rita et al., 1987].

71.3.2 Tactual Substitution

Because of a paucity of adequate tactual display technology, spatial pressure information from a robot or remote manipulator is usually displayed to the operator visually. A three-dimensional bar graph, for example, could show the two-dimensional pressure pattern on the gripper. While easy to implement, this method suffers from two disadvantages (1) the visual channel is required to process more information (it is often already heavily burdened), and (2) reaction time is lengthened, because the normal human tactual reflex systems are inhibited. An advantage of visual display is that accurate measurements of force and pressure may be displayed numerically or graphically.

Auditory display of tactual information is largely limited to warning systems, such as excessive force on a machine. Sometimes such feedback is even inadvertent. The engine of a bulldozer will audibly slow down when a heavy load is lifted; by the auditory and vibratory feedback, the operator can literally "feel" the strain.

The ubiquity of such tactual feedback systems suggests that the human-machine interface on many devices could benefit from intentionally placed tactual feedback systems. Of much current interest is the **virtual environment**, a means by which someone can interact with a mathematic model of a place that may or may not physically exist. The user normally controls the environment by hand, head, and body movements; these are sensed by the system, which correspondingly adjusts the information presented on a wide-angle visual display and sometimes also on a spatially localized sound display. The user often describes the experience as "being there," a phenomenon known as *telepresence* [Loomis, 1992]. One can only imagine how much the experience could be enhanced by adding kinesthetic and tactile feedback [Shimoga, 1993], quite literally putting the user in touch with the virtual world.

Defining Terms

Distal attribution: The phenomenon whereby events are normally perceived as occurring external to our sense organs — but also see Loomis' [1992] engaging article on this topic. The environment or

transduction mechanism need not be artificial; for example, we visually perceive objects as distant from our eyes.

Electrotactile: Stimulation that evokes tactile (touch) sensations within the skin at the location of the electrode by passing a pulsatile, localized electric current through the skin. Information is delivered by varying the amplitude, frequency, etc. of the stimulation waveform. Also called *electrocutaneous stimulation.*

Illuminance: The density of light falling on a surface, measured in lux. One lux is equivalent to 0.0929 foot-candles, an earlier measure. Illuminance is inversely proportional to the square of the distance form a point light source. A 100-W incandescent lamp provides approximately 1280 lux at a distance of 1 ft (30.5 cm). Brightness is a different measure, depending also on the reflectance of the surrounding area.

Kinesthetic perception: Information about the relative positions of and forces on body parts, possibly including efference copy (internal knowledge of muscular effort).

Sensory augmentation: The use of devices that assist a functional human sense; eyeglasses are one example.

Sensory substitution: The use of one human sense to receive information normally received by another sense. For example, Braille substitutes touch for vision.

Sound pressure level (SPL): The root-mean-square pressure difference from atmospheric pressure (≈ 100 kPa) that characterizes the intensity of sound. The conversion SPL = 20 $\log(P/P_0)$ expresses SPL in decibels, where P_0 is the threshold pressure of approximately 20 Pa at 1 kHz.

Static tactile: Stimulation that is a slow local mechanical deformation of the skin. It varies the deformation amplitude directly rather than the amplitude of vibration. This is "normal touch" for grasping objects, etc.

Tactile perception: Information about spatial pressure patterns on the skin with a fixed kinesthetic position.

Tactual (haptic) perception: The seamless, usually unconscious combination of tactile and kinesthetic information; this is "normal touch."

Vibrotactile: Stimulation that evokes tactile sensations using mechanical vibration of the skin, typically at frequencies of 10 to 500 Hz. Information is delivered by varying the amplitude, frequency, etc. of the vibration.

Virtual environment: A real-time interactive computer model that attempts to display visual, auditory, and tactual information to a human user as if he or she were present at the simulated location. The user controls the environment with head, hand, and body motions. A airplane cockpit simulator is one example.

Further Information

Presence: Teleoperators and Virtual Environments is a bimonthly journal focusing on advanced human-machine interface issues. In an effort to develop tactile displays without moving parts, our laboratory has demonstrated simple pattern recognition on the fingertip [Kaczmarek et al., 1997] and tongue [Bach-y-Rita et al., 1998] using electrotactile stimulation.

The Trace Research and Development Center, Madison, Wisc., publishes a comprehensive resource book on commercially available assistive devices, organizations, etc. for communication, control, and computer access for individuals with physical and sensory impairments.

Electronic Devices for Rehabilitation, edited by J.G. Webster [Wiley, 1985], summarizes the technologic principles of electronic assistive devices for people with physical and sensory impairments.

72.1   Introduction

The inability to express oneself through either speech or writing is perhaps the most limiting of physical disabilities. Meaningful participation in life requires the communication of basic information, desires, needs, feelings, and aspirations. The lack of full interpersonal communication substantially reduces an individual's potential for education, employment, and independence.

Today, through multidisciplinary contributions, individuals who cannot speak or write effectively have access to a wide variety of techniques, therapies and systems designed to ameliorate challenges to verbal communication. The field of augmentative and alternative communication (AAC) consists of many different professions, including speech-language pathology, regular and special education, occupational and physical therapy, engineering, linguistics, technology, and others. Experienced professionals now can become certified as Assistive Technology practitioners and/or suppliers [Minkel, 1996]. Individuals who rely on AAC, as well as their families and friends, also contribute to the field [Slesaransky-Poe, 1998].

Engineering plays a significant role in the development of the field of AAC and related assistive technology. Engineering contributions range from relatively independent work on product definition and design to the collaborative development and evaluation of tools to support the contributions of other professions, such as classical and computational linguistics and speech-language pathology.

Augmentative communication can be classified in a variety of ways ranging from unaided communication techniques, such as gestures, signs, and eye pointing, to highly sophisticated electronic devices

72-1

employing the latest technology. This chapter focuses on the review of technology-aided techniques and related issues.

Technology-based AAC systems have taken two forms: hardware designed specifically for this application and software that runs on mass market computer hardware. Three basic components comprise AAC systems. These are the language representation method (including acceleration techniques), the user interface, and the outputs. Generally, a multidisciplinary team evaluates the current and projected skills and needs of the individual, determines the most effective language representation method(s) and physical access technique(s), and then selects a system with characteristics that are a good match.

72.2 Language Representation Methods and Acceleration Techniques

The ultimate goal of AAC intervention is functional, interactive communication. The four purposes that communication fulfills are (1) communication of needs/wants, (2) information transfer, (3) social closeness, and (4) social etiquette [Light, 1988]. From the perspective of the person who uses AAC, communicative competence involves the ability to transmit messages efficiently and effectively in all four of the interaction categories, based on individual interests, circumstances, and abilities [Buekelman and Mirenda, 1998]. To achieve communication competence, the person using an AAC system must have access to language representation methods capable of handling the various vocabulary and message construction demands of the environment. Professionals rely on the theoretical models of language development and linguistics to evaluate the effectiveness of an AAC language representation method.

Language is defined as an abstract system with rules governing the sequencing of basic units (sounds, morphemes, words, and sentences), and rules governing meaning and use [McCormick and Schiefelbusch, 1990]. An individual knows a language when he or she understands and follows its basic units and rules. Knowledge of language requires both linguistic competence (understanding the rules), and linguistic performance (using these rules). Most language models identify the basic rules as phonology, semantics, morphology, syntax and pragmatics. The basic rules of language apply to AAC. For example, AAC research on vocabulary use has documented the phenomenon of core and fringe vocabulary [Yorkston et al., 1988] and the reliance on a relatively limited core vocabulary to express a majority of communication utterances [Vanderheiden and Kelso, 1987]. Research on conversations has documented topic and small talk patterns [Stuart et al., 1993; King et al., 1995]. An awareness of how a given AAC system handles these basic rules enables one to be critical of AAC language representation methods.

In addition to the language representation method, the acceleration technique(s) available in an AAC system contribute(s) to communication competence. Communication by users of AAC systems is far slower than that of the general population. Yet the speed of communication is a significant factor influencing the perceptions of the user's communication partner, and potential for personal achievement for the person relying on AAC. The development and application of techniques to accelerate communication rates is critical. Further, these techniques are most effective when developers pay attention to human factors design principles [Goodenough-Trepagnier, 1994].

Alphabet-based language representation methods involve the use of traditional orthography and acceleration techniques that require spelling and reading skills. AAC systems using orthography require the user to spell each word using a standard keyboard or alphabet overlay on a static or dynamic display. A standard or customized alphabet overlay provides use for all the rules and elements of a natural language; however, spelling letter-by-letter is a slow and inefficient AAC strategy without acceleration techniques.

Abbreviation systems represent language elements using a number of keystrokes typically smaller than that required by spelling. For example, words or sentences are abbreviated using principled approaches based on vowel elimination or the first letters of salient words. Abbreviation systems can be fast, but require not only spelling and reading skills, but memory of abbreviation codes. Typically, people with spelling and reading skills have large vocabulary needs and increased demands on production of text. Demasco [1994] offers additional background and proposes some interesting work in this area.

Word prediction is another acceleration technique available from many sources. Based on previously selected letters and words, the system presents the user with best guess choices for completing the spelling of a word. The user then chooses one of the predictions or continues spelling, resulting in yet another set of predictions. Prediction systems have demonstrated a reduction in the number of keystrokes, but recent research [Koester and Levine, 1994] reports that the actual communication rate does not represent a statistical improvement over spelling. The reason for word predication's failure to improve rate is that increased time is needed to read and select the word table choices. The cost of discontinuity and increased cognitive load in the task seems to match the benefits of reduced keystrokes.

Picture Symbol-based language representation methods involve the use of graphic or line drawn symbols to represent single word vocabulary or messages (phrases, sentences, and paragraphs). A variety of AAC symbol sets are available on devices or software depict the linguistics elements available through the system. Picture Communication Symbols (PCS), DynaSyms, and Blissymbols are popular symbol sets used in either dedicated or computer-aided systems. One taxonomy differentiates symbols according to several subordinate levels including static/dynamic, iconic/opaque, and set/system [Fuller et al., 1998].

Universal considerations regarding the selection of a symbol set include research on symbol characteristics such as size, transparency, complexity and iconicity [Romski and Sevcik, 1988; Fuller et al., 1997]. Understanding symbol characteristics is necessary to make clinical decisions about vocabulary organization and system selection. The choice of picture communication language representation methods is facilitated when teams use a goal-driven graphic symbol selection process [Schlosser et al., 1996]. For example, identification of vocabulary and language outcomes assists the selection of an AAC graphic symbol system.

Vocabulary size and representation of linguistic rules (grammar) are concerns for users relying on graphic symbol sets. Users of static display systems have a limited number of symbols available on any one overlay; however, they have ready access to that vocabulary. Dynamic display users have an almost unlimited number of symbols available as vocabulary for message generation; however, they must navigate through pages or displays to locate a word. Frequently, morphology and syntax are not graphically represented. Since research has strongly supported the need for users to construct spontaneous, novel utterances [Beukelman et al., 1984], neither method is efficient for interactive communication.

Semantic Compaction or Minspeak is perhaps the most commonly used AAC language representation method [Baker, 1994]. With this method, language is represented by a relatively small set of multi-meaning icons. The specific meaning of each icon is a function of the context in which it is used. Semantic compaction makes use of a meaningful relationship between the icon and the information it represents; it does not require spelling and reading skills, and yet is powerful even for people with these skills. The performance of Minspeak stems from its ability to handle both vocabulary and linguistic structures as found in the Minspeak Application Programs (MAPS) of Words Strategy and Unity. Both MAPS support the concept of a core and fringe vocabulary. They provide the architecture for handling rules of grammar and morphology. The number of required keystrokes is reduced relative to spelling.

Predictive selection is an acceleration technique used with Minspeak. When this feature is enabled, only those choices that complete a meaningful sequence can be selected. With scanning, for example, the selection process can be significantly faster because the number of possible choices is automatically reduced.

72.3 User Interface

Most AAC systems employ a user interface based on the selection of items that will produce the desired output [Vanderheiden and Lloyd, 1986]. Items being selected may be individual letters, as used in spelling, or whole words or phrases expressing thoughts, or symbols that represent vocabulary. The numerous techniques for making selections are based on either direct selection or scanning.
FIGURE 72.1 Direct selection.

Scanning rows
Scanning columns

FIGURE 72.2 Row–column scanning.

Direct selection refers to techniques by which a single action from a set of choices indicates the desired item. A common example of this method is the use of a computer keyboard. Each key is directly selected by finger. Expanded keyboards accommodate more gross motor actions, such as using the fist or foot. In some cases, pointing can be enhanced through the use of technology. Sticks are held in the mouth or attached to the head using a headband or helmet. Light pointers are used to direct a light beam at a target. Indirect pointing systems might include the common computer mouse, trackball, or joystick. Alternatives to these for people with disabilities are based on the movement of the head or other body part. Figure 72.1 depicts direct selection in that the desired location is pointed to directly.

Scanning refers to techniques in which the individual is presented with a time sequence of choices and indicates when the desired choice appears. A simple linear scanning system might be a clock face type display with a rotating pointer to indicate a letter, word, or picture. Additional dimensions of scanning can be added to reduce the selection time when the number of possible choices is larger. A common technique involves the arrangement of choices in a matrix of rows and columns. The selection process has two steps. First, rows are scanned to select the row containing the desired element. The selected row is then scanned to select the desired element. This method is called row–column scanning. See Figure 72.2. Either by convention or by the grouping of the elements, the order might be reversed. For example, in the United Kingdom, column–row scanning is preferred over row–column scanning. Other scanning techniques also exist and additional dimensions can be employed.

Both direct selection and scanning are used to select elements that might not of themselves define an output. In these cases the output may be defined by a code of selected elements. A common example is Morse code by which dots and dashes are directly selected but must be combined to define letters and

numbers. Another example, more common to AAC, has an output defined by a sequence of two or more pictures or icons.

Scanning, and to some degree direct selection, can be faster when the choices are arranged such that those most frequently used are easiest to access. For example, in a row–column scanning spelling system that scans top to bottom and left to right, the most frequently used letters are usually grouped toward the upper left corner.

Generally the selection technique of choice should be that which results in the fastest communication possible. Consideration of factors such as cognitive load [Cress and French, 1994], environmental changes, fatigue, aesthetics, and stability of physical skill often influence the choice of the best selection technique.

72.4 Outputs

AAC system outputs in common use are speech, displays, printers, beeps, data, infrared, and other control formats. Outputs are used to facilitate the interactive nature of "real time" communication. Users may rely on auditory and visual feedback to enhance vocabulary selection and the construction of messages. The speech and display outputs may be directed toward the communication partner to support the exchange of information. Auditory feedback such as beeps and key clicks, while useful to the individual using the system, also provide the communication partner with the pragmatic information that a user is in the process of generating a message. Finally, outputs may be used to control other items or devices such as printers.

AAC speech output normally consists of two types: synthetic and digitized.

Synthetic speech usually is generated from text input following a set of rules. Synthetic speech is usually associated with AAC systems that are able to generate text. These systems have unlimited vocabulary and are capable of speaking any word or expression that can be spelled. Commonly used synthetic speech systems like DECtalk™offer a variety of male, female, and child voices. Intelligibility has improved over recent years to the point that it is no longer a significant issue. With some systems it is actually possible to sing songs, again a feature that enhances social interaction. Most synthetic speech systems are limited to a single language, although bilingual systems are available. Further limitations relate to the expression of accent and emotion. Research and development in artificial speech technology is attacking these limitations.

Digitized speech is essentially speech that has been recorded into digital memory. Relatively simple AAC systems typically use digitized speech. The vocabulary is entered by speaking into the system through a microphone. People who use these systems can say only what someone else said in programming them. They are independent of language and can replicate the song, accent, and emotion of the original speaker.

RS-232c serial data output is used to achieve a variety of functional outcomes. Serial output permits the AAC system to replace the keyboard and mouse for computer access, a procedure known as emulation. The advantage of emulation is that the language representation method and physical access method used for speaking is used for writing and other computer tasks [Buning and Hill, 1998]. Another application for the serial output is environmental control. Users are able to operate electrical and electronic items in their daily-living surroundings. Particular sequences of characters, symbols or icons are used to represent commands such as answering the telephone, turning off the stereo, and even setting a thermostat. In addition, the serial output also may be used to monitor the language activity for purposes of clinical intervention, progress reporting, and research.

Infrared communication now is available in many AAC devices. Infrared output supports the same functions as the RS-232c serial data output, but without requiring direct wiring or linking between operating devices. Infrared interfaces providing computer access improve the independence of AAC users because no physical connection needs to be manipulated to activate the system. Infrared interfaces can perform as environmental control units by learning the codes of entertainment and other electronic systems.

72.5   Outcomes, Intervention, and Training

The choice of an AAC system should rely primarily on the best interests of the person who will be using the system. Since outcomes and personal achievement will be related directly to the ability to communicate, the choice of a system will have lifelong implications. The process of choosing the most appropriate system is not trivial and can be accomplished best with a multidisciplinary team focusing on outcomes. Team members should realize that the interests of the individual served professionally are not necessarily aligned with those of the providers and/or payers of AAC services. The temptation to select a system that is easy to apply or inexpensive to purchase frequently exists, especially with untrained teams. Teams that identify outcomes and have the goal of achieving interactive communication make informed decisions.

Following the selection (and funding) of a system, the next step is the actual intervention program. For successful outcomes to be achieved, intervention must go beyond the technical use of the AAC system and include objectives for language development and communication pragmatics. Early in the history of AAC, Rodgers postulates [1984] that AAC systems are more like tools than appliances. To be effective, there is a need for much more than simply "plugging them in and turning them on." The individual who relies on AAC must develop the skills to become a communication craftsperson. In general, as well as specific to AAC, the fastest, most efficient use of a system occurs when the individual operates from knowledge that is in the head, rather than knowledge that must be gathered from the world [Norman, 1980]. The implication for AAC is that an intervention program must include a significant training component to assure that the needed knowledge is put into the head [Romich, 1994]. Further, a drill component of training develops automaticity [Treviranus, 1994].

Perhaps the single factor limiting the widespread use of assistive technology in general and AAC in particular is the lack of awareness of its availability and the impact it can have on the lives of the people who could benefit [Romich, 1993]. This situation exists within not only the general public but also in many of the professions providing services to this population. Training opportunities continue to be limited for a majority of professionals working with persons who could benefit from AAC technology. University programs have lagged behind in their integration of this information into professional curricula.

Intervention and training should extend beyond the initial application of the system. People who rely on AAC frequently live unstable lives. Consequently they have a need for on-going services. For people with

congenital (from birth) conditions, developmental delays may have occurred that result in educational and training needs past the normal age of public school services. For people with progressive neurological disorders, such as Lou Gehrig's disease, the physical skill level will change and additional accommodations will need to be evaluated and implemented.

72.6 Future

Technological development in and of itself will not solve the problems of people with disabilities. Technology advancements, however, will continue to provide more powerful tools allowing the exploration of new and innovative approaches to support users and professionals. As access to lower cost, more powerful computer systems increases, the availability of alternative sources of information, technical support and training is possible either through software or the internet. Users and professionals will have increased opportunities to learn and exchange ideas and outcomes.

A related development is the collection and analysis of data describing the actual long term use of AAC devices. Currently, clinicians and researchers have not utilized this information in the clinical intervention process, progress reporting, or research. Tools for monitoring, editing, and analyzing language activity are just now becoming available [Hill and Romich, 1998].

Further Information

There are a number of organizations and publications that relate to AAC.

AAC (Augmentative and Alternative Communication) is the quarterly refereed journal of ISAAC. It is published by Decker Periodicals Inc., PO Box 620, L.C.D. 1, Hamilton, Ontario, L8N 3K7 CANADA, Tel. 905-522-7017, Fax. 905-522-7839. http://www.isaac-online.org

ACOLUG (Augmentative Communication On-Line User Group) is a listserve with primary participants being people who rely on AAC. Topics include a wide range of issues of importance to this population, their relatives, and friends, and those who provide AAC services. http://nimbus.ocis.temple.edu/~kcohen/listserv/homeacolug.html

American Speech-Language-Hearing Association (ASHA) is the professional organization of speech-language pathologists. ASHA has a Special Interest Division on augmentative communication. ASHA, 10801 Rockville Pike, Rockville, MD, 20852, Tel. 301-897-5700, Fax. 301-571-0457. http://www.asha.org.

Augmentative Communication News is published bi-monthly by Augmentative Communication, Inc., 1 Surf Way, Suite #215, Monterey, CA, 93940, Tel. 408-649-3050, Fax. 408-646-5428.

CAMA (Communication Aid Manufacturers Association) is an organization of manufacturers of AAC systems marketed in North America. CAMA, 518-526 Davis St., Suite 211-212, Evanston, IL, 60201, Tel. 800-441-2262, Fax. 708-869-5689. http://www.aacproducts.org.

Communicating Together is published quarterly by Sharing to Learn as a means of sharing the life experiences and communication systems of augmentative communicators with other augmentative communicators, their families, their communities, and those who work with them. Sharing to Learn, PO Box 986, Thornhill, Ontario, L3T 4A5, CANADA, Tel. 905-771-1491, Fax. 905-771-7153. http://www.isaac-online.org.

Communication Outlook is an international quarterly addressed to the community of individuals interested in the application of technology to the needs of persons who experience communication

handicaps. It is published by the Artificial Language Laboratory, Michigan State University, 405 Computer Center, East Lansing, MI, 48824-1042, Tel. 517-353-0870, Fax. 517-353-4766. http://www.msu.edu/~artlang/CommOut.html.

ISAAC is the International Society for Augmentative and Alternative Communication). USSAAC is the United States chapter. Both can be contacted at PO Box 1762 Station, R., Toronto, Ontario, M4G 4A3, Canada, Tel. 905-737-9308, Fax 905-737-0624. http://www.isaac-online.org.

RESNA is an interdisciplinary association for the advancement of rehabilitation and assistive technologies. RESNA has many Special Interest Groups including those on Augmentative and Alternative Communication and Computer Applications. RESNA, 1700 North Moore Street, Suite 1540, Arlington, VA, 22209-1903, Tel. 703-524-6686.

Trace Research & Development Center, University of Wisconsin — Madison. http://www.trace.wisc.edu.

Measurement Tools and Processes in Rehabilitation Engineering

George V. Kondraske
University of Texas-Arlington

In every engineering discipline, measurement facilitates the use of structured **procedures** and decision-making processes. In rehabilitation engineering, the presence of "a human," the only or major component of *the system of interest*, has presented a number of unique challenges with regard to measurement. This is especially true with regard to the routine processes of rehabilitation that either do or could incorporate and rely on measurements. This, in part, is due to the complexity of the human system's architecture, the variety of ways in which it can be adversely affected by disease or injury, and the versatility in the way it can be used to accomplish various **tasks** of interest to an individual.

Measurement supports a wide variety of assistive device design and prescription activities undertaken within rehabilitation engineering (e.g., Webster et al. [1985], Smith and Leslie [1990], and other chapters within this section). In addition, rehabilitation engineers contribute to the specification and design of measurement instruments that are used primarily by other service providers (such as physical and occupational therapists). As measurements of human **structure**, **performance**, and **behavior** become more rigorous and instruments used have taken advantage of advanced technology, there is also a growing role

73-1

for rehabilitation engineers to assist these other medical professionals with the proper application of measurement instruments (e.g., for determining areas that are most deficient in an individual's performance profile, objectively documenting progress during rehabilitation, etc.). This is in keeping with the team approach to rehabilitation that has become popular in clinical settings. In short, the role of measurement in rehabilitation engineering is dynamic and growing.

In this chapter, a top-down overview of measurement tools and processes in rehabilitation engineering is presented. Many of the measurement concepts, processes, and devices of relevance are common to applications outside the rehabilitation engineering context. However, the nature of the human population with which rehabilitation engineers must deal is arguably different in that each individual must be assumed to be unique with respect to at least a subset of his or her performance capacities and/or structural parameters; that is, population reference data cannot be assumed to be generally applicable. While there are some exceptions, population labels frequently used such as "head-injured" or "spinal cord-injured" represent only a gross classification that should not be taken to imply homogeneity with regard to parameters such as range of motion, strength, movement speed, information processing speed, and other performance capacities. This is merely a direct realization that many different ways exist in which the human system can be adversely affected by disease or injury and recognition of the continuum that exists with regard to the degree of any given effect. The result is that in rehabilitation engineering, compared with standard human factors design tasks aimed at the average healthy population, many measurement values must be acquired directly for the specific client.

Measurement in the present context encompasses actions that focus on (1) the human (e.g., structural aspects and performance capacities of subsystems at different hierarchical levels ranging from specific neuromuscular subsystems to the total person and his or her activities in daily living, including work), (2) assistive devices (e.g., structural aspects and demands placed on the human), (3) tasks (e.g., distances between critical points, masses of objects involved, etc.), and (4) overall systems (e.g., performance achieved by a human-assistive device-task combination, patterns of electrical signals representing the timing of muscle activity while performing a complex maneuver, behavior of an individual before and after being fitted with a new prosthetic devices, etc.). Clearly, an exhaustive treatment is beyond the scope of this chapter. Measurements are embedded in every specialized subarea of rehabilitation engineering. However, there are also special roles served by measurement in a broader and more generic sense, as well as principles that are common across the many special applications. Emphasis here is placed on these.

There is no lack of other literature regarding the types of measurement outlined to be of interest here and their use. However, it is diffusely distributed, and gaps exist with regard to how such tools can be integrated to accomplish **goals** beyond simply the acquisition of numeric data for a given parameter. With rapidly changing developments over the last decade, there is currently no comprehensive source that describes the majority of instruments available, their latest implementations, procedures for their use, evaluation of effectiveness, etc. While topics other than measurement are discussed, Leslie and Smith [1990] produced what is perhaps the single most directly applicable source with respect to rehabilitation engineering specifically, although it too is not comprehensive with regard to measurement, nor does it attempt to be.

73.1 Fundamental Principles

Naturally, the fundamental principles of human physiology manifest themselves in the respective sensory, neuromuscular, information-processing, and life-sustaining systems and impact approaches to measurement. In addition, psychological considerations are vital. Familiarization with this material is essential to measurement in rehabilitation; however, treatment here is far beyond the scope of this chapter. The numerous reference works available may be most readily found by consulting relevant chapters in this *Handbook* and the works that they reference. In this section, key principles that are more specific to measurement and of general applicability are presented.

73.1.1 Structure, Function, Performance, and Behavior

It is necessary to distinguish between structure, **function**, performance, and behavior and measurements thereof for both human and artificial systems. In addition, hierarchical systems concepts are necessary both to help organize the complexity of the systems involved and to help understand the various needs that exist.

Structural measures include dimensions, masses (of objects, limb segments), moments of inertia, circumferences, contours, compliances, and any other aspects of the physical system. These may be considered hierarchically as being pertinent to the total human (e.g., height, weight, etc.), specific body segments (e.g., forearm, thigh, etc.), or components of basic systems such as tendons, ligaments and muscles.

Function is the *purpose* of the system of interest (e.g., to move a limb segment, to communicate, to feed and care for oneself). Within the human, there are many single-purpose systems (e.g., those that function to move specific limb segments, process specific types of information, etc.). As one proceeds to higher levels, such as the total human, systems that are increasingly more multifunctional emerge. These can be recognized as higher-level configurations of more basic systems that operate to feed oneself, to conduct personal hygiene, to carry out task of a job, etc. This multilevel view of just functions begins to help place into perspective the scope over which measurement can be applied.

In rehabilitation in general, a good deal of what constitutes measurement involves the application of structured subjective observation techniques (see also the next subsection) in the form of a wide range of rating scales [e.g., Granger and Greshorn, 1984; Potvin et al., 1985; Fuhrer, 1987]. These are often termed **functional assessment scales** and are typically aimed at obtaining a global index of an individual's ability to function independently in the world. The global index is typically based on a number of items within a given scale, each of which addresses selected, relatively high-level functions (e.g., personal hygiene, mobility, etc.). The focus of measurement for a given item is often in estimate of the *level* of independence or dependence that the subject exhibits or needs to carry out the respective function. In addition, inventories of functions that an individual is able or not able to carry out (with and without assistance) are often included. The large number of such scales that have been proposed and debated is a consequence of the many possible functions and combinations thereof that exist on which to base a given scale. Functional assessment scales are relatively quick and inexpensive to administer and have a demonstrated role in rehabilitation. However, the nature and levels of measurements obtained are not sufficient for many rehabilitation engineering purposes. This latter class of applications generally begins with a function at the level and of the type used as a constituent component of functional assessment scales, considers the level of performance at which that function is executed more quantitatively, and incorporates one or more lower levels in the hierarchy (i.e., the human subsystems involved in achieving the specific functions of daily life that are of interest and their capacities for performance).

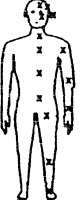
Where functions can be described and inventoried, *performance* measures directly characterize *how well* a physical system of interest executes its intended function. Performance is multidimensional (e.g., strength, range, speed, accuracy, steadiness, endurance, etc.). Of special interest are the concepts of **performance capacity** and **performance capacity measurement**. Performance capacity represents the *limits* of a given system's ability to operate in its corresponding multidimensional performance space. In this chapter, a resource-based model for both human and artificial system performance and measurement of their performance capacities is adopted [e.g., Kondraske, 1990, 1995]. Thus the *maximum* knee flexor strength available (i.e., the resource availability) under a stated set of conditions represents one unique performance capacity of the knee flexor system. In rehabilitation, the terms *impairment*, *disability*, and *handicap* (World Health Organization, 1980) have been prominently applied and are relevant to the concept of performance. While these terms place an emphasis on what is missing or what a person cannot do and imply not only a measurement but also the incorporation of an assessment or judgment based on one or more observations the resource-based performance perspective focuses on "what is present" or "what is right". (i.e., performance resource availability). From this perspective, an impairment can be determined to exist if a given performance capacity is found to be less than a specified level (e.g., less

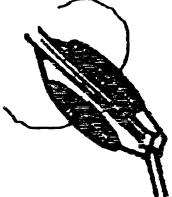
than 5th percentile value of a health reference population). A disability exists when performance resource insufficiency exists in a specified task.

While performance relates more to what a system can do (i.e., a challenge or maximal stress is implied), *behavior* measurements are used to characterize what a system does naturally. Thus a given variable such as movement speed can relate to both performance and behavior depending on whether the system (e.g., human subsystem) was maximally challenged to respond "as fast as possible" (performance) or simply observed in the course of operation (behavior). It is also possible to observe a system that it is behaving at one or more of its performance capacities (e.g., at the maximum speed possible, etc.) (see Table 73.1).

73.1.2 Subjective and Objective Measurement Methods

Subjective measurements are made by humans without the aid of instruments and objective measurements result from the use of instruments. However, it should be noted that the mere presence of an instrument does not guarantee complete objectivity. For example, the use of a ruler requires a human judgment in reading the scale and thus contains a subjective element. A length-measurement system with an integral data-acquisition system would be more objective. However, it is likely that that even this system would involve human intervention in its use, for example, the alignment of the device and making the decision as to exactly what is to be measured with it by selection of reference points. Measures with more objectivity (less subjectivity) are preferred to minimize questions of bias. However, measurements that are intrinsically more objective are frequently more costly and time-consuming to obtain. Well-reasoned tradeoffs must be made to take advantage of the ability of a human (typically a skilled professional) to quickly "measure" many different items subjectively (and often without recording the results but using them internally to arrive at some decision).

It is important to observe that identification of the variable of interest is not influenced by whether it is measured subjectively or objectively. This concept extends to the choice of instrument used for objective measurements. This is an especially important concept in dealing with human performance and behavior, since variables of interest can be much more abstract than simple lengths and widths (e.g., coordination, postural stability, etc.). In fact, many measurement variables in rehabilitation historically have tended to be treated as if they were inextricably coupled with the measurement method, confounding debate regarding *what should be measured with what should be used to measure it* in a given context.




73.1.3 Measurements and Assessments

The basic representation of a measurement itself in terms of the actual units of measure is often referred to as the *raw form*. For measures of performance, the term *raw score* is frequently applied. Generally, some form of *assessment* (i.e., judgment or interpretation) is typically required. Assessments may be applied to (or, viewed from a different perspective, may require) either a single measure of groups of them. Subjective assessments are frequently made that are based on the practitioner's familiarity with values for a given parameter in a particular context. However, due to the large number of parameters and the amount of experience that would be required to gain a sufficient level of familiarity, a more formal and objective realization of the process that takes place in subjective assessments is often employed. This process combines the measured value with objectively determined reference values to obtain new metrics, or scores, that facilitate one or more steps in the assessment process.

For aspects of performance, *percent normal scores* are computed by expressing subject Y's availability of performance resource $k[R_{A_k}(Y)]$ as a fraction of the mean availability of that resource in a specified reference population $[R_{A_k}(\text{pop})]$. Ideally, the reference population is selected to match the characteristics of the individual as closely as possible (e.g., age range, gender, handedness, etc.).

$$\text{Percent normal} = \frac{R_{A_k}(Y)}{R_{A_k}(\text{pop})} \times 100 \qquad (73.1)$$

TABLE 73.1   The Scope of Measurement in Rehabilitation Is Broad

	Hierarchical level	Structure	Function	Performance	Behavior

	Global/composite
	 • Total human
	 • Human with artificial systems
		• Height
		 • Weight
		 • Postures
		 • Subjective and instrumented methods
			• Multifunction, reconfigurable system
			 • High-level functions: tasks of daily life (working, grooming, recreation, etc.)
			 • Functional assessment scales
			   Single-number global index
			   Level of indep. estimates
				• No single-number direct measurement is possible
				 • Possible models to integrate lower-level measures
				 • Direct measurement (subjective and instrumented) of selected performance attribute for selected functions
					• Subjective self- and family reports
					 • Instrumented ambulatory activity monitors (selected attributes)
					 • See notes under "function"

	Complex body systems
	 • Cognitive
	 • Speech
	 • Lifting, gait
	 • Upper extremity
	 • Cardiovascular/ respiratory
	 • Etc.
		• Dimensions
		 • Shape
		 • Etc.
		 • Instrumented methods
			• Multifunction, reconfigurable systems
			 • System-specific functions
				• Function specific subjective rating scales
				   Often based on impairment/ disability concepts
				   Relative metrics
				 • Some instrumented performance capacity measures
				   Known also as "functional capacity" (misnomer)
					• Subjective and automated (objective) videotape evaluation
					 • Instrumented measures of physical quantities vs. time (e.g., forces, angles, motions)
					 • Electromyography (e.g., muscle timing patterns, coordination)

	Basic systems
	 • Visual information processors
	 • Flexors, extensors
	 • Visual sensors
	 • Auditory sensors
	 • Lungs
	 • Etc.
		• Dimensions
		 • Shape
		 • Masses
		 • Moments of inertia
		 • Instrumented methods
			• Single function
			 • System-specific functions
				• Subjective estimates by clinician for diagnostic and routine monitoring purposes
				 • Instrumented measures of performance capacities (e.g., strength, extremes/range of motion, speed, accuracy, endurance, etc.)
					• Instrumented systems
					   Measure and log electrophysiologic biomechanical, and other variables vs. time
					   Post-hoc parameterization

	Components of basic systems • Muscle • Tendon • Nerve • Etc.	• Mechanical properties • Instrumented methods/imaging	• Generally single-function • Component-specific functions	• Difficult to assess for individual subjects • Infer from measures at "basic system level" • Direct measurement methods with lab samples, research applications	• Difficult to assess for individual subject • Direct measurement methods with lab samples, research applications

Note: Structure, function, performance, and behavior are encompassed at multiple hierarchical levels. Both subjective and objective, instrumented methods of measurement are employed.

Aside from the benefit of placing all measurements on a common scale, a percent normal representation of a performance capacity score can be loosely interpreted as a probability. Consider grip strength as the performance resource. Assume that there is a uniform distribution of demands of demands placed on grip strength across a representative sample of tasks of daily living, with requirements ranging from zero to the value representing mean grip strength availability in the reference population. Further assuming that grip strength was the only performance resource that was in question for subject Y (i.e., all other were available in nonlimiting amounts), the percent normal score would represent the probability that a task involving grip strength, randomly selected from those which average individuals in the reference population could execute (i.e., those for which available grip strength would be adequate), could be successfully executed by subject Y. While the assumptions stated here are unlikely to be perfectly true, this type of interpretation helps place measurements that are most commonly made in the laboratory into daily-life contexts.

In contrast to percent normal metrics, *z-scores* take into account variability within the selected reference population. Subject Y's performance is expressed in terms of the difference between it and the reference population mean, normalized by a value corresponding to one standard deviation unit (σ) of the reference population distribution:

$$z = \frac{R_{A_k}(\text{Y}) - R_{A_k}(\text{pop})}{\sigma} \tag{73.2}$$

It is important to note that valid z-scores assume that the parameter in question exhibit a normal distribution in the reference population. Moreover, z-scores are useful in assessing measures of structure, performance, and behavior. With regard to performance (and assuming that measures are based on a resource construct, that is, a larger numeric value represents better performance), a z-score of zero is produced when the subject's performance equals that of the mean performance in the reference population. Positive z-scores reflect performance that is better than the population mean. In a normal distribution, 68.3% of the samples fall between z-scores of -1.0 and $+1.0$, while 95.4% of these samples fall between z-scores of -2.0 and $+2.0$. Due to variability of a given performance capacity within a healthy population (e.g., some individuals are stronger, faster, more mobile than others), a subject with a raw performance capacity score that produces a percent normal score of 70% could easily produce a z-score of -1.0. Whereas this percent normal score might raise concern regarding the variable of interest, the z-score of -1.0 indicates that a good fraction of healthy individuals exhibit lower level of performance capacity.

Both percent normal and z-scores require reference population data to compute. The best reference (i.e., most sensitive) is data for that specific individual (e.g., preinjury or predisease onset). In most cases, these data do not exist. However, practices such as preemployment screenings and regular checkups are beginning to provide individualized reference data in some rehabilitation contexts.

In yet another alternative, it is frequently desirable to use values representing demands imposed by tasks $[R_{D_k}(\text{task A})]$ as the reference for assessment of performance capacity measures. Demands on performance resources can be envisioned to vary over the time course of a task. In practice, an estimate of the worst-case value (i.e., highest demand) would be used in assessments that incorporate task demands as reference values. In one form, such assessments can produce binary results. For example, availability can be equal to or exceed demand (resource sufficiency), or it can be less than demand (resource insufficiency). These rule-based assessments are useful in identifying limiting factors, that is, those performance resources that inhibit a specified type of task from being performed successfully or that prevent achievement of a higher level of performance in a given type of task.

$$\text{If } R_{A_k} \text{ (subject Y)} \geq R_{D_k}\text{(task A)}, \quad \text{then } R_{A_k} \text{ (subject Y) is sufficient,}$$
$$\text{else } R_{A_k} \text{ (subject Y) is insufficient} \tag{73.3}$$

These rule-based assessments represent the basic process often applied (sometimes subliminally) by experienced clinicians in making routine decisions, as evidenced by statements such as "not enough strength,"

"not enough stability," etc. It is natural to extend and build on these strategies for use with objective measures. Extreme care must be employed. It is often possible, for example, for an individual to substitute another performance resource that is not insufficient for one that is. Clinicians take into account many such factors, and objective components should be combined with subjective assessments that provide the required breadth that enhances validity of objective components of a given assessment.

Using the same numeric values employed in rule-based binary assessments, a *preference capacity stress* metric can be computed:

$$\text{Performance capacity stress (\%)} = \frac{R_{D_k}(\text{task A})}{R_{A_k}(\text{subject Y})} \times 100 \tag{73.4}$$

Binary assessments also can be made using this metric and a threshold of 100%. However, the stress value provides additional information regarding how far (or close) a given performance capacity value is from the sufficiency threshold.

73.2 Measurement Objectives and Approaches

73.2.1 Characterizing the Human System and Its Subsystems

Figure 73.1 illustrates various points at which measurements are made over the course of a disease or injury, as well as some of the purposes for which they are made. The majority of measurements made in rehabilitation are aimed at characterizing the human system.

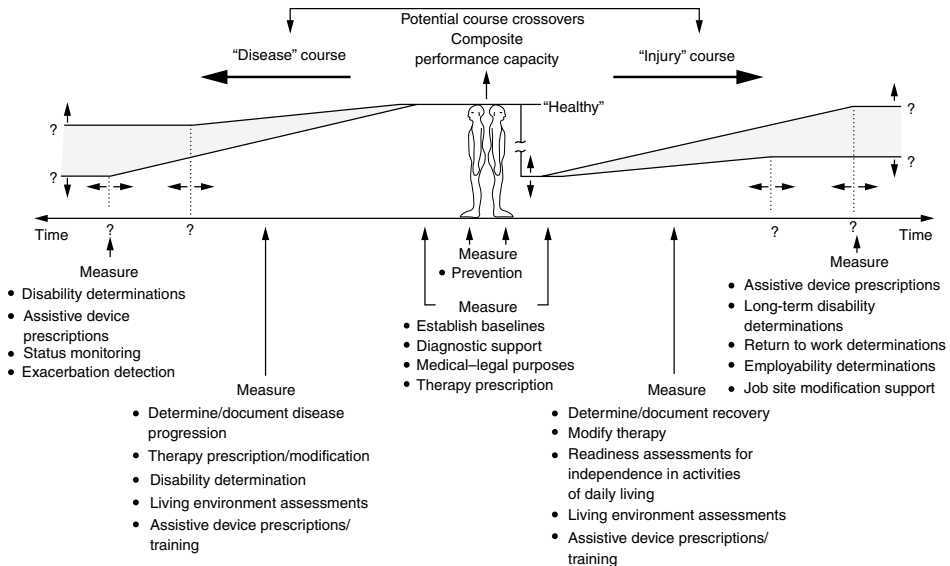
Measurements of human structure [Pheasant, 1986] play a critical role in the design and prescription of components such as seating, wheelchairs, workstations, artificial limbs, etc. Just like clothing, these items must "fit" the specific individual. Basic tools such as measuring tapes and rulers are becoming supplemented with three-dimensional digitizers and devices found in computer-aided manufacturing. Measurements of structure (e.g., limb segment lengths, moments of inertia, etc.) are also used with computer models [Vasta and Knodraske, 1995] in the process of analyzing tasks to determine demands in terms of performance capacity variables associated with basic systems such as flexors and extensors.


FIGURE 73.1 Measurements of structure, performance, and behavior serve many different purposes at different points over the course of a disease or injury that results in the need for rehabilitation services.

After nearly 50 years, during which a plethora of mostly disease- and injury-specific functional assessment scales were developed, the *functional independence measure* (FIM) [Hamilton et al., 1987; Keith et al., 1987] is of particular note. It is the partial result of a task-force effort to produce a systematic methodology (Uniform Data System for Medical Rehabilitation) with the specific intent of achieving standardization throughout the clinical service-delivery system. This broad methodology uses subjective judgements exclusively, based on rigorous written guidelines, to categorize demographic, diagnostic, functional, and cost information for patients within rehabilitation settings. Its simplicity to use once learned and its relatively low cost of implementation have helped in gaining a rather widespread utilization for tracking progress of individuals from admission to discharge in rehabilitation programs and evaluating effectiveness of specific therapies within and across institutions.

In contrast, many objective measurement tools of varying degrees of technological sophistication exist [Potvin et al., 1985; Smith and Leslie, 1990; Jones, 1995; Kondraske, 1995; Smith, 1995] (also see Further Information below). A good fraction of these have been designed to accomplish the same purposes as corresponding subjective methods, but with increased resolution, sensitivity, and repeatability. The intent is not always to replace subjective methods completely but to make available alternatives with the advantages noted for situations that demand superior performance in the aspects noted. There are certain measurement needs, however, that cannot be accomplished via subjective means (e.g., measurement of a human's visual information-processing speed, which involves the measurement of times of less than 1 sec with millisecond resolution). These needs draw on the latest technology in a wide variety of ways, as demonstrated in the cited material.

With regard to instrumented measurements that pertain to a specific individual, performance capacity measures at both complex body system and basic system levels (Figure 73.1) constitute a major area of activity. A prime example is methodology associated with the implementation of industrial lifting standards [NIOSH, 1981]. Performance-capacity measures reflect the limits of availability of one or more selected resources and require test strategies in which the subject is commanded to perform at or near a maximum level under controlled conditions. Performance tests typically last only a short time (seconds or minutes). To improve estimates of capacities, multiple trials are usually included in a given "test" from which a final measure is computed according to some established reduction criterion (e.g., average across five trials, best of three trials). This strategy also tends to improve test-retest repeatability. Performance capacities associated with basic and intermediate-level systems are important because they are "targets of therapy" [Tourtellotte, 1993], that is, the entities that patients and service providers want to increase to enhance the chance that enough will be available to accomplish the tasks of daily life. Thus measurements of baseline levels and changes during the course of a rehabilitation program provide important documentation (for medical, legal, insurance, and other purposes) as well as feedback to both the rehabilitation team and the patient.

Parameters of human behavior are also frequently acquired, often to help understand an individual's response to a therapy or new circumstance (e.g., obtaining a new wheelchair or prosthetic device). Behavioral parameters reflect what the subject does normally and are typically recorded over longer time periods (e.g., hours or days) compared with that required for a performance capacity measurement under conditions that are more representative of the subject's natural habitat (i.e., less laboratory-like). The general approach involves identifying the behavior (i.e., an event such as "head flexion," "keystrokes," "steps," "repositionings," etc.) and at least one parametric attribute of it. Frequency, with units of "events per unit time," and time spent in a given behavioral or activity state [Ganapathy and Kondraske, 1990] are the most commonly employed behavioral metrics. States may be detected with electromyographic means or electronic sensors that respond to force, motion, position, or orientation. Behavioral measures can be used as feedback to a subject as a means to encourage desired behaviors or discourage undesirable behaviors.

73.2.2 Characterizing Tasks

Task characterization or *task analysis*, like the organization of human system parameters, is facilitated with a hierarchical perspective. A highly objective, algorithmic approach could be delineated for task analysis

in any given situation [Imrhan, 1995; Maxwell, 1995]. The basic objective is to obtain both descriptive and quantitative information for making decisions about the interface of a system (typically a human) to a given task. Specifically, function, procedures, and goals are of special interest. *Function* represents the purpose of a task (e.g., to flex the elbow, to lift an object, to communicate). In contrast, task goals relate to performance, or how well the function is to be excuted, and are quantifiable (e.g., the mass of an object to be lifted, the distance over which the lift must occur, the speed at which the lift must be performed, etc.). In situations with human and artificial systems, the term **overall task goals** is used to distinguish between goals of the combined human-artificial system and goals associated with the task of operating the artificial system. Procedures represent the process by which goals are achieved. Characterization of procedures can include descriptive and quantitative components (e.g., location of a person's hands at beginning and end points of a task, path in three-dimensional space between beginning and end points). Partial or completely unspecified procedures allow for variations in **style**. *Goals* and *procedures* are used to obtain numeric estimates of task demands in terms of the performance resources associated with the systems anticipated to be used to execute the task. Task demands are time dependent. Worst-case demands, which may occur only at specific instants in time, are of primary interest in task analysis.

Estimates of task demand can be obtained (1) direct measurement (i.e., of goals and procedures), (2) the use of physics-based models to map direct measurements into parameters that relate more readily to measurable performance capacities of human subsystems, or (3) inference. Examples of direct measurement include key dimensions and mass of objects, three-dimensional spatial locations between "beginning" and "end points" of objects in tasks involving the movement of objects, etc. Instrumentation supporting task analysis is available (e.g., load cells, video and other systems for measuring human position and orientation in real-time during dynamic activities), but it is not often integrated into systems for task analysis per se. Direct measurements of forces based on masses of objects and gravity often must be translated (to torques about a given body joint): this requires the use of static and dynamic models and analysis [Winter, 1990; Vasta and Kondraske, 1995].

An example of an inferential task-analysis approach that is relatively new is nonlinear causal resource analysis (NCRA) [Kondraske, 1998, 1999; Kondraske et al., 1997]. This method was motivated by human performance analysis situations where direct analysis is not possible (e.g., determination of the amount of visual information-processing speed required to drive safely on a highway). Quantitative task demands, in terms of performance variables that characterize the involved subsystems, are inferred from a population data set that includes measures of subsystem performance, resource availabilities (e.g., speed, accuracy, etc.), and overall performance on the task in question. This method is based on the simple observation that the individual with the *least amount* of the given resource (i.e., the lowest performance capacity) who is still able to accomplish a given goal (i.e., achieve a given level of performance in the specified high-level task) provides the key clue. That amount of availability is used to infer the amount of demand imposed by the task.

The ultimate goal to which task characterization contributes is to identify limiting factors or unsafe conditions when a specific subject undertakes the task in question; this goal must not be lost while carrying out the basic objectives of task analysis. While rigorous algorithmic approaches are useful to make evident the true detail of the process, they are generally not performed in this manner in practice at present. Rather, the skill and experience of individuals performing the analysis are used to simplify the process, resulting in a judicious mixture of subjectives estimates and objective measurements. For example, some limiting factors (e.g., grip strength) may be immediately identified without measurement of the human or the task requirements because the margin between availability and demand is so great that quick subjective "measurements" followed by an equally quick "assessment" can be used to arrive at the proper conclusion (e.g., "grip strength is a limiting factor in this task").

73.2.3 Characterizing Assistive Devices

Assistive devices can be viewed as artificial systems that either completely or partially bridge a gap between a given human (with his or her unique profile of performance capacities, i.e., available performance

resources) and a particular task or class of tasks (e.g., communication, mobility, etc.). It is thus possible to consider the aspects of the device that constitute the user-device interface and those aspects which constitute, more generally, the device-task interface. In general, measurements supporting assessment of the user-device interface can be viewed to consist of (1) those which characterize the human and (2) those which characterize tasks (i.e., "operating" the assistive device). Each of these was described earlier. Measurements that characterize the device-task interface are often carried out in the context of the complete system, that is, the human-assistive device-task combination (see next subsection).

73.2.4 Characterizing Overall Systems in High-Level-Task Situations

This situation generally applies to a human-artificial system-task combination. Examples include an individual using a communication aid to communicate, an individual using a wheelchair to achieve mobility, etc. Here, concern is aimed at documenting how well the task (e.g., communication, mobility, etc.) is achieved by the composite or overall system. Specific aspects or *dimensions of performance* associated with the relevant function should first be identified. Examples include speech, accuracy, stability, efficiency, etc. The total system is then maximally challenged (tempered by safety considerations) to operate along one or more of these dimensions of performance (usually not more than two dimensions are maximally challenged at the same time). For example, a subject with a communication device may be challenged to generate a single selected symbol "as fast as possible" (stressing speed without concern for accuracy). Speed is measured (e.g., with units of symbols per second) over the course of short trial (so as not to be influenced by fatigue). Then the "total system" may be challenged to generate a subset of specific symbols (chosen at random from the set of those available with a given device) one at a time, "as accurately as possible" (stressing accuracy while minimizing stress on speed capacities). Accuracy is then measured after a representative number of such trials are administered (in terms of "percent correct," for example). To further delineate the speed-accuracy performance envelope, "the system" may be challenge to select symbols at a fixed rate while accuracy is measured. Additional dimensions can be evaluated similarly. For example, endurance (measure in units of time) can be determined by selecting an operating point (e.g., by reference to the speed-accuracy performance envelope) and challenging the total system "to communicate" for "as long as possible" under the selected speed-accuracy condition.

In general, it is more useful if these types of characterizations consider all relevant dimensions with some level of measurements (i.e., subjective or objective) than it would be to apply a high resolution, objective measurement in a process that considers only one aspect of performance.

73.3 Decision-Making Processes

Measurements that characterize the human, task, assistive device, or combination thereof are themselves only means to an end; the end is typically a decision. As noted previously, decisions are often the result of assessment processes involving one or more measurements. Although not exhaustive, many of the different types of assessments encountered are related to the following questions (1) Is a particular aspect of performance normal (or impaired)? (2) Is a particular aspect of performance improving, stable, or getting worse? How should therapy be modified? (3) Can a given subject utilize (and benefit from) a particular assistive device? (4) Does a subject possess the required capacity to accomplish a given higher level task (e.g., driving, a particular job after a work-related injury, etc.)?

In Figure 73.2, several of the basic concepts associated with measurement are used to illustrate how they enter into and facilitate systematic decision-making processes. The upper section shows raw score values as well as statistics for a healthy normal reference population in tabular form (left). It is difficult to reach any decision by simple inspection of just the raw performance capacity values. Tabular data are used to obtain percent normal (middle) and *z*-score (right) assessments. Both provide a more directly interpretable result regarding subject A's impairments. By examining the "right shoulder flexion extreme of motion" item in the figure, it can be seen that a raw score value corresponding to 51.2% normal yields a very

large-magnitude, negative z-score (-10.4). This z-score indicates that virtually no one in the reference population would have a score this low. In contrast, consider similar scores for the "grip strength" item (56.2% normal, z-score $= -1.99$). On the basis of percent normal scores, it would appear that both of these resources are similarly affected, whereas the z-score basis provides a considerably different perspective due to the fact that grip strength is *much more variable* in healthy populations than the extreme angle obtained by a given limb segment about a joint, relatively speaking. As noted, z-scores account for this variability.

The lower section of Figure 73.2 considers a situation in which the issue is a specific individual (subject A) considered in a specific task. Tabular data now include raw score values (which are the same as in upper section of the figure) and quantitative demands (typically worst case) imposed on the respective performance resources by task X. The lower-middle plot illustrates the process of individually assessing sufficiency of each performance resource in this task context using a rule-based assessment that incorporates the idea of a threshold (i.e., availability must exceed demand for sufficiency). The lower-right plot illustrates an analogous assessment process that is executed after computation of a stress metric for each of the performance capacities. Here, any demand that corresponds to more than a 100% stress level is obviously problematic. In addition to binary conclusions regarding whether a given capacity is or is not a limiting factor, it is possible to observe that of the two **limiting resources** (e.g., grip strength and right shoulder flexion extreme of motion), the former is more substantial. This might suggest, for example, that the task be modified so as to decrease the grip-strength demand (i.e., gains in performance capacity required would be substantial to achieve sufficiency) and the use of focused exercise therapy to increase shoulder flexion mobility (i.e., gains in mobility required are relatively small).

73.4 Current Limitations

73.4.1 Quality of Measurements

Key issues are measurement validity, reliability (or repeatability), accuracy, and discriminating power. At issue in terms of current limitations is not necessarily the quality of measurements but limitations with regard to methods employed to determine the quality of measurements and their interpretability.

A complete treatment of these complex topics is beyond the present scope. However, it can be said that standards are such [Potvin et al., 1985] that most published works regarding measurement instruments do address quality of measurements to some extent. Validity (i.e., how well does the measurement reflect the intended quantity) and reliability are most often addressed. However, one could easily be left with the impression that these are binary conditions (i.e., measurement is or is not reliable or valid), when in fact a continuum is required to represent these constructs. Of all attributes that relate to measurement quality, reliability is most commonly expressed in quantitative terms. This is perhaps because statistical methods have been defined and promulgated for the computation of so-called reliability coefficients [Winer, 1971]. Reliability coefficients range from 0.0 to 1.0, and the implication is that 1.0 indicates a perfectly reliable or repeatable measurement process. Current methods are adequate, at best, for making inferences regarding the relative quality of two or more methods of quantifying "the same thing." Even these comparisons require great care. For example, measurement instruments that have greater intrinsic resolving power have a great opportunity to yield smaller-reliability coefficients simply because they are capable of measuring the true variability (on repeated measurement) of the parameter in question within the system under test. While there has been widespread determination or reliability coefficients, there has been little or no effort directed toward determination of what value of a reliability coefficient is "good enough" for a particular application. In fact, reliability coefficients are relatively abstract to most practitioners.

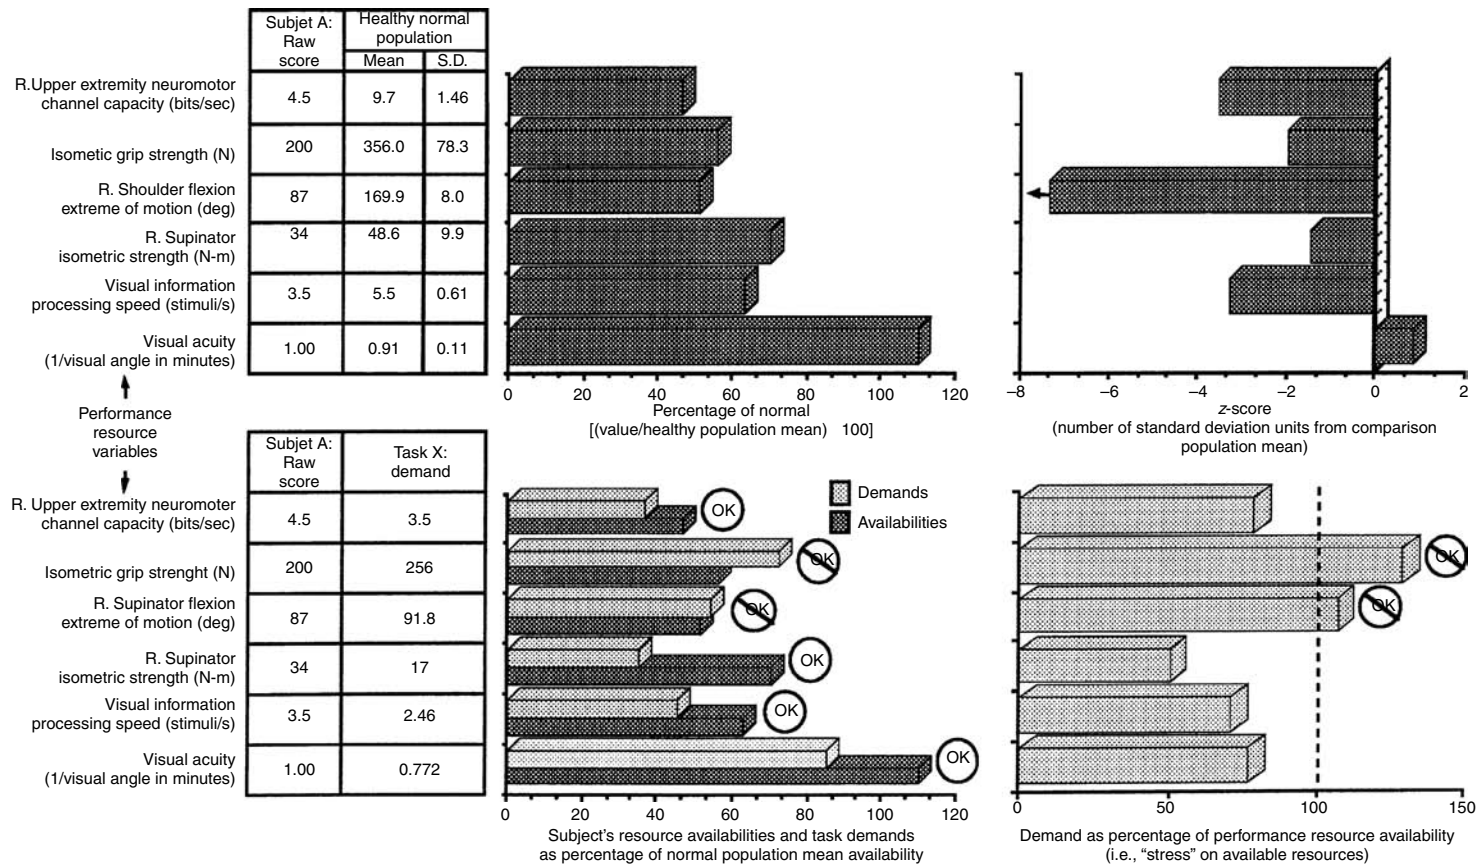
Methods for determining the quality of a measurement process (including the instrument, procedures, examiner, and actual noise present in the variable of interest) that allow a practitioner to easily reach decisions regarding the use of a particular measurement instrument in a specific application and limitations thereof are currently lacking. At the use of different measurements increases and the number of options available for obtaining a given measurement grows, this topic will undoubtedly receive additional


FIGURE 73.2 Examples of different types of assessments that can be performed by combining performance capacity measures and reference values of different types. The upper section shows raw score values as well as statistics for a healthy normal reference population in tabular form (*left*). It is difficult to reach any decision by simple inspection of just the raw performance capacity values. Tabular data are used to obtain a percent normal assessment (*middle*) and a *z*-score assessment (*right*). Both of these provide a more directly interpretable result regarding subject A's impairments. The lower section shows raw score values (same as in upper section) and quantitative demands (typically worst case) imposed on the respective performance resources by task X. The lower-middle plot illustrates the process of individually assessing sufficiency of each performance resource in this task context using a threshold rule (i.e., availability must exceed demand for sufficiency). The lower-right plot illustrates a similar assessment process after computation of a stress metric for each of the performance capacities. Here, any demand that corresponds to more than a 100% stress level is obviously problematic.

attention. Caution in interpreting literature, common sense, and the use of simple concepts such as "I need to measure range of motion to within 2 degrees in my application" are recommended in the meantime [Mayer et al., 1997].

73.4.1.1 Standards

Measurements, and concepts with which they are associated, can contribute to a shift from experience-based knowledge acquisition to rule-based, engineering-like methods. This requires (1) a widely accepted conceptual framework (i.e., known to assistive device manufacturers, rehabilitation engineers, and other professionals within the rehabilitation community), (2) a more complete set of measurement tools that are at least standardized with regard to the definition of the quantity measured, (3) special analysis and assessment software (that removes the resistance to the application of more rigorous methods by enhancing the quality of decisions as well as the speed with which they can be reached), and (4) properly trained practitioners. Each is a necessary *but not sufficient* component. Thus balanced progress is required in each of these areas.

73.4.2 Rehabilitation Service Delivery and Rehabilitation Engineering

In a broad sense, it has been argued that all engineers can be considered rehabilitation engineers who merely work at different levels along a comprehensive spectrum of human performance, which itself can represent a common denominator among all humans. Thus an automobile is a mobility aid, a telephone is a communication aid, and so on. Just as in other engineering disciplines, measurement must be recognized not only as an important end in itself (in appropriate instances) but also as an integral component or means within the overall scope of rehabilitation and rehabilitation engineering processes. The service-delivery infrastructure must provide for such means. At present, one should anticipate and be prepared to overcome potential limitations associated with factors such as third-party reimbursement for measurement procedures, recognition of equipment and maintenance costs associated with obtaining engineering-quality measurements, and education of administrative staff and practitioners with regard to the value and proper use of measurements.

Defining Terms

Behavior: A general term that relates to what a human or artificial system does while carrying out its function(s) under given conditions. Often, behavior is characterized by measurement of selected parameters or identification of unique system states over time.

Function: The purpose of a system. Some systems map to a single primary function (e.g., process visual information). Others (e.g., the human arm) map to multiple functions, although at any given time multifunction systems are likely to be executing a single function (e.g., polishing a car). Functions can be described and inventoried, whereas level of performance of a given function can be measured.

Functional assessment: The process of determining, from a relatively global perspective, an individual's ability to carry out tasks in daily life. Also, the result of such a process. Functional assessments typically cover a range of selected activity areas and include (at a minimum) a relatively gross indication (e.g., can or cannot do; with or without assistance) of status in each area.

Goal: A desired endpoint (i.e., result) typically characterized by multiple parameters, at least one of which is specified. Examples include specified task goals (e.g., move an object of specified mass from point A to point B in 3 sec) or estimated task performance (maximum mass, range, speed of movement obtainable given a specified elemental performance resource availability profile), depending on whether a reverse or forward analysis problem is undertaken. Whereas function describes the general process of task, the goal directly relates to performance and is quantitative.

Limiting resource: A performance resource at any hierarchical level (e.g., vertical lift strength, knee flexor speed) that is available in an amount that is less than the worst-case demand imposed by a task. Thus a given resource can be "limiting" only when considered in the context of a specific task.

Overall task goals: Goals associated with a task to be executed by a human-artificial system combination (to be distinguished from goals associated with the task of operating the artificial system).

Performance: Unique qualities of a human or artificial system (e.g., strength, speed, accuracy, endurance) that pertain to how well that system executes its function.

Performance capacity: A quantity in finite availability that is possessed by a system or subsystem, drawn on during tasks, and limits some aspect (e.g., speed, force, production, etc.) of a system's ability to execute tasks, or, the limit of that aspect itself.

Performance capacity measurement: A general class of measurements, performed at different hierarchical levels, intended to quantify one or more performance capacities.

Procedure: A set of constraints placed on a system in which flexibility exists regarding how a goal (or set of goals) associated with a given function can be achieved. Procedure specification requires specification of initial intermediate, and/or final states or conditions dictating how the goal is to be accomplished. Such specification can be thought of in terms of removing some degrees of freedom.

Structure: Physical manifestation and attributes of a human or artificial system and the object of one type of measurements at multiple hierarchical levels.

Style: Allowance for variation within a procedure, resulting in the intentional incomplete specification of a procedure or resulting from either international or unintentional incomplete specification of procedure.

Task: That which results from (1) the combination of specified functions, goals, and procedures or (2) the specification of function and goals and the observation of procedures utilized to achieve the goals.

Rehabilitation Engineering Technologies: Principles of Application

Douglas Hobson
Elaine Trefler
University of Pittsburgh

Rehabilitation engineering is the branch of *biomedical engineering* that is concerned with the application of science and technology to improve the quality of life of individuals with disabilities. Areas addressed within rehabilitation engineering include wheelchairs and seating systems, access to computers, sensory aids, prosthetics and orthotics, alternative and augmentative communication, home and work-site modifications, and universal design. Because many products of rehabilitation engineering require careful selection to match individual needs and often require custom fitting, rehabilitation engineers have necessarily become involved in service delivery and application as well as research, design, and development. Therefore, as we expand on later, it is not only engineers that practice within the field of rehabilitation engineering.

As suggested above, and as in many other disciplines, there are really two career tracks in the field of rehabilitation engineering. There are those who acquire qualifications and experience to advance the state

74-1

of knowledge through conducting research, education, and product development, and there are others who are engaged in the application of technology as members of service delivery teams. At one time it was possible for a person to work in both arenas. However, with the explosion of technology and the growth of the field over the past decade, one must now specialize not only within research or service delivery but often within a specific area of technology.

One can further differentiate between rehabilitation and assistive technology. *Rehabilitation technology* is a term most often used to refer to technologies associated with the acute-care rehabilitation process. Therapy evaluation and treatment tools, clinical dysfunction measurement and recording instrumentation, and prosthetic and orthotic appliances are such examples. *Assistive technologies* are those devices and services that are used in the daily lives of people in the community to enhance their ability to function independently, examples being specialized seating, wheelchairs, environmental control devices, workstation access technologies and services are now communication aids. Recognition and support of assistive technology devices and services are now embedded in all the major disability legislation that has been enacted over the last decade.

The primary focus of this chapter is on the role of the rehabilitation engineering practitioner as he or she carries out the responsibilities demanded by the application of assistive technology.

Before launching into the primary focus of this chapter, let us first set a conceptual framework for the *raison d'etre* for assistive technology and the role of the assistive technology professional.

74.1   The Conceptual Frameworks

The application of assistive technology can be conceptualized as minimizing the functional gap between the person and his or her environment. This reality is what technology does for all of us to varying degrees. For example, if you live in a suburban area that has been designed for access only by car and your car breaks down, you are handicapped. If your house has been designed to be cooled by air conditioning in the "dog days" of summer and you lose a compressor, your comfort is immediately compromised by your incompatibility with your environment. Similarly, if you live in a home that has only access by steps and you have an impairment requiring the use of a wheelchair, you are handicapped because you no longer have abilities that are compatible with your built environment. Because our environments, homes, workplaces, schools, and communities have been designed to be compatible with the abilities of the norm, young children, persons with disabilities, and many elderly people experience the consequences of their mismatch as a matter of course. The long-term utopian solution would be to design environments and their contents so that they can be used by all people of all ages, which is the essence of the universal design concept. However, given that today we do not have very many products and environments that have been universally designed, rehabilitation engineers attempt to minimize the effects of the mismatch by designing, developing, and providing technologies that will allow persons with disabilities to pursue their life goals in a manner similar to any other person. Of course, the rehabilitation engineer cannot accomplish this working in isolation but rather must function as a part of a consumer-responsive team that can best deal with the multiplicity of factors that usually impact on the successful application of assistive technology.

Let us now move to another conceptual framework, one that conceptualizes how people actually interact with technology.

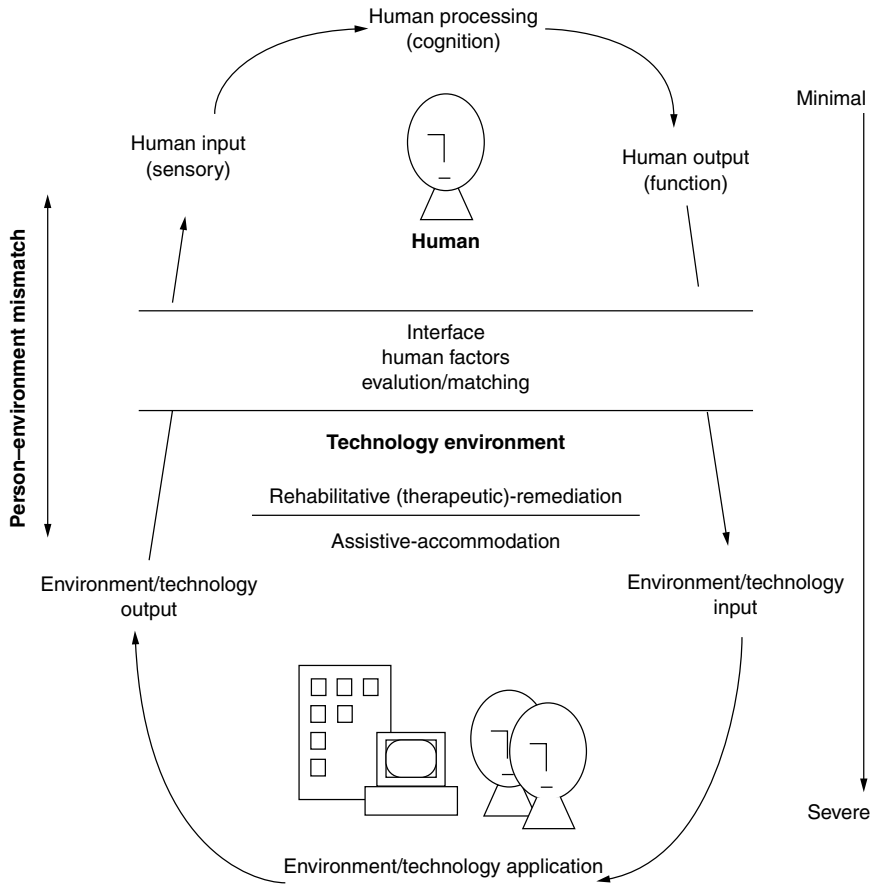
The following conceptualization has been adapted from the model proposed by Roger Smith [1992]. In Figure 74.1, Smith suggests that there are three cyclic elements that come into play when humans interact with technology: the human and his or her innate sensory, cognitive, and functional abilities; the human factor's characteristics of the interface between the human and the technology; and the technical characteristics of the technology itself in terms of its output as a result of a specific input by the user. People with disabilities may have varying degrees of dysfunction in their sensory, cognitive, and functional abilities. The interface will have to be selected or adapted to these varying abilities in order to allow the person to effectively interact with the technology. The technology itself will need to possess


FIGURE 74.1   Conceptual framework of technology and disability. (Modified from Smith, R.O. 1992. *AJOT* 1:22.)

specific electronic or mechanical capabilities in order to yield the desired outcome. The essence of assistive technology applications is to integrate all three of these element into a functional outcome that meets the specific needs of a user. This is usually done by selecting commercially available devices and technologies at a cost that can be met by either the individual or his or her third-party payment source. When technologies are not available, then they must be modified from existing devices or designed and fabricated as unique custom solutions. It is particularly in these latter activities that a rehabilitation engineer can make his or her unique contribution to team process.

Cook and Hussey [1995], published an excellent text, *Assistive Technologies — Principles and Practice.* As well as comprehensively addressing many of the assistive technologies briefly covered in this chapter, they also present a conceptual framework which builds on the one developed by Smith above. They introduce the additional concepts of activity and context. That is, understanding of a person's activity desires and the context (social, setting, physical) in which they are to be carried out are essential components to successful assistive technology intervention.

It should be realized that there are several levels of assistive technology. The first level might be termed *fundamental technology* in contrast to advanced technology. Fundamental technologies, such as walkers, crutches, many wheelchairs, activities of daily living (ADL) equipment, etc., usually do not require the involvement of the rehabilitation engineer in their application. Others on the team can better assess the need, confirm the interface compatibility, and verify that the outcome is appropriate. The rehabilitation engineer is most often involved in the application of advanced technologies, such as powered wheelchairs, computerized workstation designs, etc., that require an understanding of the underlying technological

principles in order to achieve the best match with the abilities and needs of the user, especially if custom modifications or integration of devices are required to the original equipment. The rehabilitation engineer is usually the key person if a unique solution is necessary.

Let's now discuss a few fundamental concepts related to the process by which assistive technology is typically provided in various service delivery programs.

74.2 The Provision Process

74.2.1 The Shifting Paradigm

In the traditional rehabilitation model of service delivery, a multidisciplinary team of professionals is already in place. Physicians, therapists, counselors, and social worker meet with the client and, based on the findings of a comprehensive evaluation, plan a course of action. In the field of assistive technology, the rules of the team are being charted anew. First, the decision making often takes place in a nonmedical environment and often without a physician as part of the team. Second, the final decision is rapidly moving into the hands of the consumer, not the professionals. The third major change is the addition of a rehabilitation engineer to the team. Traditional team members have experience working in groups and delegating coordination and decision making to colleagues depending on the particular situation. They are trained to be team players and are comfortable working in groups. Most engineers who enter the field of rehabilitation engineering come with a traditional engineering background. Although well versed in design and engineering principles, they often do not receive formal training in group dynamics and need to learn these skills if they are to function effectively. As well, engineers are trained to solve problems with technical solutions. The psychosocial aspects of assisting people with disabilities to make informed choices must be learned most often outside the traditional education stream. Therefore, for the engineer to be a contributing member of the team, not only must he or she bring engineering expertise, but it must be integrated in such a manner that it supports the overall objectives of the technology delivery process, which is to respond to the needs and desires of the consumer.

People with disabilities want to have control over the process and be informed enough to make good decisions. This is quite different from the traditional medical or rehabilitation model, in which well-meaning professionals often tell the individual what is best for him or her. Within this new paradigm, the role is to inform, advise, and educate, not to decide. The professional provides information as to the technical options, prices, etc. and then assists the person who will use the technology to acquire it and learn how to use it.

74.2.2 The Evaluation

An evaluation is meant to guide decision-making for the person with a disability toward appropriate and cost-effective technology. Often, more than one functional need exists for which assistive technology could be prescribed. Costly, frustrating, and time-consuming mistakes often can be avoided if a thorough evaluation based on a person's total functional needs is performed before any technology is recommended. Following the evaluation, a long-range plan for acquisition and training in the chosen technology can be started.

For example, suppose a person needs a seating system, both a powered and manual wheelchair, an augmentative communication device, a computer workstation, and an environmental control unit (ECU). Where does one begin? Once a person's goals and priorities have been established, the process can begin. First, a decision would likely be made about the seating system that will provide appropriate support in the selected manual chair. However, the specifications of seating system should be such that the components also can be interfaced into the powered chair. The controls for the computer and augmentative communication device must be located so that they do not interfere with the display of the communication device and must in some way be compatible wit the controls for the ECU. Only if all functional needs are addressed can the technology be acquired in a logical sequence and in such a manner that all components

will be compatible. The more severely disabled the individual, the more technology he or she will need, and the more essential is the process of setting priorities and ensuring compatibility of technical components.

In summary, as suggested by the conceptual model, the process begins by gaining an understanding of the person's sensory, cognitive, and functional abilities, combined with clarification of his or her desires and needs. These are then filtered through the technology options, both in terms of how the interface will integrate with the abilities of the user and how the technology itself will be integrated to meet the defined needs. This information and the associated pros and cons are conveyed to the user, or in some cases their caregiver, who then has the means to participate in the ultimate selection decisions.

