The Biomedical Engineering Handbook
Third Edition

Biomedical Engineering Fundamentals

The Electrical Engineering Handbook Series

Series Editor
Richard C. Dorf
University of California, Davis

Titles Included in the Series

The Handbook of Ad Hoc Wireless Networks, Mohammad Ilyas
The Avionics Handbook, Cary R. Spitzer
The Biomedical Engineering Handbook, Third Edition, Joseph D. Bronzino
The Circuits and Filters Handbook, Second Edition, Wai-Kai Chen
The Communications Handbook, Second Edition, Jerry Gibson
The Computer Engineering Handbook, Vojin G. Oklobdzija
The Control Handbook, William S. Levine
The CRC Handbook of Engineering Tables, Richard C. Dorf
The Digital Signal Processing Handbook, Vijay K. Madisetti and Douglas Williams
The Electrical Engineering Handbook, Third Edition, Richard C. Dorf
The Electric Power Engineering Handbook, Leo L. Grigsby
The Electronics Handbook, Second Edition, Jerry C. Whitaker
The Engineering Handbook, Third Edition, Richard C. Dorf
The Handbook of Formulas and Tables for Signal Processing, Alexander D. Poularikas
The Handbook of Nanoscience, Engineering, and Technology, William A. Goddard, III,
   Donald W. Brenner, Sergey E. Lyshevski, and Gerald J. Iafrate
The Handbook of Optical Communication Networks, Mohammad Ilyas and
   Hussein T. Mouftah
The Industrial Electronics Handbook, J. David Irwin
The Measurement, Instrumentation, and Sensors Handbook, John G. Webster
The Mechanical Systems Design Handbook, Osita D.I. Nwokah and Yidirim Hurmuzlu
The Mechatronics Handbook, Robert H. Bishop
The Mobile Communications Handbook, Second Edition, Jerry D. Gibson
The Ocean Engineering Handbook, Ferial El-Hawary
The RF and Microwave Handbook, Mike Golio
The Technology Management Handbook, Richard C. Dorf
The Transforms and Applications Handbook, Second Edition, Alexander D. Poularikas
The VLSI Handbook, Wai-Kai Chen

Introduction and Preface

During the past five years since the publication of the Second Edition — a two-volume set — of the *Biomedical Engineering Handbook*, the field of biomedical engineering has continued to evolve and expand. As a result, this Third Edition consists of a three-volume set, which has been significantly modified to reflect the state-of-the-field knowledge and applications in this important discipline. More specifically, this Third Edition contains a number of completely new sections, including:

- Molecular Biology
- Bionanotechnology
- Bioinformatics
- Neuroengineering
- Infrared Imaging

as well as a new section on ethics.

In addition, all of the sections that have appeared in the first and second editions have been significantly revised. Therefore, this Third Edition presents an excellent summary of the status of knowledge and activities of biomedical engineers in the beginning of the 21st century.

As such, it can serve as an excellent reference for individuals interested not only in a review of fundamental physiology, but also in quickly being brought up to speed in certain areas of biomedical engineering research. It can serve as an excellent textbook for students in areas where traditional textbooks have not yet been developed and as an excellent review of the major areas of activity in each biomedical engineering subdiscipline, such as biomechanics, biomaterials, bioinstrumentation, medical imaging, etc. Finally, it can serve as the "bible" for practicing biomedical engineering professionals by covering such topics as historical perspective of medical technology, the role of professional societies, the ethical issues associated with medical technology, and the FDA process.

Biomedical engineering is now an important vital interdisciplinary field. Biomedical engineers are involved in virtually all aspects of developing new medical technology. They are involved in the design, development, and utilization of materials, devices (such as pacemakers, lithotripsy, etc.) and techniques (such as signal processing, artificial intelligence, etc.) for clinical research and use; and serve as members of the healthcare delivery team (clinical engineering, medical informatics, rehabilitation engineering, etc.) seeking new solutions for difficult healthcare problems confronting our society. To meet the needs of this diverse body of biomedical engineers, this handbook provides a central core of knowledge in those fields encompassed by the discipline. However, before presenting this detailed information, it is important to provide a sense of the evolution of the modern healthcare system and identify the diverse activities biomedical engineers perform to assist in the diagnosis and treatment of patients.

Evolution of the Modern Healthcare System

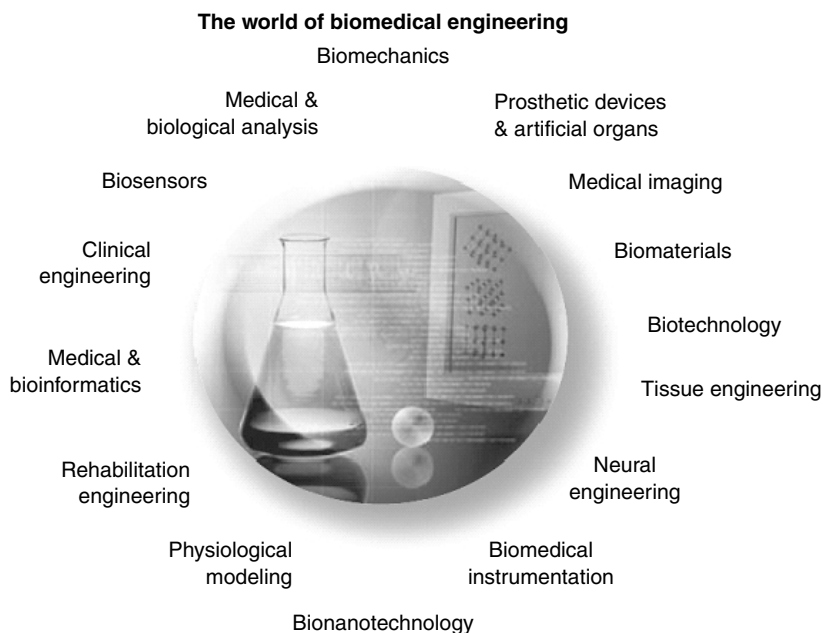
Before 1900, medicine had little to offer the average citizen, since its resources consisted mainly of the physician, his education, and his "little black bag." In general, physicians seemed to be in short supply, but the shortage had rather different causes than the current crisis in the availability of healthcare professionals. Although the costs of obtaining medical training were relatively low, the demand for doctors' services also was very small, since many of the services provided by the physician also could be obtained from experienced amateurs in the community. The home was typically the site for treatment and recuperation, and relatives and neighbors constituted an able and willing nursing staff. Babies were delivered by midwives, and those illnesses not cured by home remedies were left to run their natural, albeit frequently fatal, course. The contrast with contemporary healthcare practices, in which specialized physicians and nurses located within the hospital provide critical diagnostic and treatment services, is dramatic.

The changes that have occurred within medical science originated in the rapid developments that took place in the applied sciences (chemistry, physics, engineering, microbiology, physiology, pharmacology, etc.) at the turn of the century. This process of development was characterized by intense interdisciplinary cross-fertilization, which provided an environment in which medical research was able to take giant strides in developing techniques for the diagnosis and treatment of disease. For example, in 1903, Willem Einthoven, a Dutch physiologist, devised the first electrocardiograph to measure the electrical activity of the heart. In applying discoveries in the physical sciences to the analysis of the biologic process, he initiated a new age in both cardiovascular medicine and electrical measurement techniques.

New discoveries in medical sciences followed one another like intermediates in a chain reaction. However, the most significant innovation for clinical medicine was the development of x-rays. These "new kinds of rays," as their discoverer W.K. Roentgen described them in 1895, opened the "inner man" to medical inspection. Initially, x-rays were used to diagnose bone fractures and dislocations, and in the process, x-ray machines became commonplace in most urban hospitals. Separate departments of radiology were established, and their influence spread to other departments throughout the hospital. By the 1930s, x-ray visualization of practically all organ systems of the body had been made possible through the use of barium salts and a wide variety of radiopaque materials.

X-ray technology gave physicians a powerful tool that, for the first time, permitted accurate diagnosis of a wide variety of diseases and injuries. Moreover, since x-ray machines were too cumbersome and expensive for local doctors and clinics, they had to be placed in healthcare centers or hospitals. Once there, x-ray technology essentially triggered the transformation of the hospital from a passive receptacle for the sick to an active curative institution for all members of society.

For economic reasons, the centralization of healthcare services became essential because of many other important technological innovations appearing on the medical scene. However, hospitals remained institutions to dread, and it was not until the introduction of sulfanilamide in the mid-1930s and penicillin in the early 1940s that the main danger of hospitalization, that is, cross-infection among patients, was significantly reduced. With these new drugs in their arsenals, surgeons were able to perform their operations without prohibitive morbidity and mortality due to infection. Furthermore, even though the different blood groups and their incompatibility were discovered in 1900 and sodium citrate was used in 1913 to prevent clotting, full development of blood banks was not practical until the 1930s, when technology provided adequate refrigeration. Until that time, "fresh" donors were bled and the blood transfused while it was still warm.