74.2.3 Service Delivery Models

People with disabilities can access technology through a variety of different service delivery models. A team of professionals might be available in a university setting where faculty not only teach but also deliver technical services to the community. More traditionally, the team of rehabilitation professionals, including a rehabilitation engineer, might be available at a hospital or rehabilitation facility. More recently, technology professionals might be in private practice either individually, as a team, or part of the university, hospital, or rehabilitation facility structure. Another option is the growing number of rehabilitation technology suppliers (RTSs) who offer commercial technology services within the community. They work in conjunction with an evaluation specialist and advise consumers as to the technical options available to meet their needs. They then sell and service the technology and train the consumer in its use. Local chapters of national disability organizations such as United Cerebral Palsy and Easter Seals also may have assistive technology services. In recent years, a growing number of centers for independent living (CILs) have been developed in each state with federal support. Some of these centers have opted to provide assistive technology services, in addition to their information and referral services, which are common to all CILs. And finally, there are volunteers, either in engineering schools or community colleges (student supervised projects) or in industry (high-technology industries often have staff interested in doing community service), such as the Telephone Pioneers. Each model has its pros and cons for the consumer, and only after thoroughly researching the options will the person needing the service make the best choice as to where to go with his or her need in the community. A word of caution. Only if there is timely provision and follow-up available is a service delivery system considered appropriate, even if the cost of the service is less.

A more extensive description of service delivery options may be reviewed in a report that resulted from a RESNA-organized conference on service delivery [ANSI/RESNA, 1987].

74.3 Education and Quality Assurance

Professionals on the assistive technology team have a primary degree and credential in their individual professions. For example, the occupational or physical therapist will have a degree and most often state licensure in occupational or physical therapy. The engineer will have recognized degrees in mechanical, electrical, biomedical, or some other school of engineering. However, in order to practice effectively in the field of assistive technology, almost all will need advanced training. A number of occupational therapy curriculums provide training in assistive technology, but not all. The same is true of several of the others. Consumers and payers of assistive technology need to know that professionals practicing in the field of assistive technology have a certain level of competency. For this reason, all professionals, including rehabilitation engineers, are pursuing the ATP (assistive technology practitioner) credential through RESNA.

74.3.1 RESNA

RESNA, an interdisciplinary association of persons dedicated to the advancement of assistive technology for people with disabilities, has a credentialing program that credentials individuals on the assistive

technology team. As part of the process, the minimum skills and knowledge base for practitioners is tested. Ties with professional organizations are being sought so that preservice programs will include at least some of the knowledge and skills base necessary. Continuing education efforts by RESNA and others also will assist in building the level of expertise of practitioners and consumers. At this time RESNA has a voluntary credentialling process to determine if a person meets a predetermined minimal standard of practice in the field of Assistive Technology. Persons who meet the prerequisite requirements, pass a written exam, and agree to abide by the RESNA Standards of Practice can declare themselves as RESNA certified. They can add the ATP if they are practitioners or ATS if they are suppliers of assistive technology.

Payment for technology and the services required for its application is complex and changing rapidly as health care reform evolves. It is beyond the scope of this discussion to detail the very convoluted and individual process required to ensure that people with disabilities receive what they need. However, there are some basic concepts to be kept in mind. Professionals need to be competent. The documentation of need and the justification of selection must be comprehensive. Time for a person to do this must be allocated if there is to be success. Persistence, creativity, education of the payers, and documentation of need and outcomes are the key issues.

74.4 Specific Impairments and Related Technologies

Current information related to specific technologies is best found in brochures, trade magazines (*Report Rehab*), exhibit halls of technology-related conferences, and databases such as ABLEDATA. Many suppliers and manufacturers are now maintaining Websites, which provides a quick means to locate information on current products. What follows is only a brief introduction to specific disabilities areas to which assistive technology applications are commonly used.

74.4.1 Mobility

Mobility technologies include wheelchairs, walkers, canes, orthotic devices, FES (functional electrical stimulation), laser canes, and any other assistive device that would assist a person with a mobility impairment, be it motor or sensory, to move about in his or her environment. There are very few people who have a working knowledge of all the possible commercial options. Therefore, people usually acquire expertise in certain areas, such as wheelchairs. There are hundreds of varieties of wheelchairs, each offering a different array of characteristics that need to be understood as part of the selection process. Fortunately, there are now several published ways that the practitioner and the consumer can obtain useful information. A classification system has been developed that sets a conceptual framework for understanding the different types of wheelchairs that are produced commercially [Hobson, 1990]. *Paraplegic News and Sports and Spokes* annually publish the specifications on most of the manual and powered wheelchairs commonly found in the North American marketplace. These reviews are based on standardized testing that is carried out by manufacturers following the ANSI/RESNA wheelchair standards [ANSI/RESNA, 1990]. Since the testing and measurements of wheelchairs are now done and reported in a standard way, it is possible to make accurate comparisons between products, a tremendous recent advancement for the wheelchair specialist and the users they serve [Axelson et al., 1994].

Possibly the most significant advancement in wheelchairs is the development and application of industry, on an international scale, for testing the safety and durability of their products. These standards also mandate what and how the test information should be made available in the manufacturer's presale literature. The Rehabilitation Engineering Research Center and University of Pittsburgh [RERC, 1999] maintains a large Website, where among its many resources is a listing of wheelchair research publications and a general reference site, termed Wheelchairnet [Wheelchairnet, 1999]. The RERC site also tracks the current activities occurring in many of the wheelchair standards working groups. Finally, Cooper [1995, 1998] has published two excellent reference texts on rehabilitation engineering with emphasis on wheeled mobility.

74.4.2 Sitting

Many people cannot use the wheelchairs as they come from the manufacturer. Specialized seating is required to help persons to remain in a comfortable and functional seated posture for activities that enable them to access work and attend educational and recreational activities. Orthotic supports, seating systems in wheelchairs, chairs that promote dynamic posture in the workplace, and chairs for the elderly that fit properly, are safe, and encourage movement all fit into the broad category of sitting technology.

74.4.3 Sensation

People with no sensation are prone to skin injury. Special seating technology can assist in the preventions of tissue breakdown. Specially designed cushions and backs for wheelchairs and mattresses that have pressure-distributing characteristics fall into this category. Technology also has been developed to measure the interface pressure. These tools are now used routinely to measure and record an individual's pressure profile, making cushion selection and problem solving more of a science than an art.

Again, a classification system of specialized seating has been developed that provides a conceptual framework for understanding the features of the various technologies and their potential applications. The same reference also discusses the selection process, evaluation tools, biomechanics of supported sitting, and materials properties of weight-relieving materials [Hobson, 1990].

74.4.4 Access (Person–Machine Interface)

In order to use assistive technology, people with disabilities need to be able to operate the technology. With limitations in motor and/or sensory systems, often a specially designed or configured interface system must be assembled. It could be as simple as several switches or a miniaturized keyboard or as complex as an integrated control system that allows a person to drive a wheelchair and operate a computer and a communication device using only one switch.

74.4.5 Communication

Because of motor or sensory limitations, some individuals cannot communicate with spoken or written word. There are communication systems that enable people to communicate using synthesized voice or printed output. Systems for people who are deaf allow them to communicate over the phone or through computer interfaces. Laptop computers with appropriate software can enable persons to communicate faster and with less effort than previously possible. Some basic guidelines for selecting an augmentative communication system, including strategies for securing funding, have been proposed in an overview chapter by James Jones and Winifred Jones [Jones and Jones, 1990].

74.4.6 Transportation

Modified vans and cars enable persons with disabilities to independently drive a vehicle. Wheelchair tie-downs and occupant restraints in personal vehicles and in public transportation vehicles are allowing people to be safely transported to their chosen destination. Fortunately, voluntary performance standards for restraint and tie-down technologies have been developed by a task group within the Society for Automotive Engineers (SAE). Standards for car hand controls, van body modifications, and wheelchair lifts are also available from SAE. These standards provide the rehabilitation engineer with a set of tools that can be used to confirm safety compliance of modified transportation equipment. Currently in process and still requiring several more years of work are transport wheelchair and vehicle power control standards.

74.4.7 Activities of Daily Living (ADL)

ADL technology enables a person to live independently as much as possible. Such devices as environmental control units, bathroom aids, dressing assists, automatic door openers, and alarms are all considered aids

to daily living. Many are inexpensive and can be purchased through careful selection in stores or through catalogues. Others are quite expensive and must be ordered through vendors who specialize in technology for independent living.

Ron Mace, now deceased and creator of the Center for Universal Design at the North Carolina State University, is widely acknowledged as the father of the Universal Design concept. The concept of universal design simply means that if our everyday built environments and their contained products could be designed to meet the needs of a wider range of people, both young and old, then the needs of more persons with disabilities would be met without the need for special adaptions [Center for Universal Design, 1999]. Others like Paul Grayson have also published extensively regarding the need to re-think how we design our living environments [Grayson, 1991]. Vanderheiden and Denno have prepared human factors guidelines that provide design information to allow improved access by the elderly and persons with disabilities [Vanderheiden and Vanderheiden, 1991; Denno et al., 1992; Trace Center, 1999].

74.4.8 School and Work

Technology that supports people in the workplace or in an educational environment can include such applications as computer workstations, modified restrooms, and transportation to and from work or school. Students need the ability to take notes and do assignments, and people working have a myriad of special tasks that may need to be analyzed and modified to enable the employee with the disability to be independent and productive. Weisman has presented an extensive overview of rehabilitation engineering in the workplace, which includes a review of different types of workplaces, the process of accommodation, and many case examples [Weisman, 1990].

74.4.9 Recreation

A component of living that is often overlooked by the professional community is the desire and, in fact, need of people with disabilities to participate in recreational activities. Many of the adaptive recreational technologies have been developed by persons with disabilities themselves in their effort to participate and be competitive in sports. Competitive wheelchair racing, archery, skiing, bicycles, and technology that enables people to bowl, play pool, and fly their own airplanes are just a few areas in which equipment has been adapted for specific recreational purposes.

74.4.10 Community and Workplace Access

There is probably no other single legislation that is having a more profound impact on the lives of people with disabilities then the Americans with Disabilities Act (ADA), signed into law by President Bush in August of 1990. This civil rights legislation mandates that all people with disabilities have access to public facilities and that reasonable accommodations must be made by employers to allow persons with disabilities to access employment opportunities. The impact of this legislation is now sweeping America and leading to monumental changes in the way people view the rights of persons with disabilities.

74.5   Future Developments

The field of rehabilitation engineering, both in research and in service delivery, is at an important crossroad in its young history. Shifting paradigms of services, reduction in research funding, consumerism, credentialing, health care reform and limited formal educational options all make speculating on what the future may bring rather hazy. Given all this, it is reasonable to say that one group of rehabilitation engineers will continue to advance the state of the art through research and development, while another group will be on the front lines as members of clinical teams working to ensure that

individuals with disabilities receive devices and services that are most appropriate for their particular needs.

The demarcation between researchers and service providers will become clearer, since the latter will become credentialed. RESNA and its professional specialty group (PSG) on rehabilitation engineering are working out the final credentialing steps for the Rehabilitation Engineer RE and the Rehabilitation Engineering Technologist RET. Both must also be an ATP. They will be recognized as valued members of the clinical team by all members of the rehabilitation community, including third-party payers, who will reimburse them for the rehabilitation engineering services that they provide. They will spend as much or more time working in the community as they will in clinical settings. They will work closely with consumer-managed organizations who will be the gatekeepers of increasing amounts of government-mandated service dollars.

If these predictions come to pass, the need for rehabilitation engineering will continue to grow. As medicine and medical technology continue to improve, more people will survive traumatic injury, disease, and premature birth, and many will acquire functional impairments that impede their involvement in personal, community, educational, vocational, and recreational activities. People continue to live longer lives, thereby increasing the likelihood of acquiring one or more disabling conditions during their lifetime. This presents an immense challenge for the field of rehabilitation engineering. As opportunities grow, more engineers will be attracted to the field. More and more rehabilitation engineering education programs will develop that will support the training of qualified engineers, engineers who are looking for exciting challenges and opportunities to help people live more satisfying and productive lives.

Human Performance Engineering

George V. Kondraske
University of Texas-Arlington

THE ULTIMATE GOAL OF HUMAN PERFORMANCE engineering is the enhancement of performance and safety of humans in the execution of tasks. The more formalized conception of this field was fueled initially by military needs. It has steadily evolved to become an important component in industrial and other settings as well. In a biomedical engineering context, the scope of definition applied to the term "human" not only encompasses individuals with capabilities that differ from those of a typical healthy individual in many possible different ways (e.g., individuals who are disabled, injured, unusually endowed, etc.), but also includes those who are simply "healthy" (e.g., healthcare professionals). Consequently, one finds a wide range of problems in which human performance engineering and associated methods are employed. Just a few examples include:

- Evaluation of an individual's performance capacities to determine the efficacy of new therapeutic interventions, or so-called "level of disability" for worker's compensation and other medical–legal purposes.
- Design of assistive devices and work sites in such a way that a person with some deficiency in their performance resource profile will be able to accomplish a given task to a specified level of performance.
- Design of operator interfaces for medical instruments that promote efficient, safe, and error-free use.

But human performance engineering is not only concerned with situations that are directly linked to a medical context or motivated by a medical problem. Evaluation and optimization of performance in specific sport tasks, work tasks, playing musical instruments, and even education represent relevant application targets. Human performance engineering encompasses the exciting prospect of helping individuals achieve their personal best in selected endeavors. In general, the field encompasses applications in medical and nonmedical contexts.

In basic and most general terms, each of the representative application situations noted involves one or more of the following: (1) a human, (2) a task(s), and (3) the interface of a human to a task(s). Human performance engineering emphasizes concepts, methods, and tools that strive toward treatment of each of these areas with the same engineering rigor that is routinely applied to artificial systems (e.g., mechanical, electronic, etc.). Importance is thus placed on models (a combination of cause-and-effect and statistical), measurements (of varying degrees of sophistication that are selected to fit needs of a particular circumstance), and diverse types of analyses. Many specialty areas within biomedical engineering begin with an emphasis on a specific subsystem and then proceed to deal with it at *lower* levels of detail (sometimes even at the molecular level) to determine how it functions and often why it malfunctions. One way of characterizing human performance engineering is to note that it emphasizes subsystems and their performance capacities (i.e., *how well* a system functions), the integration of these into a whole and their interactions, and their operation in the execution of tasks that are of ultimate concern to humans. These include tasks of daily living, work, and recreation. In recent years, there has been an increased concern within medical communities on issues such as quality of life, treatment outcome measures, and treatment cost-effectiveness. By linking human subsystems into the "whole" and discovering objective

quantitative relationships between the human and tasks, human performance engineering can play the lead role in addressing these and other related concerns.

Human performance engineering combines knowledge, expertize, concepts, and methods from across many disciplines (e.g., biomechanics, neuroscience, psychology, physiology — and many others), which, in their overlapping aspect, essentially deal with similar types of problems. To capture the essence of the problems addressed by human performance engineering and the knowledge base that is unique to it, a conceptual framework is necessary. Few candidate frameworks exist even within the relevant disciplines. The Elemental Resource Model is presented in Chapter 75, including concepts of General Systems Performance Theory, to serve this role. Introduced initially almost two decades ago, its utility and appropriateness have been demonstrated in a variety of situations and has garnered wider acceptance than any other such framework known. In a further attempt to enhance continuity across this section, authors of other chapters have been requested to consider the Elemental Resource Model and to incorporate basic concepts and terms where applicable.

Chapter 76 through Chapter 78 look "toward the human" and focus on measurement of performance capacities of specific groups of human subsystem and related issues. Due to a combination of the complexity of the human system (even when viewed as a collection of rather high-level subsystems) and limited space available, treatment is not comprehensive. For example, measurement of sensory performance capacities (e.g., tactile, visual, auditory) is not included. Both systems and tasks can be viewed at various hierarchical levels. Chapter 76 and Chapter 77 focus on a rather "low" systems level and discuss basic functional units such as actuator, processor, and memory systems. Chapter 78 moves to a more intermediate level where speech, postural control, gait, and hand-eye coordination systems could be considered. Measurement of structural parameters, which play important roles in both performance measurement and many analyses, is also not allocated the separate chapter it deserves (as a minimum) due to space limitations. Chapter 79 and Chapter 80 then shift focus to consider the analysis of different types of tasks in a similar, representative fashion.

Chapter 81 through Chapter 83 are included to provide insight into a representative selection of application types. Space constraints, the complexity of human performance, and the great variety of tasks that can be considered limit the level of detail with which such material can be reasonably presented. Work in all application areas is now benefiting from computer-based tools; this is the theme of Chapter 84. The section concludes with a look to the future (Chapter 85), including a summary of selected limitations, identification of some corresponding research and development needs, and speculation regarding the nature of the anticipated evolution of the field.

Many have contributed their talents to this exciting field in terms of both research and applications, yet much remains to be done. I am indebted to the authors not only for their contributions and cooperation during the preparation of this section, but also for their willingness to accept the burdens of communicating complex subject matter reasonably, selectively, and as accurately as possible within the imposed constraints.

75

The Elemental Resource Model for Human Performance

George V. Kondraske
University of Texas-Arlington

75.1 Introduction

Humans are complex **systems**. Our natural interest in things and ourselves that we do has given rise to the study of this complex system at every conceivable level ranging from genetic, through cellular and organ systems, to interactions of the total human with the environment in the conduct of purposeful activities. At each level, there are corresponding practitioners who attempt to discover and rectify or prevent problems at the respective level. Some practitioners are concerned with specific individuals, while others (e.g., biomedical scientists and product designers) address populations as a whole. Problems dealt with span medical and nonmedical contexts, often with interaction between the two. Models play a key role not only in understanding the key issues at each level, but also in describing relationships between various levels and in providing frameworks that allow practitioners to obtain reasonably predictable results in a systematic and efficient fashion. In this chapter, a working model for human system–**task** interfaces is presented. Any such model must, of course, consider not only the interface per se, but also representations of the human system and tasks. The model presented here, the Elemental Resource Model

(ERM), represents the most recent effort in a relatively small family of models that attempt to address similar needs.

75.1.1 Background

The interface of a human to a task of daily living (e.g., work, recreation, or other) represents a level that is quite high in the hierarchy noted above. One way in which to summarize previous efforts directed at this level, across various application contexts, is to recognize two different lines along which study has evolved (1) bottom-up and (2) top-down. Taken together, these relative terms imply a focus of interest at a particular level of convergence, which, here, is the human–task interface level. It is emphasized that these terms are used here to characterize the general course of development and not specific approaches applied at a particular instant of time. A broad view is necessary to grapple with the many previous efforts that either are, or could be, construed to be pertinent.

The biomedical community has approached the human–task interface largely along the "bottom-up" path. This is not surprising given the historical evolution of interest first in anatomy (human structure) and then physiology (**function**). The introduction of chemistry, giving rise to biochemistry, and the refinement of the microscope provided motivations to include even lower hierarchical levels of inquiry and of a substantially different character. Models in this broad "bottom-up" category begin with *anatomical components* and include muscles, nerves, tendons (or subcomponents thereof), or subsets of organs (e.g., heart, lungs, vasculature, etc.). They often focus on relationships between components and exhibit a scope that stays within the confines of the human system. Many cause-and-effect models have been developed at these lower levels for specific purposes (e.g., to understand lines of action of muscle forces and their changes during motion about a given joint).

As a natural consequence of linkages that occur between hierarchical levels and our tendency to utilize that which exists, consideration of an issue at any selected level (in this case, the human–task interface level) brings into consideration *all lower levels* and all models that have been put forth with the stated purpose of understanding problems or behaviors at the original level of focus. The amount of detail that is appropriate or required at these original, lower levels results in great complexity when applied to the total human at the human–task interface level. In addition, many lower-level modeling efforts (even those which are quantitative) are aimed primarily at obtaining a basic scientific understanding of human physiology or specific pathologies (i.e., pertaining to *populations* of humans). In such circumstances, highly specialized, invasive, and cumbersome laboratory procedures for obtaining the necessary data to populate models are justified. However, it is difficult and sometimes impossible to obtain data describing *a specific individual* to be utilized in analyses when such models are extended to the human–task interface level. Another result of drawing lower-level models (and their approaches) into the human–task interface context is that the results have a specific and singular character (e.g., biomechanical vs. neuromuscular control vs. psychologic, etc.) [e.g., Card et al., 1986; Hemami, 1988; Schoner and Kelso, 1988; Gottlieb et al., 1989; Delp, 1990]. Models that incorporate most or all of the multiple aspects of the human system or frameworks for integrating multiple lower-level modeling approaches have been lacking. Lower-level models that serve meaningful purposes at the original level of focus have provided and will continue to provide insights into specific issues related to human **performance** at multiple levels of consideration. However, their direct extension to serve general needs at the human–task interface level has inherent problems; a different approach is suggested.

A "top-down" progression can be observed over the major history in human factors/ergonomic [Taylor, 1911; Gilbreth and Gilbreth, 1917] and vocational assessment [e.g., Botterbusch, 1987] fields (although the former has more recently emphasized a "human-centered" concept with regard to design applications). In contrast to the bottom-up path in which anatomical components form the initial basis of modeling efforts, the focus along the top-down developmental path begins with consideration of the *task or job* which is to be performed by the total human. The great variety in the full breadth of activities in which humans can be engaged gives rise to one aspect of complexity at this level that pertains to taxonomies for job and task classification [e.g., Fleishman and Quaintance, 1984; Meister, 1989; U.S. Department of Labor, 1992].

Another enigmatic aspect that quickly adds complexity with respect to modeling concerns the appropriate level to be used to dissect the items (e.g., jobs) at the highest level into lower level components (e.g., tasks and subtasks). In fact, the choice of level is complicated by the fact that no clear definition has evolved for a set of levels from which to choose.

After progressing through various levels at which all model elements represent tasks and are completely outside the confines of the human body, a level is eventually reached where one encounters the human. Attempts to go further have been motivated, for example, by desires to predict performance of a human in a given task (e.g., lifting an object, assembling a product, etc.) from a set of measures that characterizes the human. From the human–task interface, difficulty is encountered with regard to the strategy for approaching a system as complex, multifaceted, and multipurpose as a human [Fleishman and Quaintance, 1984; Wickens, 1984]. In essence, the full scope of options that have emerged from the bottom-up development path are now encountered from the opposite direction. Options range from relatively gross analyses (e.g., estimates of the "fraction" of a task that is physical or mental) to those which are much more detailed and quantitative. The daunting prospect of considering a "comprehensive quantitative model" has led to approaches and models, argued to be "more practical," in which sets of parameters are often selected in a somewhat mysterious fashion based on experience (including previous research) and intuition. The selected parameters are then used to develop predictive models, most of which have been based primarily on statistical methods (i.e., regression models) [Fleishman, 1967; Fleishman and Quaintance, 1984]. Although the basic modeling tools depend only on correlation, it is usually possible to envision a causal link between the independent variables selected (e.g., visual acuity) and the dependent variable to be predicted (e.g., piloting an aircraft). Models (one per task) are then tested in a given population and graded with regard to their prediction ability, the best of which have performed marginally [Kondraske and Beehler, 1994]. Another characteristic associated with many of the statistically-based modeling efforts from the noted communities is the almost exclusive use of healthy, "normal" subjects for model development (i.e., humans with impairments were excluded). Homogeneity is a requirement of such statistical models, leading to the need for one model per task per population (at best). Moreover, working with a mindset that considers only normal subjects can be observed to skew estimates regarding which of the many parameters that one might choose for incorporation in a model are "most important." The relatively few exceptions that employ cause-and-effect models (e.g., based on physical laws) at some level of fidelity [e.g., Chaffin and Andersson, 1991] often adopt methods that have emerged from the bottom-up path and are, as noted above, limited in character at the "total human" level (e.g., "biomechanical" in the example cited).

It is critical to note that the issue is *not* that no useful models have emerged from previous efforts but rather that no clear comprehensive strategy has emerged for modeling at the human–task interface level. A National Research Council panel on human performance modeling [Baron et al., 1990] considered the fundamental issues discussed here and also underscored needs for models at the human–task interface level. While it was concluded that an all-inclusive model might be desirable (i.e., high fidelity, in the sense that biomechanical, information processing, sensory and perceptual aspects, etc. are represented), such a model was characterized as being highly unlikely to achieve and perhaps ultimately not useful because it would be overly complex for many applications. The basic recommendation made by this panel was to pursue development of more limited scope submodels. The implication is that two or more submodels could be integrated to achieve a broader range of fidelity, with the combination selected to meet the needs of particular situations. The desire to divide efforts due to inherent complexity of the problem also surfaces within the histories of the bottom-up and top-down development paths discussed above. While a reasonable concept in theory, one component in the division of effort that has consistently been underrepresented is the part that ties together the so-called submodels. Without a conceptual framework for integration of relatively independent modeling efforts and a set of common modeling constructs, prospects for long-term progress are difficult to envision. This, along with the recognition that enough work had been undertaken in the submodel areas so that key issues and common denominators could be identified, motivated development of the ERM.

The broad objectives of the ERM are most like those of Fleishman and colleagues [Fleishman, 1966, 1972, 1982; Fleishman and Quaintance, 1984], whose efforts in human performance are generally well known

in many disciplines. These are the only two efforts known that (1) focus on the total human in a task situation (i.e., directly address the human–task interface level); (2) consider tasks in general, and not only a specific task such as gait, lifting, reading, and so on; (3) incorporate all aspects of the total human system (e.g., sensory, biomechanical, information processing, etc.); and (4) aim at quantitative models. There are also some similarities with regard to the incorporation of the ideas of "abilities" (of humans) and "requirements" (of tasks). The work of Fleishman and colleagues has thus been influential in shaping the ERM either directly or indirectly through its influence of others. However, there are several substantive conceptual differences that have resulted in considerably different end-points. Fleishman's work emerged from "the task" perspective and is rooted in psychology, whereas the ERM emerges from the perspective of "human system architecture" and is rooted in engineering methodology with regard to quantitative aspects of system performance and also incorporates psychology *and* physiology. Both approaches address humans *and* tasks and both efforts contain aspects identifiable with psychology and engineering, as they ultimately must. These different perspectives, however, may explain in part some of the major differences. Aspects unique to the ERM include (1) it is based on modeling and measurement of *all* aspects of a system's performance using **resource constructs**; (2) the use of cause-and-effect **resource economic principles** (i.e., the idea of threshold "costs" for achieving a given level of performance in any given high-level task); (3) the concept of monadology (i.e., the use of a finite set of "elements" to explain a complex phenomenon); and (4) a consistent strategy for identifying performance elements at different hierarchical levels.

The ERM attempts to provide a quantitative and relatively straightforward framework for characterizing the human system, tasks, and the interface of the human to tasks. It depends in large part on, and evolves directly from, a separate body of material collectively referred to as general systems performance theory (GSPT). GSPT was developed first and independently; that is, removed from the human system context. It incorporates resource constructs exclusively for modeling of the abstract idea of *system performance*, including specific rules for measuring performance resource availability, and resource economic principles to provide a cause-and-effect analysis of the interface of any system (e.g., humans) to tasks. The concept of a "performance model" is emphasized and distinguished from other model types.

75.2   Basic Principles

The history of the ERM and the context in which it was developed are described elsewhere [Kondraske, 1987a, 1990b; 1995]. It is important to note that the ERM is derived from the combination of GSPT with the philosophy of monadology and their application to the human system. As such, these two constituents are briefly reviewed before presenting and discussing the actual ERM.

75.2.1   General Systems Performance Theory

The concept of "performance" now pervades all aspects of life, especially decision-making processes that involve both human and artificial systems. Yet, it has not been well-understood theoretically, and systematic techniques for modeling and its measurement have been lacking. While a considerable body of material applicable to general systems theory exists, the concept of performance has not been incorporated in it nor has performance been addressed in a general fashion elsewhere. Most of the knowledge that exists regarding performance and its quantitative treatment has evolved within individual application contexts, where generalizations can easily be elusive.

Performance is multifaceted, pertaining to how well a given system executes an intended function and the various factors that contribute to this. It differs from **behavior** of a system in that "the best of something" is implied. The broad objectives of GSPT are:

1. To provide a common conceptual basis for defining and measuring all aspects of the performance of any *system*
2. To provide a common conceptual basis for the analysis of any *task* in a manner that facilitates system–task interface assessments and decision-making

3. To identify cause-and-effect principles, or laws, that explain what occurs when any given system is used to accomplish any given task

While GSPT was motivated by needs in situations where the human is "the system" of interest and it was first presented in this context [Kondraske, 1987a], application of it has been extended to the context of artificial systems. These experiences range from computer vision and sensor fusion [Yen and Kondraske, 1992] to robotics [Kondraske and Standridge, 1988; Kondraske and Khoury, 1992].

A succinct statement of GSPT designed to emphasize key constructs is presented below in a step-like format. The order of steps is intended to suggest how one might approach any system or system–task interface situation to apply GSPT. While somewhat terse and "to-the-point," it is nonetheless an essential prerequisite for a reasonably complete understanding of the ERM:

1. Within a domain of interest, select any level of abstraction and identify the system(s) of interest (i.e., the physical **structure)** and its *function* (i.e., purpose).

2. Consider "the system" and "the task" separately.

3. Use a *resource construct* to model the system's *performance*. First, consider the unique intangible qualities that characterize *how well a system executes its function*. Each of these is considered to represent a unique **performance resource** associated with a specific **dimension of performance**(e.g., speed, accuracy, stability, smoothness, "friendliness," etc.) of that system. Each performance resource is recognized as a *desirable* item (e.g., endurance vs. fatigue, accuracy vs. error, etc.) "possessed" by the system in a certain quantitative amount. Thus, one can consider *quantifying* the amount of given *quality* available. As illustrated, an important consequence of using the resource construct at this stage is that confusion associated with duality of terms is eliminated.

4. Looking toward the system, identify all "I" dimensions of performance associated with it. In situations where the system does not yet exist (i.e., design contexts), it is helpful to note that dimensions of performance of the system are the same as those of the task.

5a. Keeping the resource construct in mind, define a parameterized metric for each dimension of performance (e.g., speed, accuracy, etc.). If the resource construct is followed, values will be produced with these metrics that are always nonnegative. Furthermore, a larger numerical value will consistently represent *more* of a given resource and therefore *more* **performance capacity**.

5b. Measure system performance with the system *removed from* the specific intended task. This is a reinforcement of step (2). The general strategy is to *maximally stress* the system (within limits of comfort and/or safety, when appropriate) to define its **performance envelope**; or more specifically, the envelope that defines *performance resource availability*, $R_{A_S}(t)$. Note that $R_{A_S}(t)$ is a continuous surface in the system's nonnegative, multidimensional performance space. Also note that unless all dimensions of performance and parameterized metrics associated with each are defined using the resource construct, a performance envelope cannot be guaranteed. Addressing the issue of measurement more specifically, consider resource availability values, $R_{A_i}|_{Q_{i,k}}(t)$ for $i = 1$ to I, associated with each of the "I" dimensions of performance. Here, each $\mathbf{Q}_{i,k}$ represents a unique condition, in terms of a set of values R_i along *other* identified dimensions of performance, under which a specific resource availability (R_{A_i}) is measured; that is, $\mathbf{Q}_{i,k} = \{R_{1,k}, R_{2,k}, \dots, R_{p,k}\}$ for all $p \neq i$ ($1 \geq p \geq I$). The subscript "k" is used to distinguish several possible conditions under which a given resource availability (R_{A_1}) can be measured. These values are measured using a set of "test-tasks," each of which is designed to *maximally stress* the system (within limits of comfort and safety, when appropriate) (a) along each dimension of performance individually (where $\mathbf{Q}_{i,k} = \mathbf{Q}_{i,0} = \{0, 0, \dots, 0\}$), or (b) along selected subsets of dimensions of performance simultaneously (i.e., $\mathbf{Q}_{i,k} = \mathbf{Q}_{i,n}$, where each possible $\mathbf{Q}_{i,n}$ has one or more nonzero elements). The points obtained ($R_{A_i}|_{Q_{i,k}}(t)$) provide the basis to estimate the performance envelope, $R_{A_S}(t)$. Note that if only on-axis points are obtained (e.g., maximally stress one specific performance resource availability with minimal or no stress on other performance resources, or the $Q_{i,0}$ condition), a rectangular or idealized performance envelope is obtained. A more accurate representation, which would be contained within the idealized envelope, can be obtained at the expense of making additional measurements or the use of known mathematical functions that define the shape of envelope in two or more dimensions.

5c. Define estimates of single-number *system figures-of-merit*, or *composite performance capacities*, as the mathematical product of all or any selected subset of $R_{A_i}|_{\mathbf{Q}_{i,0}}(t)$. If more accuracy is desired and a sufficient number of data points is available from the measurement process described in (5b), composite performance capacities can be determined by integration over $R_{A_S}(t)$ to determine the volume enclosed by the envelope. The *composite performance capacity* is a measure of performance at a higher level of abstraction than any individual dimension of performance at the "system" level, representing the capacity of the system to perform tasks which place demands on *those performance resources availabilities included in the calculation*. Different composite performance capacities can be computed for a given system by selecting different combinations of dimensions of performance. Note that the definition of a composite performance capacity used here preserves dimensionality; for example, if speed and accuracy dimensions are included in the calculation, the result has units of speed $\times$ accuracy. (This step is used only when needed; e.g., when two general-purpose systems of the same type are to be compared. However, if decision making that involves the interface of a specific system to a specific task is the issue at hand, a composite performance capacity is generally not of any use.)

6. Assess the "need for detail." This amounts to a determination of the number of hierarchical levels included in the analysis. If the need is to determine whether the currently identified "system" can work in the given task or how well it can execute its function, go to step (7) now. If the need is to determine the *contribution of one or more constituent subsystems* or why a desired level of performance is not achieved at the system level, repeat $1 \Rightarrow 5$ for all "J" functional units (subsystems), or a selected subset thereof based on need, that form the system that was originally identified in step (1); that is, go to the next lowest hierarchical level.

7. At the "system" level, look toward the task(s) of interest. Measure, estimate, or calculate *demands* on system performance resources (e.g., the speed, accuracy, etc. required), $R_{D_i}|_{Q'_{i,k}}(t)$, where the notation here is analogous to that employed in step (5b). This represents the quantitative definition and communication of **goals**, or the set of values (P_{HLT}) representing level of performance (P) desired in a specific high-level task (HLT). Use a worst-case or other less-conservative strategy (with due consideration of the impact of this choice) to summarize variations over time. This will result in a set of "M" points (R_{D_m}, for $m = 1$ to M) that lie in the multidimensional space defined by the set of "I" dimensions of performance. Typically, $M \geq I$.

8. Use *resource economic principles* (i.e., require $R_A \geq R_D$ for "success") at the system level *and* at all system–task interfaces at the subsystem level (if included) to evaluate success/failure at each interface. More specifically, for a given system–task interface, all task-demand points (i.e., the set of R_{D_m} associated with a given task or subtask) must lie within the performance resource envelope, $R_{A_S}(t)$, of the corresponding system. This is the key law that governs system–task interfaces. If a two-level model is used (i.e., "system" and "subsystem" levels are incorporated), map system level demands to demands on constituent subsystems. That is, functional relationships between P_{HLT} and demands imposed on constituent subsystems (i.e., $R_{D_{ij}}(t, P_{HLT})$) must be determined. The nature of these mappings depends on the type of systems in question (e.g., mechanical, information processing, etc.). The basic process includes application of step (7) to the subtasks associated with each subsystem. If **resource utilization flexibility** (i.e., redundancy in subsystems of similar types) exists, select the "best" or optimal subsystem configuration (handled in GSPT with the concept of **performance resource substitution**) and **procedure** (i.e., use of performance resources over time) as that which allows *accomplishment of goals* with *minimization of stress* on available performance resources across all subsystems and over the time of task execution. Thus, redundancy is addressed in terms of a constrained performance resource optimization problem. Stress on individual performance resources is defined as $0 \leq R_{D_{ij}}(t, P_{HLT})/R_{A_{ij}}(t) \leq 1$. It is also useful to define and take note of reserve capacity; that is, the margin between available and utilized performance resources.

The above statement is intended to reflect the true complexity that exists in systems, tasks, and their interfaces when viewed primarily from the perspective of performance. This provides a basis for the judicious decision making required to realize "the best" *practical implementation* in a given situation where many engineering trade-offs must be considered. While a two-level approach is described

above, it should be apparent that it could be applied with any number of hierarchical levels by repeating the steps outlined in an iterative fashion starting at a different level each time. A striking feature of GSPT is the *threshold effect* associated with the resource economic principle. This nonlinearity has important implications in quantitative human performance modeling, as well as interesting ramifications in practical applications such as rehabilitation, sports, and education. Note also no distinction is made as to whether a given performance resource is derived from a human or artificial system; both types of systems, or subcomponents thereof, can be incorporated into models and analyses.

75.2.2   Monadology

Monadology dates back to 384 BC [Neel, 1977] but was formalized and its importance emphasized by Gottfried Wilhelm Leibniz, inventor of calculus, in his text *Monadologia* in 1714. This text presents what is commonly called *Leibniz's Monadology* and has been translated and incorporated into contemporary philosophy texts [Leibniz and Montgomery, 1992]. It is essentially the idea of "basic elements" *vis a vis* chemistry, alphabets, genetic building blocks, etc. The concept is thus already well accepted as being vital to the systematic description of human systems from certain perspectives (i.e., chemical, genetic). Success associated with previous application of monadology, whether intentional or unwitting (i.e., discovered to be at play *after* a given taxonomy has emerged), compels its serious *a priori* consideration for other problems.

Insight into how monadology is applied to human performance modeling is perhaps more readily obtained with reference to a widely known example in which monadology is evident, such as chemistry. Prior to modern chemistry (i.e., prior to the introduction of the periodic table), alchemy existed. The world was viewed as being composed of an infinite variety of unique *substances*. The periodic table captured the notion that this infinite variety of substances could all be defined in terms of a finite set of basic elements. Substances have since been analyzed using the "language" of chemistry and organized into categories of various complexity, that is, elements, simple compounds, complex compounds, etc. Despite the fact that this transition occurred approximately 200 years ago, compounds remain, which have yet to be analyzed. Furthermore, the initial periodic table was incorrect and has undergone revision up to relatively recent times. Analogously, in the alchemy of human performance the world is viewed as being composed of an infinite variety of unique tasks. A "chemistry" can be envisioned that first starts with the identification of the "basic elements," or more specifically, *basic elements of performance.* Simple and complex tasks are thus analogous to simple and complex compounds, respectively. The analogy carries over to quantitative aspects of GSPT as well. Consider typical equations of chemical reactions with resources on the left and products (i.e., tasks) on the right. Simple compounds (tasks) are realized by drawing upon basic elements in the proper combination and amounts. The amount of "product" (level of performance in a high-level task) obtained depends on availability of the **limiting resource**.

Another informative aspect of this analogy is the issue of how to deal with the treatment of hierarchical level. Clearly, the chemical elements are made up of smaller particles (e.g., protons, neutrons, and electrons). Physicists have identified even smaller, more elusive entities such as bosons, quarks, and so on. Do we need to consider items at this lowest level of abstraction each time a simple compound such as hydrochloric acid is made? Likewise, the term "basic" in basic elements of performance is clearly relative and requires the choice of a particular hierarchical level of abstraction for the identification of systems or basic functional units; a level which is considered to be both natural and useful for the purpose at hand. Just as it is possible but not always necessary or practical to map chemical elements down to the atomic particle level, it is possible to consider mapping a basic element of performance (see latter) such as elbow flexor torque production capacity down to the level of muscle fibers, biochemical reactions at neuromuscular junctions, and so forth.

75.2.3 The Elemental Resource Model

The resource and resource economic constructs used in GSPT specifically to address performance have employed and have become well-established in some segments of the human performance field, specifically with regard to attention and information processing [Navon and Gopher, 1979; Wickens, 1984]. However, in these cases the term "resource" is used mostly conceptually (in contrast to quantitatively), somewhat softly defined, and applied to refer in various instances to systems (e.g., different processing centers), broad functions (e.g., memory vs. processing), and sometimes to infer a particular aspect of performance (e.g., attentional resources). In the ERM, through the application of GSPT, these constructs are incorporated universally (i.e., applied to all human subsystems) and specifically to model "performance" at both conceptual and quantitative levels. In addition to the concept of monadology, the insights of others [Turvey et al., 1978; Shoner and Kelso, 1988] were valuable in reinforcing the basic "systems architecture" employed in the ERM and in refining description of more subtle, but important aspects.

As illustrated in Figure 75.1, the ERM contains multiple hierarchical levels. Specifically, three levels are defined (1) the basic element level; (2) the **generic intermediate level**, and (3) the high level. GSPT is to define performance measures at any hierarchical level. This implies that to measure performance, one must isolate the desired system and then stress it maximally along one dimension of performance (or more, if interaction effects are desired) to determine performance resource availability. For example, consider the human "posture stabilizing" system (at the generic intermediate level), which is stressed maximally along a stability dimension. As further illustrated below, the basic element level contains represents measurable stepping-stones in the human system hierarchy between lower-level systems (i.e., ligaments, tendons, nerves, etc.) and higher-level tasks.

A summary representation emphasizing the basic element level of the ERM is depicted in Figure 75.2. While this figure is intended to be more or less self-explanatory, a brief walk-through is warranted.

75.2.3.1 Looking Toward the Human

The entire human (lower portion of Figure 75.2) is modeled as a pool of elemental *performance resources*, which are grouped into one of the four different domains (1) life sustaining, (2) environmental interface (containing purely sensory and sensorimotor components), (3) the central processing, and (4) information. Within each of the first three domains, physical subsystems referred to as *functional units* are identified (see labels along horizontal aspect of grids) through application of fairly rigorous criteria [Kondraske, 1990b]. GSPT is applied to each functional unit, yielding first a set of dimensions of performance (defined using a resource construct) for each unit. A single **Basic Element of Performance** (BEP) is defined by specifying two items (1) the basic functional unit and (2) one of its dimensions of performance. Within a domain, not every dimension of performance indicated in Figure 75.2 is applicable to every functional unit in that domain. However, there is an increasing degree of "likeness" among functional units (i.e., fewer fundamentally different types) in this regard as one moves from life sustaining, to environmental interface, to central processing domains. The fourth domain, the information domain, is substantially different from the other three. Whereas the first three represent physical systems and their intangible performance resources, the information domain simply represents information. Thus, while memory functional units are located within the central processing domain, the contents of memory (e.g., motor programs and associated reference information) are partitioned into the information domain. As illustrated, information is grouped but within each group there are many specific skills. The set of available performance resources $(R_{A_{ij}}(t)|_{\mathbf{Q}})$ consist of both BEPs (i = dimension of performance, j = functional unit) and information sets (e.g., type "i" within group "j"). Although intrinsically different, both fit the resource construct. This approach permits even the most abstract items such as motivation and friendliness to be considered with the same basic framework as strength and speed.

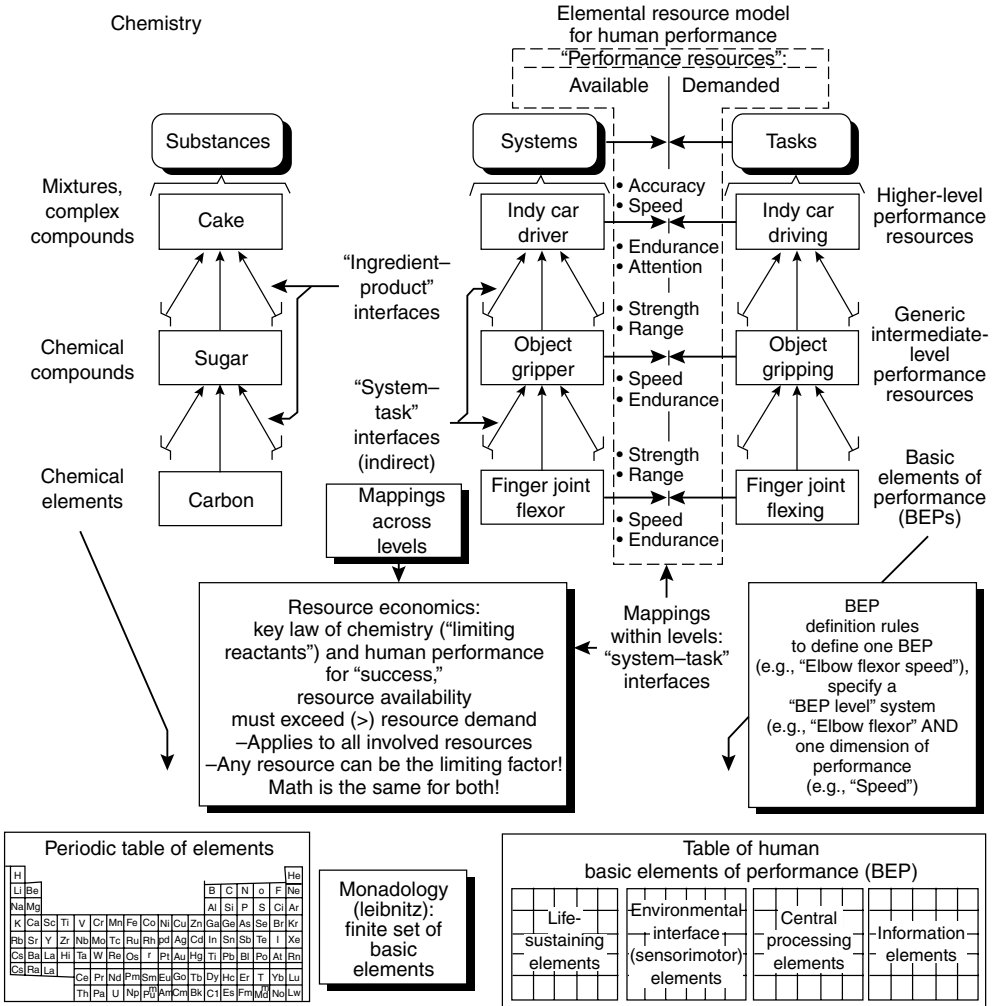
Note that resource availability in GSPT and thus in the ERM is potentially a function of time, allowing quantitative modeling of dynamic processes such as child development, aging, disuse atrophy, and rehabilitation. The notation further implies that availability of a given resource must be evaluated at a specific operating point, denoted as $\mathbf{Q}$. At least conceptually, many parameters can be used to characterize


FIGURE 75.1 The Elemental Resource Model contains multiple hierarchical levels. Performance resources (i.e., the basic elements) at the "basic element level" are finite in number, as dictated by the finite set of human subsystems and the finite set of their respective dimensions of performance. At higher levels, new "systems" can be readily created by configuration of systems at the basic element level. Consequently, there are in infinite number of performance resources (i.e., higher-level elements) at these levels. However, rules of General Systems Performance Theory (refer to text) are applied at any level in the same way resulting in the identification of the system, its function, dimensions of performance, performance resource availabilities (system attributes), and performance resource demands (task attributes).

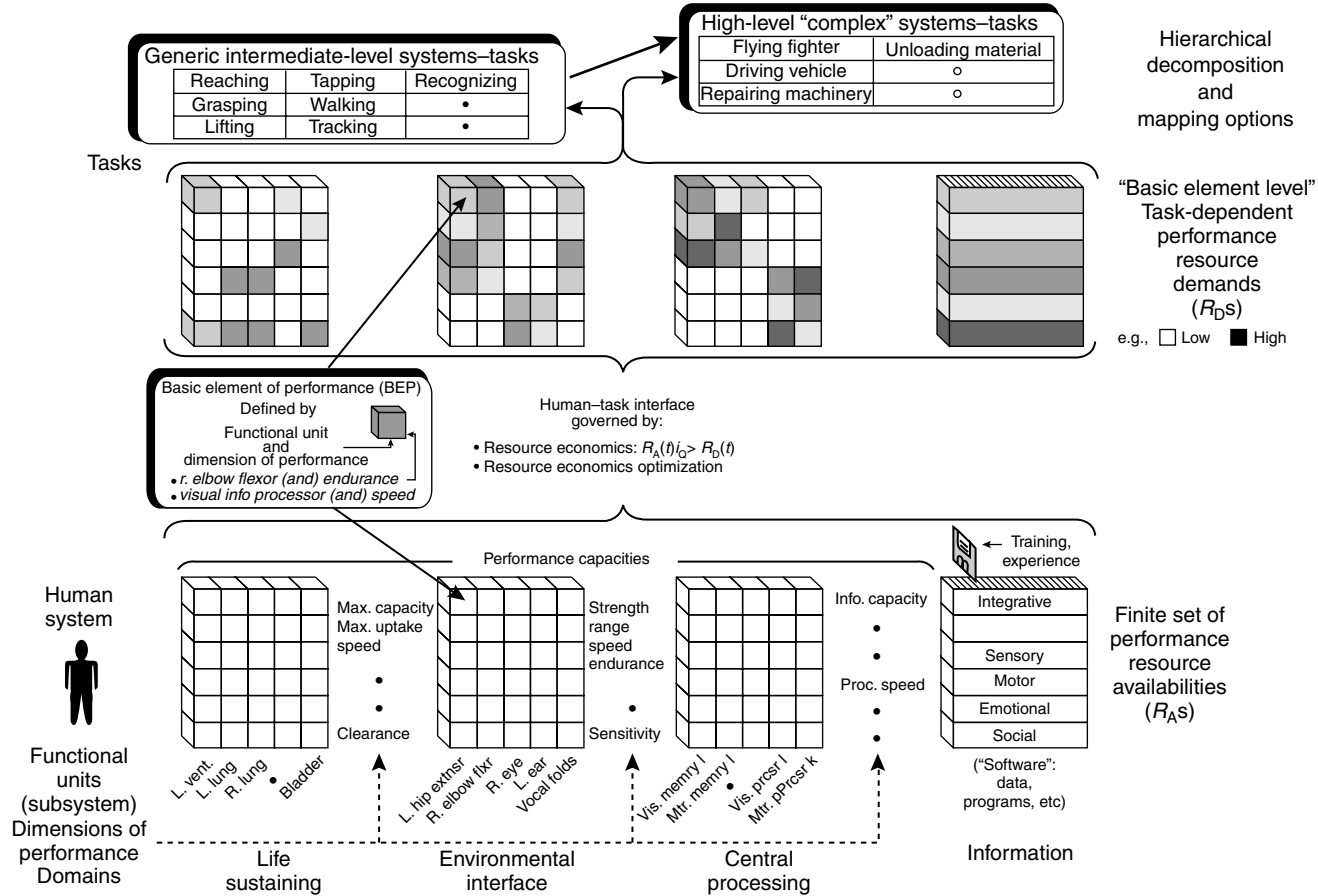
this **Q** point. In general, the goal of measurement when looking "toward the human" is to isolate functional units and maximally stress (safely) individual performance resources to determine availability. Such measures reflect performance capacities. The simplest **Q** point is one in which there is stress along only one dimension of performance (i.e., that corresponding to the resource being stressed). Higher fidelity representation is possible at the expense of additional measurements. The degree to which isolation can be achieved is of practical concern in humans. Nonetheless, it is felt that reasonable isolation can be achieved in most situations [Kondraske, 1990a, b]. Moreover, this and similar issues of practical concern should be addressed as separate problems; that is, they should not be permitted to obfuscate or thwart efforts to explain phenomenon at the human–task interface.


FIGURE 75.2 A summary of the major constructs of the Elemental Resource Model, emphasizing the categorization of performance resources at the basic element level into four: life-sustaining, environmental interface, central processing, and information domains.

75.2.3.2 Looking Toward the Task

The mid-portion of Figure 75.2 suggests the representation of any given task in terms of the unique set of demands ($R_{D_{ij}}(t)$) imposed on the pool of BEPs and information resources; that is, this is the elemental level of task representation. Shading implies that demands can be represented quantitatively in terms of amount. The upper portion of the figure defines hierarchical mapping options, where mapping is the process of translating what happens in tasks typically executed by humans to the elemental level. Two such additional levels (for a total of three, including the elemental level) are included as part of the ERM (1) generic intermediate-level tasks, and (2) higher-level complex tasks. At all three levels (Figure 75.1 and Figure 75.2) tasks are processes which occur over time and can be characterized by specific goals (e.g., in terms of speed, force, etc.) and related to systems at the same level that possess performance resources. Using established analytic techniques, even the most complex task can be divided into discrete task segments. Then mapping analyses, which take into account task procedures (e.g., a squatting subject with two hands on the side of a box . . .), are applied to each task segment to determine $R_{D_{ij}}(t)$. Once this is found, the worst case or a selected percentile point in the resource demand distribution (over a time period corresponding to a selected task segment) can be used to obtain a single numerical value representation of demand for a given resource *and* the conditions under which the given demand occurs; that is, the $\mathbf{Q}'$ point (e.g., at what speed and position angle does the worst-case demand on elbow flexor torque occur?). This reduction process requires parameterization algorithms that are similar to those used to process time series data collected during tests designed to measure performance resource availability.

75.2.3.3 The Human–Task Interface

Using GSPT, success in achieving the goals of a given task segment is governed by resource economic principles requiring that $R_{A_{ij}}(t)|_{\mathbf{Q}} \geq R_{D_{ij}}(t)$ for all is and js (i.e., $R_{A_{11}} \geq R_{D_{11}}$ AND $R_{A_{12}} \geq R_{D_{12}}$ AND $R_{A_{13}} \geq R_{D_{13}} \cdots$). In other words, all task demands, when translated to the individual subsystems involved, must fit within the envelopes that define performance resource availability. Adequacy associated with any one resource is a *necessary, but not sufficient condition* for success. Concepts and observations in human performance referred to as "compensation" or "redundancy" are explained in terms of *resource utilization flexibility,* which includes the possibility of substituting one performance resource (of the same dimensionality) for another (i.e., *resource substitution*). It has been hypothesized [Kondraske, 1990b] that an optimal performance resource utilization is achieved through learning. Furthermore, the optimization rule suggested by GSPT is that the human system is driven to accomplish task goals and use procedures that minimize performance resource stress (i.e., the fraction of available performance resources utilized) over the duration of a given task segment and across all BEPs involved. Minimizing stress is equivalent to maximizing the margin between available and utilized performance resources. Thus, optimization is highly dependent on the resource availability profile and it would be predicted, for instance, that two individuals with different resource availability profiles would not optimally accomplish the same task goals by using identical procedures.

75.3 Application Issues

Implications of the ERM and what it demonstrates regarding intrinsic demands imposed by nature and methods for creatively navigating these demands over both the short and long terms are considered. The ERM offers a number of flexibilities with regard to how it can be applied (e.g., "in whole" or "in part," "conceptually" or "rigorously," with "low-tech" or sophisticated "high-tech" tools, and to define performance measures or to develop predictive models). While immediate application is possible at a conceptual level of application, it also provides the motivation and potential to consider coordinated, collaborative developments that allow rigorous and efficient solutions to complex problems by practitioners without extraordinary training.

The ERM provides a basis for obtaining insight into the nature of routine tasks that clinicians and other practitioners are expected to perform; there are both "troublesome" and "promising" insights in this

regard. Perhaps the most obvious troublesome aspect is that the ERM makes it painfully evident that *many* BEPs are typically called into play in tasks of daily living, work, or recreation and that resource insufficiency associated with *any one* of this subset of BEPs can be the factor which limits performance in the higher-level task. The further implication is that for rigorous application, one must know (via measurement and analyses) the availability and demand associated with each and every one of these unique resources. An additional complexity with which practitioners must cope is the high degree of specificity and complexity of resources in the information domain (i.e., the "software"). There is no simple, rapid way to probe into this domain of the ERM to determine if the information required for a given task is correct; it requires methods analogous to those used to debug software source code.

The aspects that hold promise are associated with (1) the nature of hierarchical systems; (2) the threshold mathematics of resource economics; and (3) the fact that when "*n*" resources combine to address a single task, the mathematics of logical combination is employed to arrive at an overall assessment. That is, the individual "$R_A \geq R_D$?" questions result in a set of "OK" or "Not OK" results that are combined with logical "AND" operations to obtain the final "OK" or "Not OK" assessment (*Note*: the "OR" operator is used when resource substitution is possible.).

75.3.1   Conceptual, Low-Tech, Practical Application

The ERM description alone can be used simply to provide a common conceptual basis for discussing the wide range of concepts, measurements, methods, and processes of relevance in human performance or a particular application area [Mayer and Gatchel, 1988; Syndulko et al., 1988; Frisch, 1993] It can also be used at this level as a basis for structured assessment [Kondraske, 1988b, 1994b, 1995] of individuals in situations including therapy prescription, assistive device prescription, independent living decision making (e.g., self-feeding, driving, etc.), age or gender discrimination issues in work or recreational tasks, etc. At points in such processes, it is often more important to consider the full scope of different performance resources involved in a task using even a crude level of quantification than it is to consider just a select few in great depth. A "checklist" approach is recommended. The professional uses only his or her judgment and experience to consider both the specific individual and the specific task of interest to make quantitative but relatively gross assessments of resource adequacy using a triage-like categorization process (e.g., with "definitely limiting," "definitely not limiting," or "not sure" categories). This is feasible because of the threshold nature of the system–task interface; in cases where R_A and R_D are widely and separately instrumented, high resolution measurements are not required to determine if a given performance resource is limiting. Any resource(s) so identified as "definitely limiting" becomes an immediate focus of interest. If none is categorized as such, concern moves to those in the "not sure" category in which case more sensitive measurements may be required. Purely subjective methods of measuring resource availability and demands can be augmented with selected, more objective, and higher-resolution measurements in "hybrid applications."

75.3.2   Conceptual, Theoretical Application

The ERM can be used in its broadest conceptual sense as a basis for formulating context-dependent models for specific situations involving human performance. Dillon et al. [2000] utilized ERM constructs to propose approaches to deal with outcome assessment in engineering education, Chesky et al. [2002] applied the ERM as a basis for a conceptual understanding of medical problems of musicians, and Olson and Kondraske [2005] incorporated it into pain management.

It can also be employed in a theoretical fashion to reconsider previous work in human performance. For example, it can be employed to reason why Fleishman [Fleishman and Quaintance, 1984] (as well as others) achieve promising, but limited, success with statistically based predictions of performance in higher-level tasks using regression models with independent variables, which can now be viewed as representing lower-level performance resources (in most cases). Specifically, regression models rely fundamentally on an assumption that there exists some correlation between dependent and each independent

variable, the latter of which typically represent scores from maximal performance tasks and therefore reflect resource availability (using GSPT and ERM logic). Brief reflection results in the realization that correlation is not to be anticipated between the level of performance attainable in a "higher-level task" and *availability* of one of the many performance resources essential to the task (e.g., if four cups of flour are needed for a given cake, having 40 cups available will not *alone* result in a larger cake of equal quality — availability of another ingredient may in fact be limiting). Rather, correlation *is* expected between high-level task performance and the amount of resource *utilization*. Unfortunately, as noted above, the independent variables used typically reflect resource availability. The incomplete labeling of performance variables in such studies reflects the general failure to distinguish between utilization and availability. Why not, then, just use measures of resource utilization in such statistical models? Resource availability measures are simple to obtain in the laboratory without requiring that the individual execute *the* high-level task of interest. Resource utilization measures can only be obtained experimentally by requiring the subject to execute the task in question, which is counterproductive with respect to the goal of using a set of laboratory measurements to extrapolate to performance in one or more higher-level task situations. Regression models based on linear combination of resource *availability* measures do not reflect the nonlinear threshold effect accounted for with resource economic, GSPT-based performance models. One potential alternative based on GSPT and termed nonlinear causal resource analysis (NCRA) has been proposed [Kondraske, 1988a; Vasta and Kondraske, 1994]. NCRA application examples are cited in Section 75.3.4.

75.3.3 Application "In Part"

In this approach, whole domains (i.e., many BEPs) are assessed simultaneously resulting in an estimate or well-founded assumption, which states that "all performance resources in Domain X are nonlimiting in Task(s) Y." Such assumptions are often well justified. For example, it would be reasonable to assume that a young male with a sport-related knee injury would have only a reduction in performance resource availability in the environmental interface domain. More specifically, it is reasonable to assume that the scope of interest can be confined to a smaller subset of functional units, as in gait or speech. These can then be addressed with rigorous application. Examples of this level and manner of applying the ERM have been or are being developed for head/neck control in the context of assistive communication device prescription [Carr, 1989]; workplace design [Kondraske, 1988c]; evaluating worksites and individuals with disabilities for employment [Parnianpour and Marras, 1993]; gait [Carollo and Kondraske, 1987]; measurement of upper extremity motor control [Behbehani et al., 1988]; speech production performance [Jafari, 1989; Jafari et al., 1989]; and to illustrate changes in performance capacity associated with aging [Kondraske, 1989]. Additionally, in some applications only the Generic Intermediate Level need be considered. For example, one may only need to know how well an individual can walk, lift, etc. While it is sometimes painfully clear just how complex is the execution of even a relatively simple task; it can also be recognized that relatively simple, justifiable, and efficient strategies can be developed to maintain a reasonable degree of utility in a given context.

75.3.4 Rigorous, High-Tech Application

While this path may offer the greatest potential for impact, it also presents the greatest challenge. The ultimate *goal* would be to capture the analytic and modeling capability (as implied by the above discussions) for a "total human" (single subject or populations) and "any task" in a desktop computer system (used along with synergistic "peripherals" that adopt the same framework, such as measurement tools [Kondraske, 1990a]). This suggests a long-term, collaborative effort. However, intermediate tools that provide significant utility are feasible [e.g., Vasta and Kondraske, 1994] and needed [Allard et al., 1994; Vasta and Kondraske, 1995]. A promising example of such tools based directly on GSPT and the ERM is NCRA [Vasta and Kondraske, 1994; Kondraske et al., 1997]. This inferential method has recently been used [Kondraske et al., 1997] to develop models that relate performance resource demands on various human subsystems to the level of performance attained in higher level mobility tasks (e.g., gait and stair

climbing). In turn, these models have used to predict level of performance in these higher level tasks with success that exceeds that which has been obtained with regression models. Furthermore, the NCRA method inherently provides not only a prediction of high-level task performance, but also identifies which performance resources are most likely to be preventing better performance (i.e., which ones are the "limiting performance resources"). Similar applications of NCRA have been used to develop models of laparoscopic surgical performance [Gettman et al., 2003; Johnson et al., 2004], driving performance [Fischer et al., 2002], and to understand falls in elderly subjects [Murphy, 2000]. A special NCRA software package has been developed to facilitate model development and use. While such tools that are useful to practitioners are desirable, they are almost essential for the efficient conduct of in-depth experimental work with the ERM.

The issue of biologic variability and its influence on numerical analyses can be raised in the context of rigorous numerical application. In this regard, the methods underlying GSPT and the ERM (or any similar cause-and-effect model) are noted to be analogous with those used to design artificial systems. In recent years, conceptual approaches and mathematical tools widely known as Taguchi methods [Bendell et al., 1988] have shown to be effective for understanding and managing a very similar type of variability that surfaces in the manufacture of artificial systems (e.g., variability associated with performance of components of larger systems and the effect on aspects of performance of the final "product"). Such tools may prove useful in working through engineering problems such as those associated with variability.

75.4   Conclusion

The ERM is a step toward the goal of achieving an application-independent approach to modeling any human–task interface. It provides a systematic and generalizable (across all subsystem types) means of identifying performance measures that characterize human subsystems, as well as a consistent basis for performance measurement definition (and task analysis). It has also served to stimulate focus on a standardized, distinct set of variables, which facilitates clear communication of an individual's status among professionals.

After the initial presentation, refinements in both GSPT and the ERM were made. However, the basic approaches, terminology, and constructs used in each have remained quite stable. More recent work has focused on development of various components required for application of the ERM in nontrivial situations. This entails using GSPT and basic ERM concepts to guide a full "fleshing out" of the details of measurement parameterizations and models for different types of human subsystems, definition of standard conventions and notations, and development of computer-based tools. In addition, experimental studies designed to evaluate key constructs of the ERM and to demonstrate the various ways in which it can be applied are being conducted. A good portion of the developmental work is aimed at building a capability to conduct more complex, nontrivial experimental studies. Collaborations with other research groups have also emerged and are being supported to the extent possible. Experiences with it in various contexts and at various levels of application have been productive and encouraging.

The ERM is one, relatively young attempt at organizing and dealing with the complexity of some major aspects of human performance. There is no known alternative that, in a specific sense, attempts to accomplish the same goals as the working model presented here. Is it good enough? For what purposes? Is a completely different approach or merely refinement required? The process of revision is central to the natural course of the history of ideas. Needs for generalizations in human performance persist.

Defining Terms

Basic element of performance (BEP):   A modeling item at the basic element level in the ERM defined by identification of a specific system at this level and one of its dimensions of performance (e.g., functional unit = visual information processor, dimension of performance = speed, BEP = visual information processor speed).

Behavior: A general term that relates to what a human or artificial system does while carrying out its function(s) under given conditions. Often, behavior is characterized by measurement of selected parameters or identification of unique system states over time.

Composite performance capacity: A performance capacity at a higher level of abstraction, formed by combining two or more lower-level performance capacities (e.g., via integration to determine the area or volume within a performance envelope).

Dimension of performance: A unique quality that characterizes how well a system executes its function (e.g., speed, accuracy, and torque production); one of axes or the label associated with one of the axes in a multidimensional performance space.

Function: The purpose of a system. Some systems map to a single primary function (e.g., process visual information). Others (e.g., the human arm) map to multiple functions , although at any given time multifunction systems are likely to be executing a single function (e.g., polishing a car). Functions can be described and inventoried, whereas level of performance of a given function can be measured.

Generic intermediate level: One of three major hierarchical levels for systems and tasks identified in the elemental resource model. The generic intermediate level represents new systems (e.g., postural maintenance system, object gripper, object lifter, etc.) formed by the combination of functional units at the basic element level (e.g., flexors, extensors, processors, etc.). The term "generic" is used to imply the high frequency of use of systems at this level in tasks of daily life (i.e., items at the "high level" in the ERM).

Goal: A desired end-point (i.e., result) typically characterized by multiple parameters, at least one of which is specified. Examples include specified task goals (e.g., move an object of specified mass from point A to point B in 3 sec) or estimated task performance (maximum mass, range, speed of movement obtainable given a specified elemental performance resource availability profile), depending on whether a reverse or forward analysis problem is undertaken. Whereas function describes the general process of a task, the goal directly relates to performance and is quantitative.

Limiting resource: A performance resource at any hierarchical level (e.g., vertical lift strength, and knee flexor speed) that is available in an amount that is less than the worst case demand imposed by a task. Thus, a given resource can only be "limiting" when considered in the context of a specific task.

Performance: Unique qualities of a human or artificial system (e.g., strength, speed, accuracy, and endurance) that pertain to how well that system executes its function.

Performance capacity: A quantity in finite availability that is possessed by a system or subsystem, drawn on during the execution of tasks, and limits some aspects (e.g., speed, force production, etc.) of a system's ability to execute tasks; or, the limit of that aspect itself.

Performance envelope: The surface in a multidimensional performance space, formed with a selected subset of a system's dimensions of performance, that defines the limits of a systems performance. Tasks represented by points which fall within this envelope can be performed by the system in question.

Performance resource: A unique quality of a system's performance modeled and quantified using a resource construct.

Performance resource substitution: The term used in GSPT to describe the manner in which intelligent system's, such as humans, utilize redundancy or adapt to unusual circumstances (e.g., injuries) to obtain optimal procedures for executing a task.

Procedure: A set of constraints placed on a system in which flexibility exists regarding how a goal (or set of goals) associated with a given function can be achieved. Procedure specification requires specification of initial, intermediate and final states, or conditions dictating how the goal is to be accomplished. Such specification can be thought of in terms of removing some degrees of freedom.

Resource construct: The collective set of attributes that define and uniquely characterize a resource. Usually, the term is applied to only tangible items. A resource is desirable, measurable in terms of amount (from zero to some finite positive value) in such a manner that a larger numerical value indicates a greater amount of the resource.

Resource economic principle: The principle, observable in many contexts, which states that the amount of a given resource that is available (e.g., money) must exceed the demand placed on it (e.g., cost of an item) if a specified goal (e.g., purchase of the item) is to be achieved.

Resource utilization flexibility: A term used in GSPT to describe situations in which there is more than one possible source of a given performance resource type, that is, redundant supplies exist.

Structure: Physical manifestation and attributes of a human or artificial system and the object of one type of measurements at multiple hierarchical levels.

Style: Allowance for variation within a procedure, resulting in the intentional incomplete specification of a procedure or resulting from either intentional or unintentional incomplete specification of procedure.

System: A physical structure, at any hierarchical level of abstraction, that executes one or more functions.

Task: That which results from (1) the combination of specified functions, goals and procedures, or (2) the specification of function and goals and the observation of procedures utilized to achieve the goals.

Measurement of Neuromuscular Performance Capacities

Susan S. Smith
Texas Women's University

Movements allow us to interact with our environment, express ourselves, and communicate with each other. Life is movement. Movement is constantly occurring at many hierarchical levels including cellular and subcellular levels. By using the adjective "human" to clarify the term "movement," we are not only defining the species of interest, but also limiting the study to observable performance and its more overt causes. Study of human performance is of interest to a broad range of professionals including rehabilitation engineers, orthopedic surgeons, therapists, biomechanists, kinesiologists, psychologists, and so on. Because of the complexity of human performance and the variety of investigators, the study of human performance is conducted from several theoretical perspectives including (1) anatomical, (2) purpose or character of the movement (such as locomotion), (3) physiological, (4) biomechanical, (5) psychological, (6) socio-cultural, and (7) integrative. The elemental resource model (ERM), presented at the beginning of this section, is an integrative model that incorporates aspects of the other models into a singular system accounting for the human, the task, and the human–task interface [Kondraske, 2005].

The purposes of this chapter are to (1) provide reasons for measuring four selected variables of human performance: extremes/**range of motion**, strength, **speed of movement**, and **endurance**; (2) briefly define and discuss these variables; (3) overview selected instruments and methods used to measure these variables; and (4) discuss interpretation of performance for a given neuromuscular subsystem.

76.1 Neuromuscular Functional Units

While the theoretical perspectives listed previously may be useful within specific contexts or within specific disciplines, the broader appreciation of human performance and its control can be gained from the perspective of an integrative model such as the ERM [Kondraske, 2005]. This model organizes performance resources into four different domains. Basic movements, such as elbow flexion, are executed by **neuromuscular functional units** in the environmental interface domain. Intermediate and complex tasks, such as walking and playing the piano, utilize multiple basic functional units. The human performing a movement operates the involved functional units along different dimensions of performance according to the demands of the task. Dimensions of performance are factors such as joint motion, strength, speed of movement, and endurance. Lifting a heavy box off the floor requires, among other things, a specific amount of strength associated with neuromuscular functional units of the back, legs, and arms according to the weight and size of the box. Reaching for a light-weight box from the top shelf of a closet requires that the shoulder achieve certain **extremes of motion** according to the height of the shelf.

Whereas four dimensions of performance are considered individually in this chapter, they are *highly interdependent*. For example, strength availability during a movement is partly dependent on joint angle. Despite interdependence, considering the variables as different dimensions is essential to studying human performance. The components limiting the human's ability to complete a task can only be identified and subsequently enhanced by determining, for example, that the reason the human cannot reach the box off the top shelf is not because of insufficient range of motion of the shoulder, but because of insufficient strength of the shoulder musculature required to lift the arm through the range of motion. Isolating the subsystems involved in a task and maximally stressing them along one or more "isolated" dimensions of performance is a key concept in the ERM. "Maximally stressing" the subsystems means that the maximum amount of the resource available is being determined. This differs from determining the amount of the resource that happened to be used while performing a particular task. Often the distinction between obtaining maximal performance from a human and submaximal performance is in the instructions given the subject. For example, when measuring speed, we say, "move as fast as you can."

76.1.1 Purposes of Measuring Selected Neuromuscular Performance Capacities

Range of motion, strength, speed of movement, and endurance can be measured for one or more of the following purposes:

1. To determine the amount of the resource available and to compare it to the normal value for that individual. "Normal" is frequently determined by comparisons with the opposite extremity or with normative data when available. This information can be used to develop goals and a program to change the performance.
2. To assist in determining the possible affects of insufficient or imbalanced amounts of the variable on a person's performance of activities of daily living, work, sport, and leisure pursuits. In this case the amount of the variable is compared to the demands of the task, rather than to norms or to the opposite extremity.
3. To assist in diagnosis of medical conditions and the nature of movement dysfunctions.
4. To reassess status in order to determine the effectiveness of a program designed to change the amount of the variable.
5. To motivate persons to comply with treatment or training regimes.
6. To document status and the results of treatment or training and to communicate with other involved persons.
7. To assist in ergonomically designed furniture, equipment, techniques, and environments.
8. To provide information that when combined with other measures of human performance can be used to predict functional capabilities.

76.2 Range of Motion and Extremes of Motion

Range of motion (ROM) is the amount of movement that occurs at a joint. ROM is typically measured by noting the *extremes of motion (EOM)*. The designated reference or zero position must be specified for measurements of the two extremes of motion. For example, to measure elbow (radiohumeral joint) flexion and extension, the preferred starting position is with the subject supine with the arm parallel to the lateral midline of the body with the palm facing upward [Norkin and White, 2003; Reese and Bandy, 2003]. Measurements are taken with the elbow in the fully flexed position and with the elbow in the fully extended position.

76.2.1 Movement Terminology

Joint movements are described using a coordinate system with the human body in anatomical position. Anatomical position of the body is an erect position, face forward, arms at sides, palms facing forward, and fingers and thumbs in extension. The central coordinate system consists of three cardinal planes and axes with its origin located between the cornua of the sacrum [Panjabi, et al., 1974]. Figure 76.1 demonstrates the planes and axes of the central coordinate system. The same coordinate system can parallel the master system at any joint in the body by relocating the origin to any defined point.

The sagittal plane is the y, z plane; and the frontal (or coronal) plane is the y, x plane; and the horizontal (or transverse) plane is the x, z plane. Movements are described in relation to the origin of the coordinate system. The arrows indicate the positive direction of each axis. An anterior translation is $+z$; a posterior translation is $-z$. Clockwise rotations are $+\theta$, and counterclockwise rotations are $-\theta$.

Joints are described as having degrees of freedom (DOF) of movement; DOF, that is, the number of axes associated with a joint each of which allows motion in a plane in three-dimensional space. If a motion occurs in one plane and around one axis, the joint is defined as having one DOF. Joints with movements in two planes occurring around two different axes, have two DOF, and so on.
FIGURE 76.1   Planes and axes are illustrated in anatomical position. The central coordinate system with its origin between the cornua of the sacrum is shown. (From White III A.A. and Panjabi M.M. 1990. *Clinical Biomechanics of the Spine*, 2nd ed., p. 87. Philadelphia, JB Lippincott Company. With permission.)

Angular movements refer to motions that cause an increase or decrease in the angle between the articulating bones. Angular movements are flexion, extension, abduction, adduction, and lateral flexion (see Table 76.1). Rotational movements generally occur around a longitudinal (or vertical) axis except for movements of the clavicle and scapula. The rotational movements occurring around the longitudinal axis (internal rotation, external rotation, opposition, horizontal abduction, and horizontal adduction) are described in Table 76.1. Rotation of the scapula is described in terms of the direction of the inferior angle. Movement of the inferior angle of the scapula toward the midline is a medial (or downward) rotation, and movement of the inferior angle away from the midline is lateral (or upward) rotation. In the extremities, the anterior surface of the extremity is used as the reference area. Because the head, neck, trunk, and pelvis rotate about a midsagittal, longitudinal axis, rotation of these parts is designated as right or left.

A communications problem often exists in describing motion using the terms defined in Table 76.1. A body segment can be in a position such as flexion, but can be moving toward extension. This confusion is partially remedied by using the form of the word with the suffix, *-ion*, to indicate a static position and using the suffix, *-ing*, to denote a movement. Thus, an elbow can be in a position of 90° flex*ion* and also extend*ing*.