Once these surgical suites were established, the employment of specifically designed pieces of medical technology assisted in further advancing the development of complex surgical procedures. For example, the Drinker respirator was introduced in 1927 and the first heart–lung bypass in 1939. By the 1940s, medical procedures heavily dependent on medical technology, such as cardiac catheterization and angiography (the use of a cannula threaded through an arm vein and into the heart with the injection of radiopaque dye) for the x-ray visualization of congenital and acquired heart disease (mainly valve disorders due to rheumatic fever) became possible, and a new era of cardiac and vascular surgery was established.


Following World War II, technological advances were spurred on by efforts to develop superior weapon systems and establish habitats in space and on the ocean floor. As a by-product of these efforts, the development of medical devices accelerated and the medical profession benefited greatly from this rapid surge of technological finds. Consider the following examples:

1. Advances in solid-state electronics made it possible to map the subtle behavior of the fundamental unit of the central nervous system — the neuron — as well as to monitor the various physiological parameters, such as the electrocardiogram, of patients in intensive care units.
2. New prosthetic devices became a goal of engineers involved in providing the disabled with tools to improve their quality of life.
3. Nuclear medicine — an outgrowth of the atomic age — emerged as a powerful and effective approach in detecting and treating specific physiologic abnormalities.
4. Diagnostic ultrasound based on sonar technology became so widely accepted that ultrasonic studies are now part of the routine diagnostic workup in many medical specialties.
5. "Spare parts" surgery also became commonplace. Technologists were encouraged to provide cardiac assist devices, such as artificial heart valves and artificial blood vessels, and the artificial heart program was launched to develop a replacement for a defective or diseased human heart.
6. Advances in materials have made the development of disposable medical devices, such as needles and thermometers, as well as implantable drug delivery systems, a reality.
7. Computers similar to those developed to control the flight plans of the *Apollo* capsule were used to store, process, and cross-check medical records, to monitor patient status in intensive care units, and to provide sophisticated statistical diagnoses of potential diseases correlated with specific sets of patient symptoms.
8. Development of the first computer-based medical instrument, the computerized axial tomography scanner, revolutionized clinical approaches to noninvasive diagnostic imaging procedures, which now include magnetic resonance imaging and positron emission tomography as well.
9. A wide variety of new cardiovascular technologies including implantable defibrillators and chemically treated stents were developed.
10. Neuronal pacing systems were used to detect and prevent epileptic seizures.
11. Artificial organs and tissue have been created.
12. The completion of the genome project has stimulated the search for new biological markers and personalized medicine.

The impact of these discoveries and many others has been profound. The healthcare system of today consists of technologically sophisticated clinical staff operating primarily in modern hospitals designed to accommodate the new medical technology. This evolutionary process continues, with advances in the physical sciences such as materials and nanotechnology, and in the life sciences such as molecular biology, the genome project and artificial organs. These advances have altered and will continue to alter the very nature of the healthcare delivery system itself.

Biomedical Engineering: A Definition

Bioengineering is usually defined as a basic research-oriented activity closely related to biotechnology and genetic engineering, that is, the modification of animal or plant cells, or parts of cells, to improve plants or animals or to develop new microorganisms for beneficial ends. In the food industry, for example, this has meant the improvement of strains of yeast for fermentation. In agriculture, bioengineers may be concerned with the improvement of crop yields by treatment of plants with organisms to reduce frost damage. It is clear that bioengineers of the future will have a tremendous impact on the qualities of human life.

FIGURE 1   The world of biomedical engineering.

The potential of this specialty is difficult to imagine. Consider the following activities of bioengineers:

- Development of improved species of plants and animals for food production
- Invention of new medical diagnostic tests for diseases
- Production of synthetic vaccines from clone cells
- Bioenvironmental engineering to protect human, animal, and plant life from toxicants and pollutants
- Study of protein–surface interactions
- Modeling of the growth kinetics of yeast and hybridoma cells
- Research in immobilized enzyme technology
- Development of therapeutic proteins and monoclonal antibodies

Biomedical engineers, on the other hand, apply electrical, mechanical, chemical, optical, and other engineering principles to understand, modify, or control biologic (i.e., human and animal) systems, as well as design and manufacture products that can monitor physiologic functions and assist in the diagnosis and treatment of patients. When biomedical engineers work within a hospital or clinic, they are more properly called clinical engineers.

Activities of Biomedical Engineers

The breadth of activity of biomedical engineers is now significant. The field has moved from being concerned primarily with the development of medical instruments in the 1950s and 1960s to include a more wide-ranging set of activities. As illustrated below, the field of biomedical engineering now includes many new career areas (see Figure 1), each of which is presented in this handbook. These areas include:

- Application of engineering system analysis (physiologic modeling, simulation, and control) to biologic problems
- Detection, measurement, and monitoring of physiologic signals (i.e., biosensors and biomedical instrumentation)

- Diagnostic interpretation via signal-processing techniques of bioelectric data
- Therapeutic and rehabilitation procedures and devices (rehabilitation engineering)
- Devices for replacement or augmentation of bodily functions (*artificial organs*)
- Computer analysis of patient-related data and clinical decision-making (i.e., medical informatics and artificial intelligence)
- Medical imaging, that is, the graphic display of anatomic detail or physiologic function
- The creation of new biologic products (i.e., *biotechnology* and *tissue engineering*)
- The development of new materials to be used within the body (biomaterials)

Typical pursuits of biomedical engineers, therefore, include:

- Research in new materials for implanted artificial organs
- Development of new diagnostic instruments for blood analysis
- Computer modeling of the function of the human heart
- Writing software for analysis of medical research data
- Analysis of medical device hazards for safety and efficacy
- Development of new diagnostic imaging systems
- Design of telemetry systems for patient monitoring
- Design of biomedical sensors for measurement of human physiologic systems variables
- Development of expert systems for diagnosis of disease
- Design of closed-loop control systems for drug administration
- Modeling of the physiological systems of the human body
- Design of instrumentation for sports medicine
- Development of new dental materials
- Design of communication aids for the handicapped
- Study of pulmonary fluid dynamics
- Study of the biomechanics of the human body
- Development of material to be used as replacement for human skin

Biomedical engineering, then, is an interdisciplinary branch of engineering that ranges from theoretical, nonexperimental undertakings to state-of-the-art applications. It can encompass research, development, implementation, and operation. Accordingly, like medical practice itself, it is unlikely that any single person can acquire expertise that encompasses the entire field. Yet, because of the interdisciplinary nature of this activity, there is considerable interplay and overlapping of interest and effort between them. For example, biomedical engineers engaged in the development of biosensors may interact with those interested in prosthetic devices to develop a means to detect and use the same bioelectric signal to power a prosthetic device. Those engaged in automating the clinical chemistry laboratory may collaborate with those developing expert systems to assist clinicians in making decisions based on specific laboratory data. The possibilities are endless.

Perhaps a greater potential benefit occurring from the use of biomedical engineering is identification of the problems and needs of our present healthcare system that can be solved using existing engineering technology and systems methodology. Consequently, the field of biomedical engineering offers hope in the continuing battle to provide high-quality care at a reasonable cost. If properly directed toward solving problems related to preventive medical approaches, ambulatory care services, and the like, biomedical engineers can provide the tools and techniques to make our healthcare system more effective and efficient; and in the process, improve the quality of life for all.

Joseph D. Bronzino
Editor-in-Chief

Editor-in-Chief

Joseph D. Bronzino received the B.S.E.E. degree from Worcester Polytechnic Institute, Worcester, MA, in 1959, the M.S.E.E. degree from the Naval Postgraduate School, Monterey, CA, in 1961, and the Ph.D. degree in electrical engineering from Worcester Polytechnic Institute in 1968. He is presently the Vernon Roosa Professor of Applied Science, an endowed chair at Trinity College, Hartford, CT and President of the Biomedical Engineering Alliance and Consortium (BEACON), which is a nonprofit organization consisting of academic and medical institutions as well as corporations dedicated to the development and commercialization of new medical technologies (for details visit www.beaconalliance.org).

He is the author of over 200 articles and 11 books including the following: *Technology for Patient Care* (C.V. Mosby, 1977), *Computer Applications for Patient Care* (Addison-Wesley, 1982), *Biomedical Engineering: Basic Concepts and Instrumentation* (PWS Publishing Co., 1986), *Expert Systems: Basic Concepts* (Research Foundation of State University of New York, 1989), *Medical Technology and Society: An Interdisciplinary Perspective* (MIT Press and McGraw-Hill, 1990), *Management of Medical Technology* (Butterworth/Heinemann, 1992), *The Biomedical Engineering Handbook* (CRC Press, 1st ed., 1995; 2nd ed., 2000; Taylor & Francis, 3rd ed., 2005), *Introduction to Biomedical Engineering* (Academic Press, 1st ed., 1999; 2nd ed., 2005).