76.2.2 Factors Influencing ROM/EOM and ROM/EOM Measurements

The ROM and EOM available at a joint are determined by morphology and the soft tissues surrounding and crossing a joint, including the joint capsule, ligaments, tendons, and muscles. Other factors such as

TABLE 76.1 Movement Terms, Planes, Axes, and Descriptions of Movements

Movement term	Plane	Axis	Description of movement
Flexion	Sagittal	Frontal	Bending of a part such that the anterior surfaces approximate each other. However, flexion of the knee, ankle, foot, and toes refers to movement in the posterior direction.
Extension	Sagittal	Frontal	Opposite of flexion; involves straightening a body part.
Abduction	Frontal	Sagittal	Movement away from the midline of the body or body part; abduction of the wrist is sometimes called *radial deviation*.
Adduction	Frontal	Sagittal	Movement toward the midline of the body or body part; adduction of the wrist is sometimes called *ulnar deviation*.
Lateral flexion	Frontal	Sagittal	Term used to denote lateral movements of the head, neck, and trunk.
Internal (medial) rotation	Horizontal	Longitudinal	Turning movement of the anterior surface of a part towards the midline of the body; internal rotation of the forearm is referred to as *pronation*.
External (lateral) rotation	Horizontal	Longitudinal	Turning movement of the anterior surface of a part away from the midline of the body; external rotation of the forearm is referred to as *supination*.
Opposition	Multiple	Multiple	Movement of the tips of the thumb and little finger toward each other.
Horizontal abduction	Horizontal	Longitudinal	Movement of the arm in a posterior direction away from the midline of the body with the shoulder joint in 90° of either flexion or abduction.
Horizontal adduction	Horizontal	Longitudinal	Movement of the arm in an anterior direction toward the midline of the body with the shoulder joint in 90° of either flexion or abduction.
Tilt	Depends on joint	Depends on joint	Term used to describe certain movements of the scapula and pelvis. In the scapula, an anterior tilt occurs when the coracoid process moves in an anterior and downward direction while the inferior angle moves in a posterior and upward direction. A posterior tilt of the scapula is the opposite of an anterior tilt. In the pelvis, an anterior tilt is rotation of the anterior superior spines (ASISs) of the pelvis in an anterior and downward direction; a posterior tilt is movement of the ASISs in a posterior and upward direction. A lateral tilt of the pelvis occurs when the pelvis is not in level from side to side, but one ASIS is higher than the other one.
Gliding	Depends on joint	Depends on joint	Movements that occur when one articulating surface slides on the opposite surface.
Elevation	Frontal		A gliding movement of the scapula in an upward direction as in shrugging the shoulders.
Depression	Frontal		Movement of the scapula downward in a direction reverse of elevation.

age, gender, swelling, muscle mass development, body fat, passive insufficiency (change in the ROM/EOM available at one joint in a two-joint muscle complex caused by the position of the other joint), and time of day (diurnal effect) also affect the amount of motion available. Some persons, because of posture, genetics, body type, or movement habits, normally demonstrate hypermobile or hypomobile joints. Dominance has not been found to significantly affect available ROM. See discussion in Miller [1985]. The shapes of joint surfaces, which are designed to allow movement in particular directions, can become altered by disease, trauma, and posture, thereby increasing or decreasing the ROM/EOM. Additionally, the soft tissues crossing a joint can become short (contracted) or overstretched altering the ROM/EOM.

The type of movement, active or passive, also affects ROM/EOM. When measuring active ROM (AROM), the person voluntarily contracts muscles and moves the body part through the available motion. When measuring passive ROM (PROM), the examiner moves the body part through the ROM. PROM is usually slightly greater than AROM due to the extensibility of the tissues crossing and comprising the joint. AROM can be decreased because of restricted joint mobility, muscle weakness, pain, unwillingness to move, or inability to follow instructions. PROM is assessed to clinically determine the integrity of the joint and the extent of structural limitation.

76.2.3 Instrumented Systems Used to Measure ROM/EOM

The most common instrument used to measure joint ROM/EOM is a goniometer. The universal goniometer, shown in Figure 76.2a, is most widely used clinically. A variety of universal goniometers have been developed for specific applications. Two other types of goniometers are also shown in Figure 76.2.

Table 76.2 lists and compares several goniometric instruments used to measure ROM/EOM. Choice of the instrument used to measure ROM/EOM depends upon the degree of accuracy required, time available to the examiner, the measurement environment, the body segment being measured, and the equipment available.

Non-goniometric methods of joint measurement are available. Tape measures, radiographs, photography, cinematography, videotape, and various optoelectric movement-monitoring systems can also be used to measure or calculate the motion available at various joints. These methods are beyond the scope of this chapter.

76.2.4 Key Concepts in Goniometric Measurement

Numerous textbooks [Palmer and Epler, 1998; Clarkson, 2000; Reese and Bandy, 2002; Norkin and White, 2003] are available that describe precise procedures for goniometric measurements of each joint. Unfortunately, there is a lack of standardization among these references.

In general, the anatomical position of zero degrees (*preferred starting position*) is the desired starting position for all ROM/EOM measurements except rotation at the hip, shoulder, and forearm. The arms of the goniometer are usually aligned parallel and lateral to the long axis of the moving and the fixed-body segments in line with the appropriate landmarks. In the past, some authors contended that placement of the axis of the goniometer should be congruent with the joint axis for accurate measurement [Wiechec and Krusen, 1939; West, 1945]. However, the axis of rotation for joints changes as the body segment moves through its ROM; therefore, a goniometer cannot be placed in a position in line with the joint axis during movement. Robson [1966] described how variations in the placement of the goniometer's axis could affect the accuracy of ROM measurements. Miller [1985] suggested that the axis problem could be handled by ignoring the goniometer's axis and concentrating on the accurate alignment of the arms of the goniometer with the specified landmarks. Potentially some accuracy may be sacrificed, but the technique is simplified and theoretically more reproducible. When using devices such as the APM I, pictured in Figure 76.2c, the manufacturer's user's manual [Human Performance Measurement, Inc., 1998–2003] recommends placing the alignment guide of the device *along* the side of body segments vs. placing the device directly on body segments (as is frequently done when using the fluid goniometer pictured in Figure 76.2b). Placing
FIGURE 76.2 Three types of goniometric instruments used to measure range and extremes of motion are shown: (a) typical 180- and 360-degree universal goniometers of various sizes; (b) a fluid goniometer, which is activated by the effects of gravity; (c) an APM I digital electronic device that works similarly to a pendulum goniometer, but is not limited by gravity dependency.

the device along the body segment avoids minimizes procedural measurement noise caused by varying pressure on the soft tissue and interindividual differences in soft tissue structure (which can be relevant when establishing norms or comparing a given subject to norms). In any case, the subject's movement is observed during testing for unwanted motions that could result in inaccurate measurement. For example, a subject might attempt to increase forearm supination by laterally flexing the trunk.

76.2.5 Numerical Notation Systems

Three primary systems exist for expressing joint motion in terms of degrees. These are the *0–180 System*, the *180–0 System*, and the *360 System*. The 0–180 System is the most widely accepted system in medical applications and may be the easiest system to interpret. In the 0–180 System, the starting position for all movements is considered to be 0°, and movements proceed toward 180°. As the joint motion increases, the

TABLE 76.2 Comparison of Various Goniometers Commonly Used to Measure Joint Range and Extremes of Motion

Type of goniometer	Advantages/uses	Disadvantages/limitations
Universal goniometer A protractor-like device with one arm considered movable and the other arm stationary; protractor can have a 180 or 360° scale and is usually numbered in both directions; available in a range of sizes and styles to accommodate different joints (see Figure 76.2a)	Inexpensive; portable; familiar devices; size of the joint being measured determines size of the goniometer used; clear plastic goniometers have a line through the center of the arms to make alignment easier and more accurate; finger goniometers can be placed over the dorsal aspect of the joint being measured	Several goniometers of different sizes may be required, especially if digits are measured; full-circle models may be difficult to align when the subject is recumbent and axis alignment is inhibited by the protractor bumping the surface; the increments on the protractors may vary from 1, 2, or 5°; placement of the arms is a potential source of error
Fluid (or bubble) goniometer A device with a fluid-filled channel with a 360° scale that relies on the effects of gravity (see Figure 76.2b); dial turns allowing the goniometer to be "zeroed"; some models are strapped on and others must be held against the body part	Quick and easy to use because it is not usually aligned with bony landmarks; does not have to conform to body segments; useful for measuring neck and spinal movements; using a pair of fluid goniometers permits distinguishing regional spinal motion	More expensive than universal goniometers; using a pair of goniometers is awkward; useless for motions in the horizontal plane; error can be induced by slipping, skin movement, variations in amount of soft tissue owing to muscle contraction, swelling, or fat, and the examiner's hand pressure changing body segment contour; reliability may be sacrificed from lack of orientation to landmarks and difficulty with consistent realignment [Miller, 1985]
Pendulum goniometer A scaled, inclinometer-like device with a needle or pointer (usually weighted); some models are strapped on and others must be held against the body part (not shown)	Inexpensive; same advantages as for the fluid goniometer described above	Some models cannot be "zeroed"; useless for motions in the horizontal plane; same soft tissue error concerns as described above for the fluid goniometer
"Myrin" OB goniometer A fluid-filled, rotatable container consisting of compass needle that responds to the earth's magnetic field (to measure horizontal motion), a gravity-activated inclination needle (to measure frontal and sagittal motion), and a scale (not shown)	Can be strapped on the body part allowing the hands free to stabilize and move the body part; not necessary to align the goniometer with the joint axis; permits measurements in all three planes	Expensive and bulky compared with universal goniometer; not useful for measuring small joints of hand and foot; susceptible to magnetic fields [Clarkson, 2000]; subject to same soft tissue error concerns described above under fluid goniometer
Arthrodial protractor A large, flat, clear plastic protractor without arms that has a level on the straight edge (not shown)	Does not need to conform to body segments; most useful for measuring joint rotation and axioskeletal motion	Not useful for measuring smaller joints, especially those with lesser ROMs; usually scaled in large increments only

TABLE 76.2   Continued

Type of goniometer	Advantages/uses	Disadvantages/limitations
APM I		
Computerized goniometer with digital sensing and electronics; can either perform continuous monitoring or calculate individual ROM/EOM from a compound motion function (see Figure 76.2c)	Easy to use; provides rapid digital read-out; measures angles in *any* plane of motion (by using an "inertial" type of sensor gravity dependency is eliminated allowing for easier measurement of rotary movements, such as trunk rotation); one hand is free to stabilize and move body segments; particularly easy for measuring regional spinal movements	Expensive compared to most other instruments described; device must be rotated perpendicular to the direction of segment motion only; unit must stabilize prior to measurement; excessive delays in recording must be avoided; subject to the same soft tissue error concerns as described above under fluid goniometer, unless the device is aligned along (versus on) the body segment
Electrogoniometer		
Arms of a goniometer are attached to a potentiometer and are strapped to the proximal and distal body parts; movement from the device causes resistance in the potentiometer, which measures the ROM (not shown)	More useful for dynamic ROM, especially for determining kinematic variables during activities such as gait; provides immediate data; some electrogoniometers permit measurement in one, two, or three dimensions	Aligning and attaching the device is time-consuming and not amenable to all body segments; device and equipment needed to use it are moderately expensive; essentially laboratory equipment; less accurate for measurement of absolute limb position; device itself is cumbersome and may alter the movement being studied

numbers on the goniometric scale increase. In the 180–0 System, movements toward flexion approach 0° and movements toward extension approach 180°. Different rules are used for the other planes of motion. The 360 System is similar to the 180–0 System, which movements are frequently performed from a starting position of 180°. Movements of extension or adduction, which go beyond the neutral position, approach 360°. Joint motion can be reported in tables, charts, graphs, or pictures. In the 0–180 System, the starting and ending ranges are recorded separately, as 0–130°. If a joint cannot be started in the 0° position, the actual starting position is recorded, as 10–130°.

76.3   Strength

Muscle strength implies the force or torque production capacity of muscles. However, to measure strength, the term must be operationally defined. One definition modified from Clarkson [2000] states that muscular strength is the maximal amount of torque or force that a muscle or muscle groups can voluntarily exert in one maximal effort, when type of muscle contraction, limb velocity, and joint angle(s) are specified.

76.3.1   Strength Testing and Muscle Terminology

Physiologically, skeletal muscle strength is the ability of muscle fibers to generate maximal tension for a brief time interval. A muscle's ability to generate maximal tension and to sustain tension for differing time intervals is dependent on the muscle's cross-sectional area (the larger the cross-sectional area, the greater the strength), geometry (including the muscle fiber arrangement, length, moment arm, and angle of pennation), and physiology. Characteristics of muscle fibers have been classified based on twitch tension and fatigability. Different fiber types have different metabolic traits. Different types of muscle fibers are differentially stressed depending on the intensity and duration of the contraction. Ideally, strength tests should measure the ability of the muscle to develop tension rapidly and to sustain the tension for brief

time intervals. In order to truly measure muscle tension, a measurement device must be directly attached to the muscle or tendon. Whereas this direct procedure has been performed [Komi, 1990], it is hardly useful as a routine clinical measure. Indirect measures are used to estimate the strength of muscle groups performing a given function, such as elbow flexion.

Muscles work together in groups and may be classified according to the major role of the group in producing movement. The *prime mover*, or *agonist*, is a muscle or muscle group that makes the major contribution to movement at a joint. The *antagonist* is a muscle or muscle group that has an opposite action to the prime mover(s). The antagonist relaxes as the agonist moves the body part through the ROM. *Synergists* are accessory muscles that contract and work with the agonist to produce the desired movement. Synergists may work by stabilizing proximal joints, preventing unwanted movement, and joining with the prime mover to produce a movement that one muscle group acting alone could not produce.

A number of terms and concepts are important toward understanding the nature and scope of strength capacity testing. Several of these terms are defined below; however, there are no universally accepted definitions for these terms.

Dynamic contraction — the output of muscles moving body segments [Kroemer, 1991].

Isometric — tension develops in a muscle, but the muscle length does not change and no movement occurs.

Static — same as isometric.

Isotonic — a muscle develops constant tension against a load or resistance. Kroemer [1991] suggests the term, *isoforce*, more aptly describes this condition.

Concentric — a contraction in which a muscle develops internal force that exceeds the external force of resistance, the muscle shortens, and movement is produced [Gowitzke et al., 1980].

Eccentric — a contraction in which a muscle lengthens while continuing to maintain tension [Gowitzke et al., 1980].

Isokinetic — a condition where the angular velocity is held constant. Kroemer [1991] prefers the term, *isovelocity*, to describe this type of muscle exertion.

Isoinertial — a static or dynamic muscle contraction where the external load is held constant [Kroemer, 1983].

76.3.2 Factors Influencing Muscle Strength and Strength Measurement

In addition to the anatomical and physiological factors affecting strength, other factors must be considered when strength testing. The ability of a muscle to develop tension depends on the type of muscle contraction. Per unit of muscle, the greatest tension can be generated eccentrically, less can be developed isometrically, and the least can be generated concentrically. These differences in tension-generating capacity are so great that the type of contraction being strength-tested requires specification.

Additionally, strength is partially determined by the ability of the nervous system to cause more motor units to fire synchronously. As one trains, practices an activity, or learns test expectations, strength can increase. Therefore, strength is affected by previous training and testing. This is an important consideration in standardizing testing and in retesting.

A muscle's attachments define the angle of pull of the tendon on the bone and thereby the mechanical leverage at the joint center. Each muscle has a moment arm length, which is the length of a line normal to the muscle passing through the joint center. This moment arm length changes with the joint angle, which changes the muscle's tension output. Optimal tension is developed when a muscle is pulling at a 90° angle to the bony segment.

Changes in muscle length alter the force-generating capacity of muscle. This is called the *length–tension relationship*. *Active* tension decreases when a muscle is either lengthened or shortened relative to its resting length. However, applying a precontraction stretch, or slightly lengthening a muscle and the series elastic component (connective tissue), prior to a contraction causes a greater amount of *total* tension to

be developed [Soderberg, 1992]. Of course, excessive lengthening would reduce the tension-generating capacity.

A number of muscles cross over more than one joint. The length of these muscles may be inadequate to permit complete ROM of all joints involved. When a multijoint muscle simultaneously shortens at all joints it crosses, further effective tension development is prevented. This phenomena is called *active insufficiency*. For example, when the hamstrings are tested as knee flexors with the hip extended, less tension can be developed than when the hamstrings are tested with the hip flexed. Therefore, when testing the strength of multijoint muscles, the position of all involved joints must be considered.

The *load–velocity relationship* is also important in testing muscle strength. A load–velocity curve can be generated by plotting the velocity of motion of the muscle lever arm against the external load. With concentric muscle contractions, the least tension is developed at the highest velocity of movement and vice versa. When the external load equals the maximal force that the muscle can exert, the velocity of shortening reaches zero and the muscle contracts isometrically. When the load is increased further, the muscle lengthens eccentrically. During eccentric contractions, the highest tension can be achieved at the highest velocity of movement [Komi, 1973].

The force generated by a muscle is proportional to the contraction time. The longer the contraction time, the greater the force development up to the point of maximum tension. Slower contraction leads to greater force production because more time is allowed for the tension produced in contractile elements to be transferred through the noncontractile components to the tendon. This is the *force–time relationship*. Tension in the tendon will reach the maximum tension developed by the contractile tissues only if the active contraction process is of adequate (even up to 300 msec) duration [Sukop and Nelson, 1974].

Subject effort or motivation, gender, age, fatigue, time of day, temperature, occupation, and dominance can also affect force or torque production capacity. Important additional considerations may be changes in muscle function as a result of pain, overstretching, immobilization, trauma, paralytic disorders, neurologic conditions, and muscle transfers.

76.3.3 Grading Systems and Parameters Measured

Clinically, the two most frequently used methods of strength testing are actually noninstrumented tests: the manual muscle test (MMT) and the functional muscle test (see Amundsen [1990] for more information on functional muscle tests). In each of these cases interval scaled grading criteria are operationally defined. However, a distinct advantage of using instruments to measure strength is that quantifiable units can be obtained.

Deciding whether to measure force (a translational quantity) or torque (a rotational quantity) is an important issue in testing strength. Even when the functional units of interest produce rotational motion, force measurement at some point along the moment arm is common. This is due to the evolution from manual muscle tests to the use of objective measurements where a force sensor replaces the human examiner sense of force resisted or generated. If d is the distance from the point of rotation to the point of force measurement and the force vector is tangent to the arc of motion, then

$$T = Fd \tag{76.1}$$

Therefore, when force are measured, unless the measurement devices are applied at the same anatomical position for each test, force measurements can differ substantially even though the torque production capacity about the selected DOF is the same. Torque can be measured directly if the strength-testing device has an axis of rotation that can be aligned with the anatomical axis of rotation and a torque sensor is used, as in many isokinetic test devices. When this is not the case, the moment arm can be measured and torque calculated. Thus, for neuromuscular systems producing rotational motion, torque measures make the most sense and are preferred. The use of force measurements is the result of clinical traditional and these measures can be easily converted to torque units using knowledge of the applicable moment arm. Force measures are appropriate in whole-body exertions, such as lifting, where the motion

is fundamentally translational. Another issue is whether to measure and record peak or averaged values. However, if strength is defined as maximum torque production capacity, peak values are implied.

In addition to single numerical values, some strength measurement systems display and print force or torque (vs. time) curves, angle-torque curves, and graphs. Computerized systems frequently compare the "involved" with the "uninvolved" extremity calculating "percent deficits." As strength is considered proportional to body weight (perhaps erroneously, see Delitto [1990]), force and torque measurements are frequently reported as a peak torque-to-body-weight ratio. This is seemingly to facilitate use of normative data where present, as the normalization results in a reduction in the variance of the data distribution.

76.3.4 Methods and Instruments Used to Measure Muscle Strength

There are two broad categories of testing force or torque production capacity: one category consists of measuring the capacity of defined, local muscle groups (e.g., elbow flexors); the second category of tests consists of measuring several muscle groups on a whole–body basis performing a higher-level task (e.g., lifting). The purpose of the test, required level of sensitivity, and expense are primary factors in selecting the method of strength testing. No single method has emerged as being clearly superior or more widely applicable. Like screwdrivers, different types and different sizes are needed depending upon job demands.

Many of the instrumented strength-testing techniques, which are becoming more standardized clinically and which are almost exclusively used in engineering applications, are based on the concepts and methods of MMT. Although not used for performance capacity tests, because of the ease, practicality, and speed of manual testing, it is still considered a useful tool, especially diagnostically to localize lesions and confirm weakness. Several MMT grading systems prevail. These differ in the actual test positions and premises upon which muscle grading is based. For example, the approach promoted by Kendall et al. [2005] tests a specific muscle (e.g., brachioradialis) rather than a motion. The Daniels and Worthingham method [Hislop and Montgomery, 2002] tests motions (e.g., elbow flexion) that involve all the agonists and synergists used to perform the movement. The latter is considered more functional and less time-consuming, but less specific. The reader is advised to consult these references directly for more information about MMT methods. Further discussion of noninstrumented tests is beyond the scope of this chapter.

An argument can be made for using isometric strength testing because the force or torque reflects actual muscle tension as the position of the body part is held constant and the muscle mechanics do not change. Additionally, good stabilization is easier to achieve, and muscle actions can be better isolated. However, some clinicians prefer dynamic tests, perceiving them as more reflective of function. An unfortunate fact is that neither static nor dynamic strength measurements alone can reveal whether strength is adequate for functional activities. However, strength measurements can be used with models and engineering analyses for such assessments.

Selected instrumented methods of measuring force or torque production capacity are listed and compared in Table 76.3. Table 76.3 is by no means comprehensive. More in-depth review and comparisons of various methods can be found in Amundsen [1990] and Mayhew and Rothstein [1985]. Figure 76.3 illustrates three common instruments used to measure strength.

76.3.5 Key Concepts in Measuring Strength

Because of the number of factors influencing strength and strength testing (discussed in Section 76.3.2), one can become discouraged rather than challenged when faced with the need to measure strength. Optimally, strength testing would be based on the "worst-case" functional performance demands required by an individual in his or her daily life. "Worst-case" testing requires knowing the performance demands of tasks including the positions required, types of muscle contractions, and so on.

In the absence of such data, current strategy is to choose the instruments and techniques that maximally stress the system under a set of representative conditions that either (a) seem logical based on knowledge of the task, or (b) have been reported as appropriate and reliable for the population of interest. An attempt

TABLE 76.3 Comparison of Various Instrumented Methods Used to Measure Muscle Strength

Instrument/method	Advantages/uses	Disadvantages/limitations
Repetition maximum Amount of weight a subject can lift a given number of times and no more; one determines either a one-repetition maximum (1-RM) or a ten-repetition maximum (10-RM). A 1-RM is the maximum amount of weight a subject can lift once; a 10-RM is the amount of weight a subject can lift 10 times; a particular protocol to determine RMs is defined [DeLorme and Watkins, 1948]; measures dynamic strength in terms of weight (pounds or kilograms) lifted	Requires minimal equipment (weights); inexpensive and easy to administer; frequently used informally to assess progress in strength training	Uses serial testing of adding weights that may invalidate subsequent testing; no control for speed of contraction or positioning; minimal information available on the reliability and validity of this method
Hand-held dynamometer Device held in the examiner's hand used to test strength; devices use either hydraulics, strain gauges (load–cells), or spring systems (see Figure 76.3a); used with a "break test" (the examiner exerts a force against the body segment to be tested until the part gives way) or a "make test" (the examiner applies a constant force while the subject exerts a maximum force against it); "make tests" are frequently preferred for use with hand-held dynamometers [Smidt, 1984; Bohannon, 1990] measures force; unclear whether test measures isometric or eccentric force (this may depend on whether a "make test" or a "break test" is used)	Similar to manual muscle testing (MMT) in test positions and sites for load application; increased objectivity over MMT; portable; easy to administer; relatively inexpensive; commercially available from several suppliers; adaptable for a variety of test sites; provide immediate output; spring and hydraulic systems are nonelectrical; load–cell based systems provide more precise digital measurements	Stabilization of the device and body segment can be difficult; results can be affected by the examiner's strength; limited usefulness with large muscle groups; spring-based systems fatigue over time becoming inaccurate; range and sensitivity of the systems vary; shape of the unit grasped by the examiner and shape of the end-piece vary in comfort, and therefore the force a subject or examiner is willing to exert; more valuable for testing subjects with weakness than for less involved or healthy subjects due to range limits within the device (see discussion in Bohannon [1990])
Cable tensiometer One end of a cable is attached to an immovable object and the other end is attached to a limb segment; the tensiometer is placed between the sites of fixation; as the cable is pulled, it presses on the tensiometer's riser which is connected to a gauge (see discussion in Mayhew and Rothstein [1985]); measures isometric force	Mostly used in research settings; evidence presented on reliability when used with normal subjects [Clarke, 1952; Clarke et al., 1954]; relatively inexpensive	Requires special equipment for testing; testing is time-consuming and some tests require two examiners; unfamiliar to most clinicians; not readily available; less sensitive at low force levels
Strain gauge Electroconductive material applied to metal rings or rods; a load applied to the ring or bar deforms the metal and a gauge; deformation of the gauge changes the electrical resistance of the gauge causing a voltage variation; this change can be converted and displayed using a strip chart recorder or digital display; measures isometric force	Mostly used in research settings; increased sensitivity for testing strong and weak muscles	Strain gauges require frequent calibration and are sensitive to temperature variations; to be accurate the body part must pull or push against the gauge in the same line that the calibration weights were applied; unfamiliar to most clinicians; not commercially available; difficult to interface the device comfortably with the subject

Continued

TABLE 76.3 Continued

Instrument/method	Advantages/uses	Disadvantages/limitations
Isokinetic dynamometer		
Constant velocity loading device; several models marketed by a number of different companies; most consist of a movable lever arm controlled by an electronic servomotor that can be preset for selected angular velocities usually between 0 and 500° per second; when the subject attempts to accelerate beyond the pre-set machine speed, the machine resists the movement; a load cell measures the torque needed to prevent body part acceleration beyond the selected speed; computers provide digital displays and printouts (see typical device in Figure 76.3b); measures isokinetic-concentric (and in some cases, isokinetic-eccentric) and isometric strength; provides torque (or occasionally force) data; debate exists about whether data are ratio-scaled or not; accounting for the weight of the segment permits ratio-scaling [Winter et al., 1981]	Permits dynamic testing of most major body segments; especially useful for stronger movements; most devices provide good stabilization; measures reciprocal muscle contractions; widespread clinical acceptance; also records angular data, work, power, and endurance-related measures; provides a number of different reporting options; also used as exercises devices	Devices are large and expensive; need calibration with external weights or are "self-calibrating"; signal damping and "windowing" may affect data obtained; angle-specific measurements may not be accurate if a damp is used because torque readings do not relate to the goniometric measurements; joints must be aligned with the mechanical axis of the machine; inferences about muscle function in daily activities from isokinetic test results have not been validated; data obtained between different brands are not interchangeable; adequate stabilization may be difficult to achieve for some movements; may not usable with especially tall or short persons
Hand dynamometer		
Instruments to measure gripping or pinching strength specifically for the hand; usually use a spring scale or strain-gauge system (see typical grip strength testing device in Figure 76.3c); measures isometric force	Readily available from several suppliers; easy to use; relatively inexpensive; widespread use; some normative data available	Only useful for the hand; different brands not interchangeable; normative data only useful when reported for the same instrument and when measurements are taken with the same body position and instrument setting; must be recalibrated frequently

is made to standardize the testing in terms of contraction type, test administration instructions, feedback, warm-up, number of trials, time of day, examiner, duration of contraction (usually 4 to 6 sec), method and location of application of force, testing order, environmental distractions, subject posture and position of testing, degree of stabilization, and rest intervals between exertions (usually 30 sec to 2 min) [Chaffin, 1975; Smidt and Rogers, 1982]. In addition, the subject must be observed for muscle group substitutions and "trick" movements.

76.4   Speed of Movement

Speed of movement refers to the rate of movement of the body or body segments. The maximum movement speed that can be achieved represents another unique performance capacity of an identified system that is responsible for producing motion. Everyday living, work, and sport tasks are commonly described in terms of the speed requirements (e.g., repetitions per minute or per hour). For physical tasks, such descriptions translate to translational motion speeds (e.g., as in lifting) as well as rotational motion speeds (i.e., movement about a DOF of the joint systems involved). Thus, there is important motivation to characterize this capacity.
FIGURE 76.3 Three types of instrumented strength testing devices are shown (a) a representative example of a typical hand-held dynamometer; (b) an example of an isokinetic strength testing device; and (c) a hand dynamometer used to measure grip strength.

76.4.1 Speed of Movement Terminology

Speed of movement must be differentiated from *speed of contraction*. Speed of contraction refers to how fast a muscle generates tension. Two body parts may be moving through an arc with the same speed of movement; however, if one part has a greater mass, its muscles must develop more tension per unit of time to move the heavier body part at the same speed as the lighter body part.

Speed, velocity, and acceleration also can be distinguished. The terms velocity and speed are often used interchangeably; however, the two quantities are frequently not identical. Velocity means the rate of motion *in a particular direction*. *Acceleration* results from a change in velocity over time. General velocity and acceleration measurements are beyond the intent of this chapter. Reaction speed and response speed are other related variables also not considered.

76.4.2 Factors Influencing Speed of Movement and Speed of Movement Measurements

Muscles with larger moment arms, longer muscle fibers, and less pennation tend to be capable of generating greater speed. Many of the same factors influencing strength, discussed earlier, such as muscle length, fatigue, and temperature affect the muscle's contractile rate. The load–velocity relationship is especially important when testing speed of movement. In addition to these and other physiological factors, speed can be reduced by factors such as friction, air resistance, gravity, unnecessary movements, and inertia [Jensen and Fisher, 1979].

76.4.3 Parameters Measured

Speed of movement can be measured as a linear quantity or as an angular quantity. Typically, if the whole body is moving linearly in space as in walking or running, a point such as the center of gravity is picked, and translational motion is measured. Also, when an identified point on a body segment (e.g., the tip of the index finger) is moved in space, translational movement is observed, and motion is measured in translational terms. If the speed of a rotational motion system (e.g., elbow flexors) is being measured, then the angular quantity is determined. As the focus here is on measuring isolated neuromuscular performance capacities, the angular metric is emphasized. Angular speed of a body segment is obtained by: angular speed = change in angular position/change in time,

$$\partial = \frac{\triangle\phi}{\triangle t} \tag{76.2}$$

Thus, speed of movement may be expressed in revolutions, degrees, or radians per unit of time, such as degrees per second (deg/sec).

Another type of speed measure applies to well-defined (over fixed angle or distance) cyclic motions. Here repetitions per unit time or cycles per unit time measures are sometimes used. However, in almost every one of these situations, speed can be expressed in degrees per second or meters per second. The latter units are preferred because they allow easier comparison of speeds across a variety of tasks. The only occasion when this is difficult is when translation motion is not in a simple straight line, such as when a person is performing a complex assembly task with multiple subtasks.

The issue of whether to express speed as maximum, averaged, or instantaneous values must also be decided, based on which measure is a more useful indicator of the performance being measured. In addition to numerical reporting of speed data, time-history graphs of speed may be helpful in comparing some types of performance.

76.4.4 Instruments Used to Measure Speed of Movement

When movement time is greater than a few seconds and the distance is known, speed can be measured with a stopwatch or with switch plates, such as the time elapsed in moving between two points or over a specified angle. With rapid angular joint movements, switch plates or electrogoniometers with electronic timing devices are required. Speeds can also be computed from the distance or angle and time data available from cinematography, optoelectric movement monitoring systems, and videotape systems. Some dynamic strength testing devices involve presetting a load and measuring the speed of movement.

In addition, accelerometers can be used to measure acceleration directly, and speed can be derived through integration. However, piezoelectric models have no steady-state response and may not be useful for slower movements. Single accelerometers are used to measure linear motion. Simple rotary motions require two accelerometers. Triaxial accelerometers are commercially available that contain three pre-mounted accelerometers perpendicular to each other. Multiple accelerometer outputs require appropriate processing to resolve the vector component corresponding to the desired speed. Accelerometers are most appropriately used to measure acceleration when they are mounted on rigid materials. Accelerometers

have the advantage of continuously and directly measuring acceleration in an immediately usable form. They can also be very accurate if well-mounted. Because they require soft tissue fixation and cabling or telemetry, they may alter performance and further error may be induced by relative motion of the device and tissues. The systems are moderately expensive (see discussion of accelerometers in Robertson and Sprigings [1987]).

76.4.5 Key Concepts in Speed of Movement Measurement

As discussed, maximum speed is determined when there is little stress on torque production resources. As resistance increases, speed will decrease. Therefore, the load must be considered and specified when testing speed. Because speed of movement data are calculated from displacement and temporal data, a key issue is minimizing error that might result from collecting this information. Error can result from inaccurate identification of anatomical landmarks, improper calibration, perspective error, instrument synchronization error, resolution, digitization error, or vibration. The sampling rate of some of the measurement systems may become an issue when faster movements are being analyzed. In addition, the dynamic characteristics of signal conditioning systems should be reported.

76.5 Endurance

Endurance is the ability of a system to sustain an activity for a prolonged time (static endurance) or to perform repeatedly (dynamic endurance). Endurance can apply to the body as a whole, a particular body system, or to specific neuromuscular functional units. High levels of endurance imply that a given level of performance can be continued for a long time period.

76.5.1 Endurance Terminology

General endurance of the body as a whole is traditionally considered cardiovascular endurance, or aerobic capacity. Cardiovascular endurance is most frequently viewed in terms of $V_{O2\,max}$. This chapter considers only endurance of neuromuscular systems. Although many central and peripheral anatomic sites and physiologic processes contribute to a loss of endurance, endurance of neuromuscular functional units is also referred to as *muscular endurance*.

Absolute muscle endurance is defined as the amount of time that a neuromuscular system can continue to accomplish a specified task against a constant resistance (load and rate) without relating the resistance to the muscle's strength. Absolute muscle endurance and strength are highly correlated. Conversely, strength and *relative muscle endurance* are inversely related. That is, when resistance is adjusted to the person's strength, a weaker person tends to demonstrate more endurance than a stronger person. Furthermore, the same relationships between absolute and relative endurance and strength are correlated by type of contraction; in other words, there is a strong positive correlation between isotonic strength and *absolute* isotonic endurance and vice versa for strength and *relative* isotonic endurance. The same types of relationships exist for isometric strength and isometric endurance [Jensen and Fisher, 1979].

76.5.2 Factors Influencing Neuromuscular Endurance and Measurement of Endurance

Specific muscle fiber types, namely fast-twitch fatigue-resistant fibers (FR), generate intermediate levels of tension and are resistant to short-term fatigue (a duration of about 2 min or intermittent stimulation). Slow-twitch fibers (S) generate low levels of tension slowly, and are highly resistant to fatigue. Muscle contractions longer than 10 sec, but less than 2 min, will reflect local muscle endurance [Åstrand et al., 2003]. For durations longer than 2 min, the S fibers will be most stressed. A submaximal isometric contraction to the point of voluntary fatigue will primarily stress the FR and S fibers [Thorstensson

and Karlsson, 1976]. Repetitive, submaximal, dynamic contractions continued for about 2 to 6 min will measure the capacity of FR and S fibers. Strength testing requires short duration and maximal contractions; therefore, to differentiate strength and endurance testing, the duration and intensity of the contractions must be considered.

Because strength affects endurance, all of the factors discussed previously as influencing strength, also influence endurance. In addition to muscle physiology and muscle strength, endurance is dependent upon the extensiveness of the muscle's capillary beds, the involved neuromuscular mechanisms, contraction force, load, and the rate at which the activity is performed.

Endurance time, or the time for muscles to reach fatigue, is a function of the contraction force or load [von Rohmert, 1960]. As the load (or torque required) increases, endurance time decreases. Also, as speed increases, particularly with activities involving concentric muscle contractions, endurance decreases.

76.5.3 Parameters Measured

Endurance is *how long* an activity can be performed at the required load and rate level. Thus, the basic unit of measure is time. Time is the only measure of how long it takes to complete a task. If the focus is on a given variable (e.g., strength, speed, or endurance), it is necessary to either control or measure the others. When the focus is endurance, the other factors of force or torque, speed, and joint angle, can be described as conditions under which endurance is measured. Because of the interactions of endurance and load or endurance and time (as e.g.), a number of *endurance-related* measures have evolved. These endurance-related measures have clouded endurance testing.

One endurance-related measure uses either the number of repetitions that can be performed at 20, 25, or 50% of maximum peak torque or force. The units used to reflect endurance in this case are number of repetitions at a specified torque or force level. One difficulty with this definition has been described previously, that is, the issue of relative vs. absolute muscle endurance. Rothstein and Rose [1982] demonstrated that elderly subjects with selected muscle fiber type atrophy were able to maintain 50% of their peak torque longer than young subjects. However, if a high force level is required to perform the task, then the younger subject would have more endurance in that particular activity [Rothstein, 1982]. Another difficulty is that the "repetition method" can be used only for dynamic activities. If isometric activities are involved, then the time an activity can be sustained at a specified force or torque level is measured. Why have different units of endurance? Time could be used in both cases. Furthermore, the issue of absolute vs. relative muscle endurance becomes irrelevant if the demands of the task are measured.

Yet another method used to reflect endurance is to calculate an endurance-related work ratio. Many isokinetic testing devices, such as the one shown in Figure 76.3b, will calculate work (integrate force or torque over displacement). In this case, the total amount of work performed in the first five repetitions is compared with the total amount of work performed in the last five repetitions of a series of repetitions (usually 25 or more). Work degradation *reflects* endurance and is reported as percentage. An additional limitation of using these endurance ratios is that work cannot be determined in isometric test protocols. Mechanically there is no movement, and no work is being performed.

Overall, the greatest limitation with most *endurance-related* approaches is that the measures obtained cannot be used to perform task-related assessments. In a workplace assessment, for example, one can determine how long a specific task (defined by the conditions of load, range, and speed) needs to be performed. Endurance-related metrics can be used to reflect changes over time in a subject's available endurance capacity; however, endurance-related metrics cannot be compared to the demands of the task. Task demands are measured in time or repetitions (e.g., 10 h) with a given rate (e.g., 1/0.5 h) from which total time (e.g., 5 h) can be calculated. A true endurance measure (vs. an endurance-related measure) can serve both purposes. Time reflects changes in endurance as the result of disease, disuse, training, or rehabilitation and also can be linked to task demands.

76.5.4 Methods and Instruments Used to Measure Neuromuscular Endurance

Selection of the method or instrument used to measure endurance depends on the purpose of the measurement and whether endurance or endurance-related measures will be obtained. As in strength testing, endurance tests can involve simple, low-level tasks or whole-body, higher-level activities. The simplest method of measuring endurance is to define a task in terms of performance criteria and then time the performance with a stopwatch. A subject is given a load and a posture and asked to hold it "as long as possible" or to move from one point to another point at a specific rate of movement for "as long as possible."

An example of a static endurance test is the Sorensen test used to measure endurance of the trunk extensors [Biering-Sorensen, 1984]. This test measures how long a person can sustain his or her torso in a suspended prone posture. The individual is not asked to perform a maximal voluntary contraction, but an indirect calculation of load is possible [Smidt and Blanpied, 1987].

An example of a dynamic endurance test is either a standardized or nonstandardized, dynamic isoinertial (see description in Section 76.3.1 on strength testing) repetition test. In other words, the subject is asked to lift a known load with a specified body part or parts until defined conditions can no longer be met. Conditions such as acceleration, distance, method of performance, or speed may or may not be controlled. The more standardized of these tests, particularly those that involve lifting capacity, are reported and projections about performance capacity over time are estimated [Snook, 1978]. Ergometers and some of the isokinetic dynamometers discussed earlier measure work, and several can calculate endurance-related ratios. These devices could be adapted to measure endurance in time units.

76.5.5 Key Concepts in Measuring Muscle Endurance

Of the four variables of human performance discussed in this chapter, endurance testing is the least developed and standardized. Except for test duration and rest intervals, attention to the same guidelines as described for strength testing is currently recommended.

76.6 Reliability, Validity, and Limitations in Testing

Space does not permit a complete review of these important topics. However, a few key comments are in order. First, it is important to note that reliability and validity are not inherent qualities of instruments, but exist in the measurements obtained only within the context in which they are tested. Second, reliability and validity are not either present or absent but are present or absent along a continuum. Third, traditional quantitative measures of reliability might indicate how much reliability a given measurement method demonstrates, but not how much reliability is actually needed. Fourth, technology has advanced to the extent that it is generally possible to measure physical variables such as time, force, torque, angles, and speed accurately, repeatably, and with high resolution. Finally, clinical generalizability of human performance capacity ultimately measures results from looking at the body of literature on reliability as a whole and not from single studies.

For these types of variables, results of reliability studies basically report that (1) if the instrumentation is good, and (2) if established, optimal procedures are carefully followed, then results of repeat testing will usually be in the range of about 5 to 20% of each other. This range of repeatability depends on (1) the particular variable being measured (i.e., repeated endurance measures will differ more than repeated measures of hinge joint EOM), and (2) the magnitude of the given performance capacity (i.e., errors are often in fixed amounts such as 3° for ROM; thus, 3° out of 180° is smaller percentage-wise than 3° out of 20°). One can usually determine an applicable working value (e.g., 5 or 20%) by careful review of the relevant reliability studies. Much of the difference obtained in test–retest is because of limitations in how well one can reasonably control procedures and the actual variability of the parameter being measured, even in the most ideal test subjects. Measurements should be used with these thoughts in mind. If a specific

application requires extreme repeatability, then a reliability study should be conducted under conditions that most closely match those in which the need arises. Reliability discussions specific to the some of the focal measures of this chapter are presented in Amundsen [1990], Hellebrandt et al. [1949], Mayhew and Rothstein [1985], and Miller [1985].

Measurements can be reliable, but useless, without validity. Most validity studies have compared the results of one instrument to another instrument or to known quantities. This is the classical type of validity testing, which is an effort to determine whether the measurement reflects the variable being measured. In the absence of a "gold standard" this type of testing is of limited value. In addition to traditional studies of the validity of measurements, the issue of the *validity of the inferences* based on the measurements is becoming increasingly important [Rothstein and Echternach, 1993]. That is, can the measurements be used to make inferences about human performance in real-life situations? Unfortunately, measurements that have not demonstrated more than content validity are frequently used as though they are predictive. The validity of the inferences made from human performance data needs to be rigorously addressed.

Specific measurement limitations were briefly addressed in Table 76.2 and Table 76.3 and in the written descriptions of various measurement techniques and instruments. Other limitations have more to do with interpreting the data. A general limitation is that performance variables are not fixed human attributes. Another limitation is that population data are limited, and available normative data are, unfortunately, frequently extrapolated to women, older persons, and so on [Chaffin et al., 1999]. Some normative data suggest the amount of resources, such as strength, ROM, speed of movement, and endurance, *required* for given activities; other data suggest the amount *available*. As previously mentioned, these are two different issues. Performance measurements may yield information about the current status of performance, but testing rarely indicates the *cause* or the nature of dysfunction. More definitive, diagnostic studies are used to answer these questions. While, considerable information exists with regard to measuring performance capacities of human systems, much less energy has been directed to understanding requirements of tasks. The link between functional performance in tasks and laboratory-acquired measurements is a critical question and a major limitation in interpreting test data. The ERM addresses several of these limitations by using a multidimensional, individualized, cause-and-effect model.

76.7 Performance Capacity Space Representations

In both the study and practice, performance of neuromuscular systems has been characterized along one or two dimensions of performance at a time. However, human subsystems function within a *multi-dimensional* performance space. ROM/EOM, strength, movement speed, and endurance capacities are not only interdependent, but may also vary uniquely within individuals. Multiple measurements are necessary to characterize a person's performance capacity space, and performance capacity is dependent on the task to be performed. Therefore, both the individual and the task must be considered when selecting measurement tools and procedures [Chaffin et al., 1999].

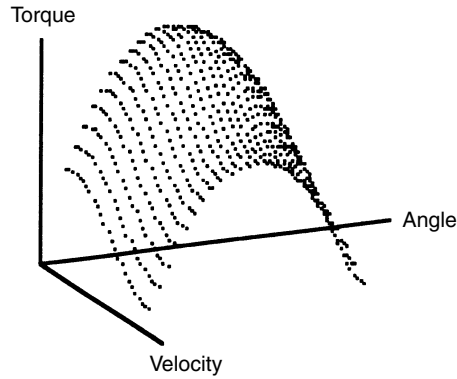
In many of the disciplines in which human performance is of interest, traditional thinking has often focused on single number measures of ROM, strength, speed, and so forth. More recent systems engineering approaches [Kondraske, 2005] emphasize consideration of the performance envelope of a given system and suggest ways to integrate single measurement points that define the limits of performance of a given system [Vasta and Kondraske, 1997]. Figure 76.4 illustrates a three-dimensional performance envelope derived from torque, angle, and velocity data for the knee extensor system. The additional dimension of endurance can be represented by displaying this envelope after performing an activity for different lengths of time. A higher-level, composite performance capacity, as is sometimes needed, could be derived by computing the volume enclosed by this envelope. Such representations also facilitate assessment of the given system in a specific task; that is, a task is defined as a point in this space that will either fall inside or outside the envelope.


FIGURE 76.4 An example of a torque–angle–velocity performance envelope for the knee extensor system. (From Vasta P.J. and Kondraske G.V. 1994. Technical Report 94-001R p. 11. University of Texas at Arlington, Human Performance Institute, Arlington, Texas. With permission.)

76.8 Conclusion

In conclusion, human movement is so essential that it demands interest and awe from the most casual observer to the most sophisticated scientists. The complexity of performance is truly inspiring. We are challenged to understand it. We want to reduce it to comprehensible units and then enhance it, reproduce it, restore it, and predict it. To do so, we must be able to define and quantify the variables. Hence, an array of instruments and methods has emerged to measure various aspects of human performance. To date, measurement of neuromuscular performance capacities along the dimensions of ROM/EOM, strength, speed of movement, and endurance represents a giant stride but only the "tip of the iceberg." Progress in developing reliable, accurate, and valid instruments and in understanding the factors influencing the measurements cannot be permitted to discourage us from the larger issues of applying the measurements toward a purpose. Yet, single measurements will not suffice; multiple measurements of different aspects of performance will be necessary to fully characterize human movement.

Defining Terms

Endurance: The amount of time a body or body segments can sustain a specified static or repetitive activity.

Extremes of motion (EOM): The end ranges of motion at a joint measured in degrees.

Muscle strength: The maximal amount of torque or force production capacity that a muscle or muscle groups can voluntarily exert in one maximal effort, when type of muscle contraction, movement velocity, and joint angle(s) are specified.

Neuromuscular functional units: Systems (that is, the combination of nerves, muscles, tendons, ligaments, and so on) responsible for producing basic movements.

Range of motion (ROM): The amount of movement that occurs at a joint, typically measured in degrees. ROM is usually measured by noting the extremes of motion, or as the difference between the extreme motion and the reference position.

Speed of movement: The rate of movement of the body or body segments.

Measurement of Sensory-Motor Control Performance Capacities: Tracking Tasks

Richard D. Jones
Christchurch Hospital

77.1 Introduction

The human nervous system is capable of simultaneous and integrated control of 100 to 150 mechanical degrees of freedom of movement in the body via tensions generated by about 700 muscles. In its widest context, movement is carried out by a sensory-motor system comprising multiple sensors (visual, auditory, proprioceptive), multiple actuators (muscles and skeletal system), and an intermediary processor which can be summarized as a multiple-input multiple-output nonlinear dynamic time-varying control system. This grand control system comprises a large number of interconnected processors and sub-controllers

at various sites in the central nervous system of which the more important are the cerebral cortex, thalamus, basal ganglia, cerebellum, and spinal cord. It is capable of responding with remarkable accuracy, speed (when necessary), appropriateness, versatility, and adaptability to a wide spectrum of continuous and discrete stimuli and conditions. Certainly, by contrast, it is orders of magnitude more complex and sophisticated than the most advanced robotic systems currently available — although the latter also have what are often highly desirable attributes such as precision and repeatability and a much greater immunity from factors such as fatigue, distraction, and lack of motivation!

This chapter addresses the control function. First, it introduces several important concepts relating to **sensory-motor control**, accuracy of movement, and **performance resources**/capacities. Second, it provides an overview of apparatuses and methods for the *measurement* and *analysis* of complex sensory-motor performance. The overview focuses on measurement of sensory-motor control performance capacities of the *upper-limbs* and by means of *tracking tasks.*

77.2 Basic Principles

77.2.1 Sensory-Motor Control and Accuracy of Movement

From the perspective of Kondraske's [Kondraske, 1995a,b] *elemental resource model* of human performance, sensory-motor control is the function of the overall sensory-motor control system. This system can be considered as a hierarchy of multiple interconnected sensory-motor controllers cited in the *central processing and skills ("software") domains* (cf. environmental interface domain, comprising sensors and actuators, and life sustaining domains) of the elemental resource model. These controllers range from low-level elemental level controllers for control of movement around single joints, through intermediate-level controllers needed to generate integrated movements of an entire limb and involving multiple joints and degrees of freedom, and high-level controllers and processors to enable coordinated synergistic multi-limb movements and the carrying out of *central executive* functions concerned with allocation and switching of resources for execution of multiple tasks simultaneously.

Each of these controllers is considered to possess limited *performance resources (PRs)* — or *performance capacities* — necessary to carry out their control functions. PRs are characterized by dimensions of performance, which for controllers are *accuracy of movement* (including steadiness and stability) and *speed of movement.* Accuracy is the most important of these and can be divided into four major classes:

1. Spatial accuracy — Required by tasks which are *self-paced* and for which time taken is of secondary or minimal importance and includes tracing (e.g., map-tracking), walking, reaching, and, in fact, most activities of daily living. Limitation in speed PRs should have no influence on this class of accuracy.
2. Spatial accuracy with time constraints — Identical to "spatial accuracy" except that, in addition to accuracy, speed of execution of task is also of importance. Because maximal performance capacities for accuracy and speed of movement cannot, in general, be realized simultaneously, the carrying out of such tasks must necessarily involve speed-accuracy tradeoffs [Fitts, 1954; Fitts and Posner, 1967]. The extent to which accuracy is sacrificed for increased speed of execution, or vice versa, is dependent on the perceived relative importance of accuracy and speed.
3. Temporal accuracy — Required by tasks which place minimal demands on positional accuracy and includes single and multi-finger tapping and foot tapping.
4. **Spatiotemporal accuracy** — Required by tasks which place considerable demand on attainment of simultaneous spatial and temporal accuracy. This includes *paced* positional tasks such as tracking, driving a vehicle, ball games and sports, and video games. It should be stressed, however, that most of the above self-paced tasks also involve a considerable interrelationship between space and time.

Tracking tasks have become well established as being able to provide one of the most accurate and flexible means for laboratory-based measurement of spatiotemporal accuracy and, thus, of the **performance capacity** of sensory-motor control or sensory-motor coordination. In addition, they provide an unsurpassed framework for studies of the underlying control mechanisms of motor function [e.g., Lynn et al., 1979; Cooper et al., 1989; Neilson et al., 1993, 1995, 1998] — the potential for which was recognized as early as 1943 as seen in writings by Craik [1966]. They have achieved this status through their (a) ability to maximally stress the accuracy **dimension of performance** and, hence, the corresponding control PR, (b) the continuous nature and wide range of type and characteristics of input target signals they permit, (c) facility for a wide range of 1-D and 2-D *sensors* for measuring a subject's motor output, and (d) measure of continuous performance (cf. reaction time tests).

From this perspective, it will be of little surprise to find that tracking tasks are the primary thrust of this chapter.

77.2.2 The Influence of Lower-Level Performance Resources on Higher-Level Control Performance Resources

By their very nature, tasks which enable one to measure spatiotemporal accuracy are complex or higher-level sensory-motor tasks. These place demands on a large number of lower-level PRs such as visual acuity, dynamic visual perception, range of movement, strength, simple reaction times, acceleration/deacceleration, static steadiness, dynamic steadiness, prediction, memory, open-loop movements, concentration span, attention switching, that is, central executive function or supervisory attentional system (multitask abilities), utilization of preview, and learning.

It is, therefore, important to ask: If there are so many PRs involved in tracking, can tracking performance provide an accurate estimate of sensory-motor control performance capacities? Or, if differences are seen in tracking performance between subjects, do these necessarily indicate comparable differences in control performance capacities? Yes, they can, but only if the control resource is the *only* resource being maximally stressed during the **tracking task**. Confirmation that the other PRs are not also being maximally stressed for a particular subject can be ascertained by two means. First, by independently measuring the capacity of the other PRs and confirming that these are considerably greater than that determined as necessary for the tracking task in question. For example, if the speed range for a certain reference group on a nontarget speed test is 650 to 1250 mm/sec and the highest speed of a tracking target signal is 240 mm/sec, then one can be reasonably confident that intra-group differences in performance on the tracking task are unrelated to intra-group differences in speed. Second, where this process is less straightforward or not possible, it may be possible to alter the demands imposed by the task on the PR in question. For example, one could see whether visual acuity was being maximally stressed in a tracking task (and hence, be a significant limiting factor to the performance obtained) by increasing or decreasing the eye-screen distance. Similarly, one could look at strength in this context by altering the friction, damping, or inertia of the **sensor**, or at range of movement by altering the gain of the sensor.

The conclusion that a task and a PR are unrelated for a particular group does not, of course, mean that this can necessarily be extrapolated to some other group. For example, strength may be completely uncorrelated with tracking performance in normal males yet be the primary factor responsible for poor tracking performance by the paretic arm of subjects who have suffered a stroke.

The foregoing discussion is based on the concept of a assumption that if a task requires less than the absolute maximum available of a particular PR then performance on that task will be independent of that PR. Not surprisingly, the situation is unlikely to be this simplistic or clear-cut! If, for example, a tracking task places moderate sub-maximal demands on several PRs, these PRs will be stressed to varying levels such that the subject may tend to optimize the utilization of those resources [Kondraske, 1995a,b] so as to achieve an acceptable balance between accuracy, speed, stress/effort, and fatigue (physical and cognitive). Thus, although strength available is much greater than strength needed (i.e., Resource available $\gg$ Resource demand) for both males and females, could the differential in strength be responsible for males performing better on tracking tasks than females? [Jones et al., 1986].

77.3 Measurement of Sensory-Motor Control Performance

77.3.1 Techniques: An Overview

Tracking tasks are the primary methodological approach outlined in this chapter for measurement of sensory-motor control performance. There are, however, a large number of other approaches, each with their own set of apparatuses and methods, which can provide similar or different data on control performance. It is possible to give only a cursory mention of these other techniques in this chapter (see also Further Information).

Hand and foot test boards comprising multiple touch-plate sensors provide measures of accuracy and speed of lateral reaching-tapping abilities [Kondraske et al., 1984, 1988].

Measurement of steadiness and tremor in an upper-limb, lower-limb, or segment of either, particularly when sustended, can be made using variable size holes, accelerometers, or force transducers [Potvin et al., 1975]. A dual-axis capacitive transducer developed by Kondraske et al. [1984] provides an improved means of quantifying steadiness and tremor due to it requiring no mechanical connection to the subject (i.e., no added inertia) and by providing an output of limb position as opposed to less informative measures of acceleration or force. Interestingly, tests of steadiness can be appropriately considered as a category of tracking tasks in which the target is static. The same is also true for measurement of postural stability using force balance platforms, whether for standing [Kondraske et al., 1984; Milkowski et al., 1993] or sitting [Riedel et al., 1992] (see also Further Information).

77.3.2 Tracking Tasks: An Overview

A tracking task is a laboratory-based test apparatus characterized by a continuous input signal — the target — which a subject must attempt to match as closely as possible by his/her output response by controlling the position of (or force applied to) some sensor. It provides unequalled opportunities for wide-ranging experimental control over sensors, displays, target signals, dimensionality (degrees of freedom), control modes, controlled system dynamics, and sensor-display compatibility, as well as the application of a vast armamentarium of linear and non-linear techniques for response signal analysis and systems identification. Because of this, the tracking task has proven to be *the* most powerful and versatile tool for assessing, studying, and modelling higher-level functioning of the human "black-box" sensory-motor system.

There are three basic categories of tracking tasks differing primarily in their visual display and in the corresponding control system (Figure 77.1). The pursuit task displays both the present input and output signals, whereas the compensatory task displays only the difference or error signal between these. The preview task [Poulton, 1964; Welford, 1968; Jones and Donaldson, 1986] (Figure 77.2) is similar to the pursuit task except that the subject can see in advance where the input signal is going to be and plan accordingly to minimize the resultant error signal. Tracing tasks [Driscoll, 1975; Stern et al., 1983; Hocherman and Aharon-Peretz, 1994] are effectively self-paced 2-D preview tracking tasks.

The input-output nature of tracking tasks has made them most suitable for analysis using engineering control theories. This has led to the common view of pursuit tracking as a task involving continuous negative feedback [Notterman et al., 1982] but there is evidence that tracking viewed as a series of discrete events would be more appropriate [Bösser, 1984; Neilson et al., 1988]. The inclusion of preview of the input signal greatly complicates characterization of the human controller and Sheridan [1966] has suggested three models of preview control which employ the notions of constrained preview and nonuniform importance of input. Lynn et al. [1979] and Neilson et al. [1992] have also demonstrated how, by treating the neurologically impaired subject as a black-box, control analysis can lead to further information on underlying neurological control mechanisms.

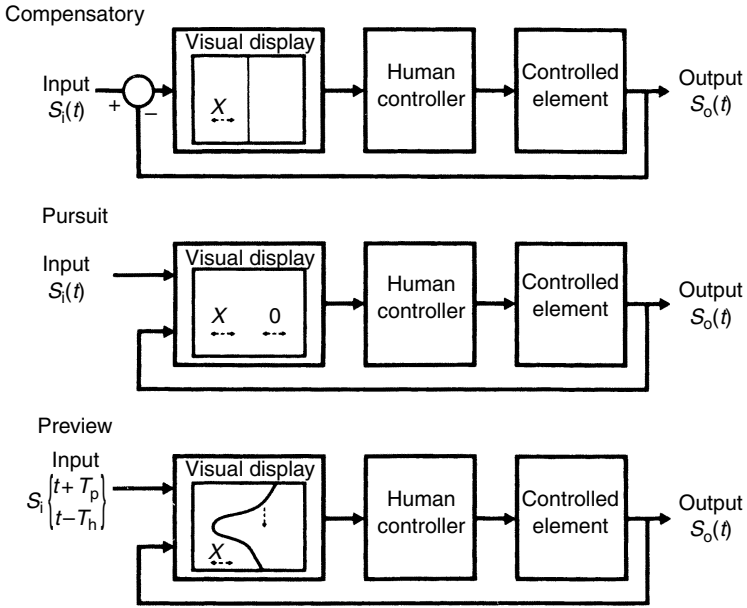
Despite the wide-spread utilization and acceptance of tracking tasks as a powerful and versatile means for quantifying and studying sensory-motor control capacities, there is little available on the market in this area. The most obvious exception to this is the photoelectric pursuit rotor which is ubiquitous in the motor behavior laboratories of university psychology departments and has been available since the 1950s


FIGURE 77.1 Modes of tracking (i) Compensatory: subject aims to keep resultant error signal X (= input signal–output signal = $s_i(t) - s_o(t)$) on stationary vertical line. (ii) Pursuit: subject aims to keep his output signal X, $s_o(t)$, on the target input signal O, $s_i(t)$. (iii) Preview: subject aims to keep his output signal X, $s_o(t)$, on the descending target input signal, $[s_i(t + T_p) - s_i(t - T_h)]$ (where t = present time, T_p = preview time, T_h = history or postview time).
FIGURE 77.2 Visual display for random tracking with a preview of 8.0 sec and postview of 1.1 sec.

[Welford, 1968; Schmidt, 1982; Siegel, 1985]. It is a paced 2-D task with a target with the periodic on each revolution. Although inexpensive, the pursuit rotor is a crude tracking task allowing limited control over target signals and possessing a very gross performance analysis in terms of time on target. Thus nearly all of the many and varied tracking tasks which have been used in countless experimental studies around the world have been developed by the users themselves for their specific objectives.

An improvement in this situation has occurred recently with the arrival on the market of a number of tracking devices from Human Performance Measurement, Inc. (Arlington, TX). These devices are a natural extension of those developed by Kondraske et al. [1984]. Off-the-shelf availability of computer-based tracking tests, including sensors for both upper- and lower-limbs, opens up the possibility of a much broader and widespread use of tracking tasks. In particular, one can look forward to a much greater utilization of tracking tasks outside of traditional research areas and in more routine assessment applications in clinical, rehabilitative, vocational, sports, and other environments.

77.3.3 Tracking Tasks: Options and Considerations

Whatever the reasons for needing quantification of sensory-motor control capacity via a tracking task, there are a number of options available and factors to be considered in choosing or designing a tracking task.

77.3.3.1 Sensors

Sensors for measuring a subject's motor output in 1-D tracking tasks can be categorized under (a) movements involving a single degree of freedom such as flexion-extension rotation around a single joint including elbow [Lynn et al., 1977; Deuschl et al., 1996; O'Dwyer et al., 1996; Soliveri et al., 1997], wrist [Johnson et al., 1996], or a finger, or pronation-supination of the wrist, and (b) movements involving two or more degrees of freedom of a body part (e.g., hand) — that is, coordinated movement at multiple joints — which are either 1-D, such as some form of linear transducer [Patrick and Mutlusoy, 1982; Baroni et al., 1984; van den Berg et al., 1987] or 2-D, such as steering wheel [Buck, 1982; Ferslew et al., 1982; Jones and Donaldson, 1986; Jones et al., 1993], stirring wheel [De Souza et al., 1980], position stick (i.e., 1-D joystick) [Potvin et al., 1977; Neilson and Neilson, 1980; O'Dwyer and Neilson, 1998], joystick [Kondraske et al., 1984; Miall et al., 1985; Jones et al., 1993], finger-controlled rotating knob [Neilson et al., 1993], and light-pen [Neilson and Neilson, 1980]. Force sticks, utilizing strain-gauge transducers mounted on a cantilever, are also commonly used as sensors [Garvey, 1960; Potvin et al., 1977; Miller and Freund, 1980; Barr et al., 1988; Stelmach and Worrington, 1988]. Isometric integrated EMG (i.e., full-wave rectification and low-pass filtering of the raw EMG) can also be used to control the tracking response cursor, as was done by Neilson et al. [1990] to help show that impairment of sensory-motor learning is the primary cause of functional disability in cerebral palsy.

Sensors for 2-D tasks must, of course, be capable of moving with and recording two degrees of freedom. Joysticks are commonly used for this and range in size from small, for finger movement [Anderson, 1986] and wrist/forearm movement [Bloxham et al., 1984; Frith et al., 1986; Neilson et al., 1998], up to large floor-mounted joysticks for arm movements primarily involving shoulder and elbow function [Kondraske et al., 1984; Anderson, 1986; Behbehani et al., 1988; Jones et al., 1993; Dalrymple-Alford et al., 1994; Watson et al., 1997; Watson and Jones, 1998]. Other 2-D task sensors include a hand-held stylus for the photoelectric pursuit rotor [Schmidt, 1982; Siegel, 1985], plexiglass tracing [Driscoll, 1975], and tasks utilizing sonic digitizers [Stern et al., 1984; Viviani and Mounoud, 1990; Hocherman and Aharon-Peretz, 1994]. Abend et al. [1982] and Flash and Hogan [1985] used a two-joint mechanical arm to restrict hand movements to the horizontal plane in the investigation of CNS control of two-joint (shoulder and elbow) movements in trajectory formation. Stern et al. [1983] simply used the subject's finger as the sensor for a tracing task on a vertical plexiglass "screen"; a video camera behind the screen recorded finger movements. Novel "whole-body" 2-D tracking is also possible by having subjects alter their posture while standing on a dual-axis force platform [Kondraske et al., 1984].

1-D sensors can also be used in 2-D tasks by way of bimanual tracking. For example, O'Dwyer and Neilson [1995] used two 1-D joysticks to investigate dynamic synergies between the right and left arms.

77.3.3.2 Displays

Early tracking devices used mechanical-based displays such as a rotating smoked drum [Vince, 1948], the ubiquitous pursuit rotor, and a paper-strip preview task [Poulton, 1964; Welford, 1968]. An oscilloscope was, and still is to a much less degree, used in a large number of tracking tasks, initially driven by analog circuitry [Flowers, 1976; Anderson, 1986] but later by D/A outputs on digital computers [Kondraske et al., 1984; Miall et al., 1985; Sheridan, M.R. et al., 1987; Cooper et al., 1989]. Standard raster-based television screens have been used by some workers [Potvin et al., 1977; Beppu et al., 1984]. Non-raster vector graphics displays, such as Digital Equipment's VT11 dynamic graphics unit, proved valuable during the PDP-era as a means for generating more complex dynamic stimuli such as squares [Neilson and Neilson, 1980; Frith et al., 1986] and preview [Jones and Donaldson, 1986] (Figure 77.2). More recently, raster-based color graphics boards have allowed impressive static displays and simple dynamic tracking displays to be generated on PCs. However, such boards are not, in general, immediately amenable for the generation of

flawless dynamic displays involving more complex stimuli, such as required for preview tracking. Jones et al. [1993] have overcome this drawback by the use of specially-written high-speed assembly-language routines for driving their display. These generate a display of the target and the subject's response marker by considering the video memory (configured in EGA mode) as four overlapping planes, each switchable (via a mask), and each capable of displaying the background color and a single color from a palette. Two planes are used to display the target, with the remaining two being used to display the subject's pointer. The current target is displayed on one target plane, while the next view of the target, in its new position, is being drawn on the other undisplayed target plane. The role of the two planes is reversed when the computer receives a vertical synchronization interrupt from the graphics controller indicating the completion of a raster. Through a combination of a high update-rate of 60.34 Hz (i.e., the vertical interrupt frequency), assembly language, and dual display buffers, it has been possible to obtain an extremely smooth dynamic color display. Their system for tracking and other quantitative sensory-motor assessments is further enhanced through its facility to generate dynamic color graphics on two high-resolution monitors simultaneously: one for the tracking display, and one for use by the assessor for task control and analysis. The monitors are driven by a ZX1000 graphic controller (Artist Graphics Inc), at 800×600, and a standard VGA controller, respectively.

In contrast to the above CRT-based displays, Warabi et al. [1986] used a laser-beam spot to indicate a subject's hand position together with a row of LEDs for displaying a step target. Similarly, Gibson et al. [1987] used a galvonometer-controlled laser spot to display smooth and step stimuli on a curved screen together with a white-light spot controlled by subject. Leist et al. [1987], Viviani and Mounoud [1990], and Klockgether [1994] also used galvonometer-controlled spots but via back-projection onto a curved screen, transparent digitizing table, and plexiglass surface respectively. Van den Berg et al. [1987] used two rows of 240 LEDs each to display target and response. 2-D arrays of LEDs have also been used to indicate step targets in 2-D tracking tasks [Abend et al., 1982; Flash and Hogan, 1985].

77.3.3.3 Target Signals

Tracking targets cover a spectrum from smoothly-changing (low-bandwidth) targets, such as sinusoidal and random, through constant velocity ramp targets, to abrupt changing step targets.

77.3.3.4 Sinusoidal Targets

The periodicity, constancy of task complexity (over cycles), and spectral purity of sine targets make them valuable for measurement of within-run changes in performance (e.g., learning, lapses in concentration) [Jones and Donaldson, 1981], the study of ability to make use of the periodicity to improve tracking performance [Jones and Donaldson, 1989], and the study of the human frequency response [Leist et al., 1987]. Several other workers have also used sine targets in their tracking tasks [Potvin et al., 1977; Miller and Freund, 1980; Ferslew et al., 1982; Notterman et al., 1982; Johnson et al., 1996; Soliveri et al., 1997].

Bloxham et al. [1984] and Frith et al. [1986] extended the use of sinewaves into a 2-D domain by having subjects track a moving circle on the screen.

77.3.3.5 Random Targets

These are commonly generated via a sum of sines approach in which a number of harmonically or non-harmonically related sinusoids of random phase are superimposed [Cassell, 1973; Neilson and Neilson, 1980; Miall et al., 1985; Baddeley et al., 1986; Frith et al., 1986; van den Berg et al., 1987; Barr et al., 1988; Cooper et al., 1989; Jones et al., 1993; Hufschmidt and Lücking, 1995; Watson et al., 1997; Watson and Jones, 1998]. If harmonically related, this can effectively give a flat spectrum target out to whatever bandwidth is required. Thus, in Jones et al.'s [Jones et al., 1993; Watson et al., 1997; Watson and Jones, 1998] system the random signal generation program asks the user for the required signal bandwidth and then calculates the number of equal amplitude harmonics that must be summed together to give this bandwidth, each harmonic being assigned a randomly selected phase from a uniform phase distribution. Each target comprises 4096 (2^{12}) or more samples, a duration of at least 68 sec (4096 samples/60.34 Hz), and a fundamental frequency of 0.0147 Hz (i.e., period of 68 sec). By this means it is possible to have

several different pseudo-random target signals that are non-periodic up to 68 sec duration, have flat spectra within a user specified bandwidth, no components above this bandwidth, and whose spectra can be accurately computed by FFT from any 68 sec block of target (or response). Another common approach to the generation of random targets is to digitally filter a sequence of pseudo-random numbers [Lynn et al., 1977; Potvin et al., 1977; Kondraske et al., 1984; van den Berg et al., 1987; Neilson et al., 1993] although this method gives less control over the spectral characteristics of the target. B'sser [1984] summed a number of these filtered sequences in such a way as to generate a target having an approximate 1/f spectrum. Another smooth pursuit target was generated by linking together short segments of sinewaves with randomly selected frequencies up to some maximum [Gibson et al., 1987] and was thus effectively a hybrid sinusoidal-random target.

77.3.3.6 Ramp Targets

These have been used in conjunction with sensory gaps of target or response to study predictive tracking and ability to execute smooth constant velocity movements in the absence of immediate visual cues in normal subjects [Flowers, 1978b] and subjects with cerebellar disorders [Beppu et al., 1987], stroke [Jones et al., 1989], and Parkinson's disease [Cooke et al., 1978; Flowers, 1978a].

77.3.3.7 Step Targets

These have been used in many applications and studies to measure and investigate subjects' abilities to predict, program, and execute ballistic (open-loop) movements. To enable this, spatial and temporal unpredictability have been incorporated into step tasks in various ways:

- Temporal predictability — The time of onset of steps has ranged from (a) explicitly predictable, with preview of the stimulus [Day et al., 1984; Jones et al., 1993], (b) implicitly predictable, with fixed interval between steps [Potvin et al., 1977; Cooke et al., 1978; Flowers, 1978; Abend et al., 1982; Deuschl et al., 1996; Johnson et al., 1996], to (c) unpredictable, with intervals between steps varied randomly over spans lying somewhere between 1.5 and 7.0 sec [Angel et al., 1970; Flowers, 1976; Baroni et al., 1984; Kondraske et al., 1984; Anderson, 1986; Jones and Donaldson, 1986; Warabi et al., 1986; Gibson et al., 1987; Sheridan et al., 1987; Jones et al., 1993; Neilson et al., 1995; Watson et al., 1997; O'Dwyer and Neilson, 1998].
- Amplitude predictability — The amplitude of steps has ranged from (a) explicitly predictable, where the endpoint of the step is shown explicitly before it occurs [Abend et al., 1982; Baroni et al., 1984; Sheridan et al., 1987; Jones et al., 1993; Deuschl et al., 1996; Watson et al., 1997], (b) implicitly predictable, where all steps have the same amplitude [Angel et al., 1970; Potvin et al., 1977; Cooke et al., 1978; Day et al., 1984; Kondraske et al., 1984; Anderson, 1986; Johnson et al., 1996; O'Dwyer and Neilson, 1998] or return-to-centre steps in variable-amplitude step tasks [Flowers, 1976; Jones and Donaldson, 1986; Jones et al., 1993], to (c) unpredictable, with between 2 and 8 randomly distributed amplitudes [Flowers, 1976; Jones and Donaldson, 1986; Warabi et al., 1986; Gibson et al., 1987; Sheridan et al., 1987; Jones et al., 1993].
- Direction predictability — Previous step tasks have had steps whose direction of steps has ranged from (a) all steps explicitly predictable, alternating between right and left [Flowers, 1976; Potvin et al., 1977; Cooke et al., 1978; Baroni et al., 1984; Kondraske et al., 1984; Deuschl et al., 1996; Johnson et al., 1996; O'Dwyer and Neilson, 1998], or all in one direction (i.e., a series of discontinuous steps) [Sheridan et al., 1987], or between corners of an invisible square [Anderson, 1986], or having preview [Abend et al., 1982; Jones et al., 1993], (b) most steps predictable but with occasional "surprises" for studying anticipation [Flowers, 1978a], (c) a combination of unpredictable (outward) and predictable (back-to-center) steps [Angel et al., 1970; Jones and Donaldson, 1986; Jones et al., 1993; Watson et al., 1997], and (d) all steps unpredictable, with multiple endpoints [Warabi et al., 1986; Gibson et al., 1987] or resetting between single steps [Day et al., 1984].

[a] Several authors have several variations of unpredictability within one task or between multiple tasks.

The three elements of unpredictability can be combined in various ways to generate tasks ranging from completely predictable to completely unpredictable (Table 77.1). Several groups have implemented several variations of unpredictability both within and between step tracking tasks to investigate the possible loss of ability to use predictability to improve performance in, for example, Parkinson's disease [Flowers, 1978; Sheridan et al., 1987; Watson et al., 1997]. In addition to unpredictability, other characteristics can be built into step tasks including explicit target zones [Sheridan et al., 1987] and visual gaps in target [Flowers, 1976; Warabi et al., 1986].

An example of a 1-D step tracking task possessing full spatial and temporal unpredictability is that of Jones and colleagues [Jones and Donaldson, 1986; Jones et al., 1993] (Figure 77.3a). The task comprises 32 abrupt steps alternating between displacement from and return to center screen. In the non-preview form, spatial unpredictability is present in the outward steps through four randomly distributed amplitude/direction movements (large and small steps requiring 90 and 22.5 deg. on a steering wheel respectively, and both to right and left of center) with temporal unpredictability achieved via four randomly distributed durations between steps (2.8, 3.4, 4.0, 4.6 sec). This task has been used, together with preview random tracking, to demonstrate deficits in sensory-motor control in the asymptomatic arm of subjects who have had a unilateral stroke [Jones et al., 1989].

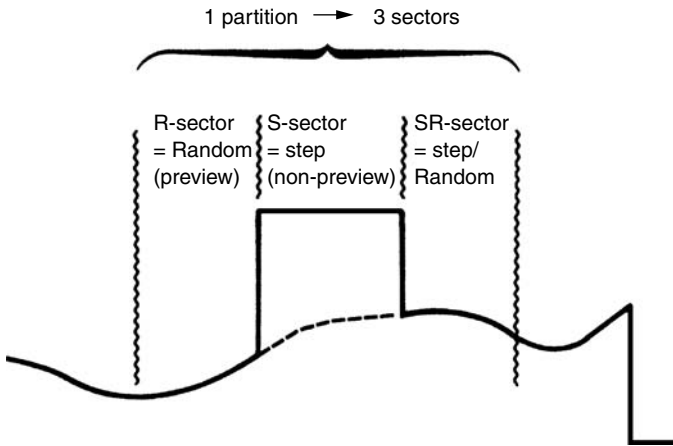
Watson and Jones [1997] also provide an example of a 2-D step tracking task with spatial and temporal unpredictability. In this task the subject must move a cross from within a central starting square to within one of eight 10 mm × 10 mm target squares that appear on the screen with temporal and spatial unpredictability (Figure 77.3b). The centers of the eight surrounding targets are positioned at the vertices and midway along the perimeter of an imaginary 100 mm × 100 mm square centered on the central square. To initiate the task, the subject places the cross within the perimeter of the central target. After a 2–5 sec delay, one of the surrounding blue targets turns green and the subject moves the cross to within the green target square as quickly and as accurately as possible. After a further delay, the central target turns green indicating onset of the spatially predictive "back-to-center" target. The task, which comprises ten outward and ten return targets, was used to show that Parkinsonian subjects perform worse than
FIGURE 77.3 Visual displays for (a) 1-D step tracking task and (b) 2-D step tracking task (bottom-right square is current target).


FIGURE 77.4 Section of input waveform in combination tracking in which the target alternates between preview-random and nonpreview-step.

matched controls on all measures of step tracking but are not impaired in their ability to benefit from spatial predictability to improve performance.

   Step tasks with explicit target zones, in 1-D [Sheridan et al., 1987] or 2-D [Watson et al., 1997], provide the possibility of altering task difficulty by varying the size of the target. On the basis that subjects need only aim to get their marker somewhere within target zone (cf. close to center) then, according to Fitt's [1954] ratio rule, the difficulty of the primary movement is proportional to $\log_2(2A/W)$, where A is the amplitude of the movement and W is the width of the target.

77.3.3.8 Combination Targets

Jones et al. [1986, 1989, 1993] have combined two quite different modes of tracking within a single task. Combination tracking involves alternating between preview random and non-preview step tracking over 11 sec cycles (Figure 77.4). Thus, while tracking the random target, the preview signal is abruptly and unpredictably replaced by a stationary vertical line at some distance from the random signal, and vice versa. Although the steps occur with a fixed foreperiod (as with the step tasks listed above with implicit temporal predictability) of 7.3 sec, subjects are not informed of this and, irrespective, Weber's law [Fitts and Posner, 1967] indicates the accuracy of prediction of steps with such a long pre-stimulus warning is very low. Combination tracking allows the study of ability to change *motor set* [Robertson and Flowers, 1990] between quite different modes of tracking and is analogous to having to quickly and appropriately respond to an unexpected obstacle, such as a child running onto the road, while driving a vehicle.

77.3.3.9   Dimensionality

The number of dimensions of a tracking task usually refers to the number of cartesian coordinates over which the *target* moves, rather than those of the response marker or sensor handle, or the number of degrees of freedom of the target or of the upper-limb. Some examples (1) Most tasks with a 2-D joystick sensor or light-pen are 2-D but, if the target moves in the vertical direction only [Neilson and Neilson, 1980; Kondraske et al., 1984; Miall et al., 1985; Jones et al., 1993], the task is only considered 1-D, irrespective of whether the response marker is confined to vertical movements on the screen or not; (2) If the target trajectory is a circle [Bloxham et al., 1984], the task is 2-D despite the target having only one degree of freedom (i.e., radius *r* is constant); (3) A pursuit rotor is a 2-D task as it has a target which moves in two dimensions (whether cartesian or polar) as well as doing so with two degrees of freedom.

Watson and Jones [1998] compared random 2-D with 1-D performance but in doing so scaled their 2-D target down so as to have an average displacement and velocity equal to that of its 1-D horizontal and vertical components. By this means they were able to unequivocally demonstrate that there is poorer performance on 2-D tasks and that is due to both the increased dimensionality and increased position/speed demands of an unscaled 2-D task.

Dual-axis tracking is a variant of 2-D tracking in which the 2-D task comprises two simultaneous orthogonal 1-D tasks in which one or more of the target, input device, control dynamics, and on-line feedback are different between the two axes. It has been used to investigate mechanisms and characteristics of 2-D tracking, such as whether it is a single task or two separate orthogonal tasks [Navon et al., 1984; Fracker and Wickens, 1989].

77.3.3.10   Tracking Mode

The two primary modes of tracking — compensatory and pursuit — have been introduced above. The majority of tasks are of the pursuit type which is appropriate in that has a more direct parallel with real-world sensory-motor tasks than the more artificial compensatory task [Vince, 1948; Garvey, 1960; Potvin et al., 1977; Miller and Freund, 1980; B'sser, 1984; Barr et al., 1988] in which the subject is only shown the instantaneous value of the error signal. The compensatory mode may be preferentially chosen for control-theory modelling due to its simpler set of defining equations [Potvin et al., 1977]. The preview task [Welford, 1968; Jones and Donaldson, 1986] is an important variation of pursuit tracking in which a still greater correspondence with everyday tasks is achieved.

77.3.3.11   Controlled System Dynamics

It has been well established that subjects can deal satisfactorily with a variety of tracking systems incorporating different control characteristics [Poulton, 1974; Neilson et al., 1995]. That notwithstanding, the majority of tracking tasks have a zero-order controlled system in which the position of the response marker is proportional to the position of the sensor and the mechanical characteristics of friction, inertial mass, and velocity damping are simply those of the input device. Van den Berg et al. [1987] eliminated even these by feeding back a force signal from a strain gauge on the tracking handle to the power amplifier of a torque motor connected to their sensor. Conversely, Neilson et al. [1993] artificially introduced mechanical characteristics into the movement of their response marker by having a linear 2nd-order filter as the controlled system; by an appropriate transfer function ($H(z) = 0.4060/(1 - 1.0616z^{-1} + 0.4610z^{-2})$), they were able to introduce inertial lag and underdamping (resonant peak at 2.0 Hz). Miall et al. [1985] introduced an analog delay of 500 msec between their joystick and display so that they could study the effect of delayed visual feedback on performance. Soliveri et al. [1997] used both 1st-order (velocity) and zero-order (position) linear control dynamics to investigate differences in learning between parkinsonian and control subjects and between on- and off-medication. Navon et al. [1984] used a combination of velocity and acceleration control dynamics in their study on dual-axis tracking. Nonlinear transfer functions, such as 2nd-order Volterra (fading memory) nonlinearities, have also been used in tracking controlled systems,

primarily as a means for investigating adaptive inverse modelling mechanisms in the brain relating to voluntary movement [Sriharan, 1997; Davidson et al., 1999].

Controlled system dynamics can also be changed during a task. In "critical tracking," a novel variation of pursuit tracking conceived by Jex [1966], the delay of the controlled system increases during the task. There is no external target but instead the subject's own instability acts as an input to an increasingly unstable controlled system, $Y(s) = K8/(s-8)$, in which the level of instability, represented by the root $8(= 1/T)$, is steadily increased during the task until a preset error is exceeded. The task has been described as analogous to driving a truck with no brakes down a hill on a winding road [Potvin et al., 1977]. The task has been applied clinically by Potvin et al. [1977] and Kondraske et al. [1984] and shown to be a reliable measure of small changes in neurological function [Potvin et al., 1977]. Alternatively, "gain-change step tracking" [Neilson et al., 1995], in which the gain of the control-display relation is increased or decreased without warning, has been used to investigate adaptive mechanisms in the brain [O'Dwyer and Neilson, 1998].

Having a torque motor as part of the sensor opens up several new possibilities. It can be operated as a "torque servo," in which applied torque is independent of position [Kondraske et al., 1984], or a "position servo," in which applied torque is proportional to position error (together with velocity damping if desired) [Thomas et al., 1976]. By adding external force perturbations, it is possible to measure and study neuromuscular reflexes and limb transfer function (i.e., stiffness, viscosity, and inertia), such as by applying constant velocity movements [Kondraske et al., 1984] or pulsatile [van den Berg et al., 1987], sinusoidal [Gottlieb et al., 1984], or random [Kearney and Hunter, 1983; van den Berg et al., 1987] force perturbations. Alternatively, the torque motor can be used to alter controlled system characteristics in tracking tasks for studies and/or improvement of voluntary movement. For example, van den Berg et al. [1987] cancelled unwanted controller characteristics. Chelette et al. [1995] used "force reflection" to improve tracking performance in both normal subjects and those with spasticity, and Johnson et al. [1996] used anti-viscous loading to investigate the cause of poor tracking in patients with Parkinson's disease.

77.3.3.12 Sensor-Display Compatibility

It is generally accepted that the level of compatibility between sensor and display in continuous tracking tasks influences the accuracy of performance [Neilson and Neilson, 1980]. The perfectly compatible sensor is the display marker itself [Poulton, 1974] where the subject holds and moves the response marker directly such as with a light-pen in tracking [Neilson and Neilson, 1980], rotary pursuit [Schmidt, 1982; Welford, 1968], handle on a two-joint mechanical arm [Abend et al., 1982], or in self-paced 2-D tracing tasks [Driscoll, 1975; Stern et al., 1984; Hocherman and Aharon-Peretz, 1994]. Similarly, van den Berg et al. [1987] achieve a high sensor-display compatibility by having the LED arrays for target and response displayed directly above a horizontally-moving handle. However, the majority of tracking tasks have sensors which are quite separate from the response marker displayed on an oscilloscope or computer screen. Sensor-display compatibility can be maximized in this case by having the sensor physically close to the display, moving in the same direction as the marker, and with a minimum of controlled system dynamics (e.g., zero-order). In the case of a joystick in a 2-D task, for example, direct compatibility (*Left–Right → Left–Right*) is easier than inverse compatibility (*Left–Right → Right–Left*), which is easier than non-compatibility (*Left–Right → Up–Down*). In contrast, fore-aft movements on a joystick appear to possess bidirectional compatibility in that *Fore–aft → Up–Down* seems as inherently natural as *Fore–aft → Down–Up* (i.e., no obvious inverse).

Sensor-display compatibility may not, however, be overly critical to performance. For example, Neilson and Neilson [1980] found no decrement in performance on random tracking of overall error scores, such as mean absolute error, between a light pen and a 1-D joystick; nevertheless, the latter did result in a decrease in gain, an increase in phase lag, and an increase in the non-coherent response component. Conversely, normal subjects find incompatible 2-D tracking very difficult to perform, taking up to 4 h of practice to reach a level of performance equal to that seen on prepractice 2-D compatible tracking [Neilson et al., 1998].

77.3.3.13   Response Sampling Rates

Although some workers have manually analyzed tracking data from multichannel analog chart recordings [Flowers, 1976; Beppu et al., 1984] or analog processed results [Potvin et al., 1977], the majority have used computers, sometimes via a magnetic tape intermediary [Day et al., 1984; Miall et al., 1985], to digitize data for automated analyses. Sampling rates used have varied from 10 Hz [Neilson and Neilson, 1980], through 20 Hz [Cooper et al., 1989; Neilson et al., 1993; Neilson et al., 1998], 28.6 Hz [Jones and Donaldson, 1986], 30.2 Hz [Watson et al., 1997; Watson and Jones, 1998], 40 Hz [Frith et al., 1986], 60 Hz [Viviani and Mounoud, 1990], 60.3 Hz (= screen's vertical interrupt rate) [Jones et al., 1993], 66.7 Hz [O'Dwyer and Neilson, 1998], 100 Hz (all 2-D tasks) [Abend et al., 1982; Stern et al., 1984; Hocherman and Aharon-Peretz, 1994], to as high as 250 Hz [Day et al., 1984].

For the most part, a relatively low sampling rate is quite satisfactory for analysis of tracking performance as long as the Nyquist criterion is met and there is appropriate analog or digital low-pass filtering to prevent aliasing. Spectral analysis indicates that the fastest of voluntary arm movements have no power above about 8.7 Hz [Jones and Donaldson, 1986]. This is very similar to the maximal voluntary oscillations of the elbow of 4-6 Hz [Neilson, 1972; Leist et al., 1987] and to maximum finger tapping rates of 6-7 Hz [Muir et al., 1995]. The sampling rate can be reduced still further if the primary interest is only in *coherent* performance, whose bandwidth is only of the order of 2 Hz for both kinesthetic stimuli [Neilson, 1972] and visual stimuli [Leist et al., 1987; Neilson et al., 1993]; that is, performance above 2 Hz must be open-loop and, hence, learned and preprogrammed [Neilson, 1972]. Thus, from an information theory point of view, there is no need to sample tracking performance beyond, say, 20 Hz. However, a higher rate may well be justified on the grounds of needing better temporal resolution than 50 ms for transient or cross-correlation analysis, unless one is prepared to regenerate the signal between samples by some form of non-linear interpolation (e.g., sinc, spline, polynomial).

77.3.3.14   Other Measures

Several researchers have further extended the information which can be derived from upper-limb tracking performance by comparison with other simultaneously recorded biosignals. The most common of these is the EMG, particularly integrated EMG due to its close parallel to force of contraction [Neilson, 1972] and where the tracking movement is constrained to be around a single joint. The EMG has been used together with step tracking for fractionating reaction times into premotor and motor components [Anson, 1987; Sheridan et al., 1987] and confirmation of open-loop primary movements [Sittig et al., 1985; Sheridan et al., 1987]. In smooth tracking, correlation/cross-spectral analysis between the EMG and limb position has been used to study limb dynamics [Neilson, 1972; Barr et al., 1988].

In contrast, Cooper et al. [1989] measured the EEG at four sites during 2-D random tracking to show that slow changes in the EEG (equivalent to the Bereitschaftspotential preceding self-paced voluntary movement), particularly at the vertex, are correlated with the absolute velocity of the target.

Simultaneous measurement of hand and eye movements has been carried out by Warabi et al. [1986] and Leist et al. [1987] using EOG to measure horizontal eye movements and by Gibson et al. [1987] who used an infra-red limbus reflection technique. Interestingly, Leist et al. [1987] found that ocular pursuit and self-paced oscillations were limited to about 1 and 2.2 Hz, respectively, whereas the equivalent values for arm movements are 2 and 4-6 Hz, respectively.

77.3.3.15   Standard Assessment Procedures

Having designed and constructed a tracking task or set of tracking tasks with the characteristics necessary to allow measurement of the sensory-motor control performance capacities under investigation, it is essential that this process be complemented by a well formulated set of standard assessment procedures. These must include (a) standard physical setup, in which positioning of subject, sensor, and screen are tightly specified and controlled, as well as factors such as screen brightness, room lighting, etc., and (b) standardized instructions. The latter are particularly important in tasks where speed-accuracy tradeoff [Fitts, 1954; Welford, 1968; Agarwal and Logsdon, 1990] is possible. This applies particularly to step tracking in which leaving the tracking strategy completely up to subjects introduces the possibility of

misinterpretation of differences in performance on certain measures, such as reaction time, risetime, and mean absolute error. For example, subjects need to know if it is more important to have the initial movement end up close to the target (i.e., emphasis on accuracy of primary movement) or to get within the vicinity of the target as soon as possible (i.e., emphasis on speed of primary movement); the latter results in greater under/overshooting but also tends to result in lower mean errors). The most common approach taken is to stress the importance of both speed and accuracy with an instruction to subjects of the form: "Follow the target as fast and as accurately as possible."

77.3.3.16   Test and Experimental Protocols

The design of appropriate test and experimental protocols is also a crucial component of the tracking task design process [Roscoe, 1975; Pitrella and Kruger, 1983]. When comparisons are made between different subjects, tasks, and/or conditions, careful consideration needs to be given to the paramount factors of *matching* and *balancing* to minimize the possibility of significant differences being due to some bias or confounding variable other than that under investigation. Matching can be achieved between experimental and control subjects in an inter-subject design by having average or one-to-one equivalence on age, gender, education, etc., or through an intra-subject design in which the subject acts as his/her own control in, say, a study of dominant versus non-dominant arm performance. Balancing is primarily needed to offset *order effects* due to learning which pervade much of sensory-motor performance [Welford, 1968; Poulton, 1974; Schmidt, 1982; Frith et al., 1986; Jones et al., 1990]. A study by Jones and Donaldson [1989] provides a good example of the application of these principles. Their study, aimed at investigating the effect of Parkinson's disease on predictive motor planning, involved 16 Parkinsonian subjects and 16 age and sex matched control subjects. These were then divided into 8 subgroups in a 3-way randomized cross-over design so as to eliminate between- and within-session order effects in determining the effect of target type, target preview, and medication on tracking performance.

77.4   Analysis of Sensory-Motor Control Performance

77.4.1   Accuracy

Analyses of raw tracking data can provide performance information which is objective and quantitative and which can be divided into two broad classes:

Measures of Global Accuracy of Performance: Measures of global (or overall or integrated) sensory-motor control capacities have proven invaluable for:

- *Vocational screening* of minimum levels of sensory-motor skills: Tracking tasks, in fact, have their origins in this area during World War II when they were used to help screen and train aircraft pilots [Welford, 1968; Poulton, 1974].
- *Clinical screening* for sensory-motor deficits (arising from one or more lesions in one or more sites in the sensory-motor system): An excellent example of the application of this in clinical practice is the provision of objective measures in off-road driving assessment programs [Jones et al., 1983; Croft and Jones, 1987].
- *Clinical and rehabilitation research* by measurement of longitudinal changes in sensory-motor function: There are many examples of subjects being assessed repeatedly on tracking tasks for periods up to 12 or more months. This has been done to quantify recovery following head injury [Jones and Donaldson, 1981] and stroke [Lynn et al., 1977; De Souza et al., 1980; Jones and Donaldson, 1981; Jones et al., 1990] as well as for studies of learning in tracking performance [Poulton, 1974; Jones and Donaldson, 1981; Schmidt, 1982; Frith et al., 1986; Jones et al., 1990]. They can also be used to quantify changes due to medication, such as in Parkinson's disease [Baroni et al., 1984; Johnson et al., 1996; Jones et al., 1996; Soliveri et al., 1997].

Measures of Characteristics of Performance: Measures of global accuracy of tracking performance can detect and quantify the presence of abnormal sensory-motor control performance capacities with

considerable sensitivity [Potvin et al., 1977; Jones et al., 1989]. Conversely, they are unable to give any indication of which of the many subsystems or performance resources in the overall sensory-motor system are, or may be, responsible for the abnormal performance. Nor can they provide any particular insight into the underlying neuromuscular control mechanisms of normal or abnormal performance.

Four approaches can be taken to provide information necessary to help identify the sensory-motor subsystems and their properties responsible for the *characteristics* of observed normal and abnormal performance:

- Batteries of neurologic sensory-motor tests — These tests can be used to, at least ideally, isolate and quantify the various sensory, motor, cognitive, and integrative functions and subsystems involved in sensory-motor control performance as measured globally by, for example, tracking tasks.
- Functional decomposition — Fractionation of the various performance resources contributing to tracking performance.
- Traditional signal processing approaches — Time domain (ballistic and nonballistic) and frequency domain techniques.
- Graphical analysis — This has primarily been developed for measurement and investigation of changes in performance and underlying PRs over time.

77.4.2   Measures of Global Accuracy of Performance

The most commonly used measure of global or overall accuracy is the *mean absolute error* (MAE) [Jones and Donaldson, 1986] which indicates the average distance the subject was away from the target irrespective of side; it is also variously called average absolute error [Poulton, 1974], modulus mean error [Poulton, 1974], mean rectified error [Neilson and Neilson, 1980], or simply tracking error [Kondraske et al., 1984; Behbehani et al., 1988]. In contrast, the mean error, or constant position error, is of little value as it simply indicates only the extent to which the response is more on one side of the target than the other [Poulton, 1974]. Measures of overall performance which give greater weighting to larger errors include mean square error [Neilson et al., 1993], root mean square error [McRuer and Krendel, 1959; Poulton, 1974; Navon et al., 1984; O'Dwyer and Neilson, 1995], variance of error [Neilson and Neilson, 1980], and standard deviation of error [Poulton, 1974]. Relative or normalized error score equivalents of these can be calculated by expressing the raw error scores as a percentage of the respective scores obtained had subject simply held the response marker stationary at the mean target position [Poulton, 1974; Neilson and Neilson, 1980; Day et al., 1984]; that is, noresponse = 100%. Alternatively, the relative root mean square error, defined as the square root of the ratio of the mean square value of the error signal to the mean square value of the target signal expressed as a percentage, allows tracking errors to be compared across tests using different target signals [Neilson et al., 1998].

Overall coherence is an important alternative to the above measures when it is wished to assess the similarity between target and response waveforms but there is a substantial delay between them. It provides an estimate of the proportion of the response that is correlated with the target over all frequencies [O'Dwyer and Neilson, 1995; O'Dwyer et al., 1996].

An issue met in viewing error scores from the perspective of Kondraske's [Kondraske, 1995a,b] elemental resource model is the unifying requirement of its associated *general systems performance theory (GSPT)* that all dimensions of performance must be in a form for which a higher numerical value indicates a superior performance. Thus scores which state that a *smaller* score indicates a superior performance, including reaction times, movement times, and all error scores, need to be transformed into *performance scores* [Kondraske, 1988]. For example:

- *Central response speed = 1/(reaction time)*
- *Information processing speed = 1/(8-choice reaction time)*
- *Movement speed = 1/(movement time)*
- *Tracking accuracy = 1/(tracking error)*

As transformation via inversion is non-linear, the distributions of raw error scores and derived performance will be quite different. This has no effect on ordinal analyses, such as non-parametric statistics, but will have some effect on linear analyses, such as parametric statistics, linear regression/correlation, etc., and may include improvements due to a possible greater normality of the distributions of derived performances. An alternative transformation which would retain a linear relationship with the error scores is:

Tracking accuracy $= 100 -$ *Relative tracking error*. However, while this gives a dimension of performance with the desired 'bigger is better' characteristic, it also raises the possibility of negative values, implying an accuracy worse than zero! — the author can attest to the fact that some subjects do indeed end up with error scores worse than the "hands off" score. Irrespective of GSPT, there is no doubt that it is beneficial to deal conceptually and analytically with multiple performance measures when *all* measures are consistently defined in terms of "bigger is better."

Time on target is a much cruder measure of tracking performance than all of the above but it has been used reasonably widely due to it being the result obtained from the pursuit rotor. The crudeness generally reflects (a) a lack of spatiotemporal sampling during a task (i.e., simple integration of time on target only) preventing the possibility of further analysis of any form, and (b) a task's performance *ceiling* due to the target having a finite zone within which greater accuracy, relative to center of zone, is unrewarded. This latter factor can, however, be used to advantage for the case where the investigator wishes to have control over the *difficulty* of a task, to gain, for example, similar levels of task difficulty across subjects irrespective of individual ability. This attribute has been used very effectively with 2-D random tracking tasks to minimize the confounding effects of major differences in task load between experimental and control subjects in dual task studies of impairment of central executive function in subjects with Alzheimer's disease [Baddeley et al., 1986] and Parkinson's disease [Dalrymple-Alford et al., 1994].

77.4.3 Measures of Characteristics of Performance

77.4.3.1 Batteries of Neurologic Sensory-Motor Tests

Potvin and associates [Potvin and Tourtellotte, 1975; Potvin et al., 1985], now led by Kondraske et al. [1984, 1988], have developed what is by far the most comprehensive battery of tests available for quantitative evaluation of neurologic function covering a number of sensory, motor, cognitive, and sensory-motor functions or performance resources. Similarly, Jones et al. [1989, 1993] have developed a battery of *component* function tests, most of which have been specifically designed to isolate and quantify the various performance resources involved in their tracking tasks. There is, therefore, a close resemblance between the component and tracking tests so as to maximize the validity of comparisons made between them.

77.4.3.2 Functional Decomposition of Tracking Performance

There are three main approaches whereby tracking performance can be fractionated or decomposed into its functional components: sensory, perceptual, cognitive, motor planning, and motor execution.

The first involves breaking the ballistic response in step tracking into reaction time, movement time, overshoot, and settling time [Flowers, 1976; Evarts et al., 1981; Jones and Donaldson, 1986; Behbehani et al., 1988; Kondraske et al., 1988] (see "Time domain (ballistic) analysis" below). This allows indirect deductions about cognitive, motor planning, and motor execution functions, although the distinction between cognitive and motor elements often remains imprecise.

The second involves calculation of differentials in tracking performance from inter-trial alterations in target and/or controlled system dynamics. This has been successfully used to study predictive motor planning [Flowers, 1976; Flowers, 1978; Bloxham et al., 1984; Day et al.,1984; Jones and Donaldson, 1989], acquisition/modification of motor sets [Frith et al., 1986], and reliance on visual feedback [Flowers, 1976; Cooke et al., 1978; Frith et al., 1986] in Parkinson's disease.

The third approach allows a more direct identification of the contribution of certain elemental resources to tracking performance during a specific tracking run. For example, by introducing the concept of a

visuoperceptual buffer-zone, it is possible to estimate the contribution of visuoperceptual function to tracking performance [Jones et al., 1996]. This technique has been used to demonstrate that impaired visuoperceptual function in Parkinsonian subjects plays only a minor role in their poor tracking performance [Jones et al., 1996] but, conversely, that impaired tracking performance in stutterers is predominantly due to reduced dynamic visuospatial perception [A.J. White, R.D. Jones, K.H.C. Lawson, and T.J. Anderson, unpublished observations]. Furthermore, the visuoperceptual function can itself be fractionated into visual acuity, static perception, and dynamic perception [Jones and Donaldson, 1995].

In contrast to fractionation of performance on a high level task (e.g., tracking, driving), Kondraske et al. [1995a,b] have developed techniques for the reverse process. They have shown how their hierarchical elemental resource model can be used to *predict* performance on high level tasks from performance on a number of lower level tasks [Kondraske, 1987; Vasta and Kondraske, 1994; Kondraske, 1995b; Kondraske et al., 1997]. This approach has considerable potential in application areas such as rehabilitation. For example, it could be used in driving assessment programs to predict on-road driving ability by off-road measurement of performance on several key lower level tasks pertinent to driving, such as reaction time, visuospatial, cognitive, and tracking.

77.4.3.3 Time Domain (Non-Ballistic) Analysis of Tracking Performance

There are several run-averaged biases which can indicate the general form of errors being made, particularly when the tracking performance is subnormal. Positive *side of target* (%) and *direction of target* (%) biases reflect a greater proportion of errors occurring to the right of the target or while the target is moving to the right respectively [Jones and Donaldson, 1986] which, if substantial, may indicate the presence of some visuoperceptual deficit. Similarly, the *side of screen* bias (assuming mean target position is mid-screen) [Jones and Donaldson, 1986] is identical to the mean error or constant position error.

Perhaps the single most important measure of performance, other than mean absolute error, for non-transient targets is that of the average time delay, or *lag*, of a subject's response with respect to the target signal. The lag is most commonly defined as being the shift, τ, corresponding to the peak of the cross-correlation function, calculated directly in the time domain or indirectly via the inverse of the cross-spectrum in the frequency domain. Although simulation studies indicate that these techniques are at least as accurate and as robust to noise/remnants as the alternatives listed below [Watson, 1994], one needs to be aware of a bias leading to underestimation of the magnitude of the lag (or lead) due to distortion of the standard cross-correlation function, but specifically of the peak towards zero shift. The distortion arises due to the varying overlap of two truncated signals (i.e., the target and the response) resulting in the multiplication of the cross-correlation function by a triangle (maximum at $\tau = 0$ and zero at $\tau = NT_S$, assuming signals of equal length NT_S). This effect is minimal as long as both signals have a mean value of zero (i.e., zero d.c.). Temporal resolution is another factor deserving consideration. If desired, greater resolution than that of the sampling period can be obtained by interpolation of the points around the peak of the cross-correlation function by some form of curve fitting (e.g., parabola [Jones et al., 1993]).

An alternative estimate of the lag, which has proven accurate on simulated responses, can be gained from the *least squares time delay estimation* by finding the time shift between the response and target at which the mean square error is minimized [Fertner and Sjölund, 1986; Jones et al., 1993]. Another approach, *phase shift time delay* estimation, calculates lag from the gradient of the straight line providing a best least-squares to the phase points in the cross-spectrum [Watson et al., 1997]. This technique has, however, proven more sensitive to non-correlated remnants in the response than the other procedures [Watson, 1994].

Several measures used to help characterize within-run variability in performance include variance of error [Neilson and Neilson, 1980], standard deviation of error [Poulton, 1974], and inconsistency [Jones and Donaldson, 1986].
FIGURE 77.5 Transient response analysis. Tolerance zones: RZ is the reaction zone, and TZ is the target zone. Performance parameters: RT is the reaction time, PMT is the primary movement time, SCT is the secondary correction time, TET is the target entry time, PV is the peak velocity, PME is the primary movement error, and MAE is the mean absolute error over a fixed interval following stimulus.

77.4.3.4 Time Domain (Ballistic) Analysis of Tracking Performance

Whether or not any of the above nonballistic analyses, evaluation of step tracking performance usually involves separate ballistic or transient analysis of each of the step responses. This generally takes the form of breaking up each response into three phases (Figure 77.5) (1) reaction time phase, or the time between onset of step stimulus and initiation of movement defined by exit from a visible or invisible reaction zone, (2) primary movement phase, or the open-loop ballistic movement made by most normal subjects aiming to get within the vicinity of the target as quickly as possible, the end of which is defined as the first stationary point, and (3) secondary correction phase, comprising one or more adjustments and the remaining time needed to enter and stay within target zone. The step measures from individual steps can then be grouped into various step categories to allow evaluation of the effect of step size, spatial predictability, arm dominance, etc., on transient performance.

Accuracy of the primary aimed movement can also be characterized in terms of a constant error and a variable error (standard deviation of error), which are considered to be indices of accuracy of central motor programming and motor execution respectively [Guiard et al., 1983].

Phase-plane (velocity vs. position) plots provide an alternative means for displaying and examining the qualitative characteristics of step tracking responses. In particular, they have proven valuable for rapid detection of gross abnormalities [Potvin et al., 1985]. Behbehani et al. [1988] have introduced a novel quantitative element to phase-plane analysis by deriving an index of coordination: $I_C = V_m^2/A$, where V_m is the maximum velocity during an outward and return step and A is the area within the resultant loop on the phase-plane plot.

77.4.3.5 Frequency Domain Analysis of Tracking Performance

Cross-correlation and spectral analysis have proven invaluable tools for quantifying the frequency dependent characteristics of the human subject. The cross-spectral density function, or cross-spectrum $S_{xy}(f)$, can be obtained from the random target $x(t)$ and random response $y(t)$ by taking the Fourier transform of the cross-correlation function $r_{xy}(\tau)$, that is, $S_{xy}(f) = F\{r_{xy}(\tau)\}$, or in the frequency domain via $S_{xy}(f) = X(f)Y(f)^*$, or by a nonparametric system identification approach (e.g., "spa.m" in MATLAB®). The cross-spectrum provides estimates of the relative amplitude (i.e., gain) and phase-lag at each frequency. Gain, phase, and remnant frequency response curves provide objective measures of pursuit

tracking behavior, irrespective of linearity, and are considered a most appropriate "quasi-linear" tool for obtaining a quantitative assessment of pursuit tracking behaviour [Neilson and Neilson, 1980]. From the cross-spectrum one can also derive the *coherence function* which gives the proportion of the response signal linearly related to the target at each frequency: $(xy^2 =^* S_{xy}(f)^*2/S_x(f)S_y(f))$. Lynn et al. [1977] emphasize, however, that one must be cognizant of the difficulty representing tracking performance by a quasi-linear time-invariant transfer function, especially if the run is of short duration or if the target waveform is of limited bandwidth, as the results can be so statistically unreliable as to make description by a 2nd- or 3rd-order transfer function quite unrealistic. Van den Berg et al. [1987] chose four parameters to characterize tracking performance: low-frequency performance via the mean gain of transfer function at the 3 lowest of 8 frequencies in target signal, high-frequency performance via the frequency at which the gain has dropped to less than 0.4, mean delay via shift of peak of cross-correlation function, and remnant via power in frequencies introduced by subject relative to total power. Spectral and coherence analysis have been used to demonstrate that the human bandwidth is about 2 Hz for both kinaesthetic tracking [Neilson, 1972] and visual tracking [Neilson et al., 1993], a much greater relative amplitude of second harmonic in the response of cerebellar subjects in sine tracking [Miller and Freund, 1980], a near constant lag except at low frequencies in normal subjects [Cassell, 1973], adaptation to time-varying signals [Bösser, 1984], 2-D asymmetry in postural steadiness [Milkowski et al., 1993], and that normal subjects can form non-dynamic and dynamic inter-limb synergies in a bimanual tracking task [O'Dwyer and Neilson, 1995].

77.4.3.6 Graphical Analysis of Tracking Performance

Most of the of the above analyses give quantitative estimates of some aspect of performance which is effectively assumed to be constant over time, other than for random fluctuations. This is frequently not the case, especially for more complex sensory-motor tasks such as tracking. Changes in performance over time can be divided into two major classes: class I: those for which the underlying PRs remain unchanged (these are due to factors such as practice, fatigue, lapses in concentration, lack of practice, and changes in task complexity) and class II: those for which one or more underlying PRs have changed (these are due to abrupt or gradual alterations at one or more sites in the sensory-motor system and include normal changes, such as due to age, and abnormal changes, due to trauma or pathology).

Studies of class I factors using tracking tasks are complicated most by the intra-run *difficulty* of a task not being constant. Changes in tracking accuracy *during* a run can be viewed via graphs of target, response, and errors [Jones et al., 1993]. The latter is particularly informative for sinusoidal targets for which the mean absolute errors can be calculated over consecutive epochs, corresponding to sine-wave cycles, and plotted both in a histogram form and as a smoothed version of this [Jones and Donaldson, 1986]. As complexity of task is constant over epochs (cf. random pursuit task), the error graph gives an accurate measure of a subject's time-dependent spatiotemporal accuracy that is not confounded by changes in task difficulty and, therefore, gives a true indication of changes in performance due to factors such as learning, fatigue, and lapses in concentration. Attempts by the author to derive an instantaneous or short epoch (up to several seconds) function or *index of task difficulty* which would allow equivalent graphs to be generated for random targets were unsuccessful.

Neilson et al. [1998] devised an alternative procedure for intra-run analysis, termed micromovement analysis. This involves segmentation of the X and Y deflections of the response cursor on the basis of discontinuities, flat regions, and changes in direction of the response. They used this to identify changes in visual-motor coupling during the first 4 min of tracking on a 2-D compatible task following 4 h of practice on a 2-D incompatible task. They propose that these changes are evidence of rapid switching between different sensory-motor models in the brain.

By comparison, as long as the task remains unchanged over successive runs, studies of class II factors using tracking tasks are complicated most by inter-run *learning*. Although most learning occurs over the first one or two runs or sessions, tracking performance can continue to improve over extended periods as evidenced by, for example, significant improvements still being made by normal subjects after nine weekly sessions [Jones and Donaldson, 1981]. Consequently, a major difficulty met in the interpretation

of serial measures of performance following acute brain damage is differentiation of neurologic recovery from normal learning. Furthermore, it is not simply a matter of subtracting off the degree of improved performance due to learning seen in normal control subjects. Jones et al. [1990] have developed graphical analysis techniques which provide for the removal of the learning factor, as much as is possible, and which can be applied to generating recovery curves for individual subjects following acute brain damage such as stroke. They demonstrated that, for tracking, percentage improvement in performance (PIP) graphs give more reliable evidence of neurologic recovery than absolute improvement in performance (PIA) graphs due to the former's greater independence from what are often considerably different absolute levels of performance.

77.4.4 Statistical Analysis

Parametric statistics (*t*-test, ANOVA) are by far the most commonly used in studies of sensory-motor/psychomotor performance due, in large part, to their availability and ability to draw out interactions between dependent variables. However, there is also a strong case for the use of non-parametric statistics. For example, the Wilcoxon matched-pairs statistic may be preferable for both between-group and within-subject comparisons due to its greater robustness over its parametric paired *t*-test equivalent, with only minimal loss of power. This is important due to many sensory-motor measures having very non-Gaussian skewed distributions as well as considerably different variances between normal and patient groups.

Defining Terms

Basic element of performance (BEP):   Defined by a *functional unit* and a *dimension of performance*, for example, right elbow flexor + speed.

Dimension of performance: A basic measure of performance such as speed, range of movement, strength, spatial perception, spatiotemporal accuracy.

Functional unit: A subsystem such as right elbow flexor, left eye, motor memory.

Performance capacity: The maximal level of performance possible on a particular dimension of performance.

Performance resource (PR):   One of a pool of elemental resources, from which the entire human is modelled (Kondraske, 1995b), and which is available for performing tasks. These resources can be subdivided into life sustaining, environmental interface, central processing, and skills domains, and have a parallel with *basic elements of performances.*

Sensor: [in context of tracking tasks] A device for measuring/transducing a subject's motor output.

Sensory-motor control: The primary (but not only) performance resource responsible for accuracy of movement.

Spatiotemporal accuracy: The class of accuracy most required by tasks which place considerable demand on attainment of simultaneous spatial and temporal accuracy; this refers particularly to *paced* tasks such as tracking, driving, ball games, and video games.

Tracking task: A laboratory apparatus and associated procedures which have proven one of the most versatile means for assessing and studying the human "black-box" sensory-motor system by providing a continuous record of a subject's response, via some *sensor*, to any one of a large number of continuous and well-controlled stimulus or *target* signals.

Measurement of Information-Processing Subsystem Performance Capacities

George V. Kondraske
Paul J. Vasta
University of Texas-Arlington

78.1 Introduction

The human brain has been the subject of much scientific research. While a tremendous amount of information exists and considerable progress has been made in unlocking its many mysteries, many gaps in understanding exist. However, it is not essential to understand in full detail how a given function of the brain is mediated in order to accept that it (i.e., the function) exists, or to understand how to maximally isolate, stress, and characterize at least selected attributes of its performance quantitatively. In this chapter, a systems view of major functional aspects of the brain is used as a basis for discussing methods employed to measure what can be termed central processing performance capacities. Central

processing capacities are distinguished from the information that is processed. In humans, the latter can be viewed to represent the contents of **memory** (e.g., facts, "programs," etc.). Clearly, both the information itself and the characteristics of the systems that process it (i.e., the various capacities discussed below) combine to realize what are commonly observed as skills whether perceptual, motor, cognitive, or other.

Investigations of how humans process information have been performed within various fields including psychology, cognitive science, and information theory with the primary motivation being to better understand how human information-processing works and the factors that influence it. On the basis that it provided a rigorous definition for the measurement of information, it can be argued that Shannon's information theory [Shannon, 1948] has been and continues to be one of the more important developments to influence both the science and engineering associated with human information processing. Several early attempts to apply it to human information processing [Hick, 1952; Hyman, 1953; Fitts, 1954] have stood the test of time and have provided the basis for subsequent efforts of both researchers and practitioners. These works are central to the material presented here. In addition, the work of Wiener [1955] is also noteworthy in that it began the process of viewing human and artificial information processing from a common perspective. Analogies between humans and computers have proven to be very useful up to certain limits.

While there is considerable overlap and frequent interchange, the roles of science and engineering are different. In the present context, the emphasis is on aspects of the latter. It has been necessary to engineer useful measurement tools and processes without complete science to serve a wide variety of purposes that have demanded **attention** in both clinical and nonclinical contexts. Whether purposeful or accidental, methods of systems engineering have been incorporated and have proven useful in dealing with the complexity of human brain structure and function. While scientific controversies continue to exist, much research has contributed to the now common view of separate (both in function and location) processing subsystems that make up the whole. Various versions of a general distributed, multiprocessor model of human brain function have been popularly sketched [Gazzaniga, 1985; Minsky, 1986; Ornstein, 1986]. For example, it is widely known that the occipital lobe of the brain is responsible for visual information processing while other areas have been found to correspond to other functions. It is not possible to do justice here to the tremendous scope of work that has been put forth and therefore to the brain itself. Nonetheless, this compartmentalistic or systems approach, which stresses major functional systems that must exist based on overwhelming empirical evidence, has proven to be useful for explaining many normal and pathologic behavioral observations. This approach is essential to the development of meaningful and practical performance measurement strategies such as those described.

78.2 Basic Principles

Many of the past efforts in which performance-related measurements have played a significant role have been directed toward basic research. Furthermore, much of this research has been aimed at uncovering the general operational frameworks of normal human information processing and not the measurement of performance capacities and their use, either alone or in combination with other capacity metrics, to characterize humans of various types (e.g., normal, aged, handicapped, etc.). However, representative models and theories provide direction for, and are themselves shaped by, subsequent measurement efforts. While there are many principles and basic observations that have some relevance, the scope of material presented later is limited to topics that more specifically support the understanding of human information-processing **performance capacity** measurement.

78.2.1 Functional Model of Central Information Processing

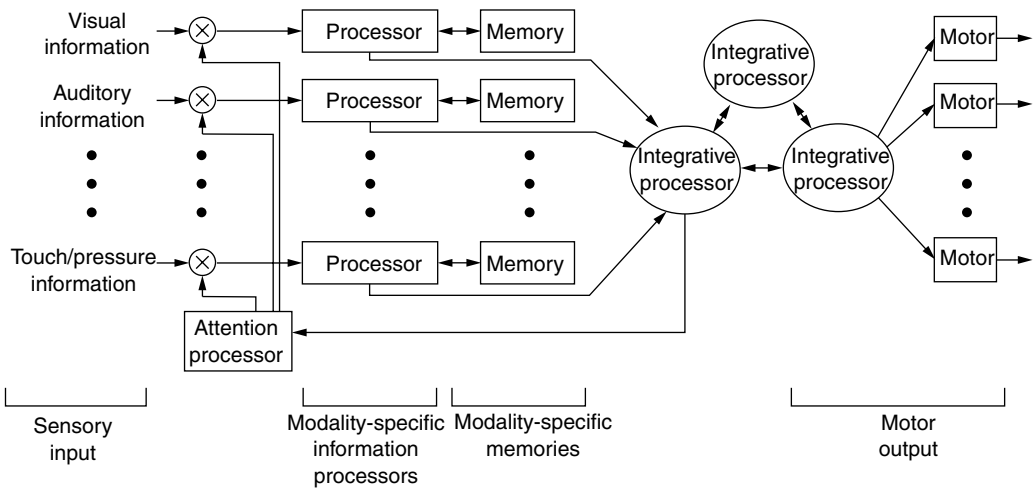
A simplified, although quite robust, model that is useful within the context of human information processing is illustrated in Figure 78.1. With this figure, attention is called to systems, their functions, and major interconnectivities. At a functional level that is relatively high within the hierarchy of the human


FIGURE 78.1 A functional systems-level block diagram of human information-processing description of the measurement of sybsystem performance capacities.

central nervous system, the central processing system can be considered to be composed of two types of subsystems (1) *information processors* and (2) *memories*. As can be seen from the diagram, information from the environment is provided to the information-processing subsystems through human sensor subsystems. These not only include the obvious sensors (e.g., the eyes) that receive input from external sources but also those specifically designed to provide information regarding the internal environment, including proprioception and state of being. The capacity to process information input from multiple sources at a conscious level is finite. Overload is prevented by limiting the amount of information simultaneously received; specific sensory information of high priority is controlled by what may be termed an *attention* **processor**. Information associated with a given sensor system is processed by a corresponding processor. The model further suggests that there are memory subsystems for each sensory modality in bidirectional communications with the associated processor. Thus, modality-specific information (e.g., visual, auditory, etc.) may be referenced and processed with new information. As information is received and processed at modality-specific levels it is combined at a higher level by integrative processors to generate situation-specific responses. These may be in the form of a musculoskeletal, cognitive, or attention-modifying events, as well as any combination of these.

General measurement issues of fidelity, validity, and reliability are natural concerns in measurement of information-processing performance capacities. Special issues emerge that increase the overall complexity of the problem when attempting to measure attributes that reflect *just* the information-processing subsystems. Unlike a computer where one may remove a memory module, place it in a special test unit, and determine its capacity, the accessibility of the subsystems within the human brain is such that it is impossible to perfectly isolate and directly measure any of the individual components. When measuring characteristics of human information-processing subsystems, it is necessary to address measurement goals that are similar to those applied to analogous artificial system within the constraint that human sensors and motoric subsystems must also be utilized.

78.2.2 Performance Capacities

In considering the performance of human information-processing systems, the resource-based perspective represented by the Elemental Resource Model [Kondraske, 2000] is adopted here. This model for human performance encompasses all types of human subsystems and is the result of the application of a general theoretical framework for system performance to the human system and its subsystems. A central idea incorporated in this framework, universal to all types of systems, is that of *performance capacity*.

This implies a finite availability of some quantity that thereby limits performance. A general two-part approach is used to identify unique performance capacities (e.g., visual information **processor speed**) (1) identify the system (e.g., visual information processor) and (2) identify the dimension of performance (e.g., speed). In this framework, system performance capacities are characterized by availability of performance resources along each of the identified dimensions. These *performance resources* are to be distinguished from less rigorously defined general processing resources described by others [e.g., Kahneman, 1973; Wickens, 1984]. However, many of the important basic constructs associated with the idea of "a resource" are employed in a similar fashion in each of these contexts. For processors, key dimensions of performance are speed and accuracy. *Processor speed* and **processor accuracy** capacities are thus identified. For memory systems, key dimensions of performance are storage capacity, speed (e.g., retrieval) and accuracy (e.g., retrieval). Other important attributes of performance capacities are discussed in other sections of this chapter.

   Many aspects of information-processing performance have been investigated resulting in discoveries that have provided insight to the capacities of subsystems as well as refinement to both system structure and function definitions [Lachman et al., 1979]. One of the oldest studies in which the basic concept of information-processing performance capacity was recognized addressed "speed of mental processes" [Donders, 1868]. The basic idea of capacity has been a central topic of interest in human information-processing research [Moray, 1967; Posner and Boies, 1971; Schneider and Shiffrin, 1977; Shiffrin and Schneider, 1977].

78.2.3   Stimulus–Response Scenario

The *stimulus–response scenario*, perhaps most often recognized in association with behavioral psychology, has emerged as a fundamental paradigm in psychology experiments [Neel, 1977]. Aside from general utility in research, it is also an essential component of strategies for measurement of human information-processing performance capacities. A typical example is the well-known reaction time test in which the maximum speed (and sometimes accuracy) at which information can be processed is of interest. Here, a subject is presented a stimulus specific to some sensory modality (e.g., visual, auditory, and tactile) and is instructed to respond in a prescribed manner (e.g., lift a hand from a switch "as fast as possible" when the identified stimulus occurs). This general approach, which has become so popular and useful in psychology, can also be recognized as one that has been commonly employed in engineering to characterize artificial systems (e.g., amplifiers, motors, etc.). A specific known signal (stimulus) is applied to the system's input and the corresponding output (response) is observed. Specified, measurable attributes of the output, in combination with the known characteristics of the input, are used to infer various characteristics of the system under test. When the focus of interest is the performance limits of processing systems, these characteristics include processing speed, processing accuracy, memory storage capacity, etc.

   In performance capacity tests, an important related component is the **prestimulus set**, or simply the way in which the system is "programmed to respond to the stimulus." This is usually accomplished by one or more components of the instructions given to the subject under test (e.g., respond "as quickly as possible," etc.) just prior to the execution of an actual test.

78.2.4   Measurement of Information (Stimulus Characterization)

Within a given sensory modality, it is easy to understand that different stimuli place different demands or "loads" on information-processing systems. Thus, in order to properly interpret results of performance tests, it is necessary to describe the stimulus. While this remains a topic of ongoing research with inherent controversies, some useful working constructs are available. At issue is not simply a qualitative description, but the *measurement* of stimulus content (or complexity). Shannon's information theory [1948], which teaches how to measure the amount of information associated with a generalized information source, has been the primary tool used in these efforts. Thus, a stimulus can be characterized in terms of the amount of information present in it. Simple stimuli (e.g., a light that is "on" or "off") possess less information

than complex stimuli (e.g., a computer screen with menus, buttons, etc.). The best successes in attempts to quantitatively characterize stimuli have been achieved for simple discrete stimuli [Hick, 1952; Hyman, 1953]. From Shannon, the amount of information associated with a given symbol "i," selected from a source with "n" such symbols is given by:

$$I_i = \log_2(1/p_i) \tag{78.1}$$

where p_i is the probability of occurrence of symbol "i" (within a finite symbol set) and the result has the units of "bits." Thus, high probability stimuli contain less information than low probability stimuli. It is a relatively straightforward matter to control the probabilities associated with symbols that serve as stimuli in test situations. The application of basic information theory to the characterization of stimuli that are more complex (i.e., multiple components, continuous stimuli) is challenging both theoretically and practically (e.g., large symbol sets, different sets with different probability distributions that must be controlled, etc.).

If stimuli are not or cannot be characterized robustly in terms of a measure with units of "bits," operationally defined units are frequently used (e.g., "items," "chunks," "stimuli," etc.). In addition, as many stimulus attributes as possible are identified and quantified and others are simply "described." This at least maximizes the opportunity for obtaining repeatable measurements. However, the additional implication is that the number of "bits per item" or "bits per chunk" is waiting to be delineated and perhaps a conversion could be substituted at a later time. While this state leaves much to be desired from a rigorous measurement perspective, it is nonetheless quite common in the evolution of measurement for many physical quantities and allows useful work to be conducted.

78.2.5 Speed–Accuracy Trade-Off

Fundamental to all human information-processing systems and tasks is the so-called **speed–accuracy trade-off**. This basic limitation can be observed in relatively high-level everyday tasks such as reading, writing, typing, listening to a lecture, etc. Psychologists [Wicklegren, 1977] have studied this trade-off in many different contexts. Fitts [1966] demonstrated a relationship between measures reflecting actual performance (reaction time and errors) to incentive-based task goals (i.e., were subjects attempting to achieve high speed or high accuracy). As shown in Figure 78.2, relationships that have been found suggest an upper limit to the combination of speed and accuracy available for information-processing tasks. In this figure, original reaction time measures have been transformed by simple inversion to obtain true speed measures, which also conform to the resource construct used in modeling performance capacities, as described in Section 78.2.2. The result then defines a two-dimensional (e.g. speed–accuracy) performance envelope for information-processing systems. The area within this envelope, given that each dimensions represents a resource-based performance capacity, represents a higher level or composite performance capacity metric (with units of speed × accuracy), analogous in some respects to a gain–bandwidth product or work (force × displacement) metric.

78.2.6 Divided Attention and Time Sharing

An approach sometimes used in a variety of measurement contexts incorporates a *dual-task or divided attention scenario* that is designed to require use of attention resources in two different simultaneously executed tasks [e.g., Wickens, 1984]. For example, visual tracking (primary task) accuracy *and* speed of response to an embedded visual stimulus (secondary task) can be measured. Details of the potential time-sharing possibilities at play are quite complex [Schneider and Shiffrin, 1977; Shiffrin and Schneider, 1977].

In comparison to single-task performance test situations, in which the attention processor may not be working at capacity, the additional demand is designed to change (compared to a single-task baseline) and sometimes maximizes the stress on attention performance resources. Performance on both primary and secondary tasks, compared to levels attained when each task is independently performed, can provide an indirect measure of capacity associated with attention [Parasuraman and Davies, 1984]. This approach
FIGURE 78.2 A typical information-processing performance envelope in two-dimensional speed–accuracy space. (Data from Wickelgren, W.A. 1977. *Acta Psychol.* 41, 67–85.)

has been useful in determining relative differences in demand imposed by two different primary tasks by comparison of results from respective tests in which a fixed secondary task is used with different primary tasks. Of more direct relevance to the present context, an appropriate secondary task can be used to control in part the conditions under which a given performance capacity (defined in a standard way and measured in association with the primary task) is measured, for example, visual information-processing speed can be measured with no additional attention load or with several different additional attention load levels. While it may be possible to rank order secondary tasks in terms of the additional load presented, there are no known methods to quantify attention load in absolute terms.

78.3   General Measurement Paradigms

Despite the complexity of human information-processing, a fairly small number of different measurement paradigms have emerged for quantification of the many unique human information-processing performance capacities. This is perhaps in part due to the limited number of system types (e.g., processors and memories). A good portion of the observed complexity can therefore be attributed to the number of different processors and memories, as well as the vastness and diversity of actual information that humans typically possess (i.e., facts, knowledge, skills, etc.). While most of the paradigms described below have been used for decades, it is helpful to recognize that they all conform to, or can be made to conform to, the more recently proposed [Kondraske, 1987, 1995] generalized strategy for measuring any aspect of performance for any human subsystem (1) maximally isolate first the system of interest, (2) maximally isolate the dimensions of performance of interest, and (3) maximally stress (tempered by safety considerations when appropriate) the system along those dimensions.

78.3.1 Information-Processing Speed

The paradigm for measuring information-processing speed is commonly referred to as a reaction time test since the elapsed time (i.e., the processing time) between the onset of a given stimulus and the occurrence of a prescribed response is the basic measurable quantity. To obtain a processing speed measure, the stimulus content in "bits," "chunks," or simply "stimuli" is divided by the processing time to yield measures with units of bits, chunks, or stimuli. Choice of stimulus modality isolates a specific sensory processor, whereas choice of a responder (e.g., index finger, upper extremity motion caused primarily by shoulder flexors, etc.) isolates a motoric processor associated with generation of the response. Much research has addressed the allocation of portions of the total processing time to various subsystem components (Sternberg, 1966).

TABLE 78.1 The Combination of the Human Sensor Subsystem (Determined by Stimulus Source) and Responder Isolates Unique Subsystems

Capacity types	Stimulus type(s)	Responder[a]	Measurements
Attention	Visual Auditory	Upper extremity Vocal system	Length of time that a task can be performed to specification and accuracy (if appropriate for task) when subject is instructed to perform for "as long as possible"
Processor speed	Visual Visual Visual Auditory Auditory Auditory Vibrotactile	Upper extremity Lower extremity Vocal system Upper extremity Lower extremity Vocal system Upper extremity	Inverse of time required to react to stimulus (i.e., stimuli/sec) when subject is instructed to respond "as quickly as possible"
Processor accuracy	Visual Visual Visual Auditory Auditory Auditory Vibrotactile	Upper extremity Lower extremity Vocal system Upper extremity Lower extremity Vocal system Upper extremity	Subject is asked to perform task (e.g., typically recognition of symbols from set with similar information content across symbols) "as accurately as possible" and without stress on speed of measures of accuracy. The correct percentage (out of a predetermined set size) is often used, although different accuracy measures have been proposed [Green and Swets, 1966; Wicklegren, 1977].
Processor speed–accuracy	Visual Visual Visual Auditory Auditory Auditory Vibrotactile	Upper extremity Lower extremity Vocal system Upper extremity Lower extremity Vocal system Upper extremity	Basically a combination of tests that stress speed and accuracy capacities individually, as well as both speed and accuracy measures are obtained as defined above to get off-axis data points in two-dimensional speed–accuracy space. Both speed and accuracy can be maximally stressed (e.g., by instructing subject to perform "as fast and accurately as possible") or accuracy can be measured at different speeds by varying time available for responses and stressing accuracy within this constraint
Memory storage capacity	Visual Visual Visual Auditory Auditory Auditory Vibrotactile	(Same options as above[b])	Maximum amount of information of type defined by stimulus that the subject is able to recall. Stimuli usually consist of sets of symbols of varying complexity in different sets (e.g., spatially distributed lights, alphanumeric characters, words, motions, etc.) but similar amount of information per symbol in a given set. Units of "bits" are ideal, but not often possible if number of bits per symbol is unknown. In such cases, units are often reported as "symbols," "chunks," or "items"

A number of representative, but not exhaustive combinations are illustrated for each information-processing capacity type. Depending on objectives of the test task (as communicated to the subject under test) and metrics obtained, many different unique capacities are defined. In some applications (e.g., in evaluating a subject who has suffered a stroke in very localized region of the brain) the specificity is important. In others (e.g., in evaluating a neurologic disease with widespread generalized effects) the responder may be chosen for convenience.

[a] General terms are used in table to illustrate combination options. Very specific definition that controls the motoric functional units involved as precisely as possible should be used for any given capacity test. For example (1) Upper extremity (shoulder flexor vs. elbow flexor vs. digit 2 flexor) and (2) Vocal system (lingua-dental "ta" vs. labial "pa" response), etc.

[b] Unless motor memory capacities are being tested, the responder is typically chosen to minimize stress on motoric processing and, compared to processor performance measures, not to isolate a unique motor memory system.

The system of primary interest as presented here is the sensory processor. Processing times associated with the motoric processor involved in the response are substantially less in normal systems. However, it is recommended that a given processor speed capacity be identified not only by the sensor subsystem stressed, but also by the responder (e.g., visual shoulder flexor information processor speed). This identifies not only the test scenario employed but also the complete information path.

78.3.2 Information-Processing Accuracy and Speed–Accuracy Combinations

In contrast to processor speed capacity that describes limits on information rate, accuracy relates to the ability to resolve content. In general, paradigms for tests that include accuracy measures typically involve a finite set of symbols with a corresponding set of responses. Various stimulus presentation–response scenarios can be used. For example, a stimulus can be randomly selected from the set with the subject required to identify the stimulus presented. Alternately, a subset of stimuli can be presented and the subject asked to select the response corresponding to the symbol not in the subset (size of subsets should be small if it is desired to minimize stress on memory capacities). A key element is that, within a poststimulus–response window, the subject is forced to select one of the available responses. This allows accuracy of the response to be measured in any of a number of ways ranging from relatively simple to complex [Green and Swets, 1966; Wicklegren, 1977]. The response window is either relatively open-ended, as short as possible and variable (based on the speed of the subject's response), or fixed at a given length of time. When only accuracy is stressed, subjects are instructed to perform as accurately as possible and the stress on speed is minimized (e.g., "take your time"). In a second type of speed–accuracy test, subjects are instructed to perform as fast and as accurately as possible, maximally stressing both dimensions while both accuracy and speed of responses are measured. In a variation of this general paradigm, a fixed-response window size is selected to challenge response speed. This provides a known point along the speed dimension of performance. In all three cases, measured response accuracy provides the second coordinate of a point in the two-dimensional speed–accuracy performance space. The combination of different paradigms can be used to determine the speed–accuracy performance envelope (see Section 78.2.5).

78.3.3 Memory Capacity

As used here, *memory capacity* refers to the amount of information that can be stored and recalled. It is well accepted that separate memory exists for different sensory modalities. Also, short-, medium-, and long-term memory systems have been identified [Crook et al., 1986]. Thus, separate capacities can be identified for each. Higher level capacities can also be identified with processes that utilize memory, such as scanning [Sternberg, 1966]. A comprehensive assessment of memory would require tasks that challenge the various memory systems to determine resources available, singly and along different combinations of their various modalities, most directly relevant to the individual's developmental stage (infant, youth, adolescent, young adult, middle aged adult, or older adult), and reflecting the diversity and depth of life experiences of that individual. No such comprehensive batteries are available. As noted by Syndulko et al. [1988], "Most typically, a variety of individual tests are utilized that evaluate selected aspects of memory systems under artificial conditions that relate best to college students." This general circumstance is in part due to the lack of generalized performance measurement strategies for memory. Despite such diversity, perhaps the most common variation of the many memory capacity tests involves providing a stimuli of the appropriate modality and requiring complete, accurate recall (i.e., a response) after some specified period of delay. The response window is selected to be relatively long so that processor speed is only minimally stressed. Typically, a test begins with a stimulus that has low information content (i.e., one that should be within capacity limits of the lowest one expects to encounter). If the response is correct, the information content of the stimuli is increased and another trial is administered. It is typically assumed that the amount of information added after each successful trial is fairly constant. Examples include: adding another light to a spatially distributed light pattern, adding another randomly selected digit (0–9) to a sequence of such digits, etc. By continuing this process of progressively increasing the amount of stimulus information until

an inaccurate response is obtained, the isolated memory capacity is assumed to be maximally stressed. The result is simply the amount of information stored and recalled, in units of bits, chunks, or items.

78.3.4 Attention

Tests for basic attention capacity can be considered to be somewhat analogous to endurance capacity tests for neuromuscular systems. Simply put, the length of time over which a specified information-processing task can be executed provides a measure of attention capacity (or attention span). The test paradigm typically involves presentation at random time intervals of a randomly selected stimulus from a finite predefined symbol set for a relatively short, fixed time (e.g., 1 sec). Within a predefined response window (with a maximum duration that is selected so that processing speed resources are minimally stressed), the subject must generate a response corresponding to the stimulus that occurred. Attention is maximally stressed by continuing this process until the subject either (1) makes no response within the allocated response window, or (2) produces an incorrect response (i.e., a response associated with a stimulus that was not presented). These criteria thus essentially define the point at which the specified task (i.e., recognize stimuli and respond correctly within a generous period of time allotted) can no longer be completed. Once again, choice of stimulus modality isolates a specific sensory processor (e.g., visual, auditory, tactile, etc.). Clearly, stimulus complexity is also important. Stress on higher-level cognitive resources can be minimized by choice of simple stimuli (e.g., lights, tones, etc.). Motoric processors associated with response generation are also involved. However, these are minimally stressed and as long as basic functionality is present the choice of responder should have little influence on results compared to, for example, the influence occurring during processor speed capacity measurements.

78.4 Measurement Instruments and Procedures

Given the above functional systems model for human information-processing (Figure 78.1) and review of measurement paradigms for information-processing subsystems, a general architecture for instruments capable of measuring information-processing performance capacities can be defined (Figure 78.3). It is interesting to observe that this architecture parallels the human information-processing system (i.e., compare Figure 78.1 and Figure 78.3).

Most such instruments are computer based, allowing for generation of stimuli with different contents, presentation of stimuli at precisely timed intervals, measurement of processing times (from which processing speeds are derived) with high accuracy (typically, to within 1 msec), and accurate recording of responses and determination of their correctness.

A typical desktop computer system fits the general architecture presented in Figure 78.3 and, as such, it has been widely exploited "as is" physically with appropriate software to conduct information-processing tests. This is adequate for tests for higher level, complex cognitive processing tasks due to the longer processing times involved. That is, screen refresh times and keyboard response times are smaller fractions of total times measured and contribute less error. However, for measurement of more basic performance
FIGURE 78.3 The general architecture for instruments used to measure human information-processing performance capacities.

capacities and to allow testing of subjects who do not possess normal physical performance capacities, custom test setups are essential. The general design goal for these stimuli generators and response sensors is to minimize the stress on human sensory, motor, and aspects of central processing resources that are not the target of the test. For example, the size of standard keyboard switches imposes demands on positioning accuracy when, for example, visual information-processing accuracy is being tested. According to Fitts' Law [Fitts, 1954], the task component involved with hitting the desired response key (i.e., the component that occurs after the visual information-processing component) requires longer processing times (associated with the motoric response task) for smaller targets. Thus, to minimize such influences, a relatively large target is suggested. Along the same lines of reasoning, these additional design guidelines are important (1) key stimulus attributes that are not related to information content should be well above normal minimum human sensing thresholds (e.g., relatively bright lights that do not stress visual sensitivity and large characters or symbols that do not stress visual acuity), (2) response speeds of stimulus generators and response sensors should be much faster than the fastest human response speed that is anticipated to be measured.

Even the many custom devices reported in the literature (as well as commercially available versions of some) have been devised to support research into fundamental aspects of information-processing and are used in studies that typically involve only healthy young college students. While such devices measure the stated or implied capacities well in this population, the often unstated assumption regarding other involved performance capacities (i.e., that they are available in "normal" amounts) is severely challenged when the subject under test is a member of a population with impairments (e.g., head injured, multiple sclerosis, Parkinson disease, etc.).

A representative instrument [Kondraske et al., 1984; Kondraske, 1990] is illustrated in Figure 78.4. This device incorporates 8 LEDs and 15 high-speed touch sensors ("home," A1–A8 and B1–B6) and a dedicated internal microprocessor to measure an array of different performance capacities associated with information-processing. Measures at the most basic hierarchical level (visual information-processing speed, visual–spatial memory capacity, visual attention span, etc.) and intermediate level (coordination tasks involving different sets of more basic functional units) are included.

For example, visual-upper extremity information-processing speed is measured in a paradigm whereby the test subject first places his/her hand on the "home" plate. A random time after an audible warning
FIGURE 78.4 Major components of a specific microprocessor-based instrument (Human Performance Measurement, Inc. Model BEP I) for measurement of a selected subset of information-processing capacities incorporating high-intensity LEDs for visual stimuli and large contact area, fast touch sensors to acquire responses (made by the upper extremity) from the subject under test (semicircle radius is 15 cm).

cue, one out of eight LEDs (e.g., LED 4) stimulates the subject to respond "as quickly as possible" by lifting his/her hand off the home plate and touching the sensor (e.g., A4) associated with the lighted LED. Each LED represents a binary (ON or OFF) information source. Since an equiprobable selection scheme is employed, the $\log_2$ (# choices) represents the number of bits of information to be processed when determining which LED is lighted. In this example, the number of choices is eight; prior to the test the subject was informed that any one of eight LEDs would be selected. Modes reflecting different information loads (1, 2, 4, or 8 choices) are available. Processing speed (in stimuli per sec) is obtained as a result from each trial by inverting the total processing time, measured as the time from presentation of the stimulus until the subject's hand is lifted off the home plate. By combining time measures from two or more tests with different information loads, a more direct measure of true processing speed in bits per second is obtained. For example, results from an 8-choice (3 bit load) test and a 1-choice test (0 bit load) are combined as follows: $(3 \text{ bits} - 0 \text{ bits})/(t_3 - t_0)$, where t_n is the reaction time measured for an "n" bit information load. This method removes transmission and other time delays not associated with the primary visual information-processing task. Multiple trials are performed (typically, $3 \times$ number of choices, but no less than five trials for any mode) to improve test–retest reliability in the final measures, which are computed by averaging over a fraction (best 80%) of the trials. While even more trials might further improve repeatability of final capacity measures in some subjects, the overall test duration must be considered in light of the desire (from a test design perspective) to minimize stress on attention resources that could vary widely over potential test subjects. Careful trade-offs are necessary.

Visual–spatial memory capacity is measured using the same device. A random sequence of LEDs, beginning with a sequence length of "one," is presented to the subject. The subject responds by contacting (with their preferred hand) the subset of touch sensors (from A1 to A8) corresponding to the LEDs incorporated in a given stimulus presentation, in the same order as the LEDs sequence was presented. A correct response causes a new trial to be initiated automatically with the sequence length increased by one. The maximum length of this sequence (in items) that the subject can repeat without error is used as the measure of visual–spatial memory capacity. The better of two trials is used as a final score. The bright LEDs, relatively large contact area of the touch sensors ($5 \times 5 \text{ cm}^2$), and a relatively long poststimulus–response window (up to 10 sec) ensure that other performance resources are minimally stressed.

A measure of visual attention span is obtained with a task in which random LEDs are lighted for 1 sec at random intervals ranging from 4 to 15 sec. After each LED is lighted, a response window is entered (3 sec maximum) during which the subject is required to indicate that a lighted LED was observed by contacting the corresponding touch sensor. The task continues until either the wrong touch sensor is contacted or no response is received within the defined response window. The time (in seconds) from the beginning of the test until an "end of test" criterion is met is used as the measure of visual attention performance capacity. The simple stimuli ensure that higher level cognitive resources are minimally stressed. This allows a wide range of populations to be tested, including young children. Some normal subjects can achieve very long attention spans (e.g., hours) with this specific scenario, while some head-injured subjects (for example) produce times less than 60 sec.

One example of a more comprehensive, computer-based memory performance test battery is that developed by Crook and colleagues [1986]. This battery is directed at older adults, evaluates memory in the visual and auditory modalities at each of the three temporal process levels, and utilizes challenges that relate well to the daily activities of the target group. The challenges (i.e., stimulus sets) are computer generated and controlled, administered by means of a color graphics terminal, and, in some cases, played from a videodisc player to provide as realistic of a stimulus representation as possible outside of using actors in the everyday environment of the subject. The battery takes 60 to 90 min to administer, and provides a profile of scores across the various measurement domains. Extensive age and gender norms are available to scale the scores in terms of percentiles. Despite its scope, it does not provide, nor was it intended to provide, information about modalities other than visual and auditory (e.g., tactile, kinesthetic, or olfactory). It also does not address long-term memory storage beyond about 45 min. (Consider the test administration complexities in doing so.) Nonetheless, it represents one of the most sophisticated memory performance measurement and assessment systems currently available.

78.5   Present Limitations

General methods and associated tools do not exist to quantify the information content of any arbitrary stimulus within a given modality (e.g., visual, auditory, etc.). Success has only been achieved for relatively simple stimuli (e.g., lights which are on or off, at fixed positions spatially, etc.). It can be said, however, that serious attempts to quantify complex stimuli even in one modality appear to be lacking. To the practitioner, this prevents standardization that could occur across many information-processing performance capacity metrics. For example, information-processing speed capacities cannot yet universally be expressed in terms of bits. Perhaps more significantly, this limitation not only impacts looking toward the human and the measurement of intrinsic performance capacities, but also the analysis of information-processing tasks in quantitative terms. This, in turn, has limited the way in which information-processing performance capacity measures can be utilized. Whereas one can measure grip strength available in a subject (a neuromuscular capacity) and also the worst-case grip force required to support turning a door knob, it is not yet possible to determine how much visual information one must process to reach out and find the door knob.

As was also noted, one cannot ideally isolate the systems under test. The required involvement of human sensory and motoric systems also requires the use of ancillary performance tests that establish at least some minimal levels of performance availabilities in these systems (e.g., visual acuity, etc.) in order to lend validity to measures of information-processing performance capacities. New imaging techniques and advanced electroencephalographic and magnetoencephalographic techniques such as brain mapping may offer the basis for new approaches that circumvent in part this limitation. While the cost and practicality of using these techniques routinely is likely to be prohibitive for the foreseeable future, the use of such techniques in research settings to optimize and establish validity of simpler methods can be anticipated.

Moray [1967] was one of many to use the analogy to data and program storage in a digital computer to facilitate understanding of a "limited capacity concept" with regard to human information-processing. In the material presented, emphasis has been placed on the components analogous to those within the realm of computer hardware (i.e., processors and memories). These have been dealt with at their most basic operational levels for testing purposes, attempting to intentionally limit stresses on the test subject's acquired skill (i.e., stored information itself). It has been implied and is argued that knowledge of these hardware system capacities is in itself quite useful (e.g., it is helpful to know whether your desktop computer's basic information-processing rate is 800 MHz or 2 GHz). However, many tasks that humans perform daily, which involve information-processing require not only processing and storage capacities, but also the use of *unique information* acquired in the past (i.e., training or "programs"). These software components, which like processor and memory performance capacities also represent a necessary but not sufficient resource for completion of the specific task at hand, present even greater challenges to evaluation. If the analogy to computer programs is used (or even musical scores, plans, scripts, etc.), it can be observed that even the smallest "programming error" can lead to a failure of the total system in accomplishing its intended purpose with the intended degree of performance. Checking the integrity of human "programs" can be envisioned to be relatively easy if the desired functionality is in fact found to be present. However, if functionality is not present and diagnostic data points to a "software problem," a more difficult challenge is at hand. Methods which can be employed to reveal the source of the error in the basic information itself (i.e., the contents of memory) can be expected to be just as tedious as checking the integrity of code written for digital computers.

Defining Terms

Attention: A performance capacity representing the length of time that an information-processing system can carry out a prescribed task when maximally stressed to do so. This is analogous to endurance in neuromuscular subsystems.

Dual-task scenario: A test paradigm characteristic by a primary and secondary task and measurement of subject performance in both.

Memory: One of two major subsystem types of the human information-processing system that performs the function of storage of information for possible later retrieval and use.

Performance capacity: A quantity in finite availability that is possessed by a system or subsystem, drawn on during the execution of tasks, and limits some aspect (e.g., speed, accuracy, etc.), a system's ability to execute tasks; or, the limit of that aspect itself.

Processor: One of two major subsystems types within the human information-processing system that performs the general function of processing information. Multiple processors at different hierarchical levels can be identified (e.g., those specific to sensory modalities, integrative processors, etc.).

Processor accuracy: The aspect, quality, or dimension of performance of a processor that characterizes the ability to correctly process information.

Processor speed: The aspect, quality, or dimension of performance of an information processor that characterizes the rate at which information is processed.

Prestimulus set: The manner in which an human system is programmed to respond to an ensuing stimulus.

Speed–accuracy trade-off: A fundamental limit of human information-processing systems at any level of abstraction that is most likely due to a more basic limit in channel capacity; that is, channel capacity can be used to achieve more accuracy at the expense of speed or to achieve more speed at the expense of accuracy.

Further Information

A particularly informative, yet concise historical review of the major perspectives in psychology leading up to much of the more recent work involving quantitative measurements of information processing and determination of information-processing capacities is provided in Neel, A. 1977. *Theories of Psychology: A Handbook,* Schenkman Publishing Co., Cambridge, MA.

Human information processing has long been and continues to be a major topic of interest of the U.S. military. Considerable in-depth information and experimental results are available in the form of technical reports, many of which are unclassified. *CSERIAC Gateway,* published by the Crew System Ergonomics Information Analysis Center (CSERIAC), is distributed free of charge and provides timely information on scientific, technical, and engineering knowledge. For subscription information contact AL/CFH/CSERIAC, Bldg. 248, 2255 H St., Wright-Patterson Air Force Base, Ohio, 45433. Also, the North Atlantic Treaty Organization AGAARD (Advisory Group for Aerospace Research & Development) Aerospace Medical Panel Working Group 12, has worked on standards for a human performance test battery for military environments (much of which addresses information processing) and has defined data exchange formats. Documents can be obtained through the National Technical Information Service (NTIS), 5285 Port Royal Road, Springfield, VA 22161, USA.

Information regarding the design, construction, and evaluation of instrumentation (including quantitative attributes of stimuli, etc.) are often embedded in journal articles with titles that emphasis the major question of the study (i.e., not the instrumentation). Most appear in the many journals associated with the fields of psychology, neurology, and neuroscience.

High-Level Task Analysis: Cognitive Components

Kenneth J. Maxwell
BMK Consultants

79.1   The Purpose of This Chapter

Effective and safe use of biomedical products requires, among other capabilities, knowledge, interpretive reasoning, attention, and memory. Biomedical products are not alone in these requirements. The integration of information technology (IT) into communications, manufacturing, transportation, power, and medical systems has shifted the predominant activities of many human-performed **tasks** from manual to cognitive. However, biomedical products support health systems and their successful use is often critical. Designers need to understand and accommodate the knowledge and cognitive abilities of users in product design. As a result, data, models, and metrics for describing and understanding **cognitive tasks**

79-1

and the cognitive capabilities of persons performing them have become very important to engineering design.

Task analysis is a generic term that refers to methods for applying task data to improve engineering design decisions. This chapter presents a process and associated methods for analyzing cognitive tasks (or the **cognitive components** of high-level tasks). It further describes the role of cognitive task analysis along with human performance and machine models (as applicable) in product design, and presents a quantitative, performance-based framework for performing a unified human–machine–task analysis. This chapter is not intended as a review. Selected techniques are presented to familiarize the reader with different major approaches that are currently applied to solving real-world engineering problems.

79.2   Fundamentals

A task is a goal-directed pattern of activities or operations. High-level tasks refer to complex, composite activities or operations that entail performing many simpler but interrelated tasks in meaningful ways [Kirwan and Ainsworth, 1992]. Typically these combinations of low-level tasks are procedural in nature. Performing tasks imposes sensory–perceptual, motor, cognitive, and emotional demands on the agents, persons, or machines performing them that result from the combination of (1) the activities and operations being performed; and (2) the level of performance needed to be achieved.

Task analysis is a process for (1) identifying and breaking down high-level tasks into their constituent, mutually exclusive, lower-level tasks; (2) describing intertask relationships and dependencies; (3) determining task goals and procedures; and (4) specifying task performance and skill requirements.

To the degree that task descriptions are quantified in terms that can be related to models of human performance and skill and to models of machine performance, the design decisions based on the analysis will be better for at least two reasons. First, the designer will be better able to ensure that the performing agents collectively have sufficient performance and skill capabilities. Second, the designer can better control and optimize the distribution, also called allocation, of performance and skill requirements among the performing agents.

79.2.1   Task Levels

Tasks are performed in the context of and to fulfill human purposes. High-level tasks are defined in terms of an applied goal that contributes to satisfying an even higher-level purpose. Low-level tasks combine to accomplish high-level tasks. Figure 79.1 depicts two general tasks: an application task and an interaction task. The interaction task is the set of all interactions between the human and the product. For illustration purposes the figure includes one human interacting with one product, but the more complex systems with many humans interacting among themselves and with many products of various complexities are possible.

In Figure 79.1, the human and product both contribute to performing the application task, and they do this in concert by successfully interacting. The application task represents high-level tasks such as monitoring blood glucose level, retrieving and reviewing a patient's medical history, delivering medications to various hospital departments using a robot, or planning a surgical procedure using simulation systems.

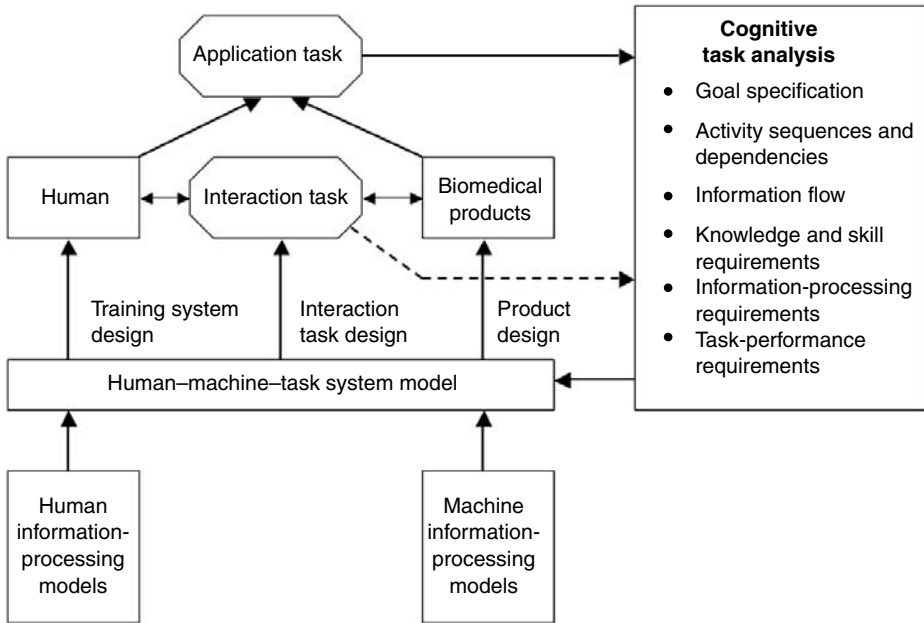
The interaction task includes the set of lower-level interactions that are performed by the human and product to accomplish the application task that may also be at different levels. For example, the application-level goal of reviewing a medical record may involve the interaction-level task of retrieving the record from an electronic database. The retrieval task, in turn, entails lower-level interaction tasks of search that involves the still lower-level task of formulating a proper search query. Each level of tasks may impose cognitive demands.