Dr. Bronzino is a fellow of IEEE and the American Institute of Medical and Biological Engineering (AIMBE), an honorary member of the Italian Society of Experimental Biology, past chairman of the Biomedical Engineering Division of the American Society for Engineering Education (ASEE), a charter member and presently vice president of the Connecticut Academy of Science and Engineering (CASE), a charter member of the American College of Clinical Engineering (ACCE), and the Association for the Advancement of Medical Instrumentation (AAMI), past president of the IEEE-Engineering in Medicine and Biology Society (EMBS), past chairman of the IEEE Health Care Engineering Policy Committee (HCEPC), past chairman of the IEEE Technical Policy Council in Washington, DC, and presently Editor-in-Chief of Elsevier's BME Book Series and Taylor & Francis' *Biomedical Engineering Handbook.*

Dr. Bronzino is also the recipient of the Millennium Award from IEEE/EMBS in 2000 and the Goddard Award from Worcester Polytechnic Institute for Professional Achievement in June 2004.

Physiologic Systems

Herbert F. Voigt
Boston University

THE *BIOMEDICAL ENGINEERING HANDBOOK* is an ambitious project to identify and catalogue the many intersections of engineering and the life sciences. The Physiologic Systems section is an attempt to describe a number of systems that have benefited from joining engineering and physiologic approaches to understanding. The "systems approach" to biology and physiology has been one of engineering's gifts to the investigator of life's secrets. There are literally endless biological and physiological systems; however, those still await careful engineering analysis and modeling. Much has been done, but so much more remains to be done.

I-1

As Robert Plonsey so aptly put it, "While the application of engineering expertise to the life sciences requires an obvious knowledge of contemporary technical theory and its applications, it also demands an adequate knowledge and understanding of relevant medicine and biology. It has been argued that the most challenging part of finding engineering solutions to problems lies in the formulation of the solution in engineering terms. In Biomedical engineering, this usually demands a full understanding of the life science substrates as well as the quantitative methodologies."

In this section, careful selections of systems that have benefited from a system's approach are offered. Because of space limitations, we are unable to offer more. We trust that these selections will provide information that will enhance the sections that follow.

An Outline of Cardiovascular Structure and Function

Daniel J. Schneck
Virginia Polytechnic Institute and State University

Because not every cell in the human body is near enough to the environment to easily exchange with it's mass (including nutrients, oxygen, carbon dioxide, and the waste products of metabolism), energy (including heat), and momentum, the physiologic system is endowed with a major highway network — organized to make available thousands of miles of access tubing for the transport to and from a different neighborhood (on the order of 10 μm or less) of any given cell whatever it needs to sustain life. This highway network, called the *cardiovascular system*, includes a pumping station, the heart; a working fluid, blood; a complex branching configuration of distributing and collecting pipes and channels, blood vessels; and a sophisticated means for both intrinsic (inherent) and extrinsic (autonomic and endocrine) control.

1.1   The Working Fluid: Blood

Accounting for about $8 \pm 1\%$ of total body weight, averaging 5200 ml, blood is a complex, heterogeneous suspension of formed elements — the *blood cells*, or *hematocytes* — suspended in a continuous, straw-colored fluid called *plasma*. Nominally, the composite fluid has a mass density of 1.057 ± 0.007 g/cm^3, and it is three to six times as viscous as water. The hematocytes (Table 1.1) include three basic types of cells: red blood cells (erythrocytes, totalling nearly 95% of the formed elements), white blood cells (leukocytes, averaging <0.15% of all hematocytes), and platelets (thrombocytes, on the order of 5% of all blood cells). Hematocytes are all derived in the active ("red") bone marrow (about 1500 g) of adults from undifferentiated **stem cells** called *hemocytoblasts*, and all reach ultimate maturity via a process called *hematocytopoiesis*.

1-1

TABLE 1.1 Hematocytes

Cell type	Number cells per mm^3 blood[a]	Corpuscular diameter (μm)[a]	Corpuscular surface area (μm^2)[a]	Corpuscular volume (μm^3)[a]	Mass density (g/cm^3)[a]	Percent water[a]	Percent protein[a]	Percent extractives[a,b]
Erythrocytes (red blood cells)	4.2–5.4 × 10^6 ♀	6–9 (7.5)	120–163 (140)	80–100 (90)	1.089–1.100 (1.098)	64–68 (66)	29–35 (32)	1.6–2.8 (2)
	4.6–6.2 × 10^6 ♂	