FIGURE 79.1   Task-to-design process flow.

79.2.2   General Analysis-to-Design Process Flow

In addition to the tasks, Figure 79.1 depicts the relationships between task analysis, human and machine models, and design activities. Design is iterative. However, prototyping and testing processes which are essential to the iteration of design are not depicted in Figure 79.1. Also absent are user-profiling activities that should be performed early in the design process and that would compliment the human performance models.

In Figure 79.1, a task analysis at both the application and interaction levels in conducted. The dashed line between the interaction task and the task analysis is meant to indicate that this can only be accomplished if there is an existing product to analyze. In some cases another similar product or product analogue may be useful to analyze.

Task data by themselves are of limited use in design because the task data address only requirements for resources. To be useful in design, task data must be analyzed along with the goals and performance capabilities of the agents (i.e., humans and machines) that will need to perform the tasks. The process of meeting particular task requirements with particular human, machine, and human–machine interaction resources is called human–machine–task modeling. Design concepts need to be consistent with this model to be successful. As depicted in Figure 79.1, designs applicable for each element flow from this model.

To the degree that the human–machine–task system analysis is coordinated by consistent, or at least relatable, constructs across all elements its effectiveness in guiding good design concepts will increase. Further, the quality and precision of applied decisions are enhanced to the degree that these constructs are quantitative. Schweickart et al. [2003] present a means of generating a quantitative computer-based model of operators performing real-world tasks from the cognitive task analysis. This technique ensures relatedness between the analysis and the model. The **Elemental Resource** Model (ERM) framework [Kondraske, 1995] for human–machine–task system design described later combines the use of task analysis and resource requirement modeling techniques with human performance and machine performance models also producing a consistent set of constructs between analysis and models to guide design.

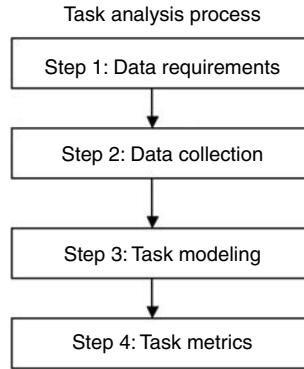
Task analysis process


FIGURE 79.2   Task analysis as a four-step process.

79.3   Cognitive Task Analysis: Process and Methods

Figure 79.2 depicts the task-analysis process in four major steps. Before any data are collected, required data should be defined on the basis of the characteristics of the design decisions the analysis is to support. Selection and use of data-collection methods, task models, and task metrics are later informed by these data requirements.

79.3.1   Step 1: Data Requirements Definition

In Step 1, the task data required for the analysis are determined. The major factors involved in determining data needs are (1) the scope of design problems being addressed (i.e., the functional scope of the human–machine–task system being analyzed); (2) the point in the system design process at which the analysis is conducted; and (3) the extent to which the product is new or being revised. Task analysis can be applied to existing systems or to proposed systems for which tasks are in the process of being defined.

Task analysis is used through the different phases and iterations of product development. Different types of task data can be collected as the fidelity of system prototypes progresses and operational systems become available. These differences are apparent by examining three points in the system engineering process at which task analysis is of particular utility.

Predesign: Task data, together with data about human and technology availability and performance, are used to (1) define and allocate tasks, (2) develop procedures to accomplish the tasks, and (3) identify the needed human–machine interfaces. Note that the description of a task depends on the technology assumed. For example, a writing task would be accomplished differently with paper and pencil, a manual typewriter, or a computer with word processing software.

Design phase: During the design phase, task scenarios, prototypes, and simulations are used to detail and refine the task procedures, task requirements, allocation decisions, and human–machine interface design.

Postdevelopment: Analyzing well-defined tasks performed by an operational system provides a detailed description of task procedures and resource requirements that can be used to improve task performance and the system design. For example, Rogers et al. [2001] were able to reveal many sources of errors and design recommendations from their task analysis of a consumer blood glucose meter. Suri [2000] used task and user analyses of an existing defibrillator to identify errors and safety concerns, and as a basis for a new design. Morphew et al. [2001] used cognitive task analysis to understand the cognitive skills needed to safely and effectively maneuver a robotic arm.

The applied purpose of the task analysis has the greatest impact on what type of data are needed. Applications of task analysis vary greatly and include decisions that may or may not involve machines.

Applications include, but are not limited to, those described as follows:

Human–machine task allocation: Allocation of tasks is a major systems-engineering decision. Task analysis is used to identify task load and performance requirements and contributes to assessing workload. Workload assessment provides a basis for assigning task responsibilities to humans and machines such that performance requirements can be satisfied and workload levels are not excessively low or high. These assessments augment qualitative allocation strategies (e.g., Fitts' lists) in which tasks are assigned on judgments of the relative performance capacities of humans and machines on generic tasks. Allocating tasks requires that the resource demands associated with each lower-level task are assessed and that the human and machine resources available can be matched against these at comparable levels of analysis.

In modern human–machine systems, task assignments may be adaptive or blended rather than strictly allocated. The information-processing capabilities of modern machines often includes some form of task knowledge and reasoning capabilities that provide for an adaptive task allocation that shifts the task demands on the basis of contextual variables. Also, in many cases human performance is augmented by (blended with) machine performance to accomplish a given task.

Task–technology tradeoffs: Task analyses may be performed for systems that have yet to be developed but for which functional and performance requirements have been defined. In these cases, the analysis will be based on the defined requirements combined with data on human performance capacities and available machine technology. These analyses can be used to assess the workload, technology, and performance tradeoffs expected with different human–machine system configurations.

Human–machine interface design: Cognitive task analysis provides not only a basis for allocating task responsibilities to humans and machines but can also be used to define display and control requirements for the interface between humans and machines.

Job design: The roles humans satisfy in complex systems and organizations (e.g., manager, operator, maintainer) are generally designed to include many cognitive tasks. By identifying and describing the mental skills and resources required for task performance, task analysis provides a basis for optimizing job performance in new and existing systems.

Personnel selection and job fitness: Cognitive task analysis yields a specification of information-processing resources (e.g., speed, accuracy) required for task performance. This specification can be used in combination with measurements of the available resources an individual possesses. Assessing performance resource sufficiency provides a basis for selecting personnel and determining if injured, rehabilitated personnel are sufficiently recovered to safely return to work.

Training systems development: Task analysis identifies and characterizes the skills, knowledge, and mental capabilities that are necessary or sufficient for task performance. More specifically, it can be used to characterize differences in these abilities and in task performance between experts and novices. These differences serve as a basis for designing effective personnel training systems.

These applications of task analysis reduce to answering the following types of questions:

- What is the best way to structure the task procedures?
- Does a specific individual have the needed cognitive resources to perform the task?
- What knowledge or skills does an individual need to acquire to perform the task with a given technology?
- Can the task be modified to accommodate the special needs of individuals?

When biomedical products or other machines are involved:

- What human and machine combinations are most capable of performing the task?
- How should human and machine components interact in performing the task?

To answer these applied questions, the following data must be defined and described:

- The cognitive demands of the application task (e.g., knowledge, required information-processing activities, speed, and accuracy in performance actions)

- The cognitive capacities of humans in the system (e.g., knowledge, learning ability, processing speed, processing accuracy)

If machines are involved:

- The information-processing capacities of machine components (e.g., knowledge, artificial intelligence, processing speed, algorithms, and data)
- The cognitive demands of the human–machine interaction task
- The human–machine interaction capacities of the humans in the system
- The human–machine interaction capacities of applicable machines

79.3.2 Step 2: Data Collection

Once the required task data are determined, they need to be collected. Table 79.1 lists four generic categories of techniques for acquiring data about cognitive tasks. The categories are not mutually exclusive. For example, all techniques use some form of observation, and instrumented human-interface techniques and **protocol analysis** are used as **knowledge-acquisition** techniques. Each generic category is described in more detail here.

Knowledge-acquisition and elicitation techniques: Knowledge acquisition refers to the process of obtaining the knowledge and reasoning processes needed to perform tasks. **Knowledge elicitation** is the activity of eliciting from persons the knowledge they possess. Initially, elicitation techniques were applied to elicit knowledge from experts for the development of knowledge-based systems. The expert knowledge elicited is only as good as the expert from which it was elicited. Recently, Weiss and Shanteau [2003] have defined three categories of expertise; expert judges, prediction experts, and performance experts and an empirical assessment technique for determining experts. More generally, knowledge-acquisition techniques have been used as a means of analyzing the cognitive components of tasks [Lehto et al., 1992].

TABLE 79.1   Task Data-Collection Techniques

Technique	Data collected	Requirements	Application phase
Knowledge acquisition	Knowledge required to perform tasks	Task performers Interaction instruments, prototypes, and simulations (dependent on techniques used)	All
Protocol analysis	Procedures Strategies Knowledge	Task performers Task scenarios	Design Postdevelopment
Instrumented human interface	Overt human action (e.g., keys pressed)	Task performers Applicable hardware and software	Design Postdevelopment
Observation	Overt machine behaviors Overt human actions Situation state and state changes	Task performers Prototypes or developed systems Monitoring instruments	Design Postdevelopment
Ethnographic design studies	How humans currently perform tasks How humans relate to technology in real-world settings	Real-world contexts Task performers Documentation instruments (e.g., video recorder)	All

Knowledge-acquisition methods include:

- Interviewing techniques
- Event-based knowledge elicitation [Fowlkes et al., 2000]
- Automatic inductive methods that infer and specify knowledge
- Protocol analysis [Ericsson and Simon, 1984]
- Psychological scaling [Cooke and McDonald, 1988]
- Repertory grids from personal construct psychology theory [Boose, 1985]
- Observational techniques [Boy and Nuss, 1988]

See Cooke [1994] for a review of knowledge elicitation techniques.

Protocol analysis: Protocol analysis refers to various techniques for collecting data in the form of verbal reports. In this methodology, persons generate thinking-aloud protocols of the unobservable (i.e., mental) activities they perform while accomplishing a task [Ericsson and Simon, 1984]. The verbal reports represent behavioral descriptions from which task strategies, requirements, procedures, and problem areas can be derived. Protocols provide data on the sequence in which tasks are performed and thus can be used to identify the strategies used by humans in accomplishing tasks that can be accomplished in multiple ways.

There are several issues that need to be considered about the validity of using verbal reports as data and inferring thought processes from them. Ericsson and Simon [1984] address these concerns by demonstrating how verbal protocols are distinct from retrospective responses and classic introspection by trained observers and detailing the methods for collecting and analyzing protocols.

Instrumented human-interface techniques: These techniques are used to passively and unobtrusively collect objective data on task performance and the procedures by instrumenting human–machine interfaces. These techniques are used to record the timing, sequences, and frequencies of explicit actions. These can, for example, model navigation through a website using search and hyperlink actions or the low-level actions that are done to accomplish the navigation such as keystrokes, button pushes, mouse movements.

The data associated with actions can be used to infer workload and to study the frequency of actions, their temporal relationships, and human error. Although these data are objective, they are restricted to overt responses and, by themselves, do not provide a basis for analyzing cognitive components. Modeling the cognitive task components involves correlating these action data with data about the situations and system behavior that elicited the actions and the changes in the situations and system state caused by the actions, that is, knowledge of context is vital to properly interpreting interactions.

Observation techniques: Observation is a generic term referring to many techniques that can use a wide range of instruments to monitor situations and the behavior of systems and task performers. Two types of observation are distinguished. In direct observation, a human observer is with the task performer as he or she performs the task. In indirect observation, a human observer monitors the task performer remotely with audio and visual monitoring systems. Indirect observation can be done as the task is being performed or after the fact by using a recording. Observation techniques may be unobtrusive or invasive, record subjective or objective data, and may be used in controlled testing or real-world environments.

Ethnographic design studies: These are in-the-field studies that have been adopted from anthropology research. The researchers are embedded to some level with the users and garner data on how they interact in real life with the products or systems under study or similar products or systems or to identify the need for such products. In an ethnographic study of independent elders, Forlizzi et al. [2004] identified two groups of elders, (1) well and (2) declining, based in part by cognitive factors identified during the study.

79.3.3 Steps 3 and 4: Data Modeling and Metric Computation

Steps 3 and 4 are the actual analysis steps. In Step 3, the task data are modeled in accordance with a selected modeling method. This task model is employed in Step 4 to compute various task metrics that are

TABLE 79.2   Analytic Techniques for Modeling Tasks

Technique	Modeled dimensions/characteristics	Analysis
Task–time line analysis	Temporal onset, duration, and concurrences	Task-load estimates Task complexity
GOMS, NGOMSL, and keystroke-level analysis	Task and system knowledge required by task performers Overt low-level actions Procedures Temporal relationships	Task complexity Knowledge requirements Performance estimates from production rule simulation
Task-action grammar	Task and system knowledge required by task performers Observable low-level actions Action sequences	Task complexity Task consistency Knowledge requirements
Fleishman and Quaintance's cognitive task taxonomy	Identifies 23 cognitive abilities underlying task performance. Tasks are modeled in terms of required abilities	Cognitive ability requirements Performance requirements
Rasmussen's cognitive task analysis	Generic activities, knowledge states, and dependencies in cognitive task performance	Knowledge requirements Task complexity
Knowledge-representation techniques	Task and System knowledge required by task performers	Knowledge requirements
Elemental resource model	Mental resources needed to perform tasks Resources are defined in terms of function and performance requirements	Functional requirements Performance requirements

useful in solving the applied problem. Table 79.2 lists seven major approaches for analyzing the cognitive components of tasks. Each has been shown to be useful in applied decision making, and each is described here. For an extended review of techniques, see Linton et al. [1989].

Task–timeline analysis: Timeline analysis organizes and relates low-level tasks on the basis of their time of onset, duration, and concurrences in the context of performing a high-level task. Any **task taxonomy** or decomposition model can be used to define the lower-level tasks that will be mapped to the high-level **task timeline**. Generally, the task–timeline mapping is constructed by decomposing a high-level task in terms of specific scenarios because different scenarios can have very different task and time requirements.

This technique is useful for analyzing workload, allocating tasks, and determining human and system performance requirements. When the resource requirements for each lower-level task are mapped to the timeline, the result is a dynamic task-demand profile.

Wickens [1984] discusses two limitations of timeline analysis. First, the technique often does not account for time-sharing capabilities in which the performance of multiple tasks can be accomplished efficiently when resource demands are low. Second, the technique is most effective when analyzing forced-pace activities. The more freedom the human has to schedule activities, the harder it is to construct a useful timeline.

GOMS and NGOMSL analysis: GOMS, an acronym for goals, operators, methods, and selection rules [Card et al., 1983, 1986], is an analytic technique for modeling (1) the knowledge about a task and a machine that a task performer must possess and (2) the operations that a task agent must execute in order to accomplish the task using the machine. It is based on work by Newell and Simon [1972] in human problem solving. The model was extended by Kieras [1988] into NGOMSL (for natural GOMS language), which affords a more detailed analysis and specification of tasks. In both GOMS and NGOMSL goals represent what a human is trying to accomplish. Operators are elementary perceptual, cognitive, or motor

acts that may be observable or unobservable. Methods are sequences of operations that accomplish a goal. Selection rules are criteria used to select one method to apply when many methods are available.

The NGOMSL analysis uses this model to predict quantitative measures of the complexity of the knowledge required to perform a task with a system. These measures include learning time, amount of transfer, and task execution time. To accomplish this, methods (i.e., procedural knowledge) are represented in the form of production rules. These are IF–THEN rules that describe knowledge in approximately equal-sized units. The number of rules needed to represent a task provides a measure of the complexity of that task. Time predictions are obtained by modeling the production rules in a computer program that stimulates the tasks being analyzed.

The keystroke-level task model is an abbreviated application of the GOMS analysis [Card et al., 1983] that models only the overt actions (i.e., the observable operators and methods) taken by the task performer. In this way it does not require the inferences about mental processes required by the full GOMS approach. The model was developed with regard to a computer system and defines six operators: a keystroke or mouse button push, pointing using a mouse, moving the mouse, moving hands between the mouse and keyboard, mental preparation, and system response. Tasks are modeled by identifying the sequence of operators needed to perform the task.

Task-action grammar analysis: Task-action grammar (TAG) [Payne and Green, 1986; Schiele and Green, 1990] is a formalism for modeling the knowledge required to perform simple tasks with a given system. Task knowledge is represented as sequences of simple acts. Similarities in the syntactic representation of simple tasks are used to derive higher-level schemas that apply across tasks possessing a family resemblance. The ability to derive schemas is used to assess the consistency of the tasks performed with a given user interface and has implications for ease of learning and overall usability. In similarity with NGOMSL, the number of grammatical rules and schemas provides a quantitative measure of task and interface complexity.

Rasmussen's cognitive task analysis: Rasmussen [1986] and Rasmussen and Goodstein [1988] define a framework for cognitive task analysis that was derived from an analysis of human–machine interaction in process-control tasks. One element of this framework is a schematic structure for describing cognitive tasks and information requirements. The schematic structure includes a sequence of (1) information-processing activities, (2) states of knowledge resulting from performing the information-processing activities, and (3) conditions (related to the experience of the human performing the task) that allow the processing sequence to be shortened. This structure constitutes a generic processing task model into which specific task data can be mapped. The information-processing activities are:

- Detecting a need for action
- Observing relevant data
- Identifying the present system state
- Interpreting the present system state
- Evaluating possible consequences of this state with reference to a goal
- Defining a desired target state
- Formulating procedures to achieve the desired state
- Executing the actions required by the procedures

Fleishman and quaintance's cognitive task taxomy: Task taxonomies classify tasks on the basis of various characteristics and properties. As such, they can serve a useful purpose in modeling tasks. Tasks of the same taxonomic classification will have similar characteristics and similar requirements. This inference provides a basis for efficiently creating models for analyzed tasks. Fleishman and Quaintance [1984] provide an extensive review of taxonomies of human performance and identify four classifications (1) behavior descriptions, (2) behavior requirements, (3) ability requirements, and (4) task characteristics. They further detail a taxonomy of human abilities that identifies 23 cognitive factors underlying task performance. These factors were derived from an analysis of empirical performance data collected from a large number of diversified tasks and individuals. The factors constitute a structure for modeling cognitive

tasks. That is, these factors can be mapped onto specific tasks and thus specify the cognitive abilities needed to perform the task.

Knowledge-representation techniques: Knowledge representation is a generic term that refers to several formalisms for modeling knowledge about tasks, systems, and the physical environment. Major representation schemes include production rules, frames, scripts, and cases. Production rules represent knowledge as a set of condition–consequence (i.e., IF–THEN) associations. The Executive Process-Interactive Control (EPIC) cognitive architecture incorporates a cognitive processor implemented as a production rule system with an associated working memory [Kieras and Meyer, 1997; Hornoff, 2004]. Barnard & May [1999] present a unified cognitive architecture based on interacting cognitive subsystems. The architecture incorporates two approaches, one of which implements cognitive activity as a production rule system.

Frames, scripts, and cases are different forms of schemas that represent knowledge as typical stereotypical chunks. Rules and scripts generally represent procedural knowledge, while frames and cases represent declarative knowledge. By formally representing data acquired from knowledge-acquisition techniques, a model of the procedural and declarative knowledge required to perform a task is created.

Elemental resource analysis of tasks: The ERM [Kondraske, 1995] defines human performance in terms of the performance and skill resources (capacities) that a human or system possesses and which can be brought to bear in performing tasks. Elemental resources are defined at a low level such that many of them may be required to perform a high-level task. In addition, intermediate-level resources are defined to provide task-analysis targets at a less granular (i.e., higher hierarchical) level. In this model, a resource is defined as a paired construct consisting of a functional capability (e.g., visual–word recognition) combined with a performance capability (e.g., recognition speed). Thus, even though the functional capability is the same, visual–word-recognition speed and visual–word-recognition accuracy are defined as two distinct resources because they model two distinct dimensions of performance. This model can be applied in task analysis by decomposing the mental components of a task in terms of the resources that a human or system performing them is required to process.

79.4   Models of Human Cognitive Processing and Performance

The analysis of task data by themselves is of limited use in solving applied problems because task data address only one side of the design problem, that is, requirements. For example, a task–timeline analysis provides a model from which a measure of task demand can be computed. However, this analysis does not indicate whether the task load is acceptable or how it could be optimally distributed among humans and machines. Making these judgments requires consideration of human and machine capabilities. Similarly, using the NGOMSL and TAG models, a measure of task complexity can be computed, indicating that one task or procedure is more complex than another. However, these judgments are based solely on the number of task steps and the amount of information needed to perform each step and do not consider how difficult each step is for a human or machine to perform.

Using these task models without incorporating human and machine models forces a general assumption that task difficulty is a linear function of complexity (modeled as more task-steps or information requirements). Even with this assumption, the task model by itself provides no indication of the acceptability of the task complexity or expected human or machine performance. Both these judgments require considerations of human and machine processing and performance models.

Because of these issues, task analysis is used in combination with human and machine models to make design decisions. Using task, human, and machine models in concert requires that the cognitive components being modeled are described in consistent, or at least relatable, terms. Further, the quality and precision of the decision will be enhanced to the degree that the task model describes requirements quantitatively, while the human and machine models describe their capabilities quantitatively.

Five models of human cognitive processes and performance are listed in Table 79.3 and discussed below. These were selected because they (1) describe concepts that are generally applicable to a wide range

TABLE 79.3 Models of Human Cognitive Processes and Performance

Model	Description	Modeled components
Multiple resource model of attention and W/INDEX	Models attention as a collection of separable processing resources. W/INDEX is a computer model of workload that adopts the multiple-resource construct and accounts for resource conflict from concurrent processing	Identifies separable processing resources Time-sharing ability Automatic processing
Model human processor (HMP)	Models human information processing in terms of processing subsystems, memories, and performance parameters	Performance is modeled by assigning time values to the model's parameters Perceptual, cognitive, motor processing subsystems Long-term and working memories
Keystroke-level performance model	Models the performance (i.e., time) estimated for executing each of six defined actions, from which overall estimated task completion times can be computed	Performance is modeled by assigning time values to each of six modeled actions
Skills, rules, and knowledge model	Models human information processing in terms of three levels of behavioral control: skill based, rule based, and knowledge based	Models the processes and requirements for each level of behavior Can be used with quantitative models of human performance to estimate task time and errors
Technique for human error-rate prediction (THERP)	Structure methodology for modeling human error and task completion in terms of probabilities	Predicts human error and task completion probabilities using a human performance database and expert judgments
Elemental resource model of human and system performance (ERM)	Models human and system performance in terms of basic elements of performance and elemental resources	Performance is modeled in terms of elemental units that can be combined to provide estimates of high-level task performance and completability
ACT-R	Models perceptual and cognitive learning and performance. A set of parameters, each of which control a specific behavior, are set to match task data	Quantitative aspects of task learning and performance

of information-processing tasks and (2) are engineering-oriented models for use on applied problems. Connectionist (e.g., neural network) models [Rumelhart and McClelland, 1986; Schneider and Detweiler, 1987] and the optimal control model [Barron and Kleinman, 1969], which represent major but different approaches to modeling human processing, are intentionally not included due to space constraints.

79.4.1 Multiple-Resource Model of Attention and W/INDEX

In psychology, resource models of attention attribute the capability to perform the mental components of tasks to the capacity of applicable and available processing resources, time-sharing skills, and automatic processes. Attention is modeled as either a single processing resource or multiple, separable processing resources. In these models, the processing resource or resources afford a capacity to perform information-processing tasks (e.g., perception, cognition, and response selection) but have limited availability. The definition of resources here is different from that used in the ERM, which formally includes a specific performance dimension as part of the definition of a performance resource, which is distinguished from the system itself.

Norman and Bobrow [1975] adopted a single-resource model to examine the theoretical relationships between the application of the resource and performance on a single and multiple tasks. For a given task, performance may be limited by insufficient processing resources (resource-limited) or by insufficient data (data-limited). In multitask situations, a human performing the tasks is assumed to be capable of controlling the allocation of a portion of the processing resource to each task. Different allocation strategies result in different relative performance on each task. The relationship between allocation strategies and relative performance is plotted on a graph called the performance–operating characteristic. Automated processing (e.g., skill-based) is assumed not to require processing resources.

The multiple-resource model of attention [Navon and Gopher, 1979; Wickens, 1980, 1984] extends and specifies the resource concept by identifying several separate processing resources that are exclusive to a subset of activities. Results of numerous dual-task studies were used to distinguish separable resources. The model identifies different resource structures for verbal and auditory modalities, spatial and verbal codes, manual and vocal responses, and between (1) selection and execution of responses and (2) perceptual and central processing stages.

W/INDEX, for workload index [North and Riley, 1989], is a computer model for predicting operator workload that uses the multiple-resource construct and accounts for time-sharing skills. A task–timeline combined with a design model that differentiates different interface channels (e.g., visual or auditory, manual or verbal) is used to compile an interface activity matrix. This matrix specifies, by subjective ratings, the amount of attention the task demands for each channel. A conflict matrix is generated with respect to each design channel that specifies a penalty resulting when the operator must attend simultaneously to multiple channels. The W/INDEX algorithm is then applied to these data resulting in a workload profile.

79.4.2 The Model Human Processor

Model human processor (MHP) [Card et al., 1983, 1986] defines three interacting processing subsystems: perceptual, cognitive, and motor. The perceptual and cognitive subsystems include memories. Within each subsystem, processing parameters (e.g., perceptual processor, long-term memory, visual-image memory, and eye movements) and metrics (e.g., capacity, speed, and decay rate) are defined. Using data from numerous empirical studies, the MHP defines typical and range values for 19 parameters. To apply the model, processing parameters are associated with an analysis of the steps involved in accomplishing a task with a given system. Values for each parameter are assigned and summed, providing time estimates for task completion.

79.4.3 Skills, Rules, and Knowledge Model

Rasmussen [1983, 1986] developed a three-level model for describing qualitatively different modes of human information processing. Skill-based processing describes sensorimotor performance that is accomplished without conscious control. The behavior exhibited is smooth, automated, and integrated and only moderately based on feedback from the environment. Skill-based processes are generally simple automated behaviors, but they can be combined by higher-level conscious processes into long sequences to fit complex situations. Rule-based processing describes performance that is goal directed and consciously controlled in a feed-forward manner from stored rules that have been developed from experience. Rule-based processing does not use feedback control.

Knowledge-based processing is the highest level and applies to unfamiliar situations for which rules are available. Performance is goal controlled and conscious. The goal and plans need to be explicitly developed, and reasoning is accomplished with knowledge (i.e., a mental model) of the system and environment.

This three-level model can be directly related to Rasmussen's framework for cognitive task analysis. Knowledge-based processing requires performing all the activities in the framework. Rule-based processing provides a means to bypass activities by applying rules that have been stored from familiarity. Skill-based processing provides a means to go directly from detection to execution. Thus the processing required is a function of the experience of the task performer and the nature of the task.

79.4.4   Technique for Human Error-Rate Prediction

The technique for human error-rate prediction (THERP) [Swain and Guttmann, 1980] is a widely applied human reliability method [Meister, 1984] used to predict human error rates (i.e., probabilities) and the consequences of human errors. The method relies on conducting a task analysis. Estimates of the likelihood of human errors and the likelihood that errors will be undetected are assigned to tasks from available human performance databases and expert judgments. The consequences of uncorrected errors are estimated from models of the system. An event tree is used to track and assign conditional probabilities of error throughout a sequence of activities.

79.4.5   ACT-R

The ACT-R architecture developed by Anderson is the basis for much work in cognitive modeling. See Anderson and Matessa [1998] for an in depth discussion of the model. It uses both procedural and declarative representations and incorporates many parameters that can be set to optimize the fit to task data. ACT-R can be used to model individual task performance as well as average performance [Rehling et al., 2004].

79.4.6   Elemental Resource Model of Human Performance

Elemental resource model [Kondraske, 1995] was discussed briefly in the preceding section as a task-analysis technique. That discussion addressed how the ERM uses the same quantitative modeling construct (i.e., elemental performance resources) for task requirements and human capabilities. Major classes of resources include motor, environmental (i.e., sensing), central processing (i.e., perception and cognition), and skills (i.e., knowledge). Central processing and information (skill) resources are of interest in this chapter. When applied to humans or to machines (i.e., agents that perform tasks), the ERM describes the perceptual, cognitive, and knowledge resources available to the agent. If the agent has a deficiency in any of these elemental resources, a task requiring that resource cannot be completed by the agent. In this case, agents with sufficient resources need to be selected, agents with insufficient resources need to be trained, or the task goals or procedures need to be modified to accommodate the resources available to the agents targeted to perform the task. ERM derives from a broader theory of general systems performance theory (GSPT) developed by Kondraske.

Gettman et al. [2003] report an application of this performance model to laparoscopic surgery. In this study, the relationships between objective measures of human basic performance resources (BPRs) and laparoscopic performance were evaluated using Nonlinear Causal Resource Analysis (NCRA), a novel predictive and explanatory modeling approach based on GSPT. Results suggest promise in predicting laparoscopic performance, and thus the predictive power of applying such analysis and modeling strategies in design.

79.5   Models of Machine Processing Capabilities

Table 79.4 describes models of machine and performance. These models vary greatly in scope and detail. They are presented to illustrate that quantitative analysis of performance resources using the ERM extends to machine capabilities. These models are not elaborated further.

79.6   A Human–Machine–Task Analytic Framework

Making applied decisions involves performing a combined human–machine–task analysis of available and required mental capacities. This analysis (1) requires that the mental components of tasks, the mental capabilities of humans, and the information-processing capabilities of machines be modeled and analyzed in compatible and consistent terms and (2) is greatly enhanced if the terms are quantitative. From the

TABLE 79.4   Models of Machine Processes and Capabilities

Machine model	Description	Components/parameters
Process models	This refers to a category of models that describe the flow of information and the process performed on information through a system. It is useful for determining the consequences of failures in THERP	Flow Transformations Dependencies Normal performance
Principles of operation models	In this category machines are modeled in terms models of their operating principles. These are also useful for determining the consequences of failures needed to apply THERP	Physical properties Mathematic formulas Mathematic relationships Logical relationships Normal range of performance
Human interaction models	In this category the characteristics of the machine side of the human–machine interface are modeled	Physical properties Information content Information display format Performance metrics
Rasmussen's abstraction hierarchy	Developed for modeling process systems. Provides a task-independent description of systems at five levels	Hierarchy levels that include process, operation, and interaction descriptions
ERM	Models machines in terms of the performance resources they possess. Resource definition is consistent across task, human, and machine domains	Elemental information-processing performance resources available to the machine

techniques and models described above for task analysis and human and machine models, a methodology for a unified, quantitative human–machine–task analysis of mental components is described.

The approach first quantifies task requirements by combining techniques that produce detailed task-decomposition analyses of goals, actions, and required procedures (e.g., GOMS, NGOMSL, TAG, keystroke-level task model, or Rasmussen's cognitive framework) with timeline analysis, where applicable, and the elementary resource analysis of tasks. The task-decomposition models are used to specify tasks at a level at which the elemental mental resources required to perform the tasks can be specified. The timeline provides a basis for specifying performance requirements. Other performance dimensions too should be used depending on the task.

The next step employs quantitative models of human performance and technology to reach an applied decision that best satisfies the required resources if sufficient resources are available. If sufficient resources are not available, additional performance and skill resources need to be obtained to complete the task, or the task requirements need to be reduced. Quantitative models of human performance include MHP, THERP, and ERM. Using the MHP, the human processing parameters needed for each task operation are identified. The time values assigned to each parameter are used to compute task time estimates. This approach is limited to estimating performance in terms of time. THERP maps operations to the tasks included in human reliability databases to estimate human error probabilities. The ERM provides a framework for specifying performance and functional capacities at the resource level. It is the only model that (1) incorporates all required dimensions of performance and skills and (2) uses consistent modeling constructs across tasks, humans, and machines.

Using the approach outlined above establishes a basis for making applied decisions objectively. The task-analysis portion of this approach is illustrated by the following example.

79.7   Brief Example: Analysis of Supervisory Control Task

Supervisory control refers to the role a human plays in operating a semiautomatic process or system. Examples include control of large systems such as a nuclear power plant and specific instrumentation such as a robotic or assistive device. Performing supervisory control is high-level task that predominantly consists of mental components. This task is used to generically illustrate the use of analytic techniques to model a task.

79.7.1   High-Level Goals

Two major modes of operation are distinguished [Wickens, 1984]. In one mode (normal), the system is behaving as expected. The primary role of the human controller is to monitor system activity and modify performance parameters in accordance with planned output goals. In the second mode (fault), the system is faulty. The goal of the human controller, in this case, is to detect and diagnose the fault and intervene to bring the process back into normal performance.

79.7.2   Task Decomposition and Procedures

Sheridan [1987] identifies 10 functions performed by a supervisory controller within these modes of operation. Rasmussen's cognitive task framework, which was developed with regard to process-control tasks, includes 8 functions applicable to the fault mode of operation. Figure 79.3 depicts these 8 generic functions as a top-level breakdown of the supervisory-control task in fault mode. For this example, only selected tasks are decomposed to lower levels. At each level, the decomposition is not intended to be complete. Selected tasks at each level are intended to be illustrative and representative of increasingly specific and simple tasks. The arrow within each level provides procedural information. The goals of the lower-level tasks are defined by their titles (e.g., acquire data). Only the situation-interpretation task is decomposed. In reference to Rasmussen's human information-processing model, the task is assumed to be knowledge based. The lower-level tasks represent a hypothesis-testing strategy for knowledge-based diagnosis described by Rasmussen and Goodstein [1988]. However, other models of lower-level tasks could be used. Note that although a Rasmussen model is illustrated, the decomposition could be accomplished with other applicable models (e.g., GOMS).

79.7.3   Required Resources

Of the task-modeling techniques presented above, only Fleishman and Quaintance's cognitive abilities taxonomy and the ERM provide for explicit analysis of required resources. The approach defined by the ERM is illustrated in this example because it defines similar analyses for human and machine performance. As such, it is the only technique that models all three components of a human–machine–task system in the same way. For three of the lowest-level tasks, a set of elemental central processing resources is identified. Humans or machines responsible for performing each task are required to possess these resources to accomplish the task successfully. Four types of elemental mental resources are identified: knowledge, memory, perception, and reasoning. Resources are distinguished by their functional type and the performance dimension they specify. In the example, the performance dimensions are generically identified. In application, values should be assigned to these dimensions to the degree they are available or obtainable. Given time and cost constraints for the analysis, the ability to quantify all resources may not be practical. Task priorities can be used to selectively quantify resources, or the resource model can be used less rigorously as a guide to decision making if specific data are not available [Maxwell, 1995]. Once values are assigned, these required resources can be analyzed in concert with sets of available resources possessed by humans and machines. Available resources will have values that indicate a performance capability.

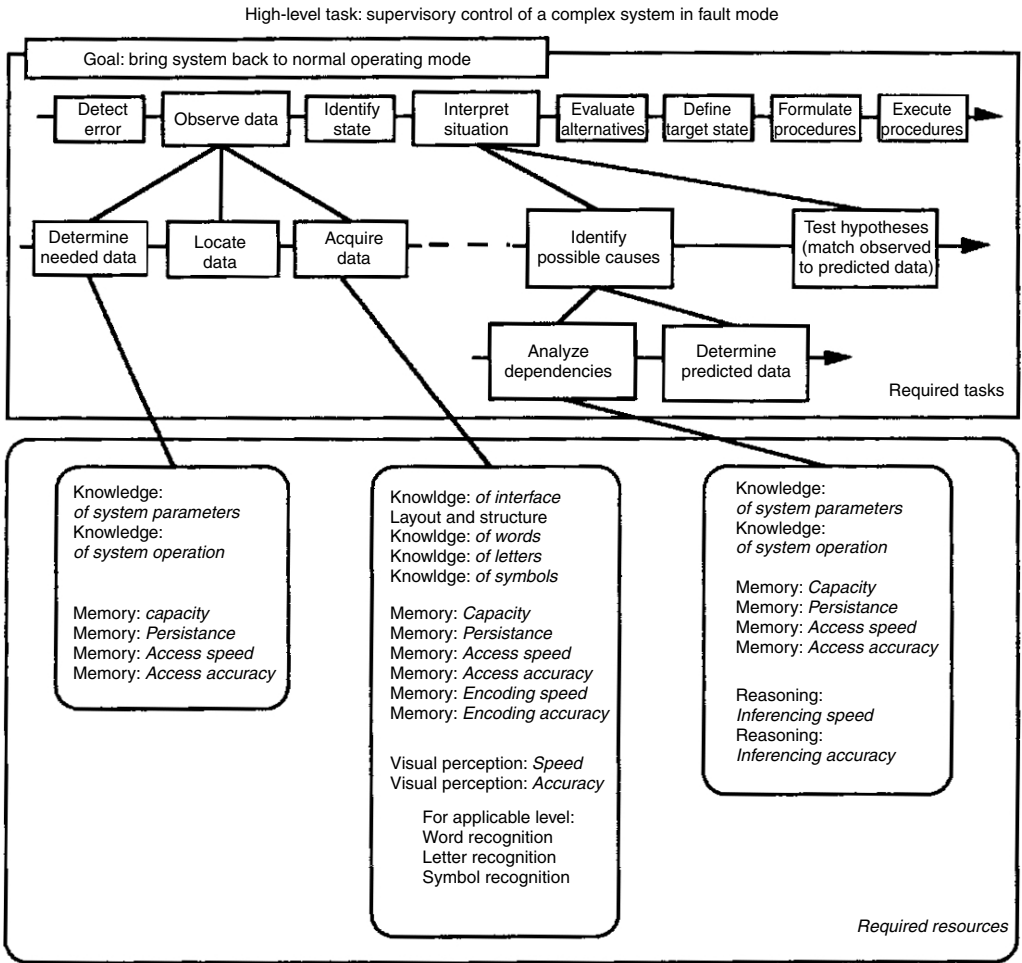
Although the MHP is a human processing and performance model, it can be adapted for use in a way analogous to the way the ERM is used in task analysis. The MHP would be applied as usual by identifying the processing parameters needed to accomplish each low-level task. However, instead of using the human


FIGURE 79.3 Selected task decomposition and resource requirements for a high-level supervisory control task.

performance values associated with these parameters, time values required by the task would be derived and assigned. These required times could then be compared with the estimated human performance times available for these low-level tasks to determine the sufficiency of human processing to meet the task's requirements.

79.7.4 Performance Assessment

After the task is specified, human and machine performance models can be applied to estimate task performance. The MHP and keystroke-level performance model can provide task performance estimates in terms of task completion time. THERP can be used to estimate human error probabilities for each task and task sequence. The ERM approach can be used to estimate performance along any required dimension and to compare required with available resources along any required dimension as long as the human performance data are available. The results of the ERM assessment would identify stress levels on capacities (e.g., resources stressed too long or beyond maximum capacity). These results indicate limiting factors to successful task performance. Limiting factors can be identified at elemental or intermediate performance resource levels. As such, the ERM represents a more comprehensive and internally consistent model than the others. It is more comprehensive in that it can be used to model any performance dimension. It is

more consistent in that (1) all resources are defined in similar terms, (2) all resources are defined at the same level of description, and (3) resource requirements for tasks and resources available to humans and machines are all defined identically.

Defining Terms

Cognitive components: The perceptual, cognitive, and knowledge-processing components of a task.

Cognitive tasks: Tasks that consist predominantly of mental components and, in ERM terms, require mental performance and skill resources to perform.

Elemental resource: These consist of performance and skill resources. Performance resources are each defined as a couplet consisting of an elementary functional capability associated with a low-level unidimensional quantitative capacity, either available or required, to perform the function. Skill resources are defined in terms of the knowledge, either available or required, to perform an elemental function.

Knowledge acquisition and elicitation: Any of several techniques for obtaining knowledge about a task or system or eliciting it from a human.

Protocol analysis: Protocols are verbal reports generated contemporaneously by a person accomplishing a task that describe the unobservable (mental) processes being performed.

Task: A goal-directed, procedural activity that is defined with regard to the resources (i.e., capabilities) that performing agents (i.e., humans or machines) must possess to accomplish the goal.

Task analysis: The process of (1) decomposing high-level tasks into their constituent, mutually exclusive, lower-level tasks; (2) describing intertask relationships and dependencies; and (3) defining each task's goals, procedures, and performance and skill requirements.

Task taxonomy: A classification of tasks in accordance with a defined method, strategy, or set of criteria.

Task timeline: A time-based profile of a high-level task that maps its lower-level tasks by time-of-onset, duration, and concurrences onto a timeline.

Task Analysis and Decomposition: Physical Components

Sheik N. Imrhan
University of Texas-Arlington

A task can be viewed as a sequence of actions performed to accomplish one or more desired objectives. Task analysis and decomposition involve breaking down a task into identifiable elements or steps and analyzing them to determine the resources (human, equipment, and environmental) necessary for the accomplishment of the task. As indicated in earlier chapters, all human tasks require the interaction of mental and physical resources, but it is often convenient, for analytical purposes, to make a distinction between tasks that require predominantly physical resources of the person performing the tasks and tasks that require predominantly mental resources. These different types of tasks are often analyzed separately. Usually, in physical tasks, the mental requirements are described but are not analyzed as meticulously as the physical requirements. For example, a heavy-lifting task in industry requires musculoskeletal strength and **endurance**, decision making, and other resources, but the successful completion of such a task is

limited by musculoskeletal strength. Decision-making and cognitive resources may be lightly tapped, and so the heavy-lifting task analysis will tend to focus only on those factors that modify the expression of musculoskeletal strength while keeping the other kinds of requirements at a descriptive level. The descriptions and analyses of manual materials handling tasks in Chaffin and Andersson [1991] and Ayoub and Mital [1991] exemplify this kind of focus. The degree with which a resource may be stressed depends on a number of factors, among which are the resource availabilities (capacities) of the person performing the task compared with the task demands.

This chapter deals with the analysis and decomposition of only the physical aspects of tasks. It is assumed that nonphysical resources are either available in nonlimiting quantities or are not crucial to task accomplishment. While the compartmentalization of task characteristics tends to blur the natural connections among the various human performance resources, it is still the most pragmatic method available for task analysis.

Physical task analysis first achieved scientific respectability in the early part of this century from the work of the industrial engineer Frederick Winslow Taylor [Taylor, 1911] and, shortly afterward, by Frank and Lillian Gilbreth [Gilbreth and Gilbreth, 1917]. Taylor and the Gilbreths showed how a task can be broken down into a number of identifiable, discrete steps that can be characterized by type of physical motions, energy expenditure, and time required to accomplish the task. By this method, they argued that many task steps, normally taken for granted, may contribute little or nothing to the accomplishment of the task and can therefore be eliminated. As a result of these kinds of analyses, Taylor and the Gilbreths were able to enhance productivity of individual workers on a scale that was considered unrealistic at that time. The basic approach to the highest level of physical task analysis today has evolved from the motion and time studies of Taylor and the Gilbreths (known as taylorism), both in the industrial and nonindustrial environments. The exact methods have become more sophisticated and refined, incorporating new technologies and knowledge accumulated about human-task interaction.

From its roots in time and motion studies, task analysis has become a very complex exercise. No longer is a single task considered in isolation, as shoveling was by Taylor and bricklaying by the Gilbreths. Today, different ideas in management and advanced data analytical methods have established the need for cohesion between physical tasks and (1) the more global processes, such as jobs and occupations encompassing them, and (2) the more detailed processes contained within them (the different types of subtasks and basic elements of performance). Campion and Medsker [1992] give examples of the first, and Kondraske [1995] gives examples of the second. This chapter describes physical task analysis, showing the approach for proceeding from higher-level tasks to lower-level ones. Figure 80.1 shows a summary of the overall approach.

80.1 Fundamental Principles

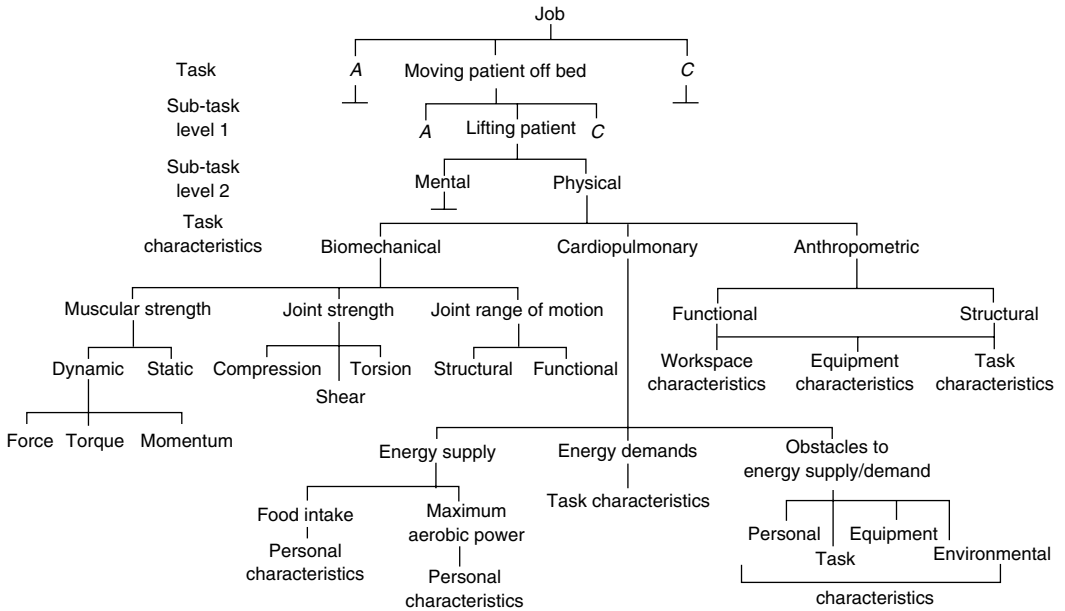
The fundamental principle of physical task analysis is the establishment of the work relationships between the person performing the task and the elements of the task under specified environmental and social conditions. The main driving forces are performance enhancement, protection from injuries and illnesses, and decision making. The order of importance depends on the particular context in which the task analysis is performed. Performance enhancement is a concern in all disciplines that deal with human performance, though the approaches and objectives may differ. In physical rehabilitation, for example, performance enhancement focuses on improving the performance of basic physical functions of the human body, such as handgrip, elbow flexion, etc., that have deteriorated from injury or illness. In athletics, it focuses on improving performance to the highest possible levels, such as the highest jump or the fastest 100-m run. In exercise and fitness, it aims at improving body functions to enhance health and quality of life. Finally, in the discipline of ergonomics, it aims at enhancing task performance as well as the health and safety of people at work.


FIGURE 80.1 Diagram showing the concept of a hierarchical task analysis for physical tasks.

80.1.1 Speed–Accuracy Principle

Performance enhancement and protection from injuries and illnesses are not necessarily mutually exclusive. In performance enhancement, the aim is to complete a task as accurately and quickly as possible. Both accuracy and speed are important in the work environment, especially in manufacturing, and are influenced by other factors. When lack of accuracy or precision leads to dire consequences, as in air traffic control jobs, then a decision to sacrifice speed is usually made. The basic concept of Fitt's law [1954] is relevant to these situations. It is difficult to find examples of cases where gross inaccuracy is tolerable, but in many cases more speed is required and less accuracy is tolerable, and a different point on the speed–accuracy continuum is selected. In the manufacturing environment, speed translates into productivity and accuracy into quality, and both determine profitability of the production enterprise. Speed and accuracy are rarely attainable at the highest levels simultaneously. In practice, a certain amount of one may be sacrificed for the other. Thus, industrial engineers who set these tolerable limits talk of "optimum" speed instead of "fastest" speed and "optimum" quality instead of "perfect" quality. These facts must be borne in mind when analyzing physical tasks. A task analysis indicating that a person can increase his or her speed of performance should not necessarily imply that the task is being done inefficiently, because quality of performance may deteriorate with increased speed. This kind of flawed reasoning can occur when a variable is dealt with in isolation, without regard to its interaction with other variables.

80.1.2 Stress–Strain Concept

In task analysis, it is common practice to distinguish between stress and strain. However, these terms are sometimes used interchangeably and confusedly. In this chapter, stress refers to a condition that may lead to an adverse effect on the body, whereas strain refers to the effect of stress on the body. For example, working at a computer job in dim lighting often leads to headaches. The dim lighting is considered the stress, and the headache is the strain. The term stressor is also widely used as a synonym for stress. Strain has often been wrongly called stress. These terms must be clearly defined to determine which factors are causative ones (stresses) and which are consequences (strains). Stress is determined by task demands, while strain is determined by the amount of physical resources expended beyond some tolerable level,

defined by the person's resource capacities. The stress–strain principle is pivotal to task analysis when one is concerned with errors, **cumulative traumas**, and injuries in the workplace and is applicable to task situations where task demands are likely to exceed human resource capacities.

Ayoub et al. [1987] developed a quantitative stress–strain index, called the **job severity index** (JSI), from empirical task analysis and epidemiologic data for manual materials handling tasks. This index computes the ratio of "job task physical demands to person physical capacities" from several interacting variables. The application of the JSI is also detailed in Ayoub and Mital [1991]. Also, Kondraske [1995] defines a quantitative measure of stress that can be applied to individual performance resources. In this measure, defined as the "ratio of resource utilization to resource availability," an adverse effect may be noted when the stress level exceeds a threshold, which may be different for different types of performance resources (e.g., strength, range of motion, etc.).

80.1.3 Cumulative Strains

The elimination of motions and other physical actions that do not contribute directly to task performance (tayloristic practice) has led to a concentration of work at specific localities in the body and to consequent overwork at those localities, but this concentration often leads to rapid consumption of the limited resources of the working systems. For example, VDT data entry is a highly repetitive task with very little variation; work is concentrated heavily on the hands (rapid finger motions for operating the keyboard) and in the neck and trunk (prolonged static muscular contraction), and this often leads to cumulative trauma disorders of the hands, wrists, neck, and shoulders. By comparison, traditional typists performed a variety of tasks in addition to using the keyboard — changing paper on the typewriter, filing documents, using the phone, etc. — and this helped to stem the depletion of physiologic resources caused by rapid finger work or sustained static muscular contractions in the neck and shoulder. Also, it is now recognized that some functions of the body that have not been considered "productive" under taylorism are highly stressed and may even be the limiting factors in task performance. In data processing, the muscles of the neck and back maintain prolonged static contractions that often result in muscular strains in the neck and back and limit work time. Traditional task analysis does not always consider this static muscular work as productive, even though it is absolutely necessary for steadying the arms (for keyboard and mouse use) and the head (for viewing the screen and documents). Likewise, **work pauses**, which have been considered wasteful, are now valued for their recuperative effects on the physical (and mental) working systems of the body. The increasing awareness of the causes of work-related cumulative trauma disorders will continue to influence the interpretation of data derived from task analyses.

80.2 Early Task-Analysis Methods

The history of physical task analysis does not show a trend toward the development of a single generalized model. The direction of physical task analysis has been influenced by Taylorism and by specific efforts in the military that were later adapted to the industrial and other nonmilitary environments. A list of influential methods, to which readers are referred, is given below:

1. Time studies of Fredrick Winslow Taylor [Taylor, 1911]
2. Time and motion studies of Frank and Lillian Gilbreth [Gilbreth and Gilbreth, 1917]
3. **Job analysis** developed by the U.S. Department of Labor in the 1930s [Drury et al., 1987]
4. The U.S. Air Force "method for man–machine task analysis" developed by R. Miller [1953]
5. Singleton's methods [Singleton, 1974]
6. **Hierarchical task analysis** (HTA) developed by Annette and Duncan [1974]
7. Checklist of worker activities developed by E.J. McCormick and others for the U.S. Office of Naval Research [Drury et al., 1987]
8. **Position analysis questionnaire** [McCormick et al., 1969]

9. The AET method (Arbeitswissenchaftliches Erhenbungsverfahen zur Tatigkeitsanalyse, or ergonomic job analysis) developed by Rohmert and Landau [Drury et al., 1987]

80.3 Methods of Physical Task Analysis

Methods of physical task analysis vary widely. Drury and colleagues [1987] point out that "the variation of task analysis format is the result of different requirements placed on the task analysis." While this is a pragmatic method for short-term results, a more general approach for long-term solutions is needed. Such an approach should aim to proceed from higher- to lower-level tasks, as discussed in other chapters [Kondraske, 1995]. The following general sequence of analysis is recommended:

1. Statement of the objectives of the task analysis
2. Description of the system within which the tasks reside
3. Identification of jobs (if relevant) within the system
4. Identification of the tasks
5. Identification of subtasks that can stand independently enough to be analyzed as separate entities
6. Determination of the specific starting point of each task
7. Determination of the specific stopping point of each task
8. Characterization of the task as discrete, continuous, or branching [Drury et al., 1987]
9. Determination of task resources (human, equipment, and environmental) required to perform the task (this step is the essence of task description)
10. Determination of other support systems (e.g., in work situations, managerial and supervisory help may be needed)
11. Determination of possible areas of **person–task conflicts**
12. Determination of possible consequences of conflict, for example, errors, slowing down of work rate, deterioration of quality of end product, decline in comfort, harm to health, and decline in safety

After the task analysis is performed and the resulting data analyzed, solutions for solving the associated problems are formulated then implemented; for example, repositioning of the mechanical hoist used for lifting and moving a patient at the beginning of the lift to minimize human muscular input. This is then followed by an evaluation period in which enough data is gathered to compare the task states before or after the changes. The evaluation criteria must be compatible with the stated objectives of the task analysis.

80.3.1 General Methods for Background Information

Many different techniques for gathering information in physical task analysis have evolved over the years, especially in the industrial and biomedical engineering environments. The quality and quantity of information that the techniques provide are limited by available equipment, and it seems that the quality and quantity of available equipment lag far behind the state of the art in technology. General data-gathering techniques, which are somewhat self-descriptive, include:

- Direct observation (predominantly visual)
- Indirect observation (e.g., replay of videotape)
- Document review
- Questionnaire survey
- Personal interview

80.3.2   Specific Techniques

Specialized data-gathering techniques [Winter, 1990; Chaffin and Andersson, 1991; Niebel, 1993] that have evolved into powerful tools in the industrial environment and which can be used for task analysis in other situations include:

- **Motion study** — details the motions made by the various segments of the body while performing the task
- **Time study** — details the time taken to perform each motion element
- Micromotion study — detailed description of motion using mainly videotapes
- Kinematic analysis — measures or estimates various motion parameters for specified body segments, for example, displacement, velocity, acceleration. (It involves micromotion studies.) The data are used for subsequent biomechanical analyses, for example, to determine mechanical strain in the musculoskeletal system [Chaffin and Andersson, 1991]
- Kinetic analysis — measures or estimates forces produced by body segments and other biomechanical parameters (e.g., center of mass, moment of inertia, etc.) and physical parameters of objects (e.g., mass, dimension, etc.) (the data are used for subsequent biomechanical analyses)

In the assessment of jobs in the occupational environment, two of the most useful motion-study methods are Rapid Upper Limb Assessment (RULA) and the Ovako Working Posture Analysis System (OWAS). These methods are used for assessing the risk to musculoskeletal cumulative strains from work postures. In RULA [McAtamney and Corlett, 1993], the geometric configurations of the upper arms, lower arms, wrists, neck, and trunk are estimated by visual observation and an overall score is calculated for posture. This score is then modified by incorporating data on the muscular forces exerted by the upper limbs and the frequency of exertion. Stressful postures and their contributing factors can therefore be identified and risk to injuries assessed. The OWAS method [Kahru et al., 1977] is similar to RULA but does not incorporate frequency of muscular force exertions.

Specialized data-analytic techniques include:

- Methods analysis — determines the overall relationships among various operations, the work force, and the equipment
- Operations analysis — determines the details of specific operations
- Worker–equipment relationship study — determines the interactions between people and their equipment

Examples of the above techniques that are frequently used for analyzing industrial jobs, but may also be used for other tasks involving people, are discussed in Gramopadhye and Thaker [1999]. Among the most useful are flow charts such as sequence diagrams, functional flow analysis, and decision diagrams, which depict the links among tasks and subtasks. These charts may also be used in conjunction with summary tables of the number of activities, duration of activities, and distance traveled by the human worker. They therefore facilitate improvements in system efficiency and identification of sources of possible operation errors. Examples of their applications are shown in Barnes [1980] for baking soda crackers and by Lock and Strutt [1985, in Gramopadhye and Thacker, 1999] for inspection in transport aircraft structures. Other techniques such as link analysis (Chapanis, 1962), critical incident technique [Meister, 1985], fault tree analysis [Green, 1983], and failure modes and effects analysis are not specific to physical task analysis but may be used in systems analysis involving physical tasks.

80.3.3   Decomposition of Physical Tasks

Physical tasks can be viewed as exchanges of energy within a system consisting of the human, the task, the equipment, and the environment. In task analysis and decomposition, we look at the human on one side and the other system components on the other side and then determine the nature of the exchange. The energy is transmitted by muscular action. Tasks are hierarchical, however, and for

systematic decomposition, it is useful to identify the various levels and proceed in a top-down sequence (see Figure 80.1). The items in the various levels given here are self-explanatory, but there is considerable content within each. Detailed descriptions of each is beyond the scope of this chapter, and readers should consult the references [Singleton, 1974; Corlett et al., 1979; Meister, 1985; Winter, 1990; Niebel, 1993; Chaffin and Andersson, 1994] for standard measurement procedures and analyses.

Level I

Identifying general types of tasks according to levels of energy requirements:

- Tasks requiring great muscular forces
- Tasks requiring medium to low levels of muscular forces

Tasks requiring very low levels of muscular forces are not predominantly physical. Their successful accomplishment is strongly dependent on cognitive resources. The application of strong and weak muscular forces is not necessarily mutually exclusive. Such forces may be exerted simultaneously by different muscular systems or may even alternate within the same system. For example, a typing task may require strong back extensor forces while sitting bent forward (if the workstation is poorly designed) and weak finger flexion forces for activating the keyboard keys, and a weak index finger flexion may be required to activate a trigger on a hand drill while strong handgrip forces stabilize the drill.

Level II

Identifying the crucial subsystems involved in the generation and transference of forces of varying intensities involved in tasks:

- Musculoskeletal — for great forces
- Cardiopulmonary — for medium to low forces
- General body posture
- Body motion
- Local segmental motion
- Local segmental configuration
- **Anthropometry**
- Workplace and equipment dimensions

The last three subsystems modify directly the expression of muscular force.

Level III

Identifying environmental requirements and constraints. Environmental conditions influence performance and functional capacities in humans. They should therefore be measured or estimated in task analyses. Table 80.1 describes common environmental constraints.

TABLE 80.1   Environmental Factors in Task Analysis

Environmental factor	Constraint	Examples of effects
Illumination	Insufficient intensity	Errors
Heat	Excessive heat and humidity	Lowering of physiologic endurance
Cold	Excessive cold	Numbness of hands — inability to grasp hand tool properly
Vibration	Excessive amplitude	Loss of grip and control of vibrating tool
Noise	Excessive intensity	Inability to coordinate job with coworkers
Body supporting surface	Slipperiness	Difficulty in balancing body
Space	Insufficient workspace	Inability to position body properly

Level IV

Identifying body actions in relation to tasks. These actions can be decomposed into two major types:

1. Those which involve body motions. They are used for either changing body positions or moving objects
2. Those which do not involve body motions. They are used primarily for balancing and stabilizing the body for performing some task. Body posture is especially important here, especially when great muscular forces must be exerted

These actions are not mutually exclusive during task performance. One part of the body may move, while another part, involved in the task, may be still. For example, the fingers move rapidly when using a keyboard, but the rest of the hand is kept motionless while the fingers are moving. Table 80.2 through Table 80.5 depict practical decompositions of these actions as well as those requiring muscular forces.

Level V

Identifying anthropometric variables. Human anthropometry interacts with workplace and equipment dimensions. Tasks are performed better when the interaction defines a close "match" between human body size and task-related physical dimensions. Therefore, physical task analysis may be inadequate without measurements of the dimensions of people performing the task and the corresponding dimensions of other aspects of the system of which the task is a part. This kind of matching is one of the basic thrusts in the discipline of ergonomics. Grandjean [1988] and Konz [1990] discuss these issues in many types of human–task environments, and Pheasant [1986] gives numerous body dimensions related to task design. Some important examples of human–system dimensions that must be considered during task analysis are shown in Table 80.6.

TABLE 80.2   Representative Actions with Motions

Class of action	Subclass	Purpose of action	Examples
Whole body		Positioning body	Walking, crawling, running, jumping, climbing
		Transporting object	Lifting, lowering, carrying horizontally, pushing, pulling, rotating
Gross segmental	Arm movement	Applying forces to object	Reaching for object, twisting, turning, lifting, lowering, transporting horizontally, positioning, pressing down, pushing, pulling, rotating
	Leg movement	Applying forces	Rotating (e.g., foot pedal), pushing
	Trunk movement	Generating momentum	Sitting and bending forward, backward, and sideways to retrieve items on a table
Fine segmental	Finger movement	Applying forces	Turning, pushing, pulling, lifting

TABLE 80.3   Representative Actions with Motions

Class of action	Subclass	Purpose of action	Examples
Whole body		Balancing body	Standing while preparing meal in kitchen
		Supporting or stabilizing object	Bracing ladder while coworker climbs on it
Segmental	Arm		Holding food item with one hand while cutting it with other hand
	Leg	Supporting body	Forcing foot on ground while sitting in constrained posture

TABLE 80.4 Representative Actions Requiring Forces, for Different Types of Forces

Class of action	Subclass	Sub-subclass	Body–object contact	Purpose of action	Examples
Whole body	Whole body	Dynamic	One hand, two hands, or other contact	Generate great forces that must be transmitted over small localized area or large area. The effort produces motion of whole body	Lift, push, pull
		Static	One hand, two hands, or other contact	Generate great forces that must be transmitted over small localized area or large area. The effort does not produce motion	Lift, push, pull
Segmental		Static	One hand, two hands, one foot, or two feet	Generate forces (over a wide range of magnitude) that must be transmitted over a relatively small localized area. The effort does not produce motion of the body segment	Gripping with whole hand, pinching, pressing down, twisting, turning, pushing, pulling, or combinations
		Dynamic	One hand, two hands, one foot, or two feet	Generate great forces that must be transmitted over small localized area or large area. The effort produces motion of the body segment	Pushing, pulling, pressing down

TABLE 80.5   Posture While Performing Tasks

Class	Subclass	Purpose	Examples
Whole body	Standing, sitting, kneeing, lying down, other	Optimize body leverage; position body for making proper contact with object; other	Squatting at beginning of a heavy lift to prevent excessive strain in the lower back
Segmental	Arms, legs, trunk, hands, other	Optimize segment leverage; position segment for making proper contact with object	Placing elbow at about right angles while using wrench to prevent excessive shoulder and muscle efforts

TABLE 80.6   Human Anthropometry and System Dimensions

Body dimensions	System dimensions
Height, arm length, shoulder width	Workspace — height of shelf, depth of space under work table, circumference of escape hatch
Leg length, knee height	Equipment size — distance from seat reference point to foot pedal of machine, height from floor to dashboard of vehicle
Hand length, grip circumference	Hand tool size — trigger length, handle circumference
Crotch height, arm length	Apparel size — leg length of pants, arm length of shirt
Face height, hand width	Personal protective equipment — height of respirator, width of glove

80.4   Factors Influencing the Conduct of Task Analysis

While task analysis traditionally focuses on what a person does and how he or she does it, other factors must be considered to complete the picture. In general, the characteristics of the task, the equipment used, and environmental conditions must all be accounted for. Human functional performance cannot be viewed in isolation because the person, the task, the equipment, and the environment form a system in which a change in one factor is likely to affect the way the person reacts to the others. For example, in dim lighting, a VDT operator may read from a document with marked flexion of the neck but with only slight flexion (which is optimal) when reading from the screen. Brighter ambient lighting may prevent sharp flexion when reading from documents but is likely to decrease contrast of characters on the screen. Screen character brightness must therefore be changed to maintain adequate reading performance to prevent sharp flexion of the neck again.

80.4.1   Knowing the Objectives of Task Analysis

Motion, speed, force, environment, and object (equipment) characteristics are common factors for consideration in task analysis. However, the reasons for performing a task are an equally important factor. Tasks that may involve the same equipment and which may seem identical may differ in their execution because of their objectives. Thus, a person opening a jar in the battlefield in the midst of enemy fire to retrieve medicines will not perform that task in exactly the same way as a person at home opening a similar jar to retrieve sugar for sweetening coffee. In the former case, speed is more important, and both the type of grasp used and the manual forces exerted are likely to be markedly different from the latter case. Napier [1980] recognized this principle, in relation to gripping tasks, when he wrote that the "nature of the intended activity influences the pattern of grip used on an object." These kinds of considerations in task analysis can influence the design of objects and other aids and the nature of education and training programs.

80.4.2 Levels of Effort

The level of required effort when performing similar tasks in different environments is not necessarily the same, and the interpretation of task-analysis data is influenced by these differences. Tasks in the workplace are designed so that human physical effort is minimized, whereas tasks in the competitive athletics environment are designed to tap the limits of human performance resources. There are other differences. An athlete paces himself or herself according to his or her own progress. He or she has greater freedom to stop performing a task should physical efforts become painful or uncomfortable. In the workplace, however, there is often little freedom to stop. Many workers often push themselves to the limits of their endurance in order to maintain (flawed) performance goals set by their employers. This is why cumulative strains are more prevalent in the workplace than in many other environments. These differences in performance levels may influence the way task analyses are performed among the different disciplines and the application of the data derived therefrom.

80.4.3 Criticality of Tasks

An inventory of task elements is necessary for describing the requirements of the task. It can tell us about the person, equipment, and environmental requirements for performing a job, but we must also be able to identify specific elements or factors that can prevent the successful completion of the task or that can lead to accidents and injuries. These critical elements are usually measured in detail or estimated and used for developing quantitative models for predicting success or failure in performance. One such widely researched element is the compression force on the L5/S1 disk in the human spine while performing heavy-lifting tasks [Chaffin and Andersson, 1984]. This force is being used by the National Institute of Occupational Safety and Health as a criterion for determining how safe a lifting activity is. If analysis of task-analysis data indicates that the **safety limit** (3400 N of compression) is exceeded then work redesign, based on task-analysis information, must be implemented [National Technical Information Service, 1991; NIOSH, 1981].

80.5 Measurement of Task Variables

During task analysis, variables must be measured for subsequent data summary and analysis. It is important to know not only what the inventory of task-related variables is but also to what degree the variables are related to or affect overall performance. The measurement of task-related variables allows for quantification of the overall system. For example, the NIOSH lifting equation [National Technical Information Service, 1991] shows how task variables such as the horizontal distance of the load from the body, the initial height of the load, the vertical height of lift, the frequency of lifting, the angular displacement of the load from the saggital plane during lifting, and the type of hand–handle coupling affect the maximal weight of the load that can be lifted safely by most people in a manual materials-handling task. The number of task-related variables measured should be adequate for describing the task and for representing it quantitatively. However, there are often constraints. These include:

1. The number of variables that can be identified
2. The number of variables that can be measured at an acceptable level of reliability and accuracy
3. The availability of measurement instruments

Merely summarizing individual measurements seldom yields the desired information. Task performance is essentially a multivariable operation, and variables often must be combined by some quantitative method that can yield models representative of the performance of the task. Sometimes a variable cannot be measured directly but can be estimated from other measured variables. The estimated variable may then be used in a subsequent modeling process. A good example of this is the intraabdominal pressure achieved during heavy lifting. Though it can be predicted by a cumbersome process of swallowing a pressure-sensitive pill, it also can be estimated from the weights of the upper body and load lifted and

other variables related to lifting posture. Its estimate can then be used to estimate the compressive force in the L5/S1 disk and the tension in the erector spinae muscles during lifting. Imrhan and Ayoub [1988] also show how estimated velocity and acceleration of elbow flexion and shoulder extension can be used, with other variables, to predict linear pulling strength.

80.5.1 Task-Related Variables

Variables that are usually measured during physical task analysis include:

1. Those related to the physical characteristics of task objects or equipment:
   (a) Weight of load lifted, pushed, carried, etc.
   (b) Dimensions of load
   (c) Location of center of mass of load
2. Those related to the nature of the task:
   (a) The frequency of performance of a cycle of the task
   (b) The range of heights over which a load must be lifted
   (c) The speed of performance
   (d) The level of accuracy of performance
3. Those related to the capacities of various physical resources of the person:
   (a) Muscular strength
   (b) Joint range of motion
   (c) Joint motion (velocity and acceleration)
   (d) **Maximal aerobic power**
   (e) Anthropometry
4. Those related to the environment:
   (a) Temperature
   (b) Illumination
   (c) Vibration
5. Those related to workplace design:
   (a) Amount of space available for the task
   (b) Geometric and spatial relationships among equipment
   (c) Furniture dimensions
6. Those related to anthropometry:
   (a) Length, breadth, depth, or circumference of a body segment
   (b) Mass and mass distribution of a body segment
   (c) Range of motion of a skeletal joint

80.5.2 Instruments for Gathering Task-Analysis Data

A great number of instruments are available for measuring variables derived from task analyses. The choice of instruments depends on the type of variables to be measured and the particular circumstances. In general, there should be instruments for recording the sequence of actions during task, for example, videotape with playback feature, and instruments for measuring kinematic, kinetic, and anthropometric variables [Winter, 1990; Chaffin and Andersson, 1994]. The main kinematic variables include displacement (of a body part), velocity, and acceleration. Kinetic variables include force and torque. Anthropometric variables include body segment length, depth, width, girth, segment center of mass, segment radius of gyration, segment moment of inertia, joint axis of rotation, and joint angle. Some variables are measured directly, for example, acceleration (with accelerometers), force applied at a point of contact between the body and an object (with load cells), and body lengths (with anthropometers); some may be measured indirectly, for example, joint angle (from a videotape image) and intraabdominal pressure (using swallowed pressure pill); and others may be estimated by mathematic computations from other measured variables, e.g., compressive force on the lumbosacral (L5/S1) disk in the lower back. Posture

targeting, a method for recording and analyzing stressful postures in work sampling [Corlett et al., 1979], is becoming popular.

The measurements of performance capacities associated with human functions should conform to certain criteria. Details can be found in Brand and Crownshield [1981] and Chaffin [1982]. A general set of psychometric criteria is also discussed by Sanders and McCormick [1993]. It includes measurement accuracy, reliability, validity, sensitivity, and freedom from contamination. Meeting these criteria depends not only on the instruments used but also on the methods of analysis and the expertise of the analyst. It is almost impossible to satisfy these criteria perfectly, especially when the task is being performed in its natural environment (as opposed to a laboratory simulation). However, the analyst must always be aware of them and must be pragmatic in measuring task variables. Meister [1985] lists the following practical requirements for measurements (1) objective, (2) quantitative, (3) unobtrusive, (4) easy to collect, (5) requiring no special data-collection techniques or instrumentation, and (6) of relatively low cost in terms of money and effort by the experimenter. However, these are not necessarily mutually exclusive.

80.6 Uses and Applications of Task Analysis

The uses of task-analysis information depend on the objectives of performing the task, which, in turn, depend on the environment in which the task is performed. Table 80.7 gives the different situations.

80.7 Future Developments

To date, there is no reliable quantitative model that can combine mental and physical resources. A general-purpose task-analysis method that uses active links between the various compartments of

TABLE 80.7   Uses and Applications of Task Analysis

Uses and applications	Examples of relevant situations
Modeling human performance and determining decision-making strategies	A model showing the sequence of the various steps required to perform a task and the type of equipment needed at each step
Predicting human performance	Using a quantitative model to predict whether an elderly person has enough arm strength to lift a pot full of water from a cupboard onto a stove
Redesigning of the existing tasks or designing of new tasks	Eliminating an unnecessary step in the packaging of production items into cartons; designing a different package for a new item based on task-analytic data gathered for a related item
Determining whether to use task-performance aids	The analysis may show that most elderly persons do not possess enough strength to open many food jars and may, therefore, need a mechanical torqueing aid
Personnel selection or placement	Matching personnel physical characteristics with task requirements can reveal which person may be able to perform a task and, hence, be assigned to it
Determining whether to use aids that enhance health or safety	Task analysis may show that too much dust always gets into the atmosphere when opening packages of a powered material and that workers should wear a respirator
Determining educational and training procedures	Identification of difficult task steps or the need for using mechanical aids, together with knowledge of workers' skills, may indicate the level of education and training needed
Allocating humans to machines and machines to humans	Matching people skills and capacities with the resource demands of machines
Determining emergency procedures	Task-analysis information may indicate which steps are likely to result in dangerous situations, and therefore, require contingency plans

human functions would be an ideal method, but our lack of knowledge about the way in which many of these "compartments" communicate precludes the development of such a method. The present approach to compartmentalization seems to be the most pragmatic approach. It offers the analyst access to paths from a gross task or job to the myriad of basic task elements of performance. Unfortunately, actual systems and subsystems used in practice seem to be loosely defined and inconsistent, often with confusing metrics and terminologies for important variables. Moreover, available task-analysis models deal only with specific classes of application [Drury, 1987]. A general-purpose model is badly needed for handling different mental and physical resources at the same time, dealing with wide ranges in a variable, and bridging the gaps across disciplines. Such a model should help us to perform task analyses and manipulate the resulting data from environments ranging from the workplace, the home (activities of daily living), athletics, exercise and fitness, and rehabilitation. Such a model can also help to eliminate the present trend of performing task analyses that are either too specific to apply to different situations or not specific enough to answer focused questions. Fleishman [1982] deals with the issue. At least one recent effort is active [Kondraske, 1995]. However, as Landau et al. [1998] points out, such generalizability has a cost in that the associated data is produced at a higher level of abstraction, which is likely to be difficult for a practitioner to apply to specific problems.

There is also a need for better quantification of performance. We need to know not only what kind of shifting in resources a person resorts to when one route to successful task accomplishment is blocked (e.g., insufficient strength for pressing down in a certain sitting posture) but also the quantity and direction of that shift. For example, we need to know not merely that a change in posture can increase manual strength for torqueing but also what the various postures can yield and what quantity of specific mental resources are involved in the change. The models today that answer the quantitative questions are mainly ones of statistical regression, and they are limited by the number of variables and the number of levels of each variable that they can deal with.

Defining Terms

Anthropometry: The science that deals with the measure of body size, mass, shape, and inertial properties.

Cumulative trauma: The accumulation of repeated insults to body structures over a period of time (usually months or years) often leading to "cumulative trauma disorders."

Endurance: The maximum time for which a person can perform a task at a certain level under specified conditions without adverse effects on the body.

Fitts' law: The equation, derived by P. Fitts, showing the quantitative relationship between the time for a human (body segment) to move from one specific point to another (the target) as a function of distance of movement and width of the target.

Hierarchical task analysis: The analysis of a task by breaking it down to its basic components, starting from an overall or gross description (e.g., lifting a load manually) and moving down in a series of steps in sequence.

Job analysis: Any of a number of techniques for determining the characteristics of a job and the interactions among workers, equipment, and methods of performing the job.

Job severity index: An index indicating the injury potential of a lifting or lowering job. It is computed as the ratio of the physical demands of the job to the physical capacities of the worker.

Local segment: A specific body segment, usually the one in contact with an object required for performing a task or the one most active in the task.

Maximal aerobic power: The maximal rate at which a person's body can consume oxygen while breathing air at sea level.

Motion study: The analysis of a task or job by studying the motions of humans and equipment related to its component activities.

Person–task conflict: The situation in which task demands are beyond a person's capacities and the task is unlikely to be performed according to specifications by that person.

Position analysis questionnaire: A checklist for job analysis, developed by the Office of Naval Research in 1969, requiring the analyst to rate or assess a job from a list of 187 job elements.

Safety limit: The maximum stress (e.g., load to be lifted) that most workers can sustain under specified job conditions without adverse effects (injuries or cumulative strains) on their bodies.

Time study: The study of a task by timing its component activities.

Work pause: A short stoppage from work.

Human–Computer Interaction Design

Kenneth J. Maxwell
BMK Consultants

81.1 Purpose of This Chapter

The fields of Biomedical Engineering and Human–Computer Interaction (HCI) share a special reciprocity. On one hand, biomedical products, including instrumentation, devices, bioinformatics systems and robots, are becoming increasingly reliant on information technology (IT). HCI factors are principal determinants of the adoption, effectiveness, and safe use of these products. On another hand, biomedical research and data play an important role in human–computer interface technology. Biomedical factors will increasingly require consideration as HCI technology extends to incorporate alternative modalities of interaction.

This chapter provides the reader with fundamentals for addressing HCI design and highlights areas of particular interest to biomedical engineers. Work in HCI is abundant in academic, government, and commercial sectors. This chapter selects from this work essential and practical information needed to incorporate (a) human experience considerations into the engineering of biomedical products and

(b) biomedical considerations into the engineering of human–computer interface technology. References to broaden the reader's knowledge of HCI are provided in the Further Information section.

81.2 HCI Directions and Design Challenges

Since the second edition of this handbook, the field of HCI has matured and expanded in several new directions relevant to biomedical engineering. Much of this expansion is linked to dramatic changes in computing technology.

Computing is becoming both more social and more personal. The Internet enables electronic social networks and communities that are supplying needed support and resources for patients. Communication and network systems provide facilities for distant collaboration among physicians. At the same time, HCI and the information provided by systems are becoming increasingly personalized. For example, the ability to search or navigate large databases, websites, and networks for focused retrieval of information is increasingly tailored to individual needs.

Computing is becoming more mobile and ubiquitous. Data services including web browsing, e-mail, and text messaging are common on cell phone and personal data assistant (PDA) form factors and are integrated with voice services. From a physical interaction perspective, mobile form factors present HCI design challenges including restricted display space and input mechanisms, function integration, management of multiple communication channels, and reduced computing power. For biomedical applications, wearable devices that monitor and transmit data from a patient will become more commonplace. Wearable devices must be comfortable emotionally as well as physically for the wearer, similar to the impact of an accessory to clothing.

Computing is becoming more embedded in devices, instruments, and other products [Norman, 1998]. Such devices have special purpose interfaces, because of their specific and limited functionality. Due to this reduced complexity, the HCI design task may appear to not require much consideration. Although the scale of the HCI design effort may be smaller for devices than for large systems, attention to HCI factors should remain prominent. Rogers et al. [2001] in an analysis of a commonly used blood glucose meter found that although the instructions listed thee general steps these actually required a total of 52 sub-steps, many of which were sources of error in operating the device for the participants in the study. Many problems can sabotage the **usability** of simple products [Darnell, 2004]. These are unnecessary and can be avoided when proper methods are applied to understand users, identify potential problems, and design a quality user experience. Satisfying user needs represents value to customers and can present a competitive advantage.

To address these new computing paradigms, HCI has increasingly diversified. Interaction is tending toward becoming more multimodal. Alternative modes of interaction such as speech, gesture, and haptic feedback, for example, can provide the means for managing interaction across a variety of user needs, device form factors, and computing contexts.

Interfaces are tending to become visually richer. Greater computing power has enabled support of visualization and visual simulation techniques that enable a myriad of biomedical applications that were impractical not long ago.

HCI is also moving beyond what Maxwell [2002] calls basic usability concerns toward broader elements of human experience including social interaction and collaboration, motivations [Fogg, 2003; Shneiderman, 2002] emotions [Norman, 2004] context [Abowd et al., 2002] and integration with real-world interactions [Streitz et al., 2002].

81.3 HCI in Biomedical Products

81.3.1 Instrumentation and Biometrics

Biomedical instruments increasingly embed computing power, and to the extent they do, the instrument's interface involves HCI. These products include simple consumer devices for home use by the general public

up through complex instruments used by researchers, physicians, and other professionals. Increasingly biometric data such as fingerprint recognition is being used to secure access to computers or devices.

81.3.2   Medical Information Systems, Bioinformatics, and Simulation

Advanced computing power and computational tools have made possible the collection and complex analysis of very large amounts of biomedical data, contributing to improvements in health care and understanding of biological processes. However, in many cases, these improvements can only be realized if researchers, practitioners, and patients themselves can effectively, satisfactorily, and safely operate equipment and systems.

One major area of large information systems in general and medical information systems in particular is search. Researchers are rapidly moving to find more efficient ways to do searches. Leroy et al. [2003] found that Genescene, a system that parses natural language text automatically using a rule-based system and which provides biological researchers with research findings was more useful and efficient than keyword searches. Wildemuth et al. [1998] although finding no performance difference between Boolean keyword searches and hypertext navigation, did report that users preferred the Boolean keyword searches. Miller et al. [2004] report findings that suggest that the quality of link labels in hypertext navigation through a website architecture has a great effect on search efficiency.

Visualization techniques have greatly improved many areas of biomedical research and practice [Johnson et al., 2004], including medical diagnosis, planning of surgical techniques, and simulation of biological behavior. Cavassa and Simo [2003] present work on a virtual patient system that provides a 3-D model of the patient and an ER room with a physiological model that can react to interventions.

81.3.3   Robotic Service Systems

Robots will be a part of our everyday lives in the near future. Biomedical applications of both professional and personal service robots are becoming increasingly common. A survey conducted by the United Nations Economic Comission for Europe (UNECE) in conjunction with the International Federation of Robotics (IFR) [2004] estimated that a stock of 21,000 professional service robots at the end of 2003 and projected 75,000 by the end of 2007. These include medical robots, underwater robots, surveillance robots, demolition robots, and many other types of robots for carrying out a multitude of tasks. Medical robots comprised 12% of the 2003 estimates.

On the professional side, robots will, among other tasks, autonomously deliver records and medicine throughout hospitals or extend a surgical team's performance. On the personal side, robots will play a role in assisting with many aspects of life, such as assisting elders in living independently or facilitating rehabilitation. For example, Forlizzi et al. [2004] reports an ethnographic study of elders living independently in their own homes for the purpose of exploring how assistive robotic products can help elders live independently longer.

Plaisant et al. [2000] developed a robotic toy with which children could interactively create and replay stories assisting with physical and developmental problems. Yanco et al. [2004] evaluated human–robot interaction at a robotics competition using a tailored set of usability criteria developed by Scholtz [2002] that can be applied to a broad range of robotic applications.

81.3.4   Biomedical Engineering and Interaction Technologies

The applications discussed above address the interaction between humans and biomedical products that embed or employ computers. However, as HCI technology develops to address new paradigms, new modes of interaction, such as haptic feedback, gestural, and speech interfaces will increasingly involve biomedical factors.

For example, early results from Keates et al. [2004] suggest that haptic-force feedback is very promising for providing significant interaction performance improvements for motion-impaired users.

Han et al. [2002] report that a 2-D force feedback device could be used to present 3-D shapes using a force-shading technique, a haptic analog to bump mapping in computer graphics. Bach-y-Rita et al. [2003] found that a system in which electrotactile stimuli were delivered to the tongue via flexible electrode arrays placed in the mouth provided a feasible means for tactile vision substitution.

81.4 Fundamentals

81.4.1 Human-Centered Design

Human-centered (also referred to as *user-centered*) is a modern design philosophy and methodology for deriving and allocating functional requirements, driving design concepts, and setting evaluation criteria from the perspectives of the person or persons that will use the products being developed. This philosophy was promoted as an alternative to design approaches that emphasized technology and market factors over user experience, resulting in designs that frequently and unnecessarily compromised the user's motivations, performance, safety, and emotional responses. **Human-centered design** does not and should not exclude technology and market factors, but is meant to ensure that along with these factors the realized products or systems satisfy human needs and desires [Norman, 1998]. Human-centered design is ubiquitous and is an enduring tradition toward achieving highly usable products. As testament an international standard [ISO 13407, 1999] provides a guide to its application.

Usability refers to the capacity of a machine or system to be used by intended persons for accomplishing intended purposes. It is a multifaceted concept that can include effectiveness, efficiency, time-to-learn, safety, and emotional satisfaction. International standard, ISO 9241-11 [1998] defines usability as, "the *effectiveness*, *efficiency*, and *satisfaction* with which specified users achieve specified goals in particular environments." Effectiveness is, "the accuracy and completeness with which specified users can achieve specified goals in particular environments." Efficiency is, "the resources expended in relation to the accuracy and completeness of goals achieved." Satisfaction relates specifically to the user and is, "the comfort and acceptability of the work system to its users and other people affected by its use." A human-centered methodology is the widely accepted path toward realizing a design that embodies usability qualities. Usability is a major factor affecting the operational performance, availability, maintainability, and reliability of a human–product system.

The following are some characteristics of human-centered design:

- The purposes of all users involved are identified.
- The product is viewed as a tool that users employ to accomplish their purpose.
- The user is always performing a higher-level task than the product.
- Tasks are allocated away from the users rather than to the users. This is not simply a matter of perspective but rather is fundamental to a human-centered approach. That is, the user is assumed to be performing a high-level task. Lower-level tasks that are better performed by the computer are allocated from the user to the computer. This approach is opposed to the one that considers the computer as the high-level task performer and allocates to the user lower-level tasks that the machine cannot do well.
- Tasks performed by users are meaningful.
- The user's responsibilities provide satisfaction and make use of the user's talents and skills.
- Intended users of the product participate in the design process.
- The user's skills and performance capabilities are explicitly considered in and accounted for in design decisions.

Many techniques, methods, and tools have been developed for the purpose of providing designers with information about users very early in the product and system development process. These approaches are employed to inform the specification of function and design requirements and the synthesis of design concepts, as well as forming a basis for test and evaluation criteria.

Of foremost concern to designers using the human-centered approach is human purpose. As computing technology and HCI has progressed, there has been a transition from focusing on what computers can do to what human can do [Shneiderman, 2003]. This transition is manifest in the evolution of human needs and wants that computer-based products are intended to satisfy [Maxwell, 2002]. The human purpose for a product or system may be broad or specific. Purpose can translate directly into the function of a product or system but not necessarily so. For example, the function of a consumer blood-pressure monitor is to measure a user's blood pressure, but its purpose is broader. It is to enable a convenient, frequent, and private monitoring of blood pressure, to inform the user, and toward the goal of keeping the user's blood pressure at a healthy level. In this broader sense the purpose fulfills not only the needs of the user of the monitor (the patient) but also the purposes of the user's doctor and more broadly of the user's health insurer. From a very different human perspective the monitor needs to serve the purposes of the people who make and sell it, and it is in this way that the human-centered approach can be used to consider user, market, and technology factors together.

A first step in employing a human-centered approach is to identify the intended users and to characterize them with attributes relevant to the product or system. This involves characterizing users along any number of relevant dimensions such as age, skill level, geographic location, context-of-use (e.g., home or work), The purpose of such an analysis is to determine the range of these characteristics and the extent to which users are similar and different. Similarities can be used to categorize users and to direct design decisions to address the needs of these categories. Design requirements can be very different across user groups. Differences within groups can be used to inform the degree of flexibility, personalization, and adaptability needed.

As part of a project to improve the usability of bioinformatics web sites, Javahery et al. [2004] report a user analysis of the biomedical research community. Their analysis described users with regard to seven characteristics: user's language, familiarity with the internet, bioinformatics background, education level, profession, experience with specific web sites, and the tasks performed on web sites. Of course, the specific characteristics that are relevant will vary with the product or system being developed or evaluated.

81.4.1.1 Ethnographic Studies

These are in-the-field studies that have been adopted from anthropology research. The researchers are embedded to some level with the users and garner data on how they interact in real life with the products or systems under study or similar products or systems or to identify the need for such products. In an ethnographic study of independent elders, Forlizzi et al. [2004] identified two groups of elders, well and declining, using characteristics of mobility, cognitive function, and household maintenance.

User groups can be defined along many different dimensions depending on the application. Two typical and general grouping criteria are function- and resource-needs-based. For biomedical applications functional user groups commonly include those identified below:

- *Practitioners and service providers*: This group includes, doctors, nurses, psychologists, social workers, paramedics, and other providers of medical care.
- *Biomedical science researchers*: This group uses biomedical instruments, simulation tools, data-analysis software, and data-mining software to conduct research and development in laboratories or in the field.
- *Administrators*: This group represents hospital administration, doctor's office, and insurance personnel that use biomedical records and data as part of their daily work.
- *Legal*: This group includes lawyers, paralegals, court and government representatives, expert witnesses, and insurance-industry representatives that employ biomedical products for legal purposes.
- *Analysts*: This group includes persons who perform data mining and other analyses of biomedical data using computer systems.
- *Patients*: This is a specific subset of the general public user group that is using biomedical products or systems under the advice of a doctor or during a period of care.

- *General public*: This group is maximally diverse and use a variety of consumer instruments and products as well as accessing a variety of online medical information belonging to online support networks.
- *Information technology support personnel*: This group includes persons that install, manage, configure, diagnose, and repair biomedical IT systems.
- *Biomedical engineers*: This group includes persons that use computer-based tools to design and build biomedical products.

Resource-needs-based groups typically are differentiated along the dimensions identified here. Users belonging to different groups along these dimensions will typically need different levels of assistance and training.

- *Age*: Elders and children make up especially important broad groups.
- *Disabilities*: These typically are further grouped by type such as vision, hearing, motor skills, and cognition.
- *Current medical condition*: Groups can be defined by any condition needing current care.
- *Current lifestyle*: Any number of cultural variables can be used to identify groups.
- *History*: Any number of medical, lifestyle, or family variables can be used to specify the relevant groups.
- *Expertise*: This dimension differentiates the level of knowledge and skill users have with a particular product or system or the functions they perform.

Another step in employing a human-centered approach is to describe what and how users will do interacting with the product or system. The methods discussed here can be employed to generate this needed information.

81.4.1.2 Use-Case Analysis

Use-case analysis is a part of the Unified Modeling Language (UML) development process [Booch et al., 1999]. This analysis is meant to specifically identify and characterize each use of a product or system by each user. UML calls these users "actors." Use-cases are valuable for identifying each functional type of user and the functions that they will perform.

81.4.1.3 Scenario-Based Analysis and Design

In this analysis a set of representative scenarios are defined and used to examine how the product or system will be used in the contexts of its use. Scenarios are especially useful for revealing and addressing highly critical, low-probability situations. Rosson [1999] develops a form of user-interaction scenarios that are an expansion of use-case scenarios. These are particularly useful for modeling a user's goals, expectations, and reactions and provide a means of tracing these user aspects through to design. See Carroll [2000] for more scenario-based design.

81.4.1.4 Participatory Design and Knowledge Acquisition

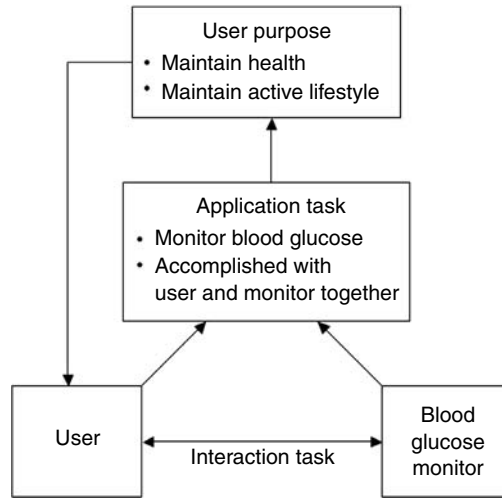
Participatory design is a cooperative approach that includes some users on the design team as active participants in the design process. This approach ensures that the design team includes domain expertise and as such represents the expectation that this expertise will translate into successful designs. Participatory design is very applicable to biomedical products because in many cases expert medical knowledge will need to be incorporated into the system and an understanding of the medical knowledge of the various user groups will be needed to inform the design. The various methods discussed in this section are not meant to be exclusive of one another and the use of more than one approach is encouraged. Carroll et al. [2002] provides a particularly good example of this, by combining participatory methods with a scenario-based design approach and ethnographic design techniques.


FIGURE 81.1 The user's purpose is served by the application task, which is accomplished through the interaction task.

81.4.1.5 Task Analysis, Allocation, and Modeling

Task analysis is a process of decomposing the activities and functions that need to be performed into their constituents. When humans interact with products or systems, two types of tasks are performed: an **interaction task** and an **application task**. The interaction task consists of the activities that the user performs to use the product or system. These activities include moving a mouse device, typing keyboard inputs, viewing displays, searching for and managing files, managing displays, setting preferences, and running programs.

The application task refers to the user's functional objectives that will in turn satisfy the user's purpose. These objectives vary widely and include planning a surgery, performing a statistical analysis, diagnosing a patient's condition, finding information in a database, monitoring blood pressure, and living independently. The application task is a higher-level task than the interaction task, meaning that the interaction tasks are subtasks that contribute to accomplishing the application task. Figure 81.1 illustrates the relationships between these two task levels and the greater purpose being satisfied for a user employing a blood glucose monitor. Note that the user and the monitor work together to accomplish the application task.

81.4.2 Quantifying Tasks

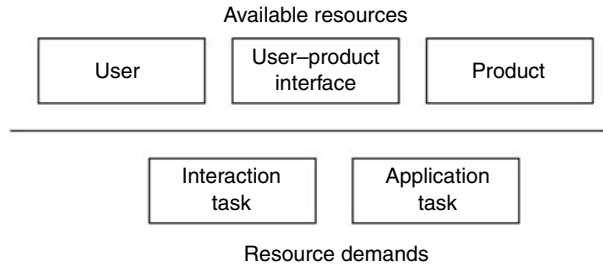
Tasks can be analyzed qualitatively and quantitatively. There are several methods for quantifying various aspects of HCI tasks. The GOMS (for goals, operators, methods, and selection rules) and keystroke-level models [Card et al., 1983, 1986], when used in combination with human-performance models such as the model human processor, provide task-performance estimates and knowledge requirements. The NGOMSL (for natural GOMS language) [Kieras, 1998] and TAG (task action grammar) [Payne and Green, 1986; Schiele and Green, 1990] models provide quantitative metrics for interaction task complexity and consistency.

Another effort to define quantitative usability metrics generated the metrics for usability standards in computing (MUSiC) methodology [Bevan and Macleod, 1994]. This methodology uses these metrics for specifying usability goals and intermittently testing to verify meeting the goals as part of the design process.

Kondraske [1995] has developed an elemental resource model (ERM) of human performance [Kondraske, 1995] that can be applied to quantify tasks in terms of the requirements for and availability of performance and skill resources. Each performance resource is defined in terms of a quantitative unidimensional capability to perform an elemental function. Skill resources are defined in terms of

Available resources

User	User–product interface	Product

Interaction task	Application task


Resource demands

FIGURE 81.2   Designs must supply adequate resources to meet resource demands.

knowledge and experience. Adopting this model allows usability tradeoffs in design decisions to be stated in terms of the relationships between (1) available resources and the sources that possess them and (2) required resources and the sinks that expend them. Sources of resources include the user, the product, and the user–product interface. Sinks are the interaction and application tasks, Figure 81.2. The ERM is the only model that (1) incorporates all required dimensions of performance and skills, (2) provides a performance-modeling capability at elementary and intermediate levels, and (3) uses consistent modeling constructs across tasks, humans, and products.

Since, as in the example in Figure 81.1, the human and the biomedical product work together to satisfy the application task, the resources needed to accomplish both tasks are distributed between the human and the product. With this model, the design process can manage required and available resources to guide acceptable solutions. The usability of a given design concept can be predicted on the basis of this resource management. The designer has partial or full control over the resources required of the user to perform the interaction and application tasks by optimally off-loading (i.e., allocating) required resources to the product and user–product interface. Figure 81.3 illustrates the resource correspondence between the user, product, and interface between them. The arrows indicate the flow of information across the interface. The arrow between the cognitive–emotive resources is dashed to indicate that this level of information exchange is indirect and managed through input–output resources.

The designer has much control over the design of the interaction task. Although tempting, it is useful not to let HCI tasks to be defined by existing noncomputer-based ways of doing the task. Meaning, do not rely solely on existing task flows. The process of creating innovative task flows for new environments is what Kramer et al. [2000] calls "exploring the blue sky."

81.4.3 Minimal and Optimal Usability

Use of the ERM enables the designer to define and explore design boundaries. For example, the ERM would define an HCI design as minimally usable when all the user's performance and skill resources needed to accomplish the interaction and application tasks are exhausted in achieving a desired level of application-task performance. This means that the user can perform the task using the product only with maximal effort and expenditure of resources. Note that this definition of usability does not address the design of the HCI specifically. Rather, it addresses the relationship between the performance that can be obtained with a given HCI design and the effort a user needs to expend to achieve it. This means that different users will have different points at which an HCI for a given task will be minimally usable.

The concept of optimal usability is more complex. An optimized design will allow users maximal use of their performance and skill resources, allocated at their discretion to the application task, to maximize their performance on the application task. Thus an optimal design minimizes the resources required to perform the interaction task and enhances the utility of the user's resources in performing the application task. This means that the interface will support the user in performing the portion of the application task allocated to the user. This is accomplished through application-level design issues associated with the organization and level of objects, actions, and information.

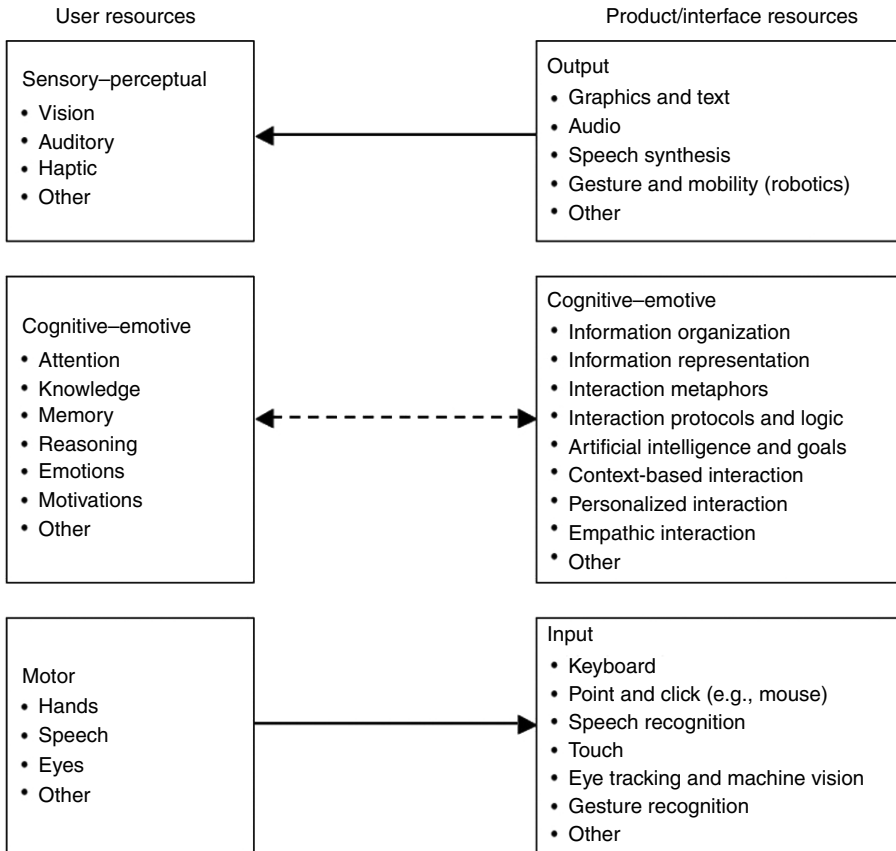
User resources   Product/interface resources


FIGURE 81.3   Resource correspondence between user resources and product/interface resources.

81.5 Performance-Based Usability Design Decisions

Successful HCI design decisions must be made on the basis of (1) knowledge about the user's performance and skill resources, (2) the performance and skill resource requirements of the application task, and (3) the performance capabilities of available technology.

Design strategies for achieving usability follows from an analysis of available and required resources and application of HCI design principles that act to reduce resource task demand on users. For example, usability will tend to increase as the resources required of the user to perform the interaction and application tasks decrease. Usability will tend to increase as interface resource availability of the resources increases.

A detailed discussion regarding performance resources is presented by Kondraske [1995] and in this Handbook. Different resource sources and tasks impose different design objectives. One performance-based design objective is to apply HCI resources to minimize the number of performance resources the user needs to perform the interaction task. This approach permits the user to allocate more resources to performing the application task. Achieving this objective includes (1) incorporating appropriate input and display devices to meet the user's sensory–motor resources and (2) use of organizations, representations, and levels of object, actions, and information that fit within the limits of the user's cognitive resources.

A second performance-based design objective is to apply HCI resources to optimize the resources the user needs to perform the application task. Many of the objects, actions, and information with which the user interacts are application-task-specific. Organization and representation decisions should be based on these task-specific requirements. For example, if the application task involves drawing, the user needs general software and hardware drawing tools and devices.

This consideration can be used to illustrate the relationship between application and interaction task-level design issues. A software-drawing package can provide different levels of drawing elements (e.g., having a tool to directly draw *n*-sided polygons vs. a line-drawing tool from which a polygon can be drawn segment by segment). Assume that the HCI provides a palette of drawing tools and that it includes primitive and complex tools. The user can draw an *n*-sided polygon using the line tool or using the polygon tool. Both tools are included in the palette. The issue here is how the decision to develop the polygon tool and include it in the product is made. The decision must be based on the user's application-task need to draw polygons. This need is established by an analysis of the application task. Thus the decision to include the polygon tool is an HCI decision at the application-task level. Once this applied need is established, the HCI design needs of how to represent, where to locate, and how to operate the tool are addressed. These are HCI design issues at the interaction-task level.

The decisions at these two task levels can be further used to illustrate interactions in assessing performance-based usability. A decision to include the polygon tool made on the basis of the application-task requirements will increase usability at the application-task level in that the user will need to use fewer sensory–motor resources to create a polygon. However, the inclusion of the polygon tool complicates the interaction-task level in that more items are added to the tool palette and that procedures need to be defined for drawing it. As discussed later, these complications are addressed by applying HCI design principles that reduce performance and skill-resource demands. Because the ERM defines performance resources at an elemental level, performance-based design can be conducted at the elemental level or at higher intermediate levels. Intermediate levels reduce the granularity of the analysis and provide for use of composite performance resources. For example, analyzing a menu-selection task performed with a mouse device at an elemental level would involve performance resources for speed, accuracy, and steadiness of positioning movements. An intermediate-level analysis could use pointing as a composite performance resource.

In exploring why users often have difficulty progressing from basic ways of doing a task to more efficient ways, Bhavnani and John [2000], conclude that there is an intermediate level of knowledge required that is not explicit in knowledge of the tool or the task. They discuss several reasons for inefficient use. Because, the ERM represents a systematic means of modeling resources at an intermediate level it provides a way to address this problem from a performance rather than from a knowledge perspective.

81.6 Heuristics for Reducing Task-Resource Demands

The ERM can be used in a rigorous way when performance data are obtainable or less rigorously as a set of principles to guide designing for enhanced usability. Rigorous application requires an analysis of available and required performance and skill resources and performance data associated with each resource. These data are usually not obtainable for all resources. Less rigorous application uses the principles of resource economics, resource stress, and analyses of the performance and skill resources involved in tasks to guide the design toward lower resource demands on the user. Usability can be improved by applying resource-demand-reducing HCI heuristics. Five major design heuristics that act to reduce task demands on performance and skill resources are described.

81.6.1 Naturalness and Familiarity of Interaction

Usability will be improved to the degree that the interaction is natural and familiar. Naturalness and familiarity reduce training requirements and increase available resources (e.g., available knowledge and sensory–motor performance). For physical components at a task level, this means that the user's sensory and effector modalities are properly matched to the required interactions, for example, keyboards used for typing, keypads for data entry, and mouse, pen, or touch-screen devices for pointing. For physical components at a feature level, this means that (1) user anthropometrics are employed in defining workstation and component configurations and dimensions and (2) that the physical characteristics of controls and displays (e.g., operating force, sensitivity, brightness, intensity, and size of displayed information) are congruous

with the users and physical capabilities. For mental components at a task level, natural interaction means that the HCI models the user's tasks in accordance with the user's knowledge and experience. For mental components at a feature level, natural interaction means that the user's perceptual and cognitive capabilities and limitations are employed in defining HCI features (e.g., icons, names, screen layouts, and the behavior of window controls such as scroll bars). Direct manipulation interaction techniques (e.g., drag and drop) are a form of natural interaction in that they create a software mechanism with a physical analogy.

81.6.2 Simplicity of Interaction

Simplicity applies across a wide variety of design issues and must be incorporated in every architectural category. Applying this principle reduces training requirements, memory demands, perceptual demands, and the cognitive demands for inference. For the physical interface component, applying this principle reduces the number of physical steps needed to select and invoke actions and reduces movement precision requirements.

81.6.3 Consistency

Consistency reduces training requirements and memory requirements and promotes skill development. Consistency applies across a wide variety of design issues and must be incorporated in every architectural category. Examples include object, action, and information organizations, task flows, representations for objects and actions, and procedures. TAG [Payne and Green, 1986; Schiele and Green, 1990] provides a formal technique for analyzing consistency.

81.6.4 Robustness

Robustness refers to the ability of the design to tolerate user error and to span the functional requirements of the user. Error tolerance reduces resources needed to recover from errors and reduces initial accuracy requirements, allowing the user to increase operating speed. Users may commit errors because of a lack of knowledge. In this case, the user may be exploring the system to learn it. These are not errors. But this type of behavior should be expected, and the design should allow the user to do this exploration and to recover from anything he or she may do. Users may commit errors because of a misunderstanding or negative transfer from other systems. Thus a user may infer that a menu item will elicit a given behavior because it does so on another system that he or she has used. Or the user may feel that he or she understands what a given menu item or icon means and be wrong. Users may commit errors through unintentional commands. For example, a user may inadvertently click a wrong button, hit a wrong key, or select a wrong item from a menu. Ensuring adequate functional coverage reduces the functional demands on the user.

81.6.5 Accommodation of User Capabilities

In resource terms, applying this design principle increases the fit between an individual user's available mental and physical resources and those required by the interaction and application tasks. There are two major dimensions on which users vary: experience and capability.

Along the experience dimension users vary between experts and novices on either the interaction or application task. Thus a user could be very experienced with the applied task but not with doing that task on a computer. Similarly, a user may be very used to using computers but not skilled in the applied task. Novice users will (1) need more guidance and feedback, (2) require more structure to the task, (3) rely more on memory-aiding design features (e.g., menus), and (4) benefit more from online help facilities than expert users. Expert users (1) will want more flexibility in task control, (2) will want shortcut methods to do high-level actions, (3) will rely more on recall rather than memory aids, and (4) will benefit more from the use of preferences and tailored configurations than novice users [Brown, 1988; Galitz, 1993].

Along the capacity dimension users vary between healthy and impaired. In the ERM, impairments are not defined differently from any other performance or skill differences among users. All differences are

defined in terms of the amount of specific performance resources available to an individual. Impaired users will vary greatly in capacity and experience. Only through an analysis of resources demanded by the task and resources available to the user can an adequate design for an impaired user be accomplished successfully.

81.7   Design Iteration

The methods described earlier generate the information needed by designers to develop design concepts. Early design concepts need not and should not be overly detailed. HCI design is an iterative process and the benefits of iteration are lost if too much detail is specified in early iterations. Generating quality designs requires imagination and unnecessary detail too early will tend to block innovations at more abstract levels of the design. Iteration guides a graceful narrowing that matches design solutions to the level of understanding of the users and the tasks available. Each cycle either corrects design problems or refines the detail of design areas that work.

After design concepts have been developed they need to be prototyped and evaluated. Prototypes are early forms of a product or system that incorporate partially or fully the functions and features of a system. Prototypes can be developed at any of a range of fidelities and are an essential tool in evaluating usability as well as engineering feasibility and marketability. Early prototypes will generally be of low fidelity and may only model part of the functionality of the product. As with the design, prototypes will evolve to greater fidelity and functionality.

Evaluation is a matter of testing, measuring, and validating the usability of the design. Usability evaluations are performed iteratively. Since the designs and their prototypes will be at evolving levels of specification their evaluations may be performed in fundamentally different ways. Relatively inexpensive and expedient evaluations include cognitive walkthroughs and expert heuristic inspections [Nielson, 1994]. More elaborate evaluations include format empirical studies that can collect objective task-performance data as well as subjective data.

Evaluations will lead to a reexamination of requirements, narrowing of the range of design concepts under consideration, and refinement of superior concepts in a subsequent design iteration.

Defining Terms

Application task: Refers to the objectives the user is employing the product to accomplish.
Human-centered design: Human-centered design refers to a philosophy of human-machine system design that places the focus of the design process on the needs of the human who uses the system to accomplish a task.
Interaction task: Refers to the activities that the user performs to use the product (e.g., moving a mouse device, typing keyboard inputs, viewing displays, searching for and managing files, managing displays, setting preferences, and executing programs).
Usability: Usability is a multidimensional quality that affords the user practical and convenient interaction with the product for achieving applied objectives. The concept of usability is fundamental to the design of any human system.

Applications of Human Performance Measurements to Clinical Trials to Determine Therapy Effectiveness and Safety

Pamela J. Hoyes Beehler
University of Texas-Arlington

Karl Syndulko
UCLA School of Medicine

A **clinical trial** is a research study involving human subjects and an intervention (i.e., device, drug, surgical procedure, or other procedure) that is ultimately intended to either enhance the professional capabilities of physicians (i.e., improve the service delivered), improve the quality of life of patients, or contribute to the field of knowledge in those sciences which are traditionally in the medical field setting — for example, physiology, anatomy, pharmacology, epidemiology, neurology, cognitive psychology, etc. [Levin, 1986]. Clinical trials research is in the business of evaluating therapeutic interventions intended to benefit humans. Its value is directly related to the relevance of the questions "Do our treatments work?" "How well do our treatments work?" and "Are our treatments safe?" For example, drug *A* is designed and anticipated to relieve sinus congestion. Is there a drug interaction when drug *A* is taken with drug *B* and/or moderate

levels of alcohol consumption such that while congestion is relieved (i.e., drug *A* is effective), human information processing capacities are reduced (i.e., is drug *A* safe?). And what is the time course of effects with regard to positive and negative (or adverse) effects? Thus it is clear that not only steady-state issues buy also dynamic questions are on interest in clinical trials research.

While clinical trials research incorporates many different components, the focus of this chapter is limited to study questions associated with human **performance capacity** variables and their measurement as they contribute to the determination of therapy effectiveness and safety. Such variables have been incorporated into trials since the use of controlled studies in the medical field began. However, the methodology employed to address human performance variables has been slowly but steadily shifting from mostly subjective to more objective instrumented methods [e.g., Tourtellotte et al., 1965] as both the understanding of the phenomena at play and the demand for improved quality of studies have increased. This chapter begins by briefly examining a classification of typical clinical trials study models, presents a summary of methods employed and key methodologic issues in both the design and conduct of studies (with special emphasis on issues related to the selection of measures and interpretation of results), and ends with a walk-through of a typical example that demonstrates the methods described. Brief discussion of the benefits that can be attributed to the use of objective, instrumented measures of human performance capacities as well as their current limitations in clinical trials research is also presented. While it is emphasized that most methods and issues addressed are applicable to any intervention, the use of human performance variables in pharmaceutical clinical trials has been most prevalent, and special attention has been given here to this application.

82.1   Basic Principles: Types of Studies

Depending on the set of primary and secondary questions to be addressed, considerable variety can exist with respect to the structure of a given trial and the analysis that is performed. Within the focus and scope of this chapter, clinical trials are classified into two categories for discussion: (1) safety-oriented and (2) efficacy-oriented. According to the Food and Drug Administration (FDA) [1977], four phases of research studies are required before a drug can be marketed in the United States. Phase I is known as *clinical pharmacology* and is intended to include the initial introduction of a drug into humans. These studies are safety-oriented; one issue often addressed is determination of the maximum tolerable dose. Phases II and III are known as *clinical investigation* and *clinical trials*, respectively, consisting of controlled and uncontrolled clinical trials research. Phase IV is the *postmarketing of clinical trials* to supplement premarketing data. Both safety and efficacy are addressed in phases II to IV investigations. As specified earlier, not all interventions studied are drugs. However, a similar phased approach is also characteristic of the investigation of therapeutic devices and treatments.

Safety-oriented trials usually involve vital sign measures (e.g., heart rate, blood pressure, respiration rate), clinical laboratory tests (e.g., blood chemistries, urinalysis, ECG), and adverse reaction tests (both mental and physical performance capacities) to evaluate the risk of the intervention. In this chapter we focus on the adverse reaction components, most of which historically have been addressed with subjective reporting methods. In the case of drug interventions, different doses (e.g., small to large) are administered within the trial, and the dose-related effects are examined. Thus the rate at which a drug is metabolized (**pharmacokinetics**), as evidenced by changes in drug concentrations in blood, cerebral spinal fluid, urine, etc., is usually addressed in safety-oriented drug studies, as well as the maximum dosage which subjects can tolerate [Baker et al., 1985; Fleiss, 1986; Tudiver et al., 1992; Jennison and Turnbull, 1993].

Efficacy-oriented trials are usually conducted after initial safety-oriented trials have established that the intervention has met safety criteria, but they will always have safety questions and elements as well. In this type of study, the goal is to objectively determine the therapeutic effect. Whatever the type of intervention, these studies are designed around the bottom-line question "Is the intervention effective?" In many cases (e.g., drugs for neurologic disorders, exercise programs for musculoskeletal injuries, etc.),

effectiveness implies improvement or retarding the rate of deterioration in one or more aspects of mental and/or physical performance. With regard to disease contexts, it is necessary to distinguish performance changes that merely reflect treatment of systems as opposed to those which reflect the slowing or reversal of the basic disease process. Studies typically include pre- and postintervention measurement points and, whenever feasible, a control group that is administered a placebo intervention [Fleiss, 1986; Weissman, 1991; Tang and Geller, 1993]. The situation is complicated because there are many performance capacities that could be affected. In response to the intervention, some capacities may improve, some may remain unchanged, and some may be adversely affected. Thus efficacy-oriented studies typically include a number of secondary questions that address specificity of effects. When the intervention is a drug, both the pharmacokinetics and *pharmacodynamics* are often addressed. Pharmacodynamic studies attempt to relate physiologic and/or metabolic changes in the concentration of the agent over time to corresponding changes in the therapeutic effect. Thus repeated measurement of selected performance capacities are required over relatively short periods of time as part of these **protocols**.

Clinical trials involving human performance metrics generally use the **randomized clinical trial** (RCT) design. The RCT is a way to compare the efficacy and safety of two or more therapies or regimens. It was originally designed to test new drugs [Hill, 1963]; however, over the last 25 years, it has been applied to the study of vaccinations, surgical interventions, and even social innovations such as multiphasic screening [Levin, 1986]. Levin [1986] describes four key elements of RCTs: (1) the trials are "controlled," that is, part of the group of subjects receive a therapy that is tested while the other subjects receive either no therapy or another therapy; (2) the significance of its results must be established through statistical analysis; (3) a double-blind experimental design should be used whenever possible; and (4) the therapies being compared should be allocated among the subjects randomly. Levin [1986] further noted that "the RCT is the gold standard for evaluating therapeutic efficacy."

82.2   Methods

Studies are defined and guided by *protocols*, a detailed statement of all procedures and methods to be employed. Figure 82.1 summarizes the major steps in clinical trials in which human performance variables represent those of primary interest, although the general process is similar for most trial involving human subjects.

82.2.1   Selecting Study Variables

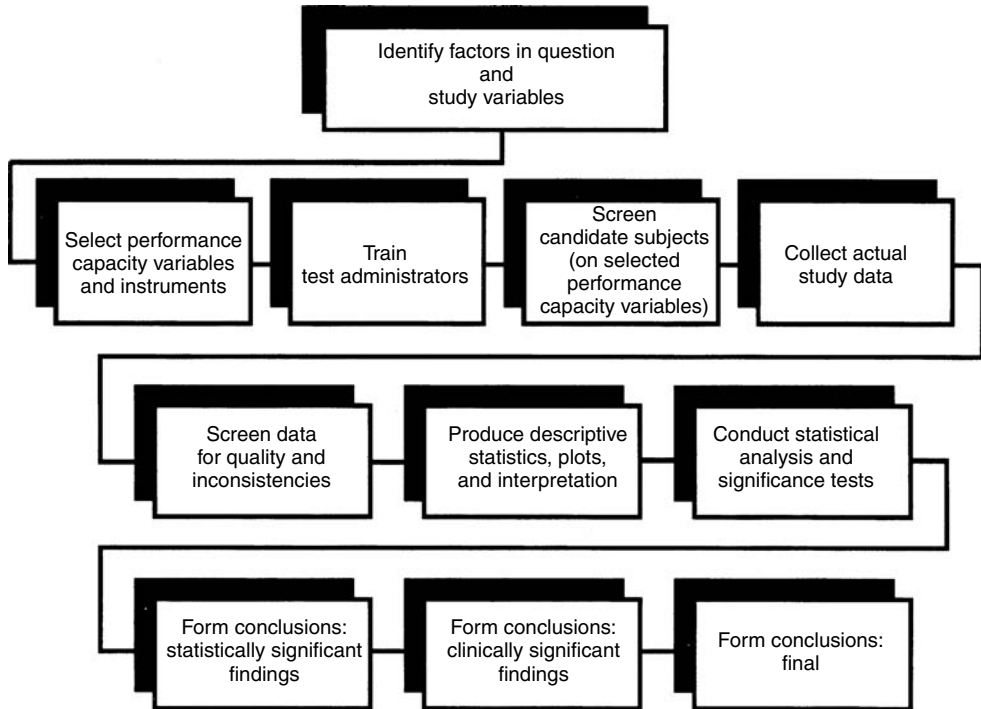
In many clinical trials, performance measurements must be focused on the specific disease or set of symptoms against which a medication or intervention is directed. The critical element is selection of an outcome assessment that will indicate directly whether the intervention can eliminate key signs or symptoms of the disease, improve function affected by the disease, or even simply delay further disease progression and loss of function. Economic and statistical constraints of such trials often indicate that a minimal set of measures must be used to provide valid, reliable, and sensitive indicators of changes in underlying disease activity related to the treatments. In many instances, there is considerable controversy about what constitutes a valid and reliable assessment of the underlying disease process, or there may be de facto standards adopted by clinicians, pharmaceutical companies, and the FDA as to the choice of outcome assessments. In many diseases, these standards may be physician rating scales of disease severity. Thus objective studies may be required in the case of specific diseases and disorders to delineate the most sensitive set of performance measures for clinical trial evaluations [Mohr and Prouwers, 1991]. Further, it often must be demonstrated to clinicians, drug companies, and the FDA that the objective performance measures selected as outcome assessments actually do provide equal or more sensitive indicators of disease progression (and improvement) than do existing rating scale measures traditionally utilized in clinical trials. Experience with human performance testing in multiple sclerosis clinical trials, discussed below, illustrates these issues.


FIGURE 82.1   Summary of major steps in the conduct of a clinical trial involving human performance capacities.

When objective measurement of performance capacities has been incorporated into many clinical trials, concepts and tools from human performance engineering can facilitate the selection of variables and shed some light on issues noted above. In either safety- or efficacy-oriented studies, study variable selection can be characterized as a two-step process: (1) identification of the factors in question (Table 82.1) and (2) selection of the relevant *performance capacities* to be measured and associated measurement instruments. This link between these two steps often represents a challenge to researchers for a number of reasons. First, duality in terminology must be overcome. Concerns about an intervention are typically initially identified with "negative" terms such as "dizziness" and not in terms of performance capacities such as "postural stability." Human performance models based on systems engineering concepts [Kondraske, 1995] can be used to facilitate the translation of both formal and lay terms used to identify adverse effects to relevant performance capacities to be measured, as shown in Table 82.1.

In Kondraske's [1995] model, performance capacities are modeled as resources that a given system possesses and draws up to perform tasks. It also provides a basis for delineation of *hierarchical* human systems and their performance capacities as well as a basis to quantitatively explain the interaction of available performance capacities with demands of higher-level tasks (e.g., such as those encountered in daily living). The hierarchical aspect is particularly important in selecting performance capacities to be measured. It is generally good practice to include a combination of carefully selected lower-level and higher-level capacity measures. This combination allows careful tradeoffs between information content (i.e., specificity) and simplicity of the protocol (e.g., number of variables, time for test administration, etc.). Higher-level capacities (characterizing systems responsible for gait, postural stability, complex mental task, etc.) are dependent on the performance capacities of multiple lower-level subsystems. Thus a few higher-level performance capacities can reflect multiple lower-level capacities (e.g., knee flexor strength, visual information processing speed, etc.). However, lower-level capacity measures are typically less variable than higher-level capacities within individuals (i.e., on retest) and within populations. Therefore, small changes in performance can be more readily discriminated statistically if they exist and are attributable primarily to localized lower-level capacities (e.g., see data in Potvin et al. [1985]). Also, more specific

TABLE 82.1 Representative Examples of Linking Factors in Question to Specific Measurable Performance Capacities

Factor in question[a]	Selected relevant performance capacities[b]
General central nervous system effects (of drug)	Selected activity of daily living execution speed Postural stability Upper extremity neuromotor channel capacity Manual manipulation speed Visual-upper extremity information processing speed Visual attention span Visual-spatial memory capacity Visual-numerical memory capacity
Alcohol interaction (of drug)	Selected activity of daily living execution speed Postural stability Visual information processing speed Visual-spatial memory capacity
Dizziness	Postural stability
Drowsiness	Selected activity of daily living execution speed Visual attention span Visual-upper extremity information procession speed Bond-Lader visual analog scale
Slowness of movement, psychomotor retardation	Visual-upper extremity information processing speed Upper extremity random reach movement speed Index finger (proximal intercarpal phalangeal joint), flexion-extension speed
Mood	Emotional stability (e.g., with Hamilton anxiety scale, Bond-Lader analog scale and other similar tools)
Speed	Reaction time
Coordination	Finger tapping
Tremors, abnormal movements	Limb steadiness Postural stability Vocal amplitude and pitch steadiness
Joint stiffness or pain	Extremes and range of motion Isomeric strength (selected joins)
Weakness, strength	Postural stability (one leg, eyes open) Isometric grip strength Isometric strength (representative set of upper and lower extremity, proximal and distal muscle groups)
Sensation	Vibration sensitivity Thermal sensitivity

[a] Terms used include those often used by pharmaceutical companies to communicate adverse effects to general public.
[b] Lists are illustrative and not exhaustive. More or fewer items can be included depending on time available or willingness to expend for data collection, with commensurate tradeoffs between specificity and protocol simplicity.

information can provide valuable insights into physiologic effects if they are present. By combing both types, broad coverage can be achieved (so that aspects of human performance in which the expectation of an effect is less remain included), as well as a degree of specificity, while keeping the total number of study variables to a reasonable size. In addition, if an effect is found in both a higher-level capacity and a related lower-level capacity, an internal cross-validation of finding is obtained. Many early studies incorporated variables representing looks across different hierarchical levels but did not distinguish them by level during analysis and interpretation. While such logic begins to remove the guesswork, much work remains to refine variable-selection methodology.

To address the broad, bottom-line questions regarding safety and efficacy, the formation of **composite scores** (i.e., some combination of scores from two or more performance capacity challenges or "tests")

is necessary. A resource model and the concept of hierarchical human systems also can be used to develop composite variables for practical use in clinical trials. Component capacities can be selected that are theoretically or empirically most sensitive to the disease or condition under study. The composite variable is then created by calculating a more traditional weighted arithmetic sum [Potvin et al., 1985] or product [Kondraske, 1989] of the component scores. In both cases, the definition of component scores is important (i.e., whether a smaller or larger number represents better performance). Treatments are not approved if only a small subset of individuals is helped. Composite measures provide the only objective means of integrating multidimensional information about an intervention's effects. The primary advantages of the composite variable is the creation of a single, global, succinct measure of the disease, condition, or intervention, which is often essential as the primary outcome assessment for efficacy. The major disadvantage is loss of detailed information about the unique profile of performance changes that each subject of a group as a whole may show. Such tradeoffs are to be expected. Thus both composite and component measures play important but different roles in clinical trials.

It is imperative that the selection of the study measures also consider a test's objectivity (nonbiased), reliability (consistency), and validity (measures what is intends to measure) to add to the quality of the measurements. Many complex issues, which are beyond the present scope, are associated with measuring and interpreting the quality of a measurement. (See Safrit [1990], Baumgartner and Jackson [1993], and Hastad and Lacy [1994] for more information.)

82.2.2   Formation of the Subject Pool

Clinical research investigations usually involve a *sample* group of subjects from a defined population. Selection of the study population so that generalizations from that sample accurately reflect the defined population is a dilemma that must be adequately addressed. If **probability sampling** is chosen, each subject in the defined population theoretically has an equal chance of being included in the sample. The advantage of this kind of sampling is that differences between treatment groups can be detected and the probability that these differences actually exist may be estimated. If **nonprobability sampling** is chosen, there is no way to ensure that each subject had an equal chance of being included in the sample. Conclusions of nonprobability sampling therefore have less merit (not as generalizable) than those based on probability sampling.

Studies with healthy subjects are believed to be necessary before exposing sick persons to some interventions because persons with disease or injuries commonly have impaired function of various organs that metabolize drugs and may take medications that can alter the absorption, metabolism, and/or excretion rates of the intervention. Gender issues also should be a concern in clinical trials because of new FDA regulations [Cotton, 1993; Merkatz et al., 1993; Stone, 1993].

All subjects selected as study candidates should be informed of the procedures that will be utilized in the clinical trials investigation by signing an informed consent document, as required by the Department of Health and Human Services *Code of Federal Regulations* [1985] and other federal regulations applicable to research involving human subjects. Using all or a subset of study measurement variables (in addition to medical history and examinations as necessary), a screening procedure is recommended to determine if each subject meets the minimum performance criteria established for subject inclusion. When patients are part of the sample group, this performance screening also can be used to establish that the sample includes the desired balance of subjects with different amounts of "room for improvement" on relevant variables. An added benefit of this screening process is that subjects and test administrators obtain experience with test protocols, equipment, an procedures that will add to the validity of the study.

Unless available from a previous similar study, it is typical for pilot data to be collected to estimate the expected size of outcome effects. With this information, the power of the statistical analysis (i.e., the likelihood that a significant difference will be detected) can be estimated so that sample size can be determined [Cochran and Cox, 1957; Kepple, 1982; Fleiss, 1986]. Another concern is that some of the original subject pool will not complete the study or will have incomplete data. High attrition rates may damage the credibility of the study, and every effort should be made to not lose subjects.

DeAngelis [1990] estimates that attrition rates higher than 50% make the interpretation of clinical trial research very difficult. Some researchers believe that no attempt should be made to replace these subjects because even random selection of new subjects will not ensure bias caused by differential participation of all the subjects.

82.2.3 Data Collection

Investigators should seek to minimize sources of variability by careful control of the test conditions and procedures. Proper control can be attained by (1) using rooms that are reasonably soundproof or sound-deadened, well lighted, and of a comfortable temperature; (2) selecting chairs and other accessories carefully (e.g., no wheels for tests in which the subject is seated); (3) testing subjects one at a time without other subjects in the test room; (4) using standardized written instructions for each test to eliminate variability in what is stated; (5) allowing for familiarization with the test instruments and procedures; (6) not commenting about subject performance to avoid biased raising or lowering of expectations; (7) arranging a test order to offset fatigue (mental and physical) or boredom and to include rest periods; and (8) training test administrators and evaluating their training using healthy subjects, especially in multicenter studies, so that consistent results can be obtained.

82.2.4 Data Integrity Screening

Despite all good efforts and features incorporated to ensure high-quality data, opportunities exist for error. It is therefore beneficial to subject data obtained during formal test sessions to quality screenings. This is a step toward forming the official study data set (i.e., the set that will be subjected to statistical and other analyses). Several independent analyses used to screen data, which are typically computer-automated, are described below.

Screening of baseline measures against inclusionary criteria: If human performance study variables with specific performance criteria are used as part of the subject selection process as recommended above, each subject's baseline score can be compared with the score obtained during inclusionary testing. For most variables, baseline scores should not differ from inclusionary testing by more than 20% [Potvin et al., 1985]. Greater deviations point to examiner training, test procedure, or subject compliance problems.

Screening against established norms: For variables that are not included in inclusionary screenings or in studies where performance variables are not used as part of the subjects inclusionary criteria, baseline data can be screened against established reference data (e.g., human performance means and standard deviations). Data are considered acceptable if they fall within an established range (e.g., two standard deviation units of the reference population mean). From the perspective of risk associated with not identifying a data point that could be a potential problem, this is a fairly liberal standard that can still identify problems in data collection and management. Standards that lessen risk can, or course, be employed at the discretion of the investigator, but at the expense of the possible identification of a larger number of data points that require follow-up.

Screening against anticipated effects: It is more difficult to screen nonbaseline data for quality because of the possible influences of the intervention. However, criteria can be established based on (1) absolute level of variables (both maximums and minimums) and (2) rates and direction of change from one measurement period to the next. Even criteria that allow a rather wide range of data (or changes across repeated measures) can be useful in detecting gross anomalies and is recommended.

If anomalies are discovered using the screening methods described above, several outcomes are possible: (1) the anomaly can be traced and rectified (e.g., it may be attributable to a human or computer error with backup available); (2) the anomaly may be explainable as a procedural error, but it may not be possible to rectify; and (3) the anomaly may be unexplainable. Data anomalies that are explainable with supporting documentation could justify classification of the given data items as "missing data" or replacement of all data for the corresponding subject in the data set (i.e., the subject could be dropped from the study and

replaced with another). There is no justification for eliminating or replacing data anomalies for which a documentable explanation does not exist.

82.2.5 Analysis and Interpretation of Results

Traditional inferential statistical analysis should be performed according to the statistical model and significance levels agreed on by the clinical research team when the study is designed. However, data also should be analyzed and interpreted from a clinical perspective as well.

In experimental research, tests of **statistical significance** are the most commonly used tools for assessing possible associations between independent and dependent variables as well as differences among treatment groups. The purpose of significance (i.e., statistical) tests is to evaluate the research hypothesis at a specific level of probability, or p value. For example, if a p value of .05 was chosen, the researcher is asking if the levels of treatment (for example) differ significantly so that these differences are not attributable to a chance occurrence more than 5 times out of 100. By convention, a p value of .01 (1%) or .05 (5%) is usually selected as the cutoff for statistical significance. Significance tests cannot accept a research hypothesis; all that significance tests can do is reject or fail to reject the research hypothesis [Thomas and Nelson, 1990]. Ultimately, significance tests can determine if treatment groups are different, but not why they are different. Good experimental design, appropriate theorizing, and sound reasoning are used to explain why treatment groups differ.

Exclusive reliance on tests of statistical significance in the present context can mislead the clinical researcher, and interpretation of **clinical significance** is required. The key issue here is the size of the observed effect; p values give little information on the actual magnitude of a finding (i.e., decrement or improvement in performance, etc.). Also, statistical findings are partially a function of sample size. Thus even an effect that is small in size can be detected with tests of statistical significance in a study with a large sample. For example, a mean difference in grip strength of 2 kg may be found in response to drug therapy. This difference is a quite small fraction of the variability in grip strength observed across normal individuals, however. Thus, although statistically significant, such a change would perhaps have a minimal impact on an individual's ability to function in daily activities which make demands on grip strength performance resources. Thus clinical significance addresses cause-and-effect relationships between study variables and performance in activities of daily life or other broad considerations such as the basic disease process. The danger of not defining clinical significance appropriately can be either that a good intervention is not used in practice (e.g., it may be rejected for a safety finding that is statistically significant but small) or that a poor intervention is allowed into practice (e.g., it may result in statistically significant improvements that are small).

Ideally, if empirical data existed that established what amount of a given performance capacity such as visual information processing speed (VIPS) was necessary to perform a task (e.g., driving safely on the highway), then it would be possible to interpret statistically significant findings (e.g., a decrement in VIPS of a known amount) to determine if the change would be a magnitude that would limit the individual from successfully accomplishing the given task. Unfortunately, while general cause–effect relationships between laboratory-measured capacities and performance in high-level tasks are evident, quantitative models do not yet exist, and completely objective interpretations of clinical significance are not yet possible. As such, the process by which clinical significance is determined is less well developed and structured. More recent concepts introduced by Kondraske [1988a,b, 1989] based on the use of **resource economic** principles (i.e., the idea of a threshold "cost" associated with lower-level variables typically employed in clinical trials for achieving a given level of human performance in any given high-level task) may be helpful in defining objective criteria for clinical significance. This approach directly addresses cause-and-effect relationships between performance capacities and high-level tasks with an approach much like that which an engineer would employ to design a system capable of performing a specified task.

Despite known limitations, interpretation of clinical significance is always incorporated into clinical trials in some fashion. Any change in human performance for a given variable should be first documented to be statistically significant before it is considered to be a candidate for clinical

significance (i.e., a statistically significant difference is a necessary but not a sufficient condition for clinical significance). Objective determination of clinical significance can be based in part on previous methods introduced by Potvin et al. [1985] in clinical trials involving neuromotor and central processing performance tests. They advocate the use of an objective criteria whereby a decrease or increase in a human performance capacity (with healthy test subjects, for example) should be greater than 20% to be classified as "clinically significant." Kondraske [1989] uses a similar approach that uses z-scores (i.e., number of standard deviation units form a population mean) as the basis for determining criteria. This accounts for population variability which is different for different performance capacity variables. A recent approach is to assess effect size, a statistical metric that is independent of sample size and which takes into account data variability. This method provides an objective basis for comparison of the magnitude of treatment effects among studies [Cohen, 1988; Ottenbacher and Barrett, 1991].

82.3 Representative Application Examples

82.3.1 Safety-Oriented Example: Drug–Alcohol Interaction

In this section, selected elements of an actual clinical trial are presented to further illustrate methods and issues noted above. To maintain confidentialities, the drug under test is simple denoted as drug *A*.

Identify factors in question: Upper respiratory infections are among the most frequent infections encountered in clinical practice and affect all segments of the general population. The pharmacologic agent of choice for upper respiratory infections are the antihistamines (reference drug), which possess a wide margin of safety and almost no lethality when taken alone in an overdose attempt. Although quite effective, antihistamines can produce several troublesome side effects (i.e., general CNS impairment, sedation, and drowsiness) and have been incriminated in automobile accidents as well as public transportation disasters. New drugs (e.g., drug *A*) are being developed to have similar benefits but fewer side effects. From prior animal studies, drug *A* has been shown to have minimal effects on muscle relaxation and muscular coordination as well as less sedative and alcohol-potentiating effects than those associated with classical antihistamines. Based on drug *A*'s history and concerns, the following factors in question were identified in this clinical trial: general CNS impairment, alcohol interaction, dizziness, drowsiness, mood, and slowness of movement/speed. The purpose of this investigation was to examine the effect of drug *A* on human performance capacity relative to a reference drug and placebo as well as the drug-alcohol potentiating interaction effects after multiple dose treatment.

Select performance capacity variables and instruments: With the factors in question identified, the following performance capacity variables and their testing instruments were selected for the clinical trial: visual information processing speed (VIPS), finger tapping speed (TS), visual arm lateral reach coordination (VALRC), visual spatial memory capacity (VSMC), postural performance (PP), digit symbol substitution task (DSST), and Bond-Lader Visual Analog Scale (BLS). These variables were collectively called the *human performance capacity test battery* (HPCTB) (Table 82.2). Due to space limitations, only one performance capacity variable (VMRS — visual information processing speed, i.e., VIPS) is discussed in this section.

Experimental design: The first primary objective of this investigation was to examine after 8 days of oral dosing the relative effects of drug *A*, reference drug, and placebo on the human performance capacity of healthy male and female adult volunteers (see Table 82.2). This effect was determined by examining the greatest decrease in human performance capacity from day 1 of testing (i.e., baseline at -0.5 h drug ingestion time) to day 8 of testing at drug ingestion times of 0.0, 1.0, 2.0, 4.0, and 6.0 h. The second primary objective was to examine after 9 days of oral dosing the relative effects of drug *A*, reference drug, and placebo in combination with a single dose of alcohol served immediately after drug administration (male alcohol dose 0.85 g/kg body weight, female alcohol dose 0.75 g/kg body weight) on the human performance capacity of healthy male and female adult volunteers (see Table 82.2). This effect was determined by comparing the greatest decrease in performance on the ninth day of study drug treatment (at drug ingestion times of 0.0, 1.0, 2.0, 4.0, and 6.0 h) to baseline on day one of

TABLE 82.2   Experimental Schedule for Human Performance Capacity
Test Battery (HPCTB)

Test day	Drug ingestion times (h)					
	−0.5	0.0	1.0	2.0	4.0	6.0
1[a]	HPCTB					
8[b]		HPCTB	HPCTB	HPCTB	HPCTB	HPCTB
9[b,c]		HPCTB	HPCTB	HPCTB	HPCTB	HPCTB

Note: The human performance capacity test battery (HPCTB) was
administered in the following order: VIPS, TS, VALRC, VSMC, PP, DSST,
and BLS.
[a] On day 1 of testing only, the −0.5 HPCTB was performed and utilized as the
baseline value for test days 8 and 9.
[b] The peak effect was determined by comparing baseline values (day 1) against
the greatest detriment in performance for the eighth and ninth testing days at
drug ingestion times of 0.0, 1.0, 2.0, 4.0, and 6.0 h.
[c] On day 9 of testing, an alcohol drink was served immediately after drug
administration and was ingested over a 15-min period.

testing (−0.5 h drug ingestion time) for the HPCTB (see Table 82.2). Independent variables were treatment
group (1 = drug *A*, 2 = reference drug, and 3 = placebo) and gender (male/female). The dependent
variable was maximum decrease in performance (peak effect) for each human performance capacity study
variable and was determined by comparing the baseline value (day 1) against the greatest decrease in per-
formance at drug ingestion times of 0.0, 1.0, 2.0, 4.0, and 6.0 h for day 8 and day 9 of testing. Inferential
statistical analysis of the data was performed using a 3 (treatment group: reference drug, drug *A*, and
placebo) by 5 (hour; 0, 1, 2, 4, and 6) mixed factorial ANOVA with repeated measures on hour for each
dependent variable. Statistical tests of significance of all ANOVAs were conducted at the 0.05 level.

Data screening: For each dependent variable, baseline treatment data were compared against the criteria
established for subject inclusion using each subject's performance score from the HPCTB to identify
data anomalies. Then the expected increases/decreases in human performance capacity from baseline
treatment data were compared against the drug therapy-influenced data to determine if these changes
were within "reasonable" limits. Potential anomalies were detected in less than 5% of the data, with most
occurring within records for only a few subjects. These cases were investigated, and in consultation with
the principal investigator, decisions were made and documented to arrive at the official data set.

Descriptive statistical analysis: Figure 82.2 illustrates the visual information processing speed (VIPS) for
treatment groups reference drug, drug *A*, and placebo. On day 1 of testing (baseline), all treatment groups
had similar VIPSs, with means between 5.7 and 5.8 stimuli per second. On day 8 of testing and at drug
ingestion time of 2 h, VIPS decreased to 4.9 stimuli per second for drug *A*, to 5.1 stimuli per second for
reference drug and to 5.65 stimuli per second for the placebo. On day 8, the greatest group impairment of
VIPS occurred at drug ingestion time of 4 h. Drug *A* appeared to have the greatest impairment of VIPS
(4.6 stimuli per second), followed by the reference drug group (4.9 stimuli per second). This decrease in
performance was not present with the placebo group (5.61 stimuli per second). By the sixth hour after drug
ingestion on day 8, VIPS improved toward baseline for treatment groups reference drug (5.1 stimuli per
second) and drug *A* (5.3 stimuli per second), while the placebo group remained unchanged (5.58 stimuli
per second). One day 9 of testing, all treatment groups received their assigned drug and alcohol. By 1 h
after drug ingestion, all treatment groups' VIPSs were impaired from baseline, with drug *A* showing the
greatest impairment (4.3 stimuli per second), followed by reference drug (4.6 stimuli per second) and
placebo (4.9 stimuli per second). All treatment groups' VIPSs improved toward baseline values by the
second hour after drug ingestion (5.0 to 5.1 stimuli per second) and the fourth hour after drug ingestion
(5.4 to 5.5 stimuli per second), respectively. By the sixth hour after drug ingestion, reference drug and
drug *A* plateaued between 5.55 and 5.6 stimuli per second, respectively, while the placebo group improved
slightly above the baseline value (5.8 stimuli per second). The basic pattern observed (i.e., decrease from
FIGURE 82.2 One performance capacity variable (visual information processing speed) for three treatment groups (drug *A* — the drug under test — reference drug, and placebo) taken from any actual efficacy-oriented study. Note changes from baseline to drug stabilization (day 8) and interaction with alcohol (day 9). See text for further explanation.

baseline, return to baseline, impairment of all groups, including placebo, with alcohol) lend validity to the overall study.

Statistical analysis and significance test results: On day 8 of testing, significant differences in VIPS for main effects treatment group and hour were observed. There was a significant interaction, however, between treatment group and hour of drug ingestion. Post hoc analysis demonstrated that treatment groups drug *A* and reference drug were significantly slower in VIPS than the placebo group at drug ingestion times of 2, 4, and 6 h, but there was no difference in VIPS between treatment groups drug *A* and reference drug. (Simple main effects and simple, simple main effects showed that the placebo group had faster VIPSs than both reference drug and drug *A* treatment groups at drug ingestion times of 2, 4, and 6 h.)

On day 9 of testing when the drug-alcohol potentiating interaction effect was of primary interest, significant differences in VIPS occurred for main effects treatment group and hour, but there were no interactions between treatment group and hour of drug ingestion. Post hoc analysis demonstrated that treatment groups drug *A* and reference group were significantly slower in VIPS than the placebo group at 1 h after drug ingestion only, but there was no statistically significant difference in VIPS between treatment groups drug *A* and reference group at any hour after drug-alcohol ingestion. Also, the drug-alcohol interaction was significant 1 h after drug-alcohol ingestion for all treatment groups.

Conclusions from statistically significant findings: After 8 days of oral dosing, while a significant difference was found for both drug treatment groups compared with the placebo group, there was no significant difference in VIPS between drug *A* and reference drug treatment groups. The effect was apparent at approximately the same drug ingestion time of 4 h. It was concluded that drug *A* had the same effect on safety as the reference drug in terms of CNS impairment as measured by VIPS.

After 9 days of oral dosing in combination with alcohol consumption, drug *A* and reference drug caused a greater decrease in VIPS compared with the placebo group. This effect was most apparent at 1 h after drug ingestion. The placebo group also decreased its VIPS at 1 h after drug ingestion at a statistically significant level. It was concluded after 9 days of oral dosing that drug *A* in combination with alcohol produced the same effect as the reference drug in combination with alcohol in terms of CNS impairment as measured by VIPS.

Conclusions from clinically significant findings. Since there was no statistically significant difference between drug *A* and the reference drug on either day 8 or day 9, the only findings requiring an interpretation

of clinical significance are the statistically significant findings for both drug *A* and reference drug relative to the placebo group. On both day 8 and day 9, these findings are clinically significant using either the Potvin et al. [1985] percentage change or Kondraske [1989] *z*-score approach. Using the resource economic model for human performance [Kondraske, 1988a,b, 1989], it can be argued that, for example, during critical events during tasks such as driving, all of an individual's available VIPS resource is drawn on. Clearly, the substantial decrease in VIPS observed can compromise safety during such events.

82.3.2   Efficacy-Oriented Study: Experiences in Neurology

Performance testing in clinical trials in neurology has grown tremendously within the last decade [Mohr and Brouwers, 1991], but within specific disease areas there remains reluctance to accept the replacement of traditional rating-scale evaluations of disease presence and progression by objective performance testing [Syndulko et al., 1993]. The evolution of clinical evaluations in multiple sclerosis clinical trials illustrates this point.

Evaluation of disability change or deterioration in multiple sclerosis (MS) historically has been limited to physician rating scales that attempt to globally summarize some or most of the salient clinical features of the disease. General consensus in the use of rating scales for MS has been achieved in the specification of a minimal record of disability (MRD) for MS that incorporates several physician- and paramedical-administered rating scales for evaluating MS disease status and its effects on the patient's life (International Federation of Multiple Sclerosis Societies, 1984). However, there has been general dissatisfaction with the use of rating scales in MS clinical trials because of issues of lack or sensitivity to disease change, lack of interrater reliability, and simply the inherent reliance on subjective ratings of signs, symptoms, and unmeasured performance changes [Paty et al., 1992].

As an alternative to MS rating scales, comprehensive, quantitative evaluation of human performance was originally proposed and developed over 25 years ago for use in MS clinical trials [Tourtellotte et al., 1965]. The first application of performance testing in a major MS clinical trial was the multicenter cooperative ACTH study [Rose et al., 1968]. The study proved that human performance testing could be incorporated into a multicenter MS clinical trial and that examiners at multiple centers could be trained to administer the tests in a standardized, repeatable fashion. The results generally supported fairly comparable levels of sensitivity among the outcome measures, including performance testing [Dixon and Kuzma, 1974]. Subsequent analyses showed that a priori composites that provided succinct summary measures of disease change in key functional areas could be formed from the data and that these composite measures were sensitive to treatment effects in relapsing/remitting MS patients [Henderson et al., 1978]. Despite the favorable results of the ACTH study, performance testing did not achieve general acceptance in MS clinical studies. Comprehensive performance testing as conducted in the ACTH trial was considered time-consuming, the instrumentation was not generally available, and despite the use of composites, the number of outcome measures remained too large. In a recent double-blind, placebo-controlled collaborative study in 12 medical centers, the study design included both rating-scale and performance measures as outcome assessments in the largest sample of chronic progressive MS patients studied to date (The Multiple Sclerosis Study Group, 1990). Analyses of the change in performance composite scores from baseline over the 2-year course of the clinical trial showed that the drug-treated patients worsened significantly less than the placebo-treated patients. In contrast, the EDSS and other clinical rating scores did not show significant treatment effects for the subset of MS patients at the same center [Syndulko et al., 1993]. This indicated that the performance composites were more sensitive than the clinical disability measures to disease progression and treatment effects. A more recent comparative analysis of the full data set also supports the greater sensitivity of composites based on performance testing compared with rating scales to both MS disease progression and to a treatment effect [Syndulko et al., 1994a,b]. Although the biomedical community remains divided regarding the best outcome assessment in MS clinical trials, the accumulating evidence favors performance testing over clinical measures.

Another type of efficacy-oriented study of particular note in the context of this chapter involves the combination of pharmacodynamic models with instrumented, objective, and sensitive performance capacity

measurements to optimize therapeutic effectiveness by fine-tuning dose prescription for individual subjects. For example, the results from a Parkinson's disease study by Hacisalihzade et al. [1989] suggest that performance capacity measurements, which would play a key role in a strategy to determine pharmacodynamics of a drug for the individual (i.e., not a population), could become a component in the management of some patients receiving long-term drug therapy.

82.4   Future Needs and Anticipated Developments

The field of clinical trials in which human performance variables are of interest has expanded at such a rapid rate in recent years that it has been difficult for researchers to keep up with all the new technologies, instrumentations, and methodologies. The type of evaluation employed has steadily shifted from mostly subjective to more objective, which can be argued to provide improved measurement quality. Increased standardization of human performance measurements has led to greater cost-effectiveness due to computer-based test batteries [Woollacott, 1983; Kennedy et al., 1993]. Thus, even if the quality of measurement were the same with methodologies that used less sophisticated methods, the initial investment would frequently be saved with newer data management techniques. This sentiment has not yet been accepted by all segments of the relevant communities. Also, the speed at which data can now be collected (which is especially important when changes over short time periods are of interest, as in pharmacodynamic studies) has led to greater cost-effectiveness. Furthermore, since instrumented devices are becoming commercially available and more widely used, it is not necessary nor desirable for researchers whose primary interest is the intervention of disease process to "reinvent" measurements (possibly with subtle but significant changes that ultimately inhibit standardization) for use in studies. Also, new measurements that may be different — but not necessarily better — must undergo long and expensive studies prior to their use in clinical trials. Although certain human performance measures are becoming standard in selected situations, more experience is needed before a substantial degree of standardization in human performance measurement is achieved in such situations.

The perfect research strategy in clinical trials involving human performance capacities to determine therapy effectiveness and safety may not be possible due to financial and/or ethical considerations. Thus the challenge of clinical trials research in the future is to maintain scientific integrity while conforming to legal mandates and staying within economic feasibility; i.e., an optimization is almost always necessary. Multidisciplinary research efforts can be useful in these circumstances.

Defining Terms

Clinical significance: An additional level of interpretation of a statistically significant finding that addresses the size of the effect found.

Clinical trial: A research study involving human subjects and an intervention (i.e., device, drug, surgical procedure, or other procedure) that is ultimately intended to either enhance the professional capabilities of physicians, improve the quality of life of patients, or contribute to the field of knowledge in those sciences which are traditionally in the medical field setting.

Composite score: A score derived by combining two or more measured performance capacities.

Efficacy-oriented clinical trial: A study that is conducted to objectively determine an intervention's effectiveness along with any pharmacokinetic or pharmacodynamic interactions.

Nonprobability sampling: A method of sampling whereby no subject in a defined population has an equal chance of being included in the sample.

Performance capacities: Dimensional capabilities or resources (e.g., speed, accuracy, strength, etc.) that a given human subsystem (e.g., visual, central processing, gait production, posture maintenance, etc.) possesses to perform a given task.

Pharmacodynamics: The physiologic and/or metabolic changes in the concentration of a drug over time to corresponding measurable performance capacity changes in the therapeutic effect.

Pharmacokinetics: The rate at which a drug is metabolized, as evidenced by changes in drug concentrations in blood, cerebral spinal fluid, urine, etc.

Probability sampling: A method of sampling whereby each subject in a defined population theoretically has an equal chance of being included in the sample.

Protocol: A detailed statement of all procedures and methods to be employed in a research investigation.

Randomized clinical trial (RCT):   A study that uses controlled trials whereby part of the group of subjects receives a therapy that is tested, while the other subjects receive either no therapy or another therapy.

Resource economics: A cause-effect type of relationship between available performance resources (i.e., capacities) and demands of higher-level tasks in which the relevant subsystems are used.

Safety-oriented clinical trial: A study that usually involves vital sign measures (e.g., heart rate, blood pressure, respiration rate), clinical laboratory tests (e.g., blood chemistries, urinalysis, ECG), and adverse reaction tests (both mental and physical performance capacities) to evaluate the risk of an intervention.

Sample: A proportion of the defined population that is studied. When used as a verb (sampling), it refers to the process of subject selection.

Significance (statistical) test: A tool used for assessing possible associations between independent and dependent variables as well as differences among treatment groups.

Statistical significance: An evaluation of the research hypothesis at a specific level of probability so that any differences observed are not attributable to a chance occurrence.

Applications of Quantitative Assessment of Human Performance in Occupational Medicine

Mohamad Parnianpour
Ohio State University

As early as 1700, Bernardino Ramazzini, one of the founders of occupational medicine, had associated certain physical activities with musculoskeletal disorders (MSD). He postulated that certain violent and irregular motions and unnatural postures of the body impair the internal structure [Snook et al., 1988]. Presently, much effort is directed toward a better understanding of work-related musculoskeletal disorders involving the back, cervical spine, and upper extremities. The World Health Organization (WHO) has defined occupational diseases as those work-related diseases where the relationship to specific causative factors at work has been fully established [WHO, 1985]. Other work-related diseases may have a weaker or unclear association to working conditions. They may be aggravated, accelerated, or exacerbated by workplace factors and lead to impairment of workers' performance. Hence obtaining the occupational history

is crucial to proper diagnosis and appropriate treatment of work-related disorders. The occupational physician must consider the conditions of both the workplace and the worker in evaluation of injured workers. Biomechanical and ergonomic evaluators have developed a series of techniques for quantification of the task demands and evaluation of the stresses in the workplace. Functional capacity evaluation also has been advanced to quantify the maximum performance capability of workers. The motto of ergonomics is to avoid the mismatch between the task demand and functional capacity of individuals. A multidisciplinary group of physicians and engineers constitutes the rehabilitation team that will work together to implement the prevention measures. Through proper workplace design, workplace stressors could be minimized. It is expected that one-third of the compensatable low back pain in industry could be prevented by proper ergonomic workplace or task design. In addition to reducing the probability of both the initial and recurring episodes, proper ergonomic design allows earlier return to work of injured workers by keeping the task demands at a lower level. Unfortunately, ergonomists are often asked to redesign the task or the workplace after a high incidence of injuries has already been experienced. The next preventive measure that has been suggested is preplacement of workers based on the medical history, strength, and physical examinations [Snook et al., 1988]. Training and education have been the third prevention strategy in the reduction of musculoskeletal disorders. Some components of these educational packages such as "back schools" and the teaching of "proper body mechanics" have been used in the rehabilitation phase of injured workers as well.

Title I of the Americans with Disability Act [ADA, 1990] prohibits discrimination with regard to any aspect of the employment process. Thus the development of preplacement tests has been impeded by the possibility of discrimination against individuals based on gender, age, or medical condition. The ADA requires physical tests to simulate the "essential functions" of the task. In addition, one must be aware of "reasonable accommodations," such as lifting aids, that may make an otherwise infeasible task possible for a disabled applicant to perform. Healthcare providers who perform physical examinations and provide recommendations for job applicants must consider the rights of disabled applicants. It is extremely crucial to quantify the specific physical requirements of the job to be performed and to examine an applicant's capabilities to perform those specific tasks, taking into account any reasonable accommodations that may be provided. Hence task analysis and functional capacity assessment are truly intertwined.

Work-related disorders of the upper extremities, unlike low back disorders, can better be related to specific anatomic sites such as a tendon or compressed nerve. Examples of the growing number of cumulative trauma disorders of the upper extremities and the neck are **carpal tunnel syndrome (CTS)**, **DeQuervain's disease**, **trigger finger**, **lateral epicondylitis (tennis elbow)**, **rotator cuff tendinitis**, **thoracic outlet syndrome**, and **tension neck syndrome**. The prevalence of these disorders is higher among some specific jobs, such as meat cutters, welders, sewer workers, grinders, meat packers, and keyboard operators. Some of the common risk factors leading to pain, impairment, and physical damage in the neck and upper extremities are forceful motion, repetitive motion, vibration, prolonged awkward posture, and mechanical stress [Kroemer et al., 1994].

This chapter is intended to illustrate the application of some principles and practices of human performance engineering, especially quantification of human performance in the field of occupational medicine. I have selected the problem of low back pain to illustrate a series of concepts that are essential to evaluation of both the worker and the workplace, while realizing the importance of the disorders of the neck and upper extremities. By inference and generalization, most of these concepts can be extended to these situations.

83.1 Principles

Assessment of function across various dimensions of performance (i.e., strength, speed, endurance, and coordination) has provided the basis for a rational approach to clinical assessment, rehabilitation strategies, and determination of return-to-work potential for injured employees [Kondraske, 1990]. To understand the complex problem of trunk performance evaluation of low back pain (LBP) patients, the terminology

of muscle exertion must first be defined. However, it should be noted that a number of excellent reviews of trunk muscle function have been performed [Andersson, 1991; Beimborn and Morrissey, 1988; Newton and Waddell, 1993; Pope, 1992]. I do not intend to reproduce this extensive literature here, since my motive is to provide a critical analysis that will lead the reader toward an understanding of the future of functional assessment techniques. A more extensive clinical application is provided elsewhere [Szpalski and Parnianpour, 1996; Parnianpour and Shirazi-adl, 1999].

83.1.1 Impairment, Disability, and Handicap

The tremendous human suffering and economic costs of disability present a formidable medical, social, and political challenge in the midst of growing healthcare costs and scarcity of resources. The WHO [1980] distinguished among impairment, disability, and handicap. Impairment is any loss or abnormality of psychological, physiologic, or anatomic structure or function — impairment reflects disturbances at the organ level. Disability is any restriction or lack of ability (resulting from impairment) to perform an activity in the manner or within the range considered normal for a human being — disability reflects disturbances at the level of person. Handicap is a disadvantage for a given individual, resulting from an impairment or a disability, that limits or prevents the fulfillment of a role that is normal (depending on age, sex, and social and cultural factors) for that individual. Since disability is the objectification of an impairment, handicap represents the socialization of an impairment or disability. Despite the immense improvement presented by the International Classification of Impairments, Disabilities, and Handicaps (ICIDH), the classification is limited from an industrial medicine or rehabilitation perspective. The hierarchical organization lacks the specificity required for evaluating the functional state of an individual with respect to task demands.

Kondraske [1990] has suggested an alternative approach using the principles of resource economics. The resource economics paradigm is reflective of the principal goal of ergonomics: fitting the demands of the task to the functional capability of the worker. The Elemental Resource Model (ERM) is based on the application of general performance theory that presents a unified theory for measurement, analysis, and modeling of human performance across all different aspects of performance, across all human subsystems, and at any hierarchical level. This approach uses the same bases to describe both the fundamental dimensions of performance capacity and task demand (available and utilized resources) of each functional unit involved in performance of the high-level tasks. The elegance of the ERM is due to its hierarchical organization, allowing causal models to be generated based on assessment of the task demands and performance capabilities across the same dimensions of performance [Kondraske, 1990].

83.1.2 Muscle Action and Performance Quantification

The details of the complex processes of muscle contraction in terms of the bioelectrical, biochemical, and biophysical interactions are under intense research. Muscle tensions is a function of muscle length and its rate of change and can be scaled by the level of neural excitation. These relationships are called the length–tension and velocity–tension relationships. From a physiologic point of view, the measured force or torque applied at the interface is a function of (1) the individual's motivation (magnitude of the neural drive for excitation and activation processes), (2) environmental conditions (muscle length, rate of change of muscle length, nature of the external load, metabolic conditions, pH level, temperature, and so forth), (3) prior history of activation (fatigue), (4) instructions and descriptions of the tasks given to the subject, (5) the control strategies and motor programs employed to satisfy the demands of the task, and (6) the biophysical state of the muscles and fitness (fiber composition, physiologic cross-sectional area of the muscle, cardiovascular capability). It cannot be overemphasized that these processes are complex and interrelated [Kroemer et al., 1994]. Other factors that may affect the performance of patients are misunderstanding of the degree of effort needed in maximal testing, test anxiety, depression, nociception, fear of pain and reinjury, as well as unconscious and conscious symptom magnification.

The following sections review some methods to quantify performance and lifting capability of isolated trunk muscles during a multilink coordinated manual materials handling task. Relevant factors that

influence the static and dynamic strength and endurance measures of trunk muscles will be addressed, and the clinical applications of these assessment techniques will be illustrated.

The central nervous system (CNS) appropriately excites the muscle, and the generated tension is transferred to the skeletal system by the tendon to cause motion, stabilize the joint, and resist the effect of external forces on the body. Hence the functional evaluation of muscles cannot be performed without the characterization of the interfaced mechanical environment.

The four fundamental types of muscle exertion or action are isometric, isokinetic, isotonic, and isoinertial. In isometric exertion, the muscle length is kept constant, and there is no movement. Although mechanical work is not achieved, physiologic work, that is, static work, is performed, and energy is consumed. When the internal force exerted by the muscle is greater than the external force offered by the resistance, then concentric, that is, shortening, muscle action occurs, whereas if the muscle is already activated and the external force exceeds the internal force of the muscle, then eccentric, that is, lengthening, muscle action occurs. When the muscle moves, either concentrically or eccentrically, dynamic work is performed. If the rate of shortening or lengthening of the muscle is constant, the exertion is called isokinetic. When the muscle acts on a constant inertial mass, the exertion is called isoinertial. Isotonic action occurs when the muscle tension is constant throughout the range of motion.

These definitions are very clear when dealing with isolated muscles during physiologic investigations. However, terminology employed in the literature of strength evaluation is imprecise. The terms are intended to refer to the state of muscles, but they actually refer to the state of the mechanical interface, that is, the dynamometer. Isotonic exertion, as defined, is not as realizable physiologically because muscular tensions change as its lever arm changes despite the constancy of external loads. Special designs may vary the resistance level in order to account for changes in mechanical efficiency of the muscles. In addition, the rate of muscle length change may not remain constant even when the joint angular velocity is regulated by the dynamometer during isokinetic exertions. During isoinertial action, the net external resistance is not only a function of the mass (inertia) but also a function of the acceleration. The acceleration, however, is a function of the input energy to the mass. Hence, to fully characterize the net external resistance, we need to have both the acceleration and the inertial parameters (mass and moment of inertia) of the load and body parts. Future research should better quantify the inertial effects of the dynamometers, particularly during nonisometric and nonisokinetic exertions.

For any joint or joint complex, muscle performance can be quantified in terms of the basic dimensions of performance: strength, speed, endurance, steadiness, and coordination. Muscle strength is the capacity to produce torque or work by voluntary activation of the muscles, whereas muscle endurance is the ability to maintain a predetermined level of motor output — for example, torque, velocity, range of motion, work, or energy — over a period of time. Fatigue is considered to be a process under which the capability of muscles diminish. However, neuromuscular adjustments take place to meet the task demands (i.e., increase in neural excitation) until there is final performance breakdown — endurance time. Coordination, in this context, is the temporal and spatial organizations of movement and the recruitment patterns of the muscle synergies.

Despite the proliferation of various technologies for measurement, basic questions such as "What needs to be measured and how can it best be measured?" are still being investigated. However, there is a consensus on the need to measure objectively the performance capability along the following dimensions: range of motion, strength, endurance, coordination, speed, acceleration, etc. Strength is one of the most fundamental dimensions of human performance and has been the focus of many investigations. Despite the general consensus about the abstract definition of strength, there is no direct method for measurement of muscle tension *in vivo*. Strength has often been measured at the interface of a joint (or joints) with the mechanical environment. A dynamometer, which is an external apparatus onto which the body exerts force, is used to measure strength indirectly.

Different modes of strength testing have evolved based on different levels of technologic sophistication. The practical implication of contextual dependencies on the provided mechanical environment of the strength measures must be considered during selection of the appropriate mode of measurement. In this regard, equipment that can measure strength in different modes is more efficient in terms of both initial

capital investment, required floor space in the clinics or laboratories, and the amount of time it takes to get the person in and out of the dynamometer.

83.2   Low Back Pain and Trunk Performance

The problem of LBP is selected to present important models that could be used by the entire multidisciplinary rehabilitation team for the measurement, modeling, and analysis of human performance [Kondraske, 1990]. The inability to relate LBP to anatomic findings and the difficulties in quantifying pain have directed much effort toward quantification of spinal performance. The problem is made even more complex by the increasing demand of the healthcare system to quantify the level of impairment of patients reporting back pain without objective findings.

There are three basic impairment evaluation systems, each having their merits and shortcomings: (1) anatomic, based on physical examination findings, (2) diagnostic, based on pathology, and (3) functional, based on performance or work capacity [Luck and Florence, 1988]. The earlier systems were anatomic, based on amputation and ankylosis. Although this approach may be more applicable to the hand, it is very inappropriate for the spine. The diagnostic-based systems suffer from lack of correspondence between the degree of impairment for a given diagnosis and the resulting disability and even more from the lack of a clear diagnosis. A large percentage of symptom-free individuals have anatomic findings detectable by the imaging technologies, while some LBP patients have no structural anomalies.

The function-based systems are more desirable from an occupational medicine perspective for the following reasons: they allow the rehabilitation team to rationally evaluate the prospect for return to light-duty work and the type of "reasonable accommodations" needed (such as assistive devices) that could reduce the task demand below the functional capability of the individual. By focusing on remaining ability and transferable skills rather than the disability or structural impairment of the injured worker, the set of feasible jobs can be identified. These points are extremely important, given the natural history of work disability after a single low back pain episode causing loss of work time: 40 to 50% of workers return to work by 2 weeks, 60 to 80% return by 4 weeks, and 85 to 90% return by 12 weeks. The small portion of disabled workers who become chronic are responsible for the majority of the economic cost of LBP. It is therefore the primary goal of the rehabilitation team to prevent the LBP, which is self-correcting in most cases, no matter what kind of therapy is used, from becoming a chronic disabling predicament. Injured workers should neither be returned to work too early nor too late, since both could complicate the prognosis. The results of functional capacity evaluation and task demand quantification should guide the timing for returning to work. It is clear that psychosocioeconomic factors become increasingly more important than physical factors as the disability progresses into "chronicity syndrome" and play a major role in defining the evolution of a low back disability claim. Future research should further establish the reliability and reproducibility of performance assessment tools to expedite their widespread use [Luck and Florence, 1988; Newton and Waddell, 1993].

83.2.1   Maximal and Submaximal Protocols

Biomechanical strength models of the trunk are usually based on static maximal strength measurement. In real-life work situations, individuals rarely exert lengthy or maximum static effort. In most clinical situations, submaximal protocols are recommended, especially in patients with pain or with cardiovascular problems. Also, submaximal testing is less susceptible to fatigue and injury. The activities of daily living also have a great deal of submaximal efforts at the self-selected pace. Hence it has been argued that testing at the preferred rate may be complementary to the maximal effort protocols. The preferred motion can be solicited by instructing the subject to perform repetitive movement at a pace and through the range of motion which he or she feels is the most comfortable. It has been shown that LBP patients and normal individuals have different resisted preferred flexion/extension motion characteristics. Having the subject perform against resistance is based on the hypothesis that, at higher resistance levels, the separation

between the performance levels of patients and normal subjects becomes more evident. It has been shown, for example, that functional impairment of trunk extensors in LBP patients with respect to the normal population is larger at higher velocities during isokinetic trunk extension. However, the proponents of unconstrained testing have argued that separation of these groups can be performed based on the position, velocity, and acceleration profiles of the trunk during self-selected flexion/extension tasks. They have noted that pain and fear of reinjury may become the limiting factors. The sudden surge in acquiring performance measures of LBP patients during the initial rehabilitation process also underscores the validity of this concept.

83.2.2 Static and Dynamic Strength Measurements of Isolated Trunk Muscles

Weakness of the trunk extensor and abdominal muscles in patients with LBP was demonstrated using the cable tensiometer to measure isometric strength. The disadvantage of the cable tensiometer (which records applied force) is that it neglects to measure the lever arm distance from the center of trunk motion. It is also recommended that cable tensiometer be used to determine peak isometric torques rather than the stable average torque exerted over a 3-sec period. Dynamometers used for testing dynamic muscle performances contain either hydraulic or servo motor systems to provide constant velocity, for example, isokinetic devices, or constant resistance, for example, isoinertial devices. The isokinetic devices can be further categorized into passive and active types. The robotics-based dynamometers can actively apply force on the body and hence allow eccentric muscle performance assessments, while only concentric exertions can be measured by the passive devices. Eccentric muscle action can stimulate the lowering phase of a manual materials handling task. Based on sports medicine literature, eccentric action has been implicated for its significant role in the muscle injury mechanism. Using isokinetic dynamometers, the isometric and isokinetic strengths of trunk extensor and abdominal muscles were shown to be weaker in LBP patients compared with healthy individuals. Dedicated trunk testing systems have become the cornerstone of objective functional evaluation and have been incorporated in the rehabilitation programs in many centers.

Two issues of importance for future research are the role of pelvic restraints and the significance of using newly developed triaxial dynamometers as opposed to more traditional uniaxial dynamometers. Studies on healthy volunteers have shown that trunk motions occur in more than one plane — lateral bending accompanies the primary motion of axial rotation. Numerous attempts have been made to measure the segmental range of motion three-dimensionally in the lumbar spine with the purpose of quantifying abnormal coupling and diagnosing instabilities.

The effect of posture on the maximum strength capability can be described based on the length-tension relationship of muscle action. Marras and Mirka [1989] studied the effect of trunk postural asymmetry, flexion angle, and trunk velocity (eccentric, isometric, and concentric) on maximal trunk torque production. It was shown that trunk torque decreased by about 8.5% of the maximum for every 15° of asymmetric trunk angle. At higher trunk flexion angles, extensor strength increased. Complex, significant interaction effects of velocity, asymmetry, and sagittal posture were detected. The ranges of velocity studies were more limited (±30°/sec) than those used customarily in spinal evaluation. Tan et al. [1993] tested 31 healthy males for the effects of standing trunk-flexion positions (0, 15, and 35°) on triaxial torques and did **electromyograms** (EMGs) of 10 trunk muscles during isometric trunk extension at 30, 50, 70, and 100% of maximum voluntary exertions (MVE). Trunk muscle strength was significantly increased at a more flexed position. However, the accessory torques in the transverse and coronal planes were not affected by trunk postures. The recorded lateral bending and rotation accessory torques were less than 5 and 16% of the primary extension torque, respectively. The rectus abdominis muscles were inactive during all the tests. The EMGs of the erector spinae varied linearly with higher values of MVE, while the latissimus dorsi had a nonlinear behavior. The obliques were coactivated only during 100% MVE. The neuromuscular efficiency ratio (NMER) was constructed as the ratio of the extension torque over the processed (RMS) EMG of the extensor muscles. It was hoped that NMER could be used in clinical

settings where generation of the maximum exertion are not indicated. However, the NMER proved to have a limited clinical utility because it was significantly affected by both exertion level and posture. The NMER of the extensor muscles increased at more flexed position. Studies that have combined the EMG activities and dynamometric evaluations have the potential of discovering the neuromuscular adaptation during different phases of injury and rehabilitation processes.

83.2.3 Static and Dynamic Trunk Muscle Endurance

The high percentage of type I fibers in the back muscles, in addition to the better vascularization of these muscle groups, contributes to their superior endurance. Physiologic studies indicate that at higher muscle utilization ratios (relative muscle loads), fatigue is detected earlier. Isometric endurance tests have been used to compute the median frequency (MF) of the myoelectrical activities of trunk muscles in both normal and LBP populations. The expected decline of the median frequency with fatigue is parameterized by the intercept (initial MF) and the slope of the fall. It has been shown that trunk range of motion (ROM) and isometric strength suffered from lower specificity and sensitivity than spectral parameters. Trunk muscle endurance does differ between healthy subjects and those reporting LBP. During isometric endurance testing, trunk flexors develop fatigue faster than extensors in symptom-free subjects. The flexor fatigability appeared significantly higher in patients with LBF as compared with controls. Chronicity also influences trunk muscle endurance. Chronic LBP patients showed reduced abdominal as well as back muscle endurance as compared with the healthy controls and lower back muscle endurance as compared with the intermittent LBP group. Individuals with a history of debilitating LBP demonstrated less isometric trunk extensor endurance than either normal individuals or patients with history of lesser LBP.

Soft tissues subjected to repetitive loading, due to their viscoelastic properties, demonstrate creep and load relaxation. The loss of precision, speed, and control of the neuromuscular system induced by fatigue reduces the ability of muscles to protect the weakened passive structure, which may explain many industrial, clinical, and recreational injury mechanisms. These results further indicate the necessity of relating clinical protocols to the job and show how short-duration maximal isometric testing alone cannot provide the complex functional interaction of strength, endurance, control, and coordination.

Parnianpour et al. [1988] studied the effect of isoinertial fatiguing of flexion and extension trunk movements on the movement pattern (angular position and velocity profile) and the motor output (torque) of the trunk. They showed that, with fatigue, there is a reduction of the functional capacity in the main sagittal plane. There is also a loss of motor control enabling a greater range of motion in the transverse and coronal planes while performing the primary sagittal task. Association of sagittal with coronal and transverse movements is considered more likely to induce back injuries; thus the effect of fatigue and reduction of motor control and coordination may be an important risk factor leading to injury-prone working postures. The endurance limit is a more useful predictor of incidence and recurrence of low back disorders than the absolute strength values. Although physiologic criteria used in the National Institute for Occupational Safety and Health Lifting Guide [NIOSH, 1981] considered cardiovascular demands of dynamic repetitive lifting tasks, the limits of muscular endurance were not explicitly addressed. Future research should fill this gap, since the maximum strength measures should not guide the design decisions. Maximum level of performance can only be maintained for short periods of time, and muscular fatigue should be avoided to prevent the development of MSD. This caveat should be applied to all dimensions of performance capability [Kondraske, 1990].

A prospective, randomized study among employees in a geriatric hospital showed that exercising during work hours to improve back muscle strength, endurance, and coordination proved cost-effective in preventing back symptoms and absence from work [Gundewall et al., 1993]. Every hour spent by the physiotherapist on the exercise group reduced the work absence by 1.3 days. In this study, both training and testing equipment were very modest. Endurance training is based on exercises with high repetition and low resistance, while strength training requires exercise with high resistance and low repetition.

83.2.4 Lifting Strength Testing

The National Institute for Occupational Safety and Health [NIOSH, 1981] recommended static, that is, isometric, strength measurements as its standard for lifting tasks. This was based on the evidence that associated LBP with inadequate isometric strength. The incidence of an individual's sustaining an on-the-job back injury increases threefold when the task-lifting requirements approached or exceed the individual's strength capacity. However, lifting strength is not a true measure of trunk function but is a global measure taking into account arm, shoulder, and leg strength as well as the individual's lifting technique and overall fitness. It has been shown that strength tests were more valid and predictive of risk of low back disorders if they simulated the demands of the job. The clinicians must be aided with easy-to-use and validated instruments or questionnaires to gather information about the task demands in order to decide what testing protocol best simulates the applicant's spinal loading conditions.

Static strength measurements have been reported to underestimate significantly the loads on the spine during dynamic lifts. Comparing static and dynamic biomechanical models of the trunk, the predicted spinal loads under static conditions were 33 to 60% less than those under dynamic conditions, depending on the lifting technique. The recruitment patterns of trunk muscles (and thus the internal loading of the spine) are significantly different under isometric and dynamic conditions. General manual materials handling tasks require a coordinated multilink activity that can be simulated using classic psychophysical techniques or the robotics-based lift task simulators. Various lifting tests, including static, dynamic, maximal, and submaximal, are currently available. The experimental results of correlational studies have confirmed the theoretical prediction that strength will be dependent on the measurement technique. Since muscle action requires external resistance, the effect of muscle action will depend on the nature of the resistance. These results refute the implicit assumption that a generic strength test exists that can be used for preplacing workers (preemployment) and predicting the risk of injury or future occurrence of LBP. The psychometric properties of isokinetic and isoresistive modes of strength testing were recently addressed. The quantification of the surface response of strength as a function of joint angle and velocity was only possible for isokinetic testing, while isoresistive tests yielded a very sparse data set. Figure 83.1 and Figure 83.2 illustrate these points graphically.
FIGURE 83.1   Bivariate distribution histogram of isokinetic trunk extension for 10 subjects.
FIGURE 83.2 Bivariate distribution histogram of isotonic trunk extension for 10 subjects.

The wide conflicting results found in the literature regarding the relationship of an individual's strength to the risk of developing LBP may be due to inappropriate modes of strength measurements, that is, lack of job specificity. Isometric strength testing of the trunk is still widely used, especially in large-scale industrial or epidemiologic studies, because it has been standardized and studied prospectively in industry. Compared with trunk dynamic strength testing protocols, the trunk isometric strength testing protocols are simpler and less expensive.

One outstanding issue during dynamic testing is the unresolved problem of how the wealth of information can be presented in a succinct and informative fashion. One approach has been to compare the statistical features of the data with the existing normal databases. This is particularly crucial because one does not have the option of comparing the results to the "contralateral asymptomatic joint," as one has with lower or upper extremity joints. Given the large differences between individuals, I recommend comparison be made to job-specific databases. For example, it is more appropriate for the trunk strength of an injured construction worker to be compared with age- and gender-controlled healthy construction workers than with data from healthy college graduate students or office workers. However, given the scarcity of such data, I argue for comparison of performance capacity with job demand based on task analysis. The performance capacity evaluation is once again linked to task demand quantification.

83.2.5 Inverse and Direct Dynamics

A major task of biomechanics has been to estimate the internal loading of musculoskeletal structure and establish the physiologic loading during various daily activities. Kinematic studies deal with joint movement, with no emphasis on the forces involved. However, kinetic studies address the effect of forces that generate such movements. Using sophisticated experimental and theoretical stress/strain analyses, hazardous/failure levels of loads have been determined. The estimated forces and stresses are used to estimate the level of deformation in the tissues. This technique allows one to assess the risk of overexertion injury associated with any physical activity. Given repetitive motions and exertion levels much lower than the ultimate strength of the tissues, an alternative injury mechanism, the cumulative trauma model, has been used to describe much of the musculoskeletal disorders of the upper extremities.

The experimental data on the joint trajectories are differentiated to obtain the angular velocity and acceleration. Appropriate inertial properties of the limb segments are used to compute the net external moments about each joint. This mapping from joint kinematics to net moments is called inverse dynamics. Direct dynamics refers to studies that simulate the motion based on known actuator torques at each joint. The key issue in these investigations is understanding the control strategies underlying the trajectory planning and performance of purposeful motion. A highly multidisciplinary field has emerged to address these unsolved questions (see Berme and Cappozzo [1990] for a comprehensive treatment of these issues.)

It should be pointed out that determination of the external moments about different joints during manual materials-handling tasks is based on the well-established laws of physics (Figure 83.3). However, the determination of human performance and assessment of functional capacity are based on other disciplines, for example, psychophysics, that are not as exact or well developed. One can describe easily the job demand, in terms of the required moments about each joint, by analyzing the workers performing the tasks. However, one is unable to predict the ability to perform an arbitrary task based on the incomplete knowledge of functional capacities at the joint levels. A task is easily decomposed to its demands at the joint level; however, one cannot compose (construct) the set of feasible tasks based on one's functional capacity knowledge. The mapping from high-level task demands to the joint-level functional capacity for a given performance trial is unique. However, the mapping from joint-level functional capacity to the high-level task demand is one to many (not unique). The challenge to the human performance research community is to establish this missing link. Much of the integration of ergonomics and functional analysis depends on removal of this obstacle. The question of whether a subject can perform a task based on knowledge of his or her functional capacity at the joint level remains an area of open research. When ergonomists or occupational physicians evaluate the fitness of task demands and worker capability, the following clinical questions will be presented; (1) Which space should be explored for determining normalcy, fit, or equivalence? (2) Should we consider the performance of the multilink system in the joint space or end-effector (cartesian workspace)? These issues have profound effects on both the development of new technologies and the evaluation of trunk or lifting performance.

The enormous degrees of freedom existing in the neuromusculoskeletal system provide the control centers both the kinematic and actuator redundancies. The redundancies provide optimization possibility. Since one can lift an object from point A to point B with infinite postural possibilities, it can be suggested that certain physical parameters maybe optimized for the learned movements. The possible candidates for objective function to be optimized are movement time, energy, smoothness, muscular activities, etc. This approach, though still in its early stage, may be very important for spine functional assessment. One could compare the given performance with the optimal performance that is predicted by the model. This approach provides specific goals and gives biofeedback with respect to the individual's performance.

83.2.6 Comparison of Task Demands and Performance Capacity

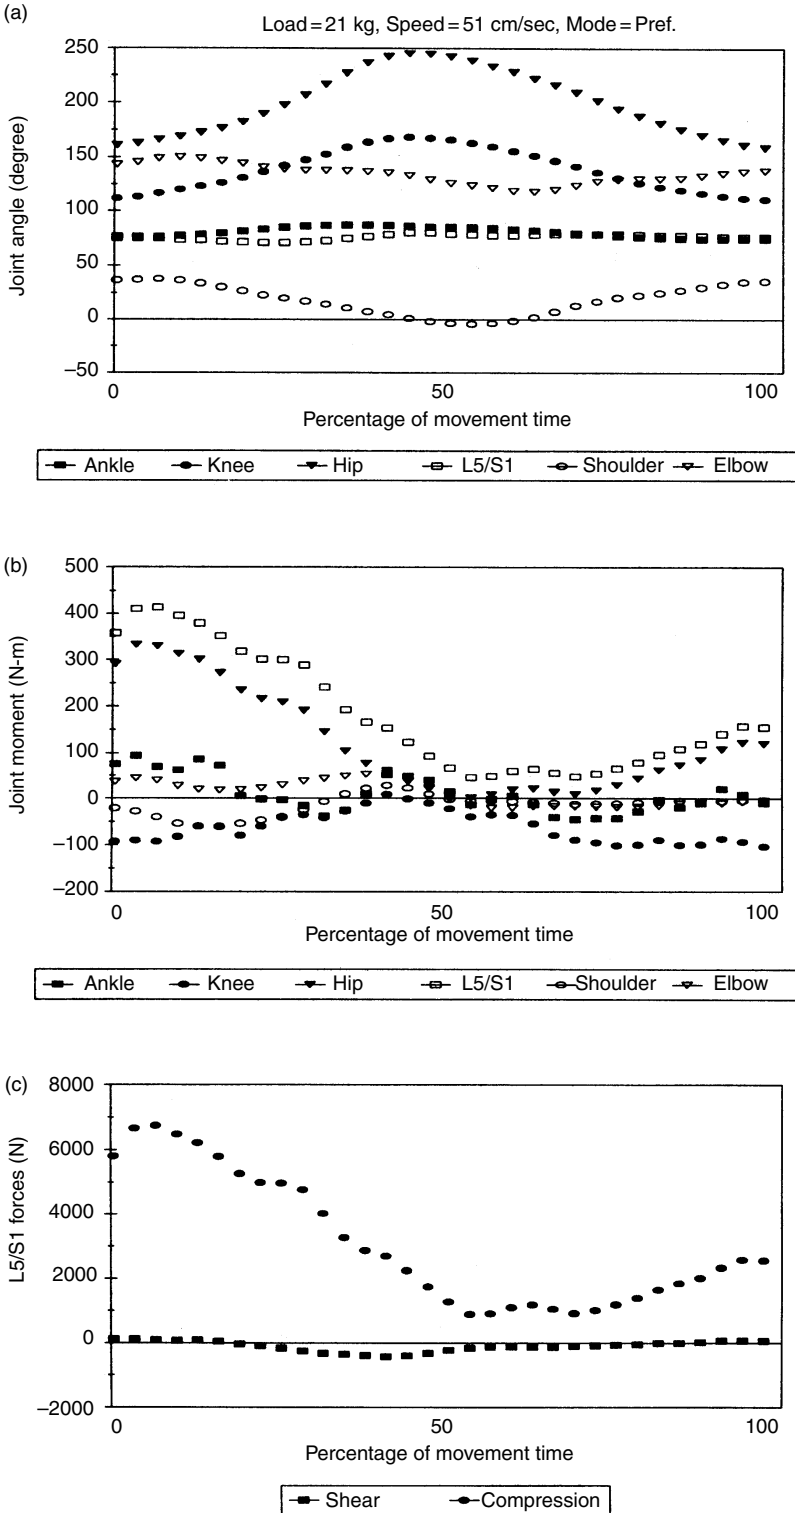
The regression analysis was used to model the dynamic torque, velocity, and power output as a function of resistance level during flexion and extension using the B-200 Isostation [Parnianpour et al., 1990]. Results indicated that the measured torque was not a good discriminator of the tenth, fiftieth, and ninetieth percentile population. However, velocity and power were shown to effectively discriminate the three populations. Based on these data, it was suggested that during clinical testing, sagittal plane resistance should not be set at higher than about 80 N · m in order to minimize the internal loading of spine while taxing trunk functional capacity. This presentation of data may be useful to the physician or ergonomist in evaluating the functional capacity requirements of workplace manual materials-handling tasks. For example, a manual material-handling task that requires about 80 N · m (61 ft · lb) of trunk extensor strength could be performed by 90% of the population in the normal database if the required average trunk velocity does not exceed 40 degrees per second, while only 50% could perform the task if the velocity requirement exceeds 70 degrees per second. More important, only the top tenth percentile population could perform the task if the velocity requirement approaches 105 degrees per second (Figure 83.4). A few versions of lumbar motion monitors that can record the triaxial motion in the workplace have been used


FIGURE 83.3 The dynamic analysis of a sagittal plane symmetrical isokinetic lift (load 21 kg, speed = 51 cm/sec, mode = preferred method of lifting): (a) joint angle; (b) net muscular joint moment; and (c) the joint reaction forces at L5/S1.
FIGURE 83.4   The average extension velocity measured during maximum trunk extension against a set resistance for 10th ($\times$), 50th ($\blacktriangle$), and 90th ($\blacksquare$) percentile distribution.

to provide the trunk movement requirements. The preceding example also illustrates the importance of having the same bases for evaluation of both task and the functional capability of the worker.

83.3   Clinical Applications

Clinical studies have utilized quantitative human performance, that is, strength and endurance measures, to predict the first incidence or recurrence of LBP and disability outcome and also as a prognosis measure during the rehabilitation process. Training programs to enhance the endurance and strength of workers have been implemented in some industries. More studies on the effectiveness of these programs are needed. It can be hypothesized that these programs complement the stress-management programs to enhance both worker satisfaction and coping strategies with regard to physical and nonphysical stressors at the workplace.

Functional-based impairment evaluation schemes traditionally have used spinal mobility. Given the poor reliability of range of motion (ROM), its large variability among individuals, and the static psychometric nature of ROM, the use of continuous dynamic profiles of motion with the higher-order derivatives has been suggested. Dynamic performances of 281 consecutive patients from the Impairment Evaluation Center at the Mayo Clinic were used. As part of the comprehensive physical and psychological evaluation, 281 consecutive LBP patients underwent isometric and dynamic trunk testing using the B200 Isostation. **Feature extraction** and **cluster analysis** techniques were used to find the main profiles in dynamic patient performances. The middle three cycles of movements were interpolated and averaged into 128 data points; thus the data were normalized with respect to cycle time. This allowed for comparison between individuals. Figure 83.5 presents the main profiles of sagittal trunk angular position. The number of patients in each group is also noted on the graph. Patients in the first ($n = 48$) and second ($n = 55$) groups had similar flexion mobility; however, those in the first group had more limited extension mobility. The time to peak sagittal position also varied among the five groups. Forty-seven patients in the fifth group showed extreme impairment in both flexion and extension. The third group (26 patients) showed differential impairments with respect to direction of motion. A marked improvement over the use of ROM has been achieved by preserving information in the continuous profiles. The LBP patients in this study are heterogeneous with respect to their movement profile. Uniform treatment of these patients is questionable, and rehabilitation programs should consider their specific impairments. Future research should incorporate the clinical profiles with these movement profiles to further delineate the heterogeneity of LBP patients. Marras et al. [1993] used similar feature-extraction techniques to characterize the

Five principal profiles for 281 LBP: 25% resistance level
FIGURE 83.5 The five principal profiles of trunk sagittal movement for 281 low back pain patients.

movement profiles of 510 subjects belonging to normal ($n = 339$) and 10 LBP patient groups ($n = 171$). Subjects were asked to perform flexion/extension trunk movement at five levels of asymmetry, while the three-dimensional movement of the spine was monitored by the Lumbar Motion Monitor (an exoskeleton goniometer developed at the Biodynamics Lab of The Ohio State University). Trunk motions were performed against no resistance, and no pelvic stabilization was required. The quadratic discriminant analysis was able to correctly classify over 80% of the subjects. The same technology was used to develop logistic regression models to identify the high-risk jobs in industrial workplaces. Hence principles of human performance can be applied successfully to the worker and the task to avoid the mismatch between performance capability and task demand.

The key limitations in the development of the discriminate functions for classification purposes, are the data-driven nature of the algorithms and the lack of theoretical orientation in the process of development and validation of these models. It is suggested that the mathematical simulation of flexion or extension trunk movement may identify an objective basis for the evaluation and assessment of trunk kinematic performance. A catalog of movement patterns that are optimal with respect to physical and biomechanical quantities may contribute to the emergence of a more theoretically based computational paradigm for the evaluation of kinematic performance of normal subjects and patients. It must be emphasized that in this paradigm one has no intention to claim that the central nervous system actually optimizes any single or composite cost function.

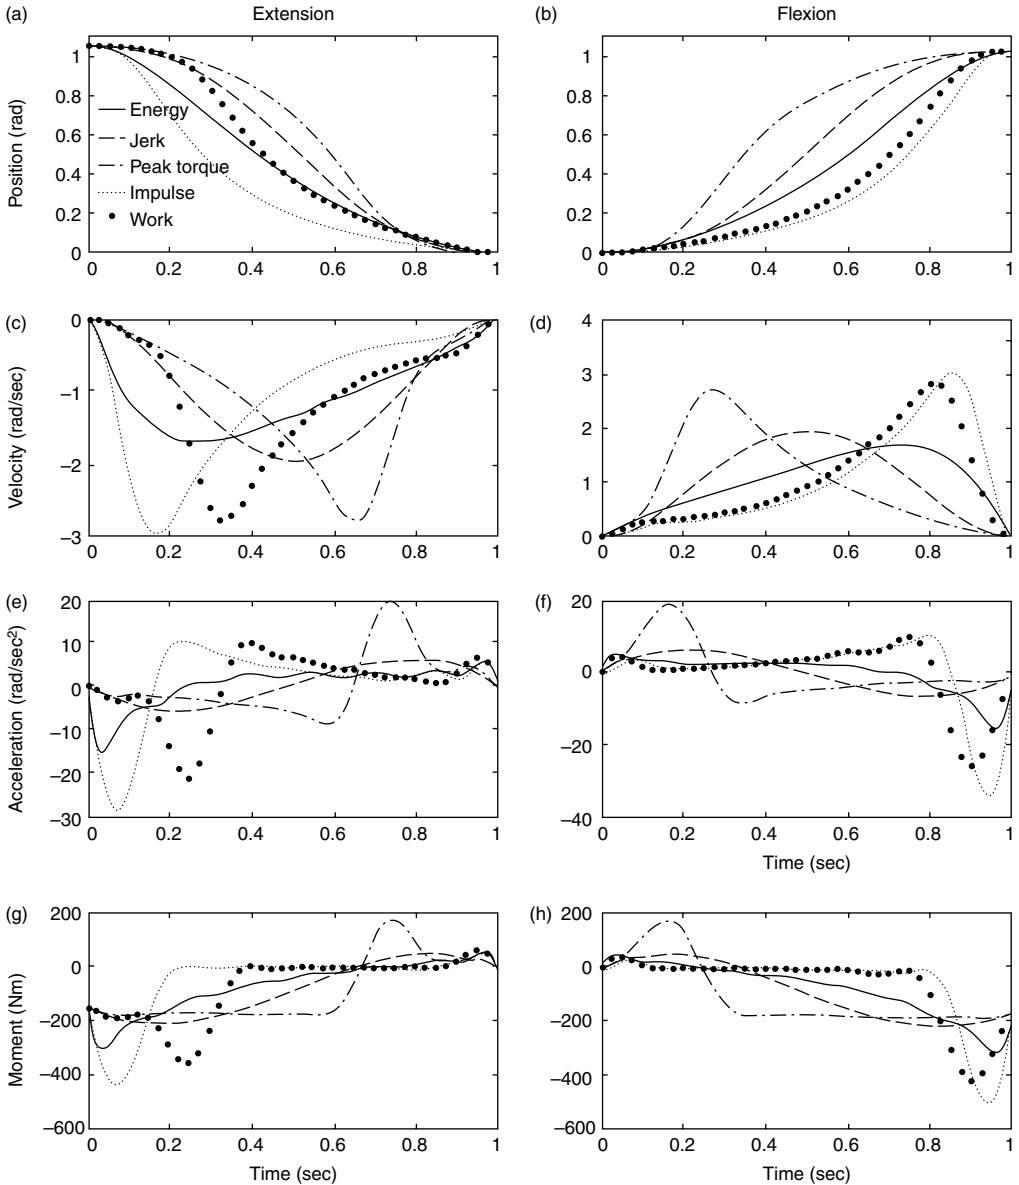
To provide clinical insight for interpretation of the distinctive features in the movement profiles, Parnianpour et al. [1999] have suggested an optimization-based approach for simulation of dynamic point-to-point sagittal trunk movement. The effect of strength impairment on movement patterns was simulated based on minimizing different physical cost functions: Energy, Jerk, Peak Torque, Impulse, and Work. During unconstrained simulations, the velocity patterns of all models are predicted, while time to peak velocity is distinct for each cost function (Figure 83.6). Imposing an 80% reduction in extensor muscle strength diminished the significant differences between unimpaired optimal movement profiles (Figure 83.7). The results indicate that the search for finding the objective function being used by central nervous system is an ill-posed problem since we are sure if we have included all the active constraints in the simulation. The four application areas of these results are (1) providing optimized trajectories for biofeedback to patients during the rehabilitation process; (2) training workers to lift safely; (3) estimating the task demand based on the global description of the job; and (4) aiding the engineering evaluation to develop ergonomic and workplace interventions which are needed to accommodate individuals with prior disability.


FIGURE 83.6 The optimized unconstrained trunk flexion and extension trajectories for the five cost functions: Energy, Jerk, Peak Torque, Impulse, and Work.

83.4 Conclusions

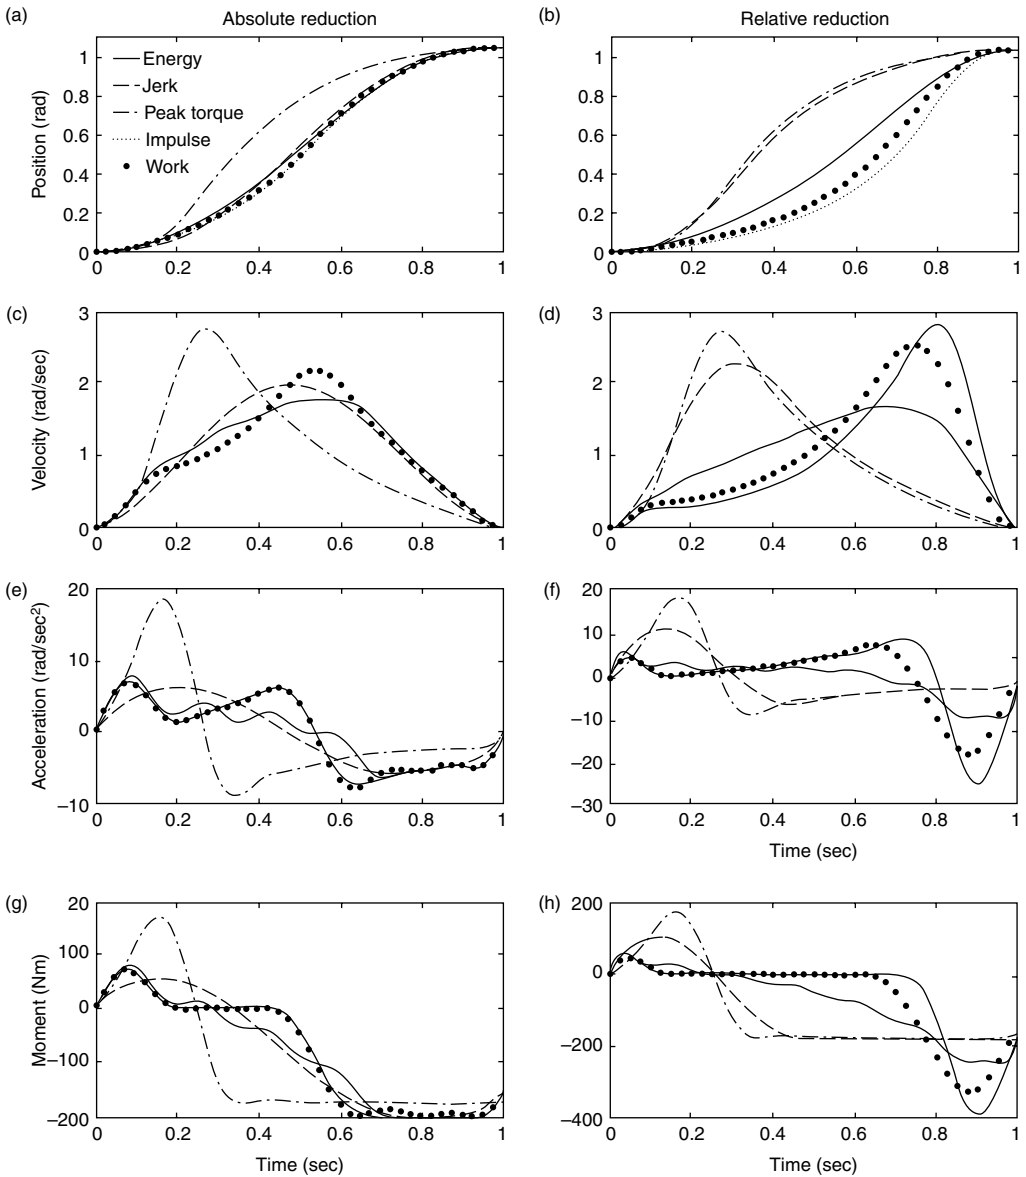
The outcome of trunk performance is affected by the many neural, mechanical, and environmental factors that must be considered during quantitative assessment. The objective evaluation of the critical dimensions of functional capacity and its comparison with the task demands is crucial to the decision-making processes in the different stages of the ergonomic prevention and rehabilitation process. Knowing the tissue tolerance limits from biomechanical studies, task demands from ergonomic analysis, and function capacities from performance evaluation, the rehabilitation team will optimize the changes to the workplace or the task that will maximize the functional reserves (unutilized resources) to reduce the occurrence of fatigue and overexertion. This will enhance worker satisfaction and productivity while reducing the risk of the MSD.


FIGURE 83.7 The optimized trunk flexion trajectories for the five cost functions with the relative and absolute peak extensor strength impairments. The relative strength reduction meant that the extensor strength was reduced to 80% of the peak extension moment required during unconstrained simulations. The absolute strength reduction meant that the extensor strength was set to 200 Nm.

Based on ergonomic and motor control literature, the testing protocols that best simulate the loading conditions of the task will yield more valid results and better predictive ability. Ergonomic principles indicate that the ratio of the functional capacity to the task demand (utilization ratio) is critical to the development of muscular fatigue, which may lead to more injurious muscle recruitment patterns and movement profiles due to loss of motor control and coordination. However, large prospective studies are still needed to verify this. The most promising application for these quantitative measures is to be used as a benchmark for the safe return to work of injured workers, given the enormous variations within the normal population. With the advent of technologies to monitor trunk performance in the workplace, one

can obtain estimates of the injurious levels of task demands (kinematic and kinetic parameters), which can be used to guide preplacement and rehabilitation strategies. The more functional the clinical tests become, the more clinicians need a complex interpretation scheme. An increasingly complex interpretation scheme opens the possibility of using mathematical modeling with intelligent computer interfaces. The ability to identify subgroups of patients or high-risk individuals based on their functional performance will remain an open area of research to interested biomedical engineers within the multidisciplinary group of experts addressing neuromusculoskeletal occupational disorders.

Defining Terms

Carpal tunnel syndrome (CTS):   The result of compression of the median nerve in the carpal tunnel of the wrist.

Cluster analysis: A statistical technique to identify natural groupings in data.

DeQuervain's disease: A special case of tendosynovitis (swelling and irritation of the tendon sheath) which occurs in the abductor and extensor tendons of the thumb, where they share a common sheath.

Electromyogram: Recordings of the electric potentials produced by muscle action.

Feature extraction: A statistical technique to allow efficient representation of variability in the original signals while reducing the dimensions of the data.

Lateral epicondylitis (tennis elbow):   Tendons attaching to the epicondyle of the humerus bone become irritated.

Rotator cuff tendinitis: The irritation and swelling of the tendon or the bursae of the shoulder that is caused by continuous muscle or tendon effort to keep the arm elevated.

Tension neck syndrome: An irritation of the levator scapulae and trapezius group of muscles of the neck commonly occurring after repeated or sustained overhead work.

Thoracic outlet syndrome: A disorder resulting from compression of nerves and blood vessels between the clavicle and the first and second ribs at the brachial plexus.

Trigger finger: A special case of tendosynovitis where the tendon becomes nearly locked so that forced movement is not smooth.

Human Performance Engineering Design and Analysis Tools

Paul J. Vasta
George V. Kondraske
University of Texas-Arlington

84.1 Introduction

Computer software applications have been implemented in virtually every aspect of our lives and the field of human performance has not proven to be an exception. Due to the growing recognition of the role of human performance engineering in many different areas (e.g., clinical medicine, industrial design, etc.) and the resulting increase in requirements of the methods involved, having the "right tool for the job" is becoming of vital importance. Software developers bear the brunt of the responsibility of determining the qualities of a software application that define it as being "the right tool" for a specific job. In contrast, users of this class of tools must determine when their application extends a given tool beyond its intended scope. These abilities require a knowledge base spanning a number of different fundamental concepts and methods encompassing not only the obvious aspects of human performance and computer programming, but also many other less obvious issues related to database requirements, parameter standards, systems engineering principles, and software architecture. In addition, foresight of how specific components can best be integrated to fit the needs of a particular usage is also necessary.

84-1

This chapter addresses selected aspects of computer software tools specifically directed toward human performance design and analysis. The majority of tools currently available emphasize biomechanical models, and as such, this emphasis is reflected here. However, a much broader scope in terms of the body systems incorporated is anticipated, and an effort is made to consider the evolution of more versatile and integrated packages. Selected key functional components of tools are described and a representative sample of currently emerging state-of-the-art packages is used to illustrate not only a snapshot of the capabilities now available, but also those which are needed and options that exist in terms of the fundamental approach taken to address similar problems.

In general, the development of computer software applications, especially in maturing fields such as human performance engineering, serves multiple purposes. The most apparent is the relative speed and accuracy that can be achieved in computationally intensive tasks (e.g., dynamic analysis) compared to performing the processes by hand. In addition, computers can handle large amounts of data and help keep track of the multitude of parameters associated with the human architecture. This allows otherwise impossible procedures, such as the detailed analysis of a complex **human–task interface**, visualization of a human figure in a **virtual workspace**, or the computation of time-series multibody joint torques, to be realized. Perhaps more important, though, are the indirect benefits provided. For example, relatively complex analytic methods utilized in research facilities can be directly implemented in the field by practitioners, with the need for only a complete knowledge of how to effectively *use* the capability available (which is substantially different than the knowledge required to *create* that ability). Moreover, because the software environment demands rigor (e.g., coding structure requirements, data handling and storage, etc.) and since the potential scope of end-user needs in terms of functional and parametric components encompassed is broad, decisions are forced and rules must be clearly delineated. These characteristics thus serve as a motivation to develop standards for (or at least decide upon the use of) many items including methods, parameters, parameter definition conventions, and units of measure. Such efforts can expose and correct inadequacies inherent in current standards while successful software tools (i.e., those which make their way into everyday use) facilitate dissemination of key knowledge and standards to both researchers and practitioners alike.

It can be anticipated that most analysis or decision-making tasks required of practitioners will be made available in computer-based form, including some that are not currently feasible to perform at all except, perhaps, by using intuitive methods that are inconsistently applied and produce results of questionable validity. Given the extent of the possible list of tools within a given package, and considering the substantial overlap of various support functions, classification of packages is difficult. This has been seen already in the relatively modest number of those currently available.

84.2 Selected Fundamentals

It is typical to think of a software capability in terms of a high-level process, for example "gait analysis," where the end result is of primary interest since the underlying processes are performed "invisibly." Yet these supportive processes, many of which have common mathematical methodologies and modeling approaches, determine the ultimate usability and applicability of the software to a given problem and, therefore, deserve closer examination. It makes sense to consider these methods generically not only because they are common to several existing packages, but also because they will undoubtedly be important in others.

84.2.1 Physics-Based Models and Methods

Physics-based methods are implemented when direct analysis of the system or its resources is feasible. With regard to the human system, such methods are commonly applied in biomechanical analysis where unknown parameters, such as joint torque, are derived from known characteristics, such as segment lengths and reaction forces, based on established physical laws and relationships.

Given that relatively simple biomechanical analyses typically include multiple segments and degrees of freedom, the feasibility of employing such methods depends not only on the availability of the required input data, but on the capability to process large amounts of information as well. As the analytical complexity of the task increases, for example, with the inclusion of motion, the significance of implementing such processes within a computer software application becomes readily apparent.

Physical motion is common to most situations in which the human functions and is therefore fundamental to the analysis of performance. Parameters such as segment position, orientation, velocity, and acceleration are derived using kinematic or dynamic analysis or both. This approach is equally appropriate for operations on a single joint system or **linked multibody systems**, such as is typically required for human analysis. Depending on the desired output, foreword (direct) or inverse analysis may be employed to obtain the parameters of interest. For example, inverse dynamic analysis can provide joint torque, given motion and force data while foreword (direct) dynamic analysis uses joint torque to derive motion. Especially for three-dimensional analyses of multijoint systems, the methods are quite complex and are presently a focal point for computer implementation [Allard et al., 1994].

Physics models used to address biomechanical aspects of human performance are relatively well established and utilized in both research and applied domains. In contrast, concepts and methods directed toward other aspects of human performance, such as information processing (in purely perceptual contexts as well as in neuromotor control contexts), are based on strong science and have been incorporated into one-of-a-kind computer models, but to our knowledge have not been engineered into any general-purpose computer tools. It can be argued that Shannon's information theory provides the basis for a similar set of "physics-based" cause-and-effect models to support the incorporation of this aspect of human performance into computer-based modeling and analysis tools. Considerable work has gone into the application of information theory to human information processing [Lachman et al., 1979] within research domains. The definition of neuromotor **channel capacity** [Fitts, 1954] and metrics for the information content of a visual stimulus measured in bits [Hick, 1952; Hyman, 1953] are some examples of the influence of information theory that have become well established. Given the considerable science that now exists, useful computer-based analytic tools that use these ideas as basic modeling constructs are likely to emerge.

84.2.2 Inference-Based Models

Often, direct measurement of a **performance resource** or structural element is not feasible or practical and estimates must be inferred from models based on representative populations. Inferential-based methods, therefore, utilize derived relationships between parameters to provide an estimation (or prediction) of an unknown quantity based on other available measures. One type of modeling approach in such a situation is through statistical regression. This process utilizes data measured from a population of subjects with characteristics similar to the subject or population of interest, to derive a function which represents a "typical" relationship between the independent (measured) variable and the dependent (desired) variable. Specifically, this is achieved through the determination of the function that minimizes the error between the actual and the predicted value across all observations of the independent variable. This process results in an approximation of the desired parameter with a quantified standard error [Remington and Schork, 1985]. Applications of this method require that the dependent variable is distributed normally and with constant variance, and correspondingly, that an estimation of its typical value (for a given population) is desired. Applied to the human system, regression is often implemented to develop **data models**, which are then used to estimate unknown structural parameter values from known parameters, such as the estimation of body segment moments of inertia from stature and weight [McConville et al. 1980]. Regression has also been used to predict task performance from a wide variety of other variables (e.g., height, weight, age, other performance variables, etc.). A specific example is the determination of the maximum acceptable load during lifting tasks as a function of variables such as body weight and arm strength [Jiang and Ayoub, 1987].

A conceptually different and relatively new example of an inferential model, motivated by human performance problems specifically, is nonlinear causal resource analysis (NCRA) [Kondraske, 1988; Vasta and Kondraske, 1994]. Quantitative task demands, in terms of performance variables that characterize the involved subsystems, are inferred from a population data set that includes measures of subsystem performance resource availabilities (e.g., speed, accuracy, etc.) and overall performance on the task in question. This method is based on the following simple concept: Consider a sample of 100 people, each with a known amount of cash (e.g., a fairly even distribution from $0 to $10,000). Each person is asked to try to purchase a specific computer, the "cost" of which is unknown. In the subgroup that was able to make the purchase (some would not have enough cash), the individual who had the least amount of cash provides the key clue. That "amount of cash availability" provides an estimate of the computer's cost (i.e., the unknown value). Thus, in human performance, demand is inferred from resource availabilities.

84.2.3 Fidelity

An important principle that has not often received the scrutiny it deserves is that of the level of fidelity desired, or perhaps more critically, necessary for a particular application. This includes anything that affects the range of applicability or quality of the results provided in a given application. Fidelity can be characterized in terms of three distinctly different components: (1) model scope, (2) computational quality (e.g., resolution limits, compounding of errors, convergence limits of numerical methods, etc.), and (3) data quality (e.g., noise, intrinsic resolution limits, etc.). Model scope considers the extent to which major systems are incorporated (e.g., neuromuscular, sensory, cognitive, etc.) and, as a separate issue, the extent to which these major subsystems are represented (e.g., peak torque and angle limits vs. a three-dimensional torque-angle-speed envelope for neuromuscular systems of rotational joints).

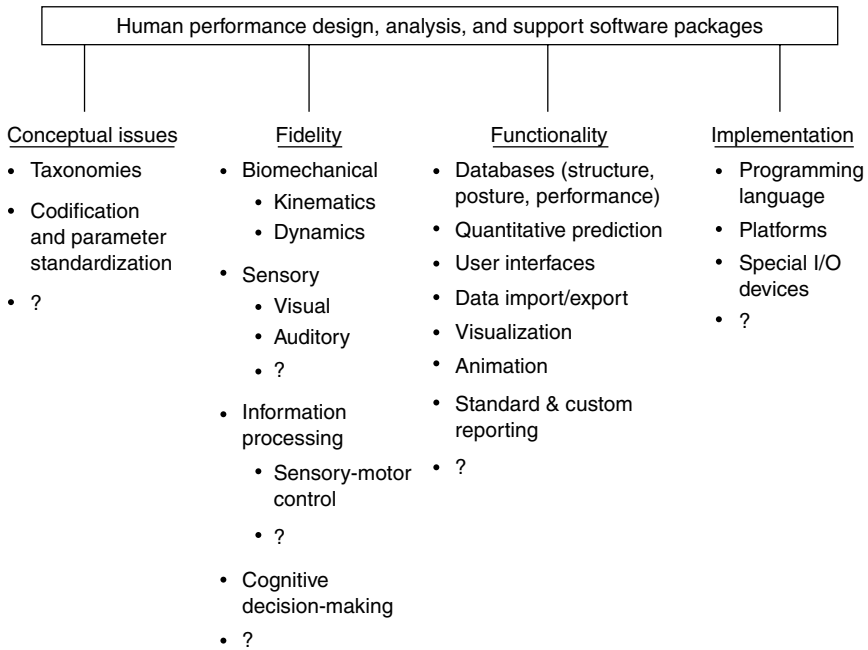
84.2.4 **Parameter Conventions**

Often, the exact definition of parameters across (and even within) scientific disciplines varies, limiting communication of findings and inhibiting dissemination of knowledge. Careful selection and clear documentation of **parameter conventions** is an important principle in producing analytic software that can be understood, accepted, and used.

Within the broad scope of parameters that could possibly be incorporated in analytic and other software tools, there are many parameter convention challenges that arise. Due to the fact that of the reported analyses in which various parameters that appear have been of restricted scope and largely special purpose, more generalized situations where convention is important have escaped standardization in terms broad enough to support all application needs. As one example, consider the description of relative orientation between two object-attached coordinate systems in three dimensions (in the context of the human system, this specifies joint angle). There are two basic forms of angle set representations, each derived in terms of the method of rotation of one coordinate system (attached to a moving object) about a specific axis: (1) Fixed angle representation, which involves referencing each rotation of the moving system to some fixed reference frame and, (2) Euler angle representation, indicating that each consecutive rotation of the moving system is referenced to the coordinate axes of its present orientation. Given multiple degrees of freedom, multiple angles result representing the amount of rotation about a specific axis and at a defined position in the order of rotations. The specification of these parameters defines the associated angle set convention (i.e., fixed or Euler). Utilization of the terms "roll, pitch, and yaw" [Chao, 1980] in communicating this convention, originally used to describe ship and aircraft orientation, can also lead to confusion. This is not only due to the lack of similarity between the defined reference frame of an aircraft and that of a human segment, but also due to its altered definition within other disciplines (e.g., fixed angle representation [Spong and Vidyasagar, 1989]. Thus, depending on the "type" of Euler angle used and the sequence of axes about which the rotations occur, two entirely different orientations are likely to result. This discussion does not even consider the clinical perspective on joint angles, where only angles measured in three orthogonal planes [Panjabi et al., 1974] are considered. Despite the fact that the human

architecture has remained constant (unlike many artificial systems), to our knowledge there is no standard convention that defines all angles in a total human link model for three-dimensional motion.

84.2.5 Data Formats

The utilization of data, especially within a software environment, involves both communication and manipulation not only within a single stand-alone application, but often across facilities, databases, and platforms. Data formats, in this light, can be considered among the most important of the components fundamental to analytic software. Problematic effects may result from aspects including inconsistent adoption of terminology (e.g., endurance vs. fatigue), units of measure specifications, file structures, parameter coding, and database structure. Computer-aided design (CAD) environments in traditional engineering disciplines (e.g., drafting, mechanical design, etc.) have confronted such issues with standardization such as the DXF file formats (used for two- and three-dimensional geometric drawings; even accepted by some numerical machining systems) and the Gerber format (used to communicate a printed circuit board specification to board manufacturers). Within the realm of human performance engineering, standards for data formats remain at the forefront of developmental needs. Some limited standards are emerging, such as the relatively consistent use of ASCII text files with either labeled or position-dependent parameters. However, there are currently no known, agreed upon, or de facto standards for positions, labels, units of measure, and so on.


84.3 Scope, Functionality, and Performance

As summarized in Figure 84.1, CAD-like human performance software depends on conceptual issues as well as decisions regarding fidelity, functionality, and implementation. There is also a great deal of interaction among these categories. Topics within each category were derived in part from a review of current packages (e.g., those described below) and an assessment of other issues and needs. These lists are intended to be illustrative and not exhaustive. While *every* major category applies to *any* given software tool, not all topics listed within a category will always be relevant.

Conceptual issues include taxonomies on which a given package is based (e.g., basic approaches to motor control, system performance, task categorizations and analysis, data estimation, etc.), parameter choices and codification (e.g., hierarchical level of representation, identification in structured input/output file formats), and compliance with or deviation from accepted standards with the varied communities that deal with human performance. They may well deserve special recognition given the impressionable developmental stage of the class of software tools addressed. Perhaps because developers are so familiar with a given perspective or body of knowledge, key conceptual issues are often overlooked or incorporated de facto from previous work (e.g., research studies) that is similar (but perhaps not identical) to the intended purpose of a given package, which is frequently broader and more general than the research efforts or projects that inspired it. Software packages impose on users the constructs on which they are based and this may result in conflicts within an already structured environment. Conceptual foundations and approaches are not yet as clearly defined in human performance as they are in disciplines such as electrical and mechanical engineering. This is further complicated by the wide variety of disciplines (and therefore educational backgrounds) represented by those with interest in participating in software development. Clear and complete disclosure of the conceptual foundation used by developers is thus helpful to both users (potential and actual) and developers.

The concept and scope of fidelity in the present context has been delineated in Section 84.2.3 and is further represented by the subtopics in Figure 84.1. We have chosen to apply it here in its broadest sense. In a fairly recent National Research Council panel on human performance modeling [Baron et al., 1990], recommendations were made toward problems regarding design and implementation issues. Though not specifically addressing computer software, the extension of the discussion is natural given present technology and implementation methods. While it was concluded that an all-inclusive model (i.e., high

fidelity, in the sense that biomechanical, information processing, sensory, and perceptual aspects, etc. are represented) might be desirable, it is highly unlikely that it could be achieved or would be useful, as the inherent complexity would impede effective usage. The basic recommendation made was to pursue more limited scope submodels. The implication is that two or more computer-based versions of such submodels could be integrated to achieve a wide range of fidelity, with the combination selected to meet the needs of particular situations. However, there is neither a general framework nor set of guidelines for developers of submodels (i.e., an **open-architecture concept**) that would facilitate integration of relatively independent software development efforts. Thus, integration is left to the end user and typically only cumbersome methods are available.

Fidelity should be considered in combination with productivity and both must be carefully assessed against needs. For example, a package that provides the user with control over a large number of parameters (e.g., joint stiffness, balance control, etc.) that define the human system under analysis, typically allows for greater intrinsic fidelity and can be valuable if the ability to specify parameters at that level of detail is an absolute user requirement. If not, this level of specificity only increases the number of prerequisite steps to achieve a given analysis and leads to a more complex program in terms of operation and function (which is perhaps most evident in the user interface). Furthermore, more accurate results are not necessarily obtained. Programs that are structured to automatically rely on default parameter values that can be inspected or changed when desired serve both types of needs. However, concern is typically raised that "lazy" users will forego the entry of values more appropriate to the situation at hand. Thus, while software developers can provide features that greatly simplify procedures and recommendations regarding their proper use, users bear the responsibility of choosing when to invoke such features. Fidelity issues are often viewed as "either" or "or" choices, when many times a "both" or "all" approach is quite feasible. This gives the user the decision-making power and responsibility for decisions that may affect quality of results. Such approaches also typically result in a greater user pool for a given package. The manner in how such flexibility is implemented, however, is critical. For example, if fidelity decisions are likely to be made once in a given installation, schemes that require decision making with each analysis can prove to be cumbersome and ineffective.

Functionality can be considered in terms of basic and special subcategories. Far too often, attention is given to special features while those that are more basic (such as import/export capabilities) are ignored. Most items listed in Figure 84.1 under the "functionality" category are self explanatory, although it should be noted that features such as importing and exporting are more complex in the present context than one might anticipate due in part to the lack of standards for parameters representation (see above). Developers must carefully select functionality and potential users must carefully evaluate the impact of those choices against their specific needs. For example, the processing power required to display and animate contoured multisegment human figures in real time and in three dimensions is substantial. Programs with this ability typically require high-end platforms and also require that a large fraction of the programming effort and user interface be used for this functionality. The addition of processes such as a dynamic analysis places even a greater stress on processing power and complexity. Visualization of human figures in three dimensions along with some environmental components is essential for some applications. For many applications, such as those in which numerical results are required and conveyed to others with simple printed reports, such visualization are not required, or contribute little, to achieving the desired end purpose (although they are almost always viewed as "attractive" by potential users). Functionality options are further developed and exemplified in the discussion of actual software packages below (Section 84.4).

The last of these four categories describes the support structure upon which the software packages are built. Software implementation in today's ever-changing computer market requires careful thought. In addition to host platform and standard accessories, special input/output interfaces are often necessary (e.g., to allow direct access to laboratory acquired kinematic data). Support software for such special hardware is not always available on all platforms, preventing operation with analytic software in the same environment. Choice of programming language (supporting modules and libraries, platform diversity) and the operating system (Macintosh®, Windows™, Unix, etc.) are also critical. As exemplified in Section 85.4, no existing packages run on all platforms and under all operating systems users who wish to employ multiple packages are left with cumbersome and often costly solutions.

As computing power at the single-user level (i.e., personal computer) increases, there is little doubt that a full set of state-of-the-art features covering a broad scope of human performance and data needs *could* be integrated into a single package. At present, though, limitations are real and necessary. These are the result of specific trade-offs that must be considered during development when determining target users. Operational costs include software acquisition, maintenance, basic platform acquisition and outfitting, and training costs. A large feature set and high performance are not always indicative of a software tool's value. Value is lost if a user's requirements are either unfulfilled or greatly exceed by the functionality and performance of a program. Unfortunately, general trade-offs that are acceptable within different groups of users have not yet become evident.

84.4 Functional Overview of Representative Packages

In this section, a selected set of different types of software packages intended specifically for human design and performance analysis applications are described. At least one example of each type exists and is noted for reference and to illustrate the types of functionality developers are addressing in response to perceived needs. No endorsement of any example cited is implied. The packages included vary widely in function and performance and should not be considered to be directly comparable. Operational costs reflect this diversity, ranging from relatively inexpensive (e.g., approximately $100.00 plus the price of a moderately equipped PC™) to the level defined by high-end workstations (e.g., thousands of dollars for software licenses plus the cost of a Unix-based workstation). As with desktop computer applications, such as word processors and spreadsheets, the packages used to illustrate functionality are under constant development, and changing feature-sets, performance, and cost are to be anticipated.

The types of packages included illustrate fundamental options with regard to general or dedicated analysis (e.g., user-defined tasks vs. gait), different levels of analysis (e.g., "muscle" vs. "joint" levels in biomechanical analyses), body-function-specific or general-purpose analysis (e.g., gait vs. user-defined

function), fidelity in terms of scope (e.g., biomechanical, sensory, neuromotor control, etc.), and target user orientation (medical vs. nonmedical design; although overlap is possible). It should be noted that while particular packages are highlighted under certain categories, underlying features and functions are common across many applications.

### 84.4.1 Human Parameter Databases

The need for data is evident in all aspects of human-related CAD and the analysis of human performance. In certain situations, requirements may be for a specific individual or a representative population. In the former case, there are certain parameters that are not readily attainable (e.g., location of center of mass for a segment, inertia, etc.) and therefore must be estimated, as in the latter case, from normative values derived from studies. For a number of years, these estimates have been available in book form primarily as lookup tables. This format, however, does not take advantage of current technology and is not sufficient for use with software-based analytic tools. Some currently available packages, in addressing this need, have included data tables that are utilized exclusively within the program. Programs such as *MannequinPro* and *SafeWork* (detailed below) for example, each include a significant database of anthropometric measures for various populations. The user specifies design parameter values by choosing characteristics such as gender, ethnic origin, and morphology representative of the desired population. Various other stand-alone database software packages, for example, *PeopleSize* (targeted initially for clothing design), allow data to be exported, thereby providing at least an indirect support for external applications.

In addition to measures such as segment lengths, parameters including reach and range of motion for selected postures are frequently provided in databases (e.g., horizontal sitting reach, etc.). Because it is prohibitive (if not impossible) to measure and report all possible situations, this issue may be more adequately addressed through the use of parametric data models. Data derived from such models would provide estimates for all possible conditions as well as having the additional advantage of requiring lesser storage and management requirements. Caution is warranted with regard to issues such as model validity, statistical sample sizes and variations, combinatory effects of merging databases or data models, and traceability of data to original sources.

84.4.2 Biomechanical, Muscle-Level Modeling and Analysis

Software for interactive musculoskeletal modeling *SIMM* is a graphics-based tool for modeling and visualization of any human or animal musculoskeletal system and is directed at lower-level structures, that is, individual muscles. The program allows users to model any type of musculoskeletal system using files, which specify (1) the skeletal structure through polygonal surface objects, (2) the joint kinematics, and (3) the muscle architecture through specifications of a line of action for each muscle and isometric force data. *SIMM* contains various tools for observing and editing the model (see Figure 84.2). The user can visualize and animate the model, display or hide the individual muscles (shown as line segments), manipulate joint angles, muscle forces, and moment arms. Joint torques (static) can be analyzed via plots and graphs and all of the muscle parameters may be edited including visual alteration of muscle lines of action. Finally, the user also has control over joint kinematics by altering the cubic splines used to control the animated joint movements. Developers claim that *SIMM* is aimed at biomechanics researchers, kinesiologists, workspace designers, and students who can benefit from visual feedback showing muscle locations and actions.

Musculographics, the developers of *SIMM*, also produce a component as part of the SIMM suite specifically directed toward gait analysis that provides ground reaction force vectors and color-highlighted muscle activity through animation of the model. The software is designed to input data files written by movement analysis systems and can display plots of data such as muscle lengths and ground reaction forces. Another application, the *Dynamics Pipeline*, is a general-purpose package that provides forward and inverse dynamics to calculate motions resulting from forces or torques required to generate a given motion,
FIGURE 84.2 Muscle attachments and utilization (indicated by shading) for the lower extremities during gait, created and displayed using SIMM software.

respectively. *SIMM* was also made available for Microsoft Windows. However, the original Unix-based version is still available.

84.4.3 Body Function–Specific Tools

GaitLab is a Windows™-based software package that allows fundamental parameters of human gait to be derived, analyzed, and inspected. At this time it is available inexpensively ($49.95) as part of a larger package from Kiboho Publishers. The program is divided into two main sections (i.e., subprograms that run under the "shell" of the main application): (1) a mathematics section, which provides processes for generating text files representing various gait parameters throughout a gait cycle; and (2) a graphics section that creates plots of the parameters as well as a representation of gait through an animated stick figure. Documentation covers the gait parameters and equations associated with the software package as well as the underlying principles for their use in gait analysis. Software accepts different, custom-formatted data files (ASCII text) based on direct measurements of a human subject. These include anthropometric, kinematic (i.e., three-dimensional positions of anatomic landmarks), force plate, and electromyographic (EMG) measures. Sample files are included for a healthy adult male, female, and an adult male with cerebral palsy. From this data, text files are created for lower-extremity body segment parameters (mass, center of gravity position, and moment of inertia), linear kinematics (joint center, heel, and toe locations, segment reference frames), center of gravity (position, velocity, and acceleration), angular kinematics (joint angles, angular velocity, and acceleration), and dynamics (joint forces and torques). The package can also display up to three simultaneous plots of these parameters in any combination. Time, percent of gait cycle, and marker position scales are also available for plotting against any of the variables.

GaitLab provides a useful function in its ability to generate the above mentioned parameters and is effective with its simplistic stick figure animation, allowing minimal processing power/speed requirements while providing the nuances of lower limb movement pertinent to gait analysis. It is just one of many examples of function-specific packages.

84.4.4   Biomechanical, Joint-Level, Total Human Analysis

ADAMS is a software package designed for mechanical design and system simulation in general. It is an extensive package incorporating specific components for both modeling and kinematic/dynamic analysis. What sets *ADAMS* apart from other nonperformance-based simulation/dynamics packages is the availability of a module, LifeMOD, specifically designed to allow the user to create a human model. The human model may be edited as needed but is provided in a default configuration of a 19 joint-body architecture with five anthropometric body size databases. Because the package focuses on mechanical systems in general, a great deal of control is provided to the user over the parameters of the model including contact forces, joint friction, damping, and nonlinear stiffness as well as control parameters. Having this capability, the human model is able to affect control over objects in its environment as well as responding biomechanically to contact. Supplemental toolsets may be (custom) developed to provide proper control over model parameters such as motion resistance relationships, joint strength and range of motion limits, and delays in neuromuscular response. For a given model, kinematic or dynamic simulations may be run and values for any parameter can be plotted on screen. Both forward and inverse dynamic analyses are available and graphics-based facilities such as the specification of trajectories via mouse input are available. The simulations may be used to generate detailed animation movie (.avi) files.

Because *ADAMS*' capabilities are so extensive, it has become one of the most widely used mechanical system simulation packages. Outside of the realm of human performance analysis, the package is targeted at engineers and scientists who require complete observation and control of the model parameters across many hierarchical levels. While this format affords great fidelity and specificity in the analysis, there is also a great deal of complexity and detail that must be addressed in every new simulation run. Though **performance assessment** is not an inherent or recognized feature in the package, custom modules may be incorporated, which would allow for direct comparison of system resource utilization and stress against the demands of the task.

84.4.5   Visualization for Low-End Computer Platforms

MannequinPro, while having inherent database functionality, is essentially a visualization tool that allows users to quickly create three-dimensional humanoid figures, which may be represented in stick-figure form, as a wireframe "robot" with polygonal segments, or as its name implies, a mannequin with higher-resolution segments. These figures may be postured within preset (i.e., noneditable) range-of-motion limits, as well as viewed from many different perspectives. They are created automatically by the program according to user-defined structural aspects chosen from a list of specifications for gender, population percentile, body type, age, and nationality. The package also provides a modest drawing (CAD-type) tool for creating various objects to be placed in the scene with the figure. Two additional features extend *MannequinPro* beyond the domain of a "simple" object rendering tool. The first is provided through animation effects, allowing the mannequin to walk via an internally generated gait sequence (a specific path may be defined through a virtual workspace), reach to a specific location, or move through any sequence of positions created on a frame-by-frame basis by the user. The second feature allows the user to specify forces acting on the mannequins hands or feet from which static torques are calculated for both left and right wrists, elbows, shoulders, neck, back, hips, knees, and ankles.

As a visualization tool, *MannequinPro* provides a needed capability for a modest price and requires only a personal computer to run. Figures are easily produced to the anthropometric specifications available and posing, reaching, and walking functions, though limited, are simple to control. The package is primarily operated from mouse input with standard point, click, and drag operations that should be familiar to most users of current commercial software. Once the scene is created with humans and objects in their workspace, it is up to the user to extract any information regarding function and performance from the visual images presented by the package. These features, as well as others, are also contained within the software package *Jack* and *SafeWork* (described below), which provide greater functionality but are targeted toward workstation environments. In sum, *MannequinPro*, with a good price-to-performance

ratio, is an effective tool when human visualization with moderate graphics is required at the single-user platform level.

84.4.6 Extended Visualization for the High-End Workstations

Jack, developed within the University of Pennsylvania Center for Human Modeling and Simulation [Badler et al., 1993], and *SafeWork* are a high-end CAD-oriented design and visualization packages. Similar in function to *MannequinPro* (above), but with considerably more flexibility and detail, they are designed to allow human factors engineers to place a human in a virtual workstation environment while still in the design phase. Both extend far beyond the capabilities of *MannequinPro*, trading simplicity for specificity in that they provide users with control over a large range of variables regarding many aspects of the human figure and its virtual environment. Human models are fully articulated and preset or user-definable anthropometric parameters that include segment dimensions, joint limits, moments of inertia, and strength allow highly specific representation. The total functionality of these packages are far too great to list the individual aspects here, but examples include reach, hand gripping, balance (including reorientation behavior), collision detection, light and camera (view) manipulation, animation, and kinematic/dynamic analysis. *Jack* also allows for real-time posture tracking of a human operator through position and orientation sensors (see Figure 84.3).

Similar to the functionality of *ADAMS*, these packages provide a great deal of control over the design and manipulation of the human figure. Because of the large number of controllable parameters and the difficulty involved in providing an interface allowing three-dimensional manipulation of high-end graphics in a two-dimensional environment, the majority of users will require training. *Jack* and *SafeWork* require a Silicon Graphics workstation to run.

84.4.7 Total Human, Performance-Based, Human–Task Interface Analysis

While now under development, *HMT–CAD* represents yet a different perspective in that it is based primarily on performance modeling constructs [e.g., Kondraske, 2005] and is aimed at producing bottom-line assessments regarding human-to-task, human-to-machine, and eventually machine-to-task interfaces using a logic similar to that used by systems-level designers. In a joint effort between Photon Research Associates, Inc. and the University of Texas at Arlington Human Performance Institute, performance models and decision-making strategies are combined with advanced multibody dynamic analysis.
FIGURE 84.3   A human/workspace figure created and displayed using Jack software.

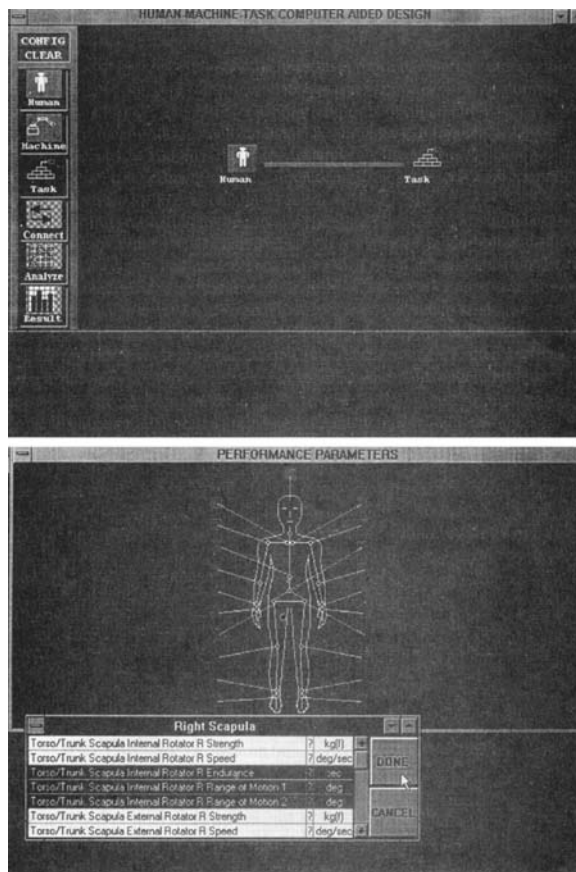
HMT-CAD's initial development emphasized a top-down approach that set out with the goal of realizing a shell that would allow systematic incorporation of increasingly higher fidelity in a modular, stepwise fashion. The initial modules encompass biomechanical and neuromuscular aspects of performance that bases analyses on knowledge of range/extremes of motion, torque, and speed capacities. Gross total human (23 links and 41 degrees of freedom) and hand link models (16 links and 22 degrees of freedom each) are included. The Windows™-based tool provides a predefined framework for specifying human structure and performance parameters (e.g., anthropometry, strength, etc.) for individuals or populations. A task library is included based on an object-oriented approach to task analysis. HMT–CAD attempts to help communicate information about many parameters via a custom graphical–button interface. For example, one analysis result screen shows a human figure surrounded by buttons connected to body joints. Button color (e.g., red or green) communicates whether an analysis found limiting factors for the specified person in the specified task associated with that joint system. Using computer mouse input, clicking on red buttons produces a new window showing a list of performance capacities and stress levels associated with systems of that joint. Maximally stressed performance resources are tagged. *HMT–CAD* uses the same systems of level modeling constructs for human and artificial systems. A novel technique that transparently draws upon a large set of data models as needed is used to provide "the best analysis possible" with the data provided by the user. This allows users to directly specify values for all parameters if desired, but does not require this for each analysis (see Figure 84.4).


FIGURE 84.4 A desktop environment of the HMT-CAD performance assessment package including system model development and analysis result reporting.

In the present prototype, analysis scope is very limited (upper extremity, object moving tasks). Databases are being populated to allow a similar fidelity of analysis for trunk and lower-extremity analyses. Development of an optimization engine based on minimizing stress across performance resources [Kondraske and Khoury, 1992] to solve problems in which redundant approaches are possible is underway. No capability is currently provided for animation of human movement, as binary assessments (e.g., red and green buttons) and numerical results (stress levels on performance capacities) are emphasized. However, an interface to emerging general-purpose animation tools is planned. Long-term development will proceed to increase fidelity in a stepwise fashion by the inclusion of performance capacities for other major systems (e.g., information processing associated with motor control) as well as additional performance capacities for major systems represented at any given time (e.g., the inclusion of neuromuscular endurance limits).

The inferential NCRA methodology discussed earlier has recently been used to create a companion NCRA software package by the University of Texas at Arlington's Human Performance Institute. It is based on General System Performance Theory concepts and the Elemental Resource Model [Kondraske, 2005] and performs the following functions:

- *Perform Task Analyses (Build NCRA models):* Models consist of a set of Resource Demand Functions, each of which relates the amount of a given performance resource required to achieve a specific level of High Level Task (HLT) performance.
- *Predict HLT Performance:* Using an NCRA model and a set of measures representing basic performance resource availability (i.e., performance capacities) for a set of "n" subjects as "inputs" to the model (i.e., independent variables), individualized predictions of performance in the HLT are computed.
- *Identify Limiting Performance Resources:* In addition to a prediction of HLT performance, for each subject in a Prediction Source Data set, the performance resource that prevents that subject from "performing better" is identified.
- *Obtain Other Useful Performance-Related Measures:* Various options are available to explore the stress on the performance resources of individuals associated with a given level of HLT performance.

Importantly, NCRA allows models to be formulated that mix neuromuscular, information processing, sensory, and life-sustaining performance resources. It is anticipated that many existing data sets, which have been previously used to develop regression-based models, can be used with NCRA (see Figure 84.5).

84.5 Anticipated Development

While it is relatively easy to outline the functionality and unique aspects of the software discussed above, it is a great deal harder to describe the level of difficulty required to achieve a desired end result and to characterize how well functions are performed. Online "help" systems, multimedia components, associated software development tools, improved parameter measurement tools, and higher-fidelity models will no doubt impact these aspects.

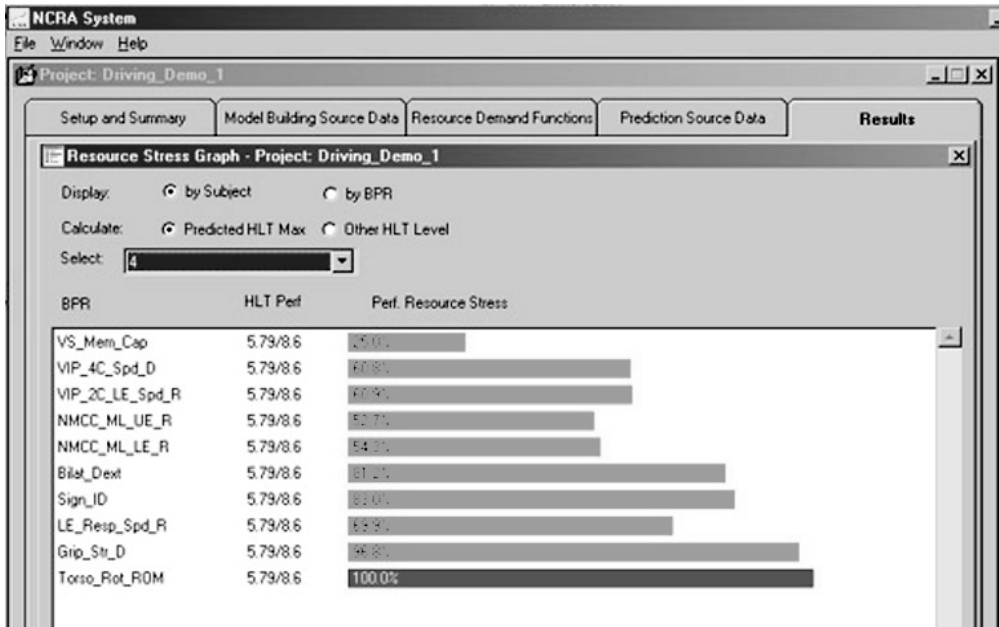
As mundane as it may seem, perhaps nothing is more important to the overall advancement of this class of software tools than the development of standards for parameters used, parameter conventions, and data formats. It is likely that de facto standards will emerge from individual commercial endeavors. Due to the diversity of professionals involved, it is difficult to envision the evolution of "standards by committee." Observation of success stories in analogous efforts also supports this opinion. This, in turn, will enable progress to be made in database and data model development, which is vital to the many of the more routine functions such software will perform. Combined with modular object-oriented programming techniques, the emergence of true multitasking operating systems on desktop computers, and the support for interprocess communication (such as dynamic data exchange) will encourage developers. Many new tools, both similar to and completely different than those describe here, can be anticipated.


FIGURE 84.5   Screen capture from NCRA software illustrating results for one individual applied to a model of driving performance. Overall driving performance level (HLT performance) and limiting performance resources (in this case "torso rotation range of motion") are predicted based on a set of more basic performance resource measures (BPRs). BPR measures are lower-level performance capacities relative to the higher-level task modeled.

Defining Terms

Channel capacity: The maximum rate of information flow through a specific pathway from source to receiver. In the context of the human, a sensorimotor pathway (e.g., afferent sensory nerves, processors, descending cerebrospinal nerve and α-motoneuron) is an example of a channel through which motor control information flows from sensors to actuators (muscle).

Data model: A mathematical equation derived as a representation of the relationship between a dependent variable and one or more independent variables. Similar in function to a database, data models provide parameter values across conditions of other related parameters.

Human–task interface: The common boundary between the human and a task specified by the demands of a task on the respective resources of the human and the capacities of the human's resources involved in performing the task.

Linked multibody system: A system of three or more individual segments joined (as an open or closed chain) in some manner with the degree of freedom between any two segments defined by the characteristics of the corresponding hinge.

Open-architecture concept: A general methodology for the development of functional modules that may be readily integrated to form a higher-level system through well-defined design and interface constructs.

Parameter conventions: Aspects and usage of a parameter that are specifically defined with respect to general implementation.

Performance assessment: The process of determining the level or degree in which a system can perform a specific task given the demands required and the availabilities of the resources of the system which are involved in performing the task.

Performance resource: Defined as a functional unit and an associated dimension of performance (e.g., knee extensor strength) that is available to a system.

Virtual workspace: A representation of a three-dimensional physical workspace generated by computer software and displayed on a video monitor or similar device. This enables, for example, the inclusion and manipulation of computer-generated objects within the virtual workspace such that designs can be tested and modified prior to manufacturing.

Human Performance Engineering: Challenges and Prospects for the Future

George V. Kondraske
University of Texas-Arlington

85.1 Introduction

Human Performance Engineering is a dynamic area with rapid changes in many facets and constantly emerging developments that affect application possibilities. Materials presented in other chapters of this section of the text illustrate the breadth and depth of effort required as well as the variety of applications in this field. At the same time, the field is relatively young and as is often the case in such instances, some "old" issues remain unresolved and new issues emerge with new developments. With the other material in this section as background, this chapter focuses on selected issues of a general nature (i.e., cutting across various human subsystem types and applications) in three major areas vital to the future of the field (1) human performance modeling; (2) measurement; and (3) data-related topics. In addition to the identification of some key issues, some speculation is presented with regard to the lines along which future work may develop. Awareness of the specific issues raised is anticipated to be helpful to practitioners who must operate within the constraints of the current state-of-the-art. Moreover, the issues selected represent scientific and engineering challenges for the future that will require not only awareness but also the collaboration of researchers and practitioners from the varied segments of the community to resolve.

85-1

85.2   Models

It is important to distinguish various types of models encountered in human performance. They include conceptual, statistically-based predictive models, predictive models based on cause-and-effect [Kondraske et al., 1997], and data models [Vasta and Kondraske, 1995]. Issues related to data models are described in Section 85.4 of this chapter, while those related to the remaining types are discussed in this section.

Traditionally, a tremendous amount of activity in various segments of the human performance community has been directed toward development of statistically-based predictive models (e.g., regression models). This remains the most popular approach. By their very nature, each of these is very application specific. Even within the intended application, success of these models has mostly ranged from poor to marginal, with a few reports of models that look "very good" in the populations in which they were tested. However, the criteria for "good" has been skewed by the early performance achieved with these methods and statistically significant "r" values of 0.6 have come to be considered "good." Even if predictive performance was excellent, the long-term merit of statistically-based prediction methods can be questioned on the basis that this approach is intrinsically inefficient. A unique and time-consuming modeling effort, requiring new data collection with human subjects, is required for every situation. At the same time, powerful computer-based tools are commonly available that facilitate the generation of what is estimated to be hundreds and perhaps thousands of these regression models on an annual basis. It appears that many researchers and practitioners have forgotten that one purpose of such statistical methods is to provide insight into the cause-and-effect principles at play and into generalizations that might be more broadly applied. Statistically-based regression models will continue to serve useful purposes within the specific application contexts for which they are developed. However, the future of predictive modeling in human performance engineering must be based on cause-and-effect principles. The sentiment for the need to shift from statistical to more physically based models is present and growing in several of the related application disciplines as evidenced by a sampling of quotations from the literature presented in Table 85.1.

A National Research Council panel on human performance modeling [Baron et al., 1990] conducted one of the more broad-looking investigations regarding complex human performance models; that is, those that consider one or more major attributes (e.g., biomechanical, sensory, cognitive, structural details, etc.) of a total or near-total human. The convening of this panel itself underscored the interest in and need for human performance models. As an interesting aside, while the panel's focus was on modeling, a large fraction of the efforts cited as background represented major software packages, most of which were developed to support defense industry needs. A major application for such models is in computer simulation of humans in various circumstances, which could be used to support prediction and

TABLE 85.1   Representative Quotations Illustrating the Need for a Shift Toward the Development of Causal Models

Quote	Field	References
…there has been little advancement of the science of ergonomics…the degree of advancement is so low that, in my opinion, ergonomics does not yet qualify as a science…There has been no progress in the accumulation of general knowledge…because nearly all studies have not been general studies.	Human factors	Smith, 1987
…experiments are performed year after year to answer the same questions, those questions — often fundamental ones — remain unanswered…the methodology employed today is a hodgepodge of quick fixes that evolved over the years into a paradigm that is taught and employed as sacrosanct, when in fact it is woefully inadequate and frequently incompetent…	Human factors	Simmon, 1987
…authors and users of these instruments lacked a conceptual model…lack of a well-developed conceptual model is unfortunately characteristic of the entire history of the field…	Rehabilitation	Frey, 1987

other analysis needs. A series of useful recommendations were included in panel's report regarding the direction that should be taken in future work. However, recommendations were quite general in nature and no specific plans were outlined regarding how some of these objectives might actually be achieved. Nonetheless, it was clear from the choice of the previous works cited and from the recommendations that development of cause-and-effect, general-purpose models should receive priority. The elemental resource model presented at the beginning of this section of the text [Kondraske, 2005] is one example of a causal, integrative model that reflects an initial attempt to incorporate many of this panel's recommendations.

Whether primarily statistical or causal in nature, frustration with what has been characterized or perceived as "limited success" achieved to date in efforts to unlock and formalize the underpinnings of complex human functions such as speech, gait, lifting, and memory have led to attacks in recent years on the basic reductionistic approach that has been pursued most aggressively. In fact, reductionism has been characterized as a "dead end" methodology — one that has been tried and has failed [Gardner, 1985; Bunge, 1977], as further evidenced by the following somewhat representative quote [Weismer and Liss, 1991]:

> [T]his view held the scientific community spellbound until people started looking past the techno-logical issues, and asking how well the reductionist observations were doing at explaining behavior, and the answer was, miserably. Many microscopic facts had been accumulated, and incredible tech-nological advances had been made, but the sum of all of these reductionist observations could not make good sense of macroscopic levels of movement behavior.

Prior to total abandonment, it is perhaps wise not only to characterize the performance of reductionism, but also to question why it might have failed *thus far*. For example, it may be prudent to entertain the proposition that reductionism may be "a correct approach" that has failed to date because of a problem with one or more components associated with its implementation. Are we certain that this is not the case?

One potential explanation for an apparent failure of reductionism is simply the manner in which manpower has been organized (i.e., the research infrastructure) to attack problems of the magnitude of those considered, for example, by the National Research Council panel noted earlier. With some exceptions, the majority of funded research efforts is short term and involve very small teams. Is it possible that the amount of information "to reduce" is too much to produce results that would be characterized as "success" (i.e., does the equivalent of an undercapitalized business venture exist?)? It is further observed that the value of *reduction* is often only demonstrable by the ability to *assemble*. As noted, the prime tool of assembly thus far has been statistical in nature and relatively few causal models have been seriously entertained. With regard to human systems, it is clear that there are many such "items" to assemble and many details to consider if "assembly" — with high fidelity — is to result. Furthermore, it is clear that tools (i.e., special computer software) are needed to make such assembly efforts efficient enough to consider undertaking. Has the data management and analytic power of computers, which have only been readily available in convenient-to-use forms and with required capacities for less than a decade, been fully exploited in a "fair test" of reductionism?

Reductionism is clearly a methodology for understanding "that which is." Drawing by inference from engineering design in general, a close relationship can be observed to systems engineering synthesis methods used to define "that which will be." In artificial systems (as opposed to those which naturally occur, like humans), reverse engineering (basically, a reductionistic method) has been used quite successfully to create functionally equivalent replicas of products. The methodology employed is guided by knowledge of the synthesis process. The implementation of reductionism in human performance modeling can possibly benefit from the reverse mental exercise of "building a human," which may not be so abstract given current efforts and achievements in rehabilitation engineering. In looking toward the future, it is fair to ask, "To what extent have those who have attempted to apply reductionism, or who have dismissed it, attempted to bring to bear methods of synthesis?" The real support for reductionism is success obtained with methods based on this concept; new findings of an extremely encouraging nature are beginning to come forth [Kondraske et al., 1997].

The issue of biological variability is also frequently raised in the context of the desire to develop predictive models of human performance. It is perhaps noteworthy that variability is an issue with which one must deal in the manufacture of man-made products (i.e., particularly with regard to quality assurance in manufacturing), which are designed almost exclusively using causal principles. Taguchi methods [Bendell et al., 1988], a collection of mathematics and concepts, have been used in widespread fashion with remarkable success in modeling and controlling variability in the characteristics of a final product, which is based on the combination of many components, each of which has multiple characteristics, which also range within tolerance bands. Similarity of these circumstances suggests that Taguchi methods may also be valuable in human performance engineering. Investigations of this nature are likely to be a part of future work.

85.3   Measurements

85.3.1   Standardization of Variables and Conditions

Human performance literature is replete with different measures that characterize human performance. Despite the number and magnitude of efforts where human performance is of interest, a standard set of measurement variables has yet to emerge. Relatively loose, descriptive naming conventions are used to identify variables reported leading to the perception of differences when, upon careful inspection, the variables used in two different studies or modeling efforts are the same. In other cases, the names of variables are the same, but conditions under which measures are acquired are different or not reported with enough detail to evaluate if numerical data is comparable (across the reports in question) or not.

The needs of science and engineering are considerably different. Although standardization is generally considered to be desirable in both arenas, the former stresses that only those methods used be accurately reported so that they may be replicated. There has been, unfortunately, little motivation to achieve standardization in any broad sense in the human performance research world. In traditional areas of engineering, it is the marketplace that has forced the development of standards for naming of variables such as performance characteristics of various components (e.g., sensors, actuators, etc.) and for conditions under which these variables are measured. In more recent years, product databases (e.g., for electronic, mechanical, and electromechanical components) and systems level modeling software (i.e., computer-aided design and computer-aided manufacturing), along with the desire to reduce concept-to-production cycle times, have further increased the levels of standardization in these areas.

Despite the somewhat gloomy circumstance at present, there are some signs of potential improvement. An increasing number of research groups are beginning to attack problems of larger scale and interest is growing with regard to the ability to exchange data and models. Several small standards development efforts have surfaced recently in specific areas such as biomechanics to develop, for example, standards for kinematic representation of various body joints. The advent of an increasing number of commercially available measurement tools has also driven a trend to similarity in conventions used in some specific subareas. However, the quest for standardization in measurement that is often heard voiced is still a distant vision. A willingness to suffer the inconvenience of "standardizing" in the short run in exchange for a greater convenience and "power" over the long run must be recognized by a critical mass of researchers, instrument manufacturers, and practitioners before a significant breakthrough can occur. The large number of different professional bodies and societies that may potentially become involved in promulgating an official set of standards will most likely contribute to slow progress in this area.

85.3.2   New Instruments

Instruments to acquire measures of both human structure and performance have been improving at a rapid pace, commensurate with the improvement of base technologies (e.g., sensors, signal conditioning, microprocessors, and desktop computer systems, etc.). Compared to one decade ago, a practitioner or researcher can today assemble a relatively sophisticated and broad-based measurement laboratory with

commercially available devices instead of facing the burden of fabricating his or her own instruments. However, a considerable imbalance still exists across the profile of human performance with regard to commercial availability of necessary tools. This imbalance extends to the profile of tools seen in use in contexts such as rehabilitation and sports training. In particular, devices that measure sensory performance capacities are not nearly as commonplace or well developed as those which measure, for example, strength and range of motion. Likewise, there are few commercially available instruments that measure aspects of neuromotor control in any general sense other than, for example, in a selected task such as maintaining stable posture. The complexity and diversity of higher-level human cognitive processes has also hindered development of measurement instruments in this domain that possess any true degree of commonality in content across products. A wide variety of computer-based test batteries have been proliferating that are more or less implementations of the great number of tests formerly administered in paper–pencil format.

From a practitioner's perspective, prospects for the future are both good and bad. There is some evidence that suppliers of instruments that cover areas of the performance where there has been vigorous competition (e.g., dynamic strength) are experiencing market saturation and uncertainty on the part of consumers regarding what is "the best way" to acquire necessary information. This may force some groups to drop product lines, while others are expressing subtle interests in expanding measurement instrument product lines to fill empty niches. This latter behavior is good in that it will likely increase the scope of measurement tools that is commercially available. However, problems associated with standardization often confuse potential users and this, in general, has slowed progress in the adoption of more objective measurement instruments (compared to subjective methods) in some application areas. This, in turn, has inhibited product providers from taking the risk associated with the introduction of new products.

Compared to the commercial availability of tools that characterize the performance of various human subsystems, instruments that quantify task attributes are much less prevalent. However, the perception that increased emphasis on this area will increase the utility of measures that characterize the human will likely motivate a substantial increase in the number and variety of products available for task characterization. In addition, factors such as the Americans with Disabilities Act (ADA), which encourages worksite evaluations and modifications to facilitate employment of individuals with disabilities and the increase in work-site related injuries such as carpal tunnel syndrome have led to an increased demand for such tools.

There has been a subtle but noticeable developing sense of awareness in the various communities that there is room for more than one kind of instrument to measure a given variable. Thus, debates regarding "the correct approach," which were commonplace, are beginning to be replaced with debates concerned with determining "the best approach for a given situation." A prime example is in the area of strength measurement. Devices range from relatively inexpensive handheld dynamometers that provide rapid measurements and meaningful results with neurologic patients to expensive devices with electric or hydraulic servomotor systems that are more suited, for example, for use in sports medicine contexts. This trend is quite healthy and is likely to spread too though it has been driven by different constraints in different circumstances.

85.3.3 Measuring the Measurements

Reliability and validity have been the keywords associated with characterizing the quality of measures of human structure and performance [Potvin et al., 1985]. Often, these terms are used in a manner that implies that a given test "has it" or "does not have it" (i.e., reliability or validity) when in fact both should be recognized as continuums.

There are traditional, well-known methods used in academic circles to quantify reliability. The result produced implies an interpretation of "how much" reliability a given test has, but there is no corresponding way to determine how much is needed (in the same terms that reliability of a test is measured) so that one could determine if one has "enough." Other aspects of the academic treatment of human performance measurement quality are similarly troublesome with regard to the implications for widespread, general use of measurements. For example, there is an inherent desire (and need) to generalize the results of a given reliability study for a given instrument and, at the same time, a reluctance on the part of those who conduct

such studies to do so in writing. The strictly academic position is that one can *never* generalize a reliability study; that is, it applies only to a situation which is identical to that reported (i.e., that instrument, those subjects, that examiner, that room, that time of day, etc.). So, one may ask, what is the value of reporting any such study? The purely academic view may be the most correct, but strict interpretation is completely useless to a practitioner who needs to reach a conclusion regarding the applicability of a given instrument in given application. The mere fact that reliability studies are reported implies that there is an expectation of generalization to *some* degree. The question is, "How much generalization can one make? This issue has not been adequately addressed from a general methodological standpoint. However, awareness of this issue and the need for improved methods are growing.

What is the general "quality" of measurement available today? The following is offered as a reasonably "healthy" perspective on this complex issue:

1. Technology has advanced to the point where it is now possible to measure many of the basic physical variables employed measurement such as time, force, torque, angles, linear distance, etc. very accurately, with high repeatability, and with high resolution without significant difficulty.

2. Most of the difference on test–retest is due to limitations in how well one can reasonably control procedures and actual variability of the parameter measured — even in the most ideal test subjects.

3. Many studies have been conducted on the reliability of a wide variety of human performance capacities. Some true generalization can be achieved by looking at this body of work as a whole and not from attempts to generalize from only single studies.

4. Across the many types of variables investigated, results of such studies are amazingly quite similar. Basically, they say that if your instrumentation is good, and if you carefully follow established, optimal test administration procedures, then it should be possible to obtain results on repeat testing that are within a range of 5 to 20% of each other. The exact location achieved in this range depends in large part on the particular variable in question (e.g., repeated measures associated with complex tasks with many degrees of freedom such as lifting or gait will differ more than repeated measures of hinge joint range of motions). In addition, the magnitude of the given metric will influence such percentage characterizations since errors are often fixed amounts and independent of the size of the quantity measured. Thus, when measuring quantities with small magnitudes, a larger variability (i.e., more like 20%) should be anticipated. One can usually determine an applicable working value in these straightforward, usable terms (e.g., 5 or 20%) that allow direct comparison to an evaluation of needs by careful review of the relevant reliability studies.

A major point of this discussion is to illustrate that traditional methods used to "measure the measurements" do not adequately communicate the information that current and potential users of measurements often need to know. Traditional methods were valuable to some degree in providing relative indicators within the context of academic group studies. However, methods that are more similar to those used to characterize measurement system performance in physics and other traditional engineering areas (e.g., accuracy, signal-noise-ratio concepts, etc.) are needed. This will help practitioners who must make single measurements on individual subjects (i.e., not populations) to support clinical decision making [Mayer et al., 1997]. As the manner in which measurements are used continues to change to include more of the latter, new interest and methods for quantifying the quality of measurements can be anticipated.

85.4   Databases and Data Modeling

Much research has been conducted to define measurements of human structure and performance and to collect and characterize data as basis to increase understanding and make inferences in different contexts. A wide variety of problems of major medical and other societal significance require the use of such data:

1. For diagnostic purposes (i.e., when assessing measures obtained from a subject-under-test, such as to determine the efficacy of an intervention or treatment in a medical context).

2. for modeling and simulation (e.g., analyses for return-to-work decisions of injured employees, to support job-site modifications for individuals with disabilities, design specifications for virtual reality systems).

3. Status/capacity evaluations (e.g., disability determinations for insurance settlements, worker's compensation claims, etc.).

4. To obtain a better understanding of disease and aging processes (e.g., associated with such problems as falls in elderly populations, etc.).

5. To gain insight into the impact of environmental and occupational factors (e.g., as in epidemiologic studies, such as in lead toxicity or carpal tunnel syndrome).

6. To support ergonomic design of consumer products and living environments for use by the public in general. Despite such a diverse range in needs for basically the same information, there has been little — if any — attempt to organize, integrate, and represent available data in a compact, accessible form that can serve the cited needs.

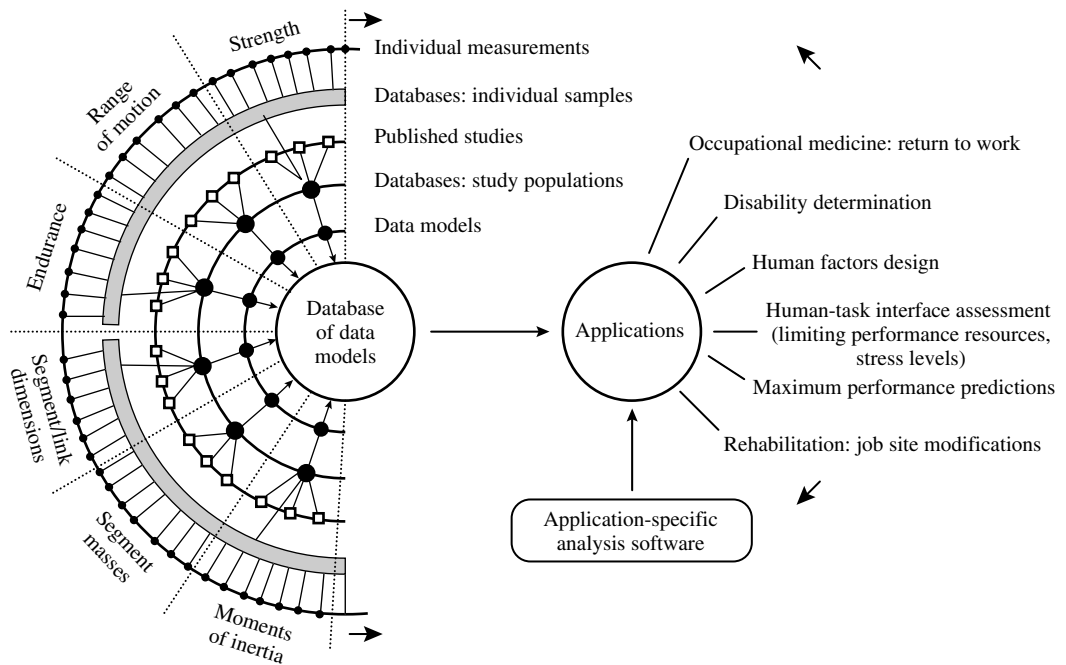
Figure 85.1 illustrates the scope of the general problem and infers a potential approach to integration. At the most basic level, individual measurements for a given variable must be collected and databased. In addition, databases of data from published studies are required to identify specific gaps that limit either analytic functionality or fidelity in the types of tasks, which data must support. Data from the literature is typically available only in summary form, that is, in terms of means and standard deviations for defined populations. Future research is required to define and validate methods for integrating data, for example, from multiple studies to form a single, more robust data model for a given performance or structure parameter. This will involve testing data models developed from databases of individual measures and databases of studies against each other. Development of data warping methods (e.g., to adapt predictions of


FIGURE 85.1 Schematic summary of proposed integration of human structural and performance data to realize compact representations (i.e., parametric data models) to support analyses in multiple application areas. Only several types of performance resources and aspects of structure are represented. The problem of realizing a complete array of such models in a form generally useable by multiple analysis tools is complex.

expected performance levels to subjects of different body sizes and ages) is required to provide models that would be transparent operationally and would allow analyses to proceed in data-limited situations with predictable tradeoffs in fidelity. In many areas, especially with regard to practitioners such as occupational and physical therapists, performance characterization has been viewed only unidimensionally. More multidimensional perspectives are needed for an adequate representation of fidelity [e.g., Kondraske, 2000]. Another major aspect of data modeling therefore involves the development of multivariate models of performance envelopes [Vasta and Kondraske, 1997] for individual human subsystems (e.g., knee flexors, visual information processors, etc.). Such models would support, for example, prediction of available torque production capacity under different specified conditions (e.g., joint angle, speed, etc.). In summary, a basic strategy is required for harvesting the vast amount of previously collected data to obtain compact, accessible representations. Means must be incorporated in this strategy to allow for integration of data from multiple sources and continuous update as new data are collected to enhance fidelity and range of applicability of composite models.

As previously noted, individuals within the human performance community typically adopt a variety of terms or identification schemes for structures and parameters employed in both the execution and communication of their work. The sheer number of parameters and variety of combinations in which they may be required to meet analysis needs may be sufficient to justify a more formal approach [e.g., Kondraske, 1993], thereby facilitating the development of common data structures. The engineering contexts in which data models can be envisioned to be used require more rigor and stability. Computer-based models and analyses beg for codification of terms and parameters (i.e., for databases, etc.). In this regard, these emerging applications bring to light the lack of precision in terminology and confusion in definitions. Moreover, the ability to integrate models and analysis modules developed independently within more narrow subsets of the field to address more complex problems requires standardized notation if for no other reason than for efficiency. Development of a standardized systematic notation is compelling; it is postulated that without such a notation, progress to the next level of sophistication cannot occur.

85.5 Measure or Predict?

The large number of different human performance parameters discussed in this section of the text motivates an often-heard question from practitioners: "What is the most important thing to measure?" Clearly, the interest behind such questions is efficiency; it takes time to measure and practitioners are generally under many pressures to be efficient. Figure 85.2 casts the issue in a way that reflects a hierarchical organization of parameters, where each box can represent many different parameters. It can generally be argued that in many situations the "need to know" exists at multiple levels in this hierarchy. Thus, this presents a somewhat bleak outlook for practitioners that generally results in the use of only the most gross level of measurement (e.g., subjective rating scales) because it is "quick." Significant advancement in applications beyond the research lab demands that this problem be addressed.

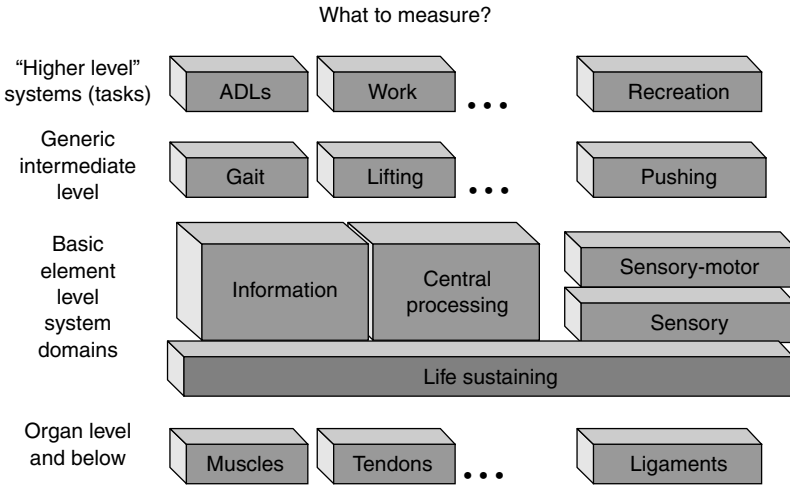
One possibility that could contribute to solving this dilemma is to utilize models to estimate performance at a given hierarchical level using measurements obtained at lower hierarchical levels. It is argued that this may be an optimal long-term strategy. Methods such as Nonlinear Causal Resource Analysis and other discussed in Chapter 156 [Vasta and Kondraske, 2005], and promising results that have been obtained thus far in limited contexts, provide a basis for believing in the promise of this strategy. In the ideal situation, many different laboratories could contribute to building and evaluating high-quality models for many different "higher-level tasks" (emphasizing that "higher level" is a relative concept). Independently developed models could be integrated into computer-based tools available to practitioners. A reasonable set of measurements made at selected levels could then be used with such tools to obtain a huge "added value" by having performance in a number of different higher-level tasks estimated through use of the models. In essence, one would obtain the equivalent of measurements that would otherwise require hours of measurement time in an instant.


FIGURE 85.2 Performance capacity and related parameters are of interest at many hierarchical levels, posing the problem of deciding what to measure in any given application and presenting a problem of complexity for which solutions must be defined.
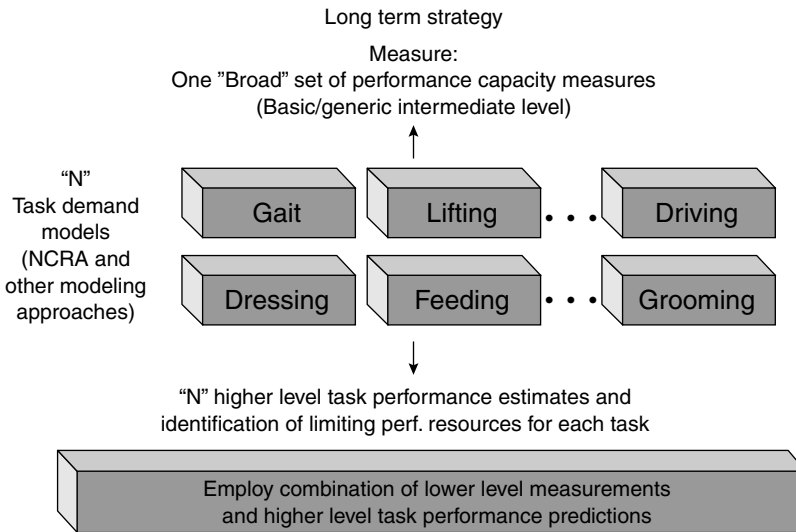

FIGURE 85.3 Summary of a long-term strategy in which models are used to predict performance capacities at higher levels using measurements obtained at lower levels to provide the required scope of information that is generally of interest.

85.6 Summary

A relatively high degree of sophistication currently exists with regard to the science, engineering, and technology of human performance. The field is, nonetheless, relatively young and undergoing natural maturation processes. Remaining needs in terms of both conceptual underpinnings and tools (which are not independent) are enormous. Future progress, however, is likely to be more dependent on collaborative efforts of different types. The magnitude and nature of problems that are at the forefront demand the achievement of agreement among a critical mass of researchers and practitioners. Both the challenges and prospects for the future are significant.

Beneficence, Nonmaleficence, and Medical Technology

Joseph D. Bronzino
Trinity College

86.1 Introduction

Two moral norms have remained relatively *constant across* the various moral codes and oaths that have been formulated for health-care deliverers since the beginnings of Western medicine in classical Greek civilization, namely beneficence — the provision of benefits — and nonmaleficence — the avoidance of doing harm. These norms are traced back to a body of writings from classical antiquity known as the *Hippocratic Corpus*. Although these writings are associated with the name of Hippocrates, the acknowledged founder of Western medicine, medical historians remain uncertain whether any, including the *Hippocratic Oath*, were actually his work. Although portions of the Corpus are believed to have been authored during the sixth century BC, other portions are believed to have been written as late as the beginning of the Christian Era. Medical historians agree, though, that many of the specific moral directives of the *Corpus* represent neither the actual practices nor the moral ideals of the majority of physicians of ancient Greece and Rome.

Nonetheless, the general injunction, "*As to disease, make a habit of two things — to help or, at least, to do no harm,*" was accepted as a fundamental medical ethical norm by at least some ancient physicians. With the decline of Hellenistic civilization and the rise of Christianity, beneficence and nonmaleficence became increasingly accepted as the fundamental principles of morally sound medical practice. Although beneficence and nonmaleficence were regarded merely as concomitant to the craft of medicine in classical Greece and Rome, the emphasis upon compassion and the brotherhood of humankind, central to Christianity, *increasingly made* these norms the only acceptable motives for medical practice. Even today the provision

of benefits and the avoidance of doing harm are stressed just as much in virtually all contemporary Western codes of conduct for health professionals as they were in the oaths and codes that guided the health-care providers of past centuries.

Traditionally, the ethics of medical care have given greater prominence to nonmaleficence than to beneficence. This priority was grounded in the fact that, historically, medicine's capacity to do harm far exceeded its capacity to protect and restore health. Providers of health care possessed many treatments that posed clear and genuine risks to patients but that offered little prospect of benefit. Truly effective therapies were all too rare. In this context, it is surely rational to give substantially higher priority to avoiding harm than to providing benefits.

The advent of modern science changed matters dramatically. Knowledge acquired in laboratories, tested in clinics, and verified by statistical methods has increasingly dictated the practices of medicine. This *ongoing alliance* between medicine and science became a critical source of the plethora of technologies that now pervades medical care. The impressive increases in therapeutic, preventive, and rehabilitative capabilities that these technologies have provided have pushed beneficence to the forefront of medical morality. Some have even gone so far as to hold that the old medical ethic of *"Above all, do no harm"* should be superseded by the new ethic that *"The patient deserves the best."* However, the rapid advances in medical technology capabilities have also produced great uncertainty as to what is most beneficial or least harmful for the patient. In other words, along with increases in ability to be beneficent, medicine's technology has generated much debate about what actually counts as beneficent or nonmaleficent treatment. To illustrate this point, let us turn to several specific moral issues posed by the use of medical technology [Bronzino, 1992; 1999].

86.2   Defining Death: A Moral Dilemma Posed by Medical Technology

Supportive and resuscitative devices, such as the respirator, found in the typical modern intensive care unit provide a useful starting point for illustrating how technology has rendered medical morality more complex and problematic. Devices of this kind allow clinicians to sustain respiration and circulation in patients who have suffered massive brain damage and total permanent loss of brain *function*. These technologies force us to ask: precisely when does a human life end? When is a human being indeed dead? This is not the straightforward factual matter it may appear to be. All of the relevant facts may show that the patient's brain has suffered injury grave enough to destroy its functioning forever. The facts may show that such an individual's circulation and respiration would permanently cease without artificial support. Yet these facts do not determine whether treating such an individual as a corpse is morally appropriate. To know this, it is necessary to know or perhaps to decide on those features of living persons that are essential to their status as "living persons." It is necessary to know or decide which human qualities, if irreparably lost, make an individual identical in all morally relevant respects to a corpse. Once those qualities have been specified, deciding whether total and irreparable loss of brain function constitutes death becomes a straightforward factual matter. Then, it would simply have to be determined if such loss itself deprives the individual of those qualities. If it does, the individual is morally identical to a corpse. If not, then the individual must be regarded and treated as a living person.

The traditional criterion of death has been irreparable cessation of heartbeat, respiration, and blood pressure. This criterion would have been quickly met by anyone suffering massive trauma to the brain prior to the development of modern supportive technology. Such technology allows indefinite artificial maintenance of circulation and respiration and, thus, forestalls what once was an inevitable consequence of severe brain injury. The existence and use of such technology therefore challenges the traditional criterion of death and forces us to consider whether continued respiration and circulation are in themselves sufficient to distinguish a living individual from a corpse. Indeed, total and irreparable loss of brain function, referred to as "brainstem death," "whole brain death," and, simply, "brain death," has been widely

accepted as the legal standard for death. By this standard, an individual in a state of brain death is legally indistinguishable from a corpse and may be legally treated as one even though respiratory and circulatory functions may be sustained through the intervention of technology. Many take this legal standard to be the morally appropriate one, noting that once destruction of the brain stem has occurred, the brain *cannot function* at all, and the body's regulatory mechanisms will fail unless artificially sustained. Thus, mechanical sustenance of an individual in a state of brain death is merely postponement of the inevitable and sustains nothing of the personality, character, or consciousness of the individual. It is merely the mechanical intervention that differentiates such an individual from a corpse and a mechanically ventilated corpse is a corpse nonetheless.

Even with a consensus that brainstem death is death and thus that an individual in such a state is indeed a corpse, hard cases remain. Consider the case of an individual in a persistent vegetative state, the condition known as "neocortical death." Although severe brain injury has been suffered, enough brain function remains to make mechanical *sustenance* of respiration and circulation unnecessary. In a persistent vegetative state, an individual exhibits no purposeful response to external stimuli and no evidence of self-awareness. The eyes may open periodically and the individual may exhibit sleep–wake cycles. Some patients even yawn, make chewing motions, or swallow spontaneously. Unlike the complete unresponsiveness of individuals in a state of brainstem death, a variety of simple and complex responses can be elicited from an individual in a persistent vegetative state. Nonetheless, the chances that such an individual will regain consciousness virtually do not exist. Artificial feeding, kidney dialysis, and the like make it possible to sustain an individual in a state of neocortical death for decades. This sort of condition and the issues it raises were exemplified by the famous case of Karen Ann Quinlan. James Rachels [1986] provided the following description of the situation created by Quinlan's condition:

> In April 1975, this young woman ceased breathing for at least two 15-minute periods, for reasons that were never made clear. As a result, she suffered severe brain damage, and, in the words of the attending physicians, was reduced to a "chronic vegetative state" in which she "no longer had any cognitive function." Accepting the doctors' judgment that there was no hope of recovery, her parents sought permission from the courts to disconnect the respirator that was keeping her alive in the intensive care unit of a New Jersey hospital.
>
> The trial court, and then the Supreme Court of New Jersey, agreed that Karen's respirator could be removed. So it was disconnected. However, the nurse in charge of her care in the Catholic hospital opposed this decision and, anticipating it, had begun to wean her from the respirator so that by the time it was disconnected she could remain alive without it. So Karen did not die. Karen remained alive for ten additional years. In June 1985, she finally died of acute pneumonia. Antibiotics, which would have fought the pneumonia, were not given.

If brainstem death is death, is neocortical death also death? Again, the issue is not a straightforward factual matter. For, it too, is a matter of specifying which features of living individuals distinguish them from corpses and so make treatment of them as corpses morally impermissible. Irreparable cessation of respiration and circulation, the classical criterion for death, would entail that an individual in a persistent vegetative state is not a corpse and so, morally speaking, must not be treated as one. The brainstem death criterion for death would also entail that a person in a state of neocortical death is not yet a corpse. On this criterion, what is crucial is that brain damage be severe enough to cause failure of the body's regulatory mechanisms.

Is an individual in a state of neocortical death any less in possession of the characteristics that distinguish the living from cadavers than one whose respiration and circulation are mechanically maintained? Of course, it is a matter of what the relevant characteristics are, and it is a matter that society must decide. It is not one that can be settled by greater medical information or more powerful medical devices. Until society decides, it will not be clear what would count as beneficent or nonmaleficent treatment of an individual in a state of neocortical death.

86.3   Euthanasia

A long-standing issue in medical ethics, which has been made more pressing by medical technology, is euthanasia, the deliberate termination of an individual's life for the individual's own good. Is such an act ever a permissible use of medical resources? Consider an individual in a persistent vegetative state. On the assumption that such a state is not death, withdrawing life support would be a deliberate termination of a human life. Here a critical issue is whether the quality of a human life can be so low or so great a liability to the individual that deliberately taking action to hasten death or at least not to postpone death is morally defensible. Can the quality of a human life be so low that the value of extending its quantity is totally negated? If so, then Western medicine's traditional commitment to providing benefits and avoiding harm would seem to make cessation of life support a moral requirement in such a case.

Consider the following hypothetical version of the kind of case that actually confronts contemporary patients, their families, health-care workers, and society as a whole. Suppose a middle-aged man suffers a brain hemorrhage and loses consciousness as a result of a ruptured aneurysm. Suppose that he never regains consciousness and is hospitalized in a state of neocortical death, a chronic vegetative state. He is maintained by a surgically implanted gastronomy tube that drips liquid nourishment from a plastic bag directly into his stomach. The care of this individual takes 7 and 1.5 h of nursing time daily and includes (1) shaving, (2) oral hygiene, (3) grooming, (4) attending to his bowels and bladder, and so forth.

Suppose further that his wife undertakes legal action to force his caregivers to end all medical treatment, including nutrition and hydration, so that complete bodily death of her husband will occur. She presents a preponderance of evidence to the court to show that her husband would have wanted this result in these circumstances.

The central moral issue raised by this sort of case is whether the quality of the individual's life is sufficiently compromised by neocortical death to make intentioned termination of that life morally permissible. While alive, he made it clear to both family and friends that he would prefer to be allowed to die rather than be mechanically maintained in a condition of irretrievable loss of consciousness. Deciding whether the judgment in such a case should be allowed requires deciding which capacities and qualities make life worth living, which qualities are sufficient to endow it with value worth sustaining, and whether their absence justifies deliberate termination of a life, at least when this would be the wish of the individual in question. Without this decision the traditional norms of medical ethics, beneficence and nonmaleficence, provide no guidance. Without this decision, it cannot be determined whether termination of life support is a benefit or a harm to the patient.

An even more difficult type of case was provided by the case of Elizabeth Bouvia. Bouvia, who had been a lifelong quadriplegic sufferer of cerebral palsy, was often in pain, completely dependent upon others, and spent all of her time bedridden. Bouvia, after deciding that she did not wish to continue such a life, entered Riverside General Hospital in California. She desired to be kept comfortable while starving to death. Although she remained adamant during her hospitalization, Bouvia's requests were denied by hospital officials with the legal sanction of the courts.

Many who might believe that neocortical death renders the quality of life sufficiently low to justify termination of life support, especially when this agrees with the individual's desires, would not arrive at this conclusion in a case like Bouvia's. Whereas neocortical death completely destroys consciousness and makes purposive interaction with the individual's environment impossible, Bouvia was fully aware and mentally alert. She had previously been married and had even acquired a college education. Televised interviews with her portrayed a very intelligent person who had great skill in presenting persuasive arguments to support her wish not to have her life continued by artificial means of nutrition. Nonetheless, she judged her life to be of such low quality that she should be allowed to choose to deliberately starve to death. Before the existence of life-support technology, maintenance of her life against her will might not have been possible at all and at least would have been far more difficult.

Should Elizabeth Bouvia's judgment have been accepted? Her case is more difficult than the care of a patient in a chronic vegetative state because, unlike such an *individual, she* was able to engage in meaningful

interaction with her environment. Regarding an individual who cannot speak or otherwise meaningfully interact with others as nothing more than living matter, as a "human vegetable," is not especially difficult. But to regard Bouvia this way is not easy. Her awareness, intelligence, mental acuity, and ability to interact with others means that although her life is one of discomfort, indignity, and complete dependence, she is not a mere "human vegetable."

Despite the differences between Bouvia's situation and that of someone in a state of neocortical death, the same issue is posed. Can the quality of an individual's life be so low that deliberate termination is morally justifiable? How that question is answered is a matter of what level of quality of life, if any, is taken to be sufficientK low to justify deliberately acting to end it or deliberately failing*teK"rt"ifd it. If there is such a level, the conclusion that it is not always beneficent or even nonmalefkent to use life-support technology must be accepted.

Another important issue here is respect for individual autonomy. For the cases of Bouvia and the hypothetical instance of neocortical death discussed earlier, both concern voluntary euthanasia, that is, euthanasia voluntarily requested by the patient. A long-standing commitment, vigorously defended by various schools of thought in Western moral philosophy, is the notion that competent adults should be free to conduct their lives as they please as long as they do not impose undeserved harm on others. Does this commitment entail a right to die? Some clearly believe that it does. If one owns anything at all, surely one owns one's life. In the two cases discussed earlier, neither individual sought to impose undeserved harm on anyone else, nor would satisfaction of their wish to die do so. What justification can there be then for not allowing their desires to be fulfilled?

One plausible answer is based upon the very respect of individual autonomy at issue here. A necessary condition, in some views, of respect for autonomy is the willingness to take whatever measures necessary to protect it, including measures that restrict autonomy. An autonomy-respecting reason offered against laws that prevent even competent adults from voluntarily entering lifelong slavery is that such an exercise of autonomy is self-defeating and has the consequence of undermining autonomy altogether. By the same token, an individual who acts to end his own life thereby exercises his autonomy in a manner that places it in jeopardy of permanent loss. Many would regard this as justification for using the coercive force of the law to prevent suicide. This line of thought does not fit the case of an individual in a persistent vegetative state because his/her autonomy has been destroyed by the circumstances that rendered him/her neocortically dead. It does fit Bouvia's case though. Her actions indicate that she is fully competent and her efforts to use medical care to prevent the otherwise inevitable pain of starvation is itself an exercise of her autonomy. Yet, if allowed to succeed, those very efforts would destroy her autonomy as they destroy her. On this reasoning, her case is a perfect instance of limitation of autonomy being justified by respect for autonomy and of one where, even against the wishes of a competent patient, the life-saving power of medical technology should be used.

86.3.1 Active vs. Passive Euthanasia

Discussions of the morality of euthanasia often distinguish active from passive euthanasia in light of the distinction made between killing a person and letting a person die, a distinction that rests upon the difference between an act of commission and an act of omission. When failure to take steps that could effectively forestall death results in an individual's demise, the resultant death is an act of omission and a case of letting a person die. When a death is the result of doing something to hasten the end of a person's life (giving a lethal injection, e.g.) that death is caused by an act of commission and is a case of killing a person. When a person is allowed to die, death is a result of an act of omission, and the motive is the person's own good; the omission is an instance of passive euthanasia. When a person is killed, death is the result of an act of commission, and the motive is the person's own good; the commission is an instance of active euthanasia.

Does the difference between passive and active euthanasia, which reduces to a difference in how death comes about, make any moral difference? It does in the view of the American Medical Association. In a

statement adopted on December 4, 1973, the House of Delegates of the American Medical Association asserted the following [Rachels, 1978]:

> The intentional termination of the life of one human being by another — mercy killing — is contrary to that for which the medical profession stands and is contrary to the policy of the American Medical Association (AMA).
>
> The cessation of extraordinary means to prolong the life of the body where there is irrefutable evidence that biological death is imminent is the decision of the patient and immediate family. The advice of the physician would be freely available to the patient and immediate family.

In response to this position, Rachels [1978; 1986] answered with the following:

> The AMA policy statement isolates the crucial issue very well, the crucial issue is "intentional termination of the life of one human being by another." But after identifying this issue and forbidding "mercy killing," the statement goes on to deny that the cessation of treatment is the intentional termination of a life. This is where the mistake comes in, for what is the cessation of treatment in those circumstances (where the intention is to release the patient from continued suffering), if it is not "the intentional termination of the life of one human being by another?"

As Rachels correctly argued, when steps that could keep an individual alive are omitted for the person's own good, this omission is as much the intentional termination of life as taking active measures to cause death. Not placing a patient on a respirator due to a desire not to prolong suffering is an act intended to end life as much as the administration of a lethal injection. In many instances the main difference between the two cases is that the latter would release the individual from his pain and suffering more quickly than the former. Dying can take time and involve considerable pain even if nothing is done to prolong life. Active killing can be done in a manner that causes death painlessly and instantly. This difference certainly does not render killing, in this context, morally worse than letting a person die. Insofar as the motivation is merciful (as it must be if the case is to be a genuine instance of euthanasia) because the individual is released more quickly from a life that is disvalued than otherwise, the difference between killing and letting one die may provide support for active euthanasia. According to Rachels, the common rejoinder to this argument is the following:

> The important difference between active and passive euthanasia is that in passive euthanasia the doctor does not do anything to bring about the patient's death. The doctor does nothing and the patient dies of whatever ills already afflict him. In active euthanasia, however, the doctor does something to bring about the patient's death: he kills the person. The doctor who gives the patient with cancer a lethal injection has himself caused his patient's death; whereas if he merely ceases treatment, the cancer is the cause of death.

According to this rejoinder, in active euthanasia someone must do something to bring about the patient's death, and in passive euthanasia the patient's death is caused by illness rather than by anyone's conduct. Surely this is mistaken. Suppose a physician deliberately decides not to treat a patient who has a routinely curable ailment and the patient dies. Suppose further that the physician were to attempt to exonerate himself by saying, "I did nothing. The patient's death was the result of illness. I was not the cause of death." Under current legal and moral norms, such a response would have no credibility. As Rachels noted, "*it would be no defense at all for him to insist that he didn't do anything. He would have done something very serious indeed, for he let his patient die.*"

The physician would be blameworthy for the patient's death as surely as if he had actively killed him. If causing death is justifiable under a given set of circumstances, whether it is done by allowing death to occur or by actively causing death is morally irrelevant. If causing someone to die is not justifiable under a given set of circumstances, whether it is done by allowing death to occur or by actively causing death is also morally irrelevant. Accordingly, if voluntary passive euthanasia is morally justifiable in the light of the duty of beneficence, so is voluntary active euthanasia. Indeed, given that the benefit to be achieved is

more quickly realized by means of active euthanasia, it may be preferable to passive euthanasia in some cases.

86.3.2 Involuntary and Nonvoluntary Euthanasia

An act of euthanasia is involuntary if it hastens the individual's death for his own good but against his wishes. To take such a course would be to destroy a life that is valued by its possessor. Therefore, it is no different in any morally relevant way from unjustifiable homicide. There are only two legitimate reasons for hastening an innocent person's death against his will: self-defense and saving the lives of a larger number of other innocent persons. Involuntary euthanasia does not fit either of these justifications. By definition, it is done for the good of the person who is euthanized and for self-defense or saving innocent others. No act that qualifies as involuntary euthanasia can be morally justifiable. Hastening a person's death for his own good is an instance of nonvoluntary euthanasia when the individual is incapable of agreeing or disagreeing. Suppose it is clear that a particular person is sufficiently conscious enough to be regarded a person but cannot make his wishes known. Suppose also that he is suffering from the kind of ailment that, in the eyes of many persons, makes one's life unendurable. Would hastening his death be permissible? It would be if there was substantial evidence that he has given prior consent. This person may have told friends and relatives that under certain circumstances efforts to prolong his life should not be undertaken or continued. He might have recorded his wishes in the form of a Living Will (provided later) or on audio- or videotape. Where this kind of substantial evidence of prior consent exists, the decision to hasten death would be morally justified. A case of this scenario would be virtually a case of voluntary euthanasia.

To My Family, My Physician, My Clergyman, and My Lawyer:

If the time comes when I can no longer take part in decisions about my own future, let this statement stand as testament of my wishes: If there is no reasonable expectation of my recovery from physical or mental disability. I, _____, request that I be allowed to die and not be kept alive by artificial means or heroic measures. Death is as much a reality as birth, growth, maturity, and old age — it is the one certainty. I do not fear death as much as I fear the indiginity of deterioration, dependence, and hopeless pain. I ask that drugs be mercifully administered to me for the terminal suffering even if they hasten the moment of death.

This request is made after careful consideration. Although this document is not legally binding, you who care for me will, I hope, feel morally bound to follow its mandate. I recognize that it places a heavy burden of responsibility upon you, and it is with the intention of sharing that responsibility and of mitigating any feelings of guild that this statement is made.

Signed: _____
Date: _____

Witnessed by:
_____
_____

But what about an instance in which such evidence is not available? Suppose the person at issue has never had the capacity for competent consent or dissent from decisions concerning his life. It simply cannot be known what value the individual would place on his life in his present condition of illness. What should be done is a matter of what is taken to be the greater evil — mistakenly ending the life of an innocent person for whom that life has value or mistakenly forcing him to endure a life that he radically disvalues.

Living Will statutes have been passed in at least 35 states and the District of Columbia. For a Living Will to be a legally binding document, the person signing it must be of sound mind at the time the will is made and shown not to have altered his opinion in the interim between the signing and his illness. The witnesses must not be able to benefit from the individual's death.

86.3.3 Should Voluntary Euthanasia be Legalized?

Recent events have raised the question: "Should voluntary euthanasia be legalized?" Some argue that even if voluntary euthanasia is morally justifiable, it should be prohibited by social policy nonetheless. According to this position, the problem with voluntary euthanasia is its impact on society as a whole. In other words, the overall disutility of allowing voluntary euthanasia outweighs the good it could do for its beneficiaries. The central moral concern is that legalized euthanasia would eventually erode respect for human life and ultimately become a policy under which "socially undesirable" persons would have their deaths hastened (by omission or commission). The experience of Nazi Germany is often cited in support of this fear. What began there as a policy of euthanasia soon became one of eliminating individuals deemed racially inferior or otherwise undesirable. The worry, of course, is that what happened there can happen here as well. If social policy encompasses efforts to hasten the deaths of people, respect for human life in general is eroded and all sorts of abuses become socially acceptable, or so the argument goes.

No one can provide an absolute guarantee that the experience of Nazi Germany would not be repeated, but there is reason to believe that its likelihood is negligible. The medical moral duty of beneficence justifies only voluntary euthanasia. It justifies hastening an individual's death only for the individual's benefit and only with the individual's consent. To kill or refuse to save people judged socially undesirable is not to engage in euthanasia at all and violates the medical moral duty of nonmaleficence. As long as only voluntary euthanasia is legalized, and it is clear that involuntary euthanasia is not and should never be, no degeneration of the policy need occur. Furthermore, such degeneration is not likely to occur if the beneficent nature of voluntary euthanasia is clearly distinguished from the maleficent nature of involuntary euthanasia and any policy of exterminating the socially undesirable. Euthanasia decisions must be scrutinized carefully and regulated strictly to ensure that only voluntary cases occur, and severe penalties must be established to deter abuse.

Ethical Issues Related to Clinical Research

Joseph D. Bronzino
Trinity College

87.1 Introduction

The Medical Device Amendment of 1976, and its updated 1990 version, requires approval from the Food and Drug Administration (FDA) before new devices are marketed and imposes requirements for the clinical investigation of new medical devices on human subjects. Although the statute makes interstate commerce of an unapproved new medical device generally unlawful, it provides an exception to allow interstate distribution of unapproved devices in order to conduct clinical research on human subjects. This investigational device exemption (IDE) can be obtained by submitting to the FDA *"a protocol for the proposed clinical testing of the device, reports of prior investigations of the device, certification that the study has been approved by a local institutional review board, and an assurance that informed consent will be obtained from each human subject"*[Bronzino et al., 1990a, b, 1992, 1995, 1999, 2000].

With respect to clinical research on humans, the FDA differentiates devices into two categories: those devices that pose significant risk and those that involve insignificant risk. Examples of the former include orthopedic implants, artificial hearts, and infusion pumps. Examples of the latter include various dental devices and daily-wear contact lenses. Clinical research involving a significant-risk device cannot begin until an institutional review board (IRB) has approved both the protocol and the informed consent form and the FDA itself has given permission. This requirement to submit an IDE application to the FDA is waived in the case of clinical research where the risk posed is insignificant. In this case, the FDA requires only that approval from an IRB be obtained certifying that the device in question poses only insignificant risk. In deciding whether to approve a proposed clinical investigation of a new device, the IRB and the FDA must determine the following:

1. Risks to subjects are minimized
2. Risks to subjects are reasonable in relation to the anticipated benefit and knowledge to be gained

87-1

3. Subject selection is equitable
4. Informed consent materials and procedures are adequate
5. Provisions for monitoring the study and protecting patient information are acceptable

The FDA allows unapproved medical devices to be used without an IDE in three types of situations: emergency use, treatment use, and feasibility studies. However, in each instance there are specific ethical issues.

87.2 Ethical Issues in Feasibility Studies

Manufacturers seeking more flexibility in conducting investigations in the early developmental stages of a device have submitted a petition to the FDA, requesting that certain limited investigations of significant-risk devices be subject to abbreviated IDE requirements. In a feasibility study, or "limited investigation," human research on a new device would take place at a single institution and involve no more than ten human subjects. *The sponsor of a limited investigation would be required to submit to the FDA a "Notice of Limited Investigation," which would include a description of the device,* a *summary of the purpose of the investigation, the protocol, a sample of the informed consent form, and a certification of approval by the responsible IRB. In certain circumstances, the FDA could require additional information, or require the submission of a full IDE application, or suspend the investigation* [Bronzino et al., 1990a, b].

Investigations of this kind would be limited to certain circumstances *(1) investigations of new uses of existing devices, (2) investigations involving temporary or permanent implants during the early developmental stages, and (3) investigations involving modification of an existing device.*

To comprehend adequately the ethical issues posed by clinical use of unapproved medical devices outside the context of an IDE, it is necessary to utilize the distinctions between practice, nonvalidated practice, and research elaborated in the previous pages. How do those definitions apply to feasibility studies?

Clearly, the goal of this sort of study, that is, generalizable knowledge, makes it an issue of research rather than practice. Manufacturers seek to determine the performance of a device with respect to a particular patient population in an effort to gain information about its efficacy and safety. Such information would be important in determining whether further studies (animal or human) need to be conducted, whether the device needs modification before further use, and the like. The main difference between use of an unapproved device in a feasibility study and use under the terms of an IDE is that the former would be subject to significantly less intensive FDA review than the latter. This, in turn, means that the responsibility for ensuring that use of the device is ethically sound would fall primarily to the IRB of the institution conducting the study.

The ethical concerns posed here are best comprehended with a clear understanding of what justifies research. Ultimately, no matter how much basic research and animal experimentation has been conducted on a given device, the risks and benefits it poses for humans cannot be adequately determined until it is actually used on humans.

The benefits of research on humans lie primarily in the knowledge that is yielded and the generalizable information that is provided. This information is crucial to medical science's ability to generate new modes and instrumentalities of medical treatment that are both efficacious and safe. Accordingly, for necessary but insufficient condition for experimentation to be ethically sound, it must be scientifically sound [Capron, 1978, 1986].

Although scientific soundness is a necessary condition of ethically acceptable research on humans, it is not of and by itself sufficient. Indeed, it is widely recognized that the primary ethical concern posed by such investigation is the use of one person by another to gather knowledge or other benefits where these benefits may only partly or not at all accrue to the first person. In other words, the human subjects of such research are at risk of being mere research resources, as having value only for the ends of the research. Research upon human beings runs the risk of failing to respect them as people. The notion that human

beings are not mere things but entities whose value is inherent rather than wholly instrumental is one of the most widely held norms of contemporary Western society. That is, human beings are not valuable wholly or solely for the uses to which they can be put. They are valuable simply by being the kinds of entities they are. To treat them as such is to respect them as people.

Respecting individuals as people is generally agreed to entail two requirements in the context of bio-medical experimentation. First, since what is most generally taken to make human beings people is their autonomy — their ability to make rational choices for themselves — treating individuals as people means respecting that autonomy. This requirement is met by ensuring that no competent person is subjected to any clinical intervention without first giving voluntary and informed consent. Second, respect for people means that the physician will not subject a human to unnecessary risks and will minimize the risks to patients in required procedures.

Much of the ethical importance of the scrutiny that the FDA imposes upon use of unapproved medical devices in the context of an IDE derives from these two conditions of ethically sound research. The central ethical concern posed by use of medical devices in a feasibility study is that the decreased degree of FDA scrutiny will increase the likelihood that either or both of these conditions will not be met. This possibility may be especially great because many manufacturers of medical devices are, after all, commercial enterprises, companies that are motivated to generate profit and thus to get their devices to market as soon as possible with as little delay and cost as possible. These self-interested motives are likely, at times, to conflict with the requirements of ethically sound research and thus to induce manufacturers to fail (often unwittingly) to meet these requirements. Note that profit is not the only motive that might induce manufacturers to contravene the requirements of ethically sound research on humans. A manufacturer may sincerely believe that its product offers great benefit to many people or to a population of especially needy people and so from this utterly altruistic motive may be prompted to take shortcuts that compromise the quality of the research. Whether the consequences being sought by the research are desired for reasons of self-interest, altruism, or both, the ethical issue is the same. Research subjects may be placed at risk of being treated as mere objects rather than as people.

What about the circumstances under which feasibility studies would take place? Are these not sufficiently different from the "normal" circumstances of research to warrant reduced FDA scrutiny? As noted above, manufacturers seek to be allowed to engage in feasibility studies in order to investigate new uses of existing devices, to investigate temporary or permanent implants during the early developmental stages, and to investigate modifications to an existing device. As also noted earlier, a feasibility study would take place at only one institution and would involve no more than ten human subjects. Given these circumstances, is the sort of research that is likely to occur in a feasibility study less likely to be scientifically unsound or to fail to respect people in the way that normal research upon humans does in "normal" circumstances?

Such research would be done on a very small subject pool, and the harm of any ethical lapses would likely affect fewer people than if such lapses occurred under more usual research circumstances. Yet even if the harm done were limited to a failure to respect the ten or fewer subjects in a single feasibility study, the harm would still be ethically wrong. To wrong ten or fewer people is not as bad as to wrong in the same way more than ten people but it is to engage in wrongdoing nonetheless. In either case, individuals are reduced to the status of mere research resources and their dignity as people is not properly respected.

Are ethical lapses more likely to occur in feasibility studies than in studies that take place within the requirements of an IDE? Although nothing in the preceding discussion provides a definitive answer to this question, it is a question to which the FDA should give high priority in deciding whether to allow this type of exception to IDE use of unapproved medical devices. The answer to this question might be quite different when the device at issue is a temporary or permanent implant than when it is an already approved device being put to new uses or modified in some way. Whatever the con-templated use under the feasibility studies mechanism, the FDA would be ethically advised not to allow this kind of exception to IDE use of an unapproved device without a reasonably high level of certainty that research subjects would not be placed in greater jeopardy than in "normal" research circumstances.

87.3   Ethical Issues in Emergency Use

What about the mechanism for avoiding the rigors of an IDE for emergency use?

The FDA has authorized emergency use where an unapproved device offers the only alternative for saving the life of a dying patient, but an IDE has not yet been approved for the device or its use, or an IDE has been approved but the physician who wishes to use the device is not an investigator under the IDE [Bronzino et al., 1990a, b].

Because the purpose of emergency use of an unapproved device is to attempt to save a dying patient's life under circumstances where no other alternative is at hand, this sort of use constitutes practice rather than research. Its aim is primarily benefit to the patient rather than provision of new and generalizable information. Because this sort of use occurs prior to the completion of clinical investigation of the device, it constitutes a nonvalidated practice. What does this mean?

First, it means that while the aim of the use is to save the life of the patient, the nature and likelihood of the potential benefits and risks engendered by use of the device are far more speculative than in the sort of clinical intervention that constitutes validated practice. In validated practice, thorough investigation, including preclinical studies, animal studies, and studies on human subjects of a device has established its efficacy and safety. The clinician thus has a well-founded basis upon which to judge the benefits and risks such an intervention poses for his patients.

It is precisely this basis that is lacking in the case of a nonvalidated practice. Does this mean that emergency use of an unapproved device should be regarded as immoral? This conclusion would follow only if there were no basis upon which to make an assessment of the risks and benefits of the use of the device. The FDA requires that a physician who engages in emergency use of an unapproved device must *"have substantial reason to believe that benefits will exist. This means that there should be a body of preclinical and animal tests allowing a prediction of the benefit to a human patient."*

Thus, although the benefits and risks posed by use of the device are highly speculative, they are not entirely speculative. Although the only way to validate a new technology is to engage in research on humans at some point, not all nonvalidated technologies are equal. Some will be largely uninvestigated and assessment of their risks and benefits will be wholly or almost wholly speculative. Others will at least have the support of preclinical and animal tests. Although this is not sufficient support for incorporating use of a device into regular clinical practice, it may, however, represent sufficient support to justify use in the desperate circumstances at issue in emergency situations. Desperate circumstances can justify desperate actions, but desperate actions are not the same as reckless actions; hence, the ethical soundness of the FDA's requirement that emergency use be supported by solid results from preclinical and animal tests of the unapproved device.

A second requirement that the FDA imposes on emergency use of unapproved devices is the expectation that physicians *"exercise reasonable foresight with respect to potential emergencies and make appropriate arrangements under the IDE procedures. Thus, a physician should not 'create' an emergency in order to circumvent IRB review and avoid requesting the sponsor's authorization of the unapproved use of a device."*

From a Kantian point of view, which is concerned with protecting the dignity of people, it is a particularly important requirement to create an emergency in order to avoid FDA regulations which prevent the patient being treated as a mere resource whose value is reducible to a service of the clinician's goals. Hence, the FDA is quite correct to insist that emergencies are circumstances that reasonable foresight would not anticipate.

Also especially important here is the nature of the patient's consent. Individuals facing death are especially vulnerable to exploitation and deserve greater measures for their protection than might otherwise be necessary. One such measure would be to ensure that the patient, or his legitimate proxy, knows the highly speculative nature of the intervention being offered. That is, to ensure that it is clearly understood that the clinician's estimation of the intervention's risks and benefits is far less solidly grounded than in the case of validated practices. The patient's consent must be based upon an awareness that the particular device has not undergone complete and rigorous testing on humans and that estimations of its potential

are based wholly upon preclinical and animal studies. Above all the patient must not be lead to believe that there is complete understanding of the risks and benefits of the intervention. Another important point here is to ensure that the patient is aware that the options he is facing are not simply life or death but may include life of a severely impaired quality, and therefore that even if his life is saved, it may be a life of significant impairment. Although desperate circumstance may legitimize desperate actions, the decision to take such actions must rest upon the informed and voluntary consent of the patient, especially when he/she is an especially vulnerable patient.

It is important here for a clinician involved in emergency use of an unapproved device to recognize that these activities constitute a form of nonvalidated practice and not research. Hence, the primary obligation is to the well-being of the patient. The patient enters into the relationship with the clinician with the same trust that accompanies any normal clinical situation. To treat this sort of intervention as if it were an instance of research and hence justified by its benefits to science and society would be to abuse this trust.

87.4   Ethical Issues in Treatment Use

The FDA has adopted regulations authorizing the use of investigational new drugs in certain circumstances where a patient has not responded to approved therapies. This "treatment use" of unapproved new drugs is not limited to life-threatening emergency situations, but rather is also available to treat "serious" diseases or conditions.

The FDA has not approved treatment use of unapproved medical devices, but it is possible that a manufacturer could obtain such approval by establishing a specific protocol for this kind of use within the context of an IDE.

The criteria for treatment use of unapproved medical devices would be similar to criteria for treatment use of investigational drugs (1) the device is intended to treat a serious or life-threatening disease or condition, (2) there is no comparable or satisfactory alternative product available to treat that condition, (3) the device is under an IDE, or has received an IDE exemption, or all clinical trials have been completed and the device is awaiting approval, and (4) the sponsor is actively pursuing marketing approval of the investigational device. The treatment use protocol would be submitted as part of the IDE, and would describe the intended use of the device, the rationale for use of the device, the available alternatives and why the investigational product is preferred, the criteria for patient selection, the measures to monitor the use of the device and to minimize risk, and technical information that is relevant to the safety and effectiveness of the device for the intended treatment purpose.

Were the FDA to approve treatment use of unapproved medical devices, what ethical issues would be posed? First, because such use is premised on the failure of validated interventions to improve the patient's condition adequately, it is a form of practice rather than research. Second, since the device involved in an instance of treatment use is unapproved, such use would constitute nonvalidated practice. As such, like emergency use, it should be subject to the FDA's requirement that prior preclinical tests and animal studies have been conducted that provide substantial reason to believe that patient benefit will result. As with emergency use, although this does not prevent assessment of the intervention's benefits and risks from being highly speculative, it does prevent assessment from being totally speculative. Here too, although desperate circumstances can justify desperate action, they do not justify reckless action. Unlike emergency use, the circumstances of treatment use involve serious impairment of health rather than the threat of premature death. Hence, an issue that must be considered is how serious such impairment must be to justify resorting to an intervention whose risks and benefits have not been solidly established.

In cases of emergency use, the FDA requires that physicians not use this exception to an IDE to avoid requirements that would otherwise be in place. This particular requirement would be obviated in instances of treatment use by the requirement that a protocol for such use be previously addressed within an IDE.

As with emergency use of unapproved devices, the patients involved in treatment use would be particularly vulnerable patients. Although they are not dying, they are facing serious medical conditions and are

thereby likely to be less able to avoid exploitation than patients under less desperate circumstances. Consequently, it is especially important that patients be informed of the speculative nature of the intervention and of the possibility that treatment may result in little or no benefit to them.

87.5   The Safe Medical Devices Act

On November 28, 1991, the Safe Medical Devices Act of 1990 (Public Law 101-629) went into effect. This regulation requires a wide range of health-care institutions, including hospitals, ambulatory-surgical facilities, nursing homes, and outpatient treatment facilities, to report information that "reasonably suggests" the likelihood that the death, serious injury, or serious illness of a patient at that facility has been caused or contributed to by a medical device. When a death is device related, a report must be made directly to the FDA *and* to the manufacturer of the device. When a serious illness or injury is device related, a report must be made to the manufacturer *or* to the FDA in cases where the manufacturer is not known. In addition, summaries of previously submitted reports must be submitted to the FDA on a semiannual basis. Prior to this regulation, such reporting was voluntary. This new regulation was designed to enhance the FDA's ability to quickly learn about problems related to medical devices. It also supplements the medical device reporting (MDR) regulations promulgated in 1984. MDR regulations require that reports of device-related deaths and serious injuries be submitted to the FDA by manufacturers and importers. The new law extends this requirement to users of medical devices along with manufacturers and importers. This act represents a significant step forward in protecting patients exposed to medical devices.
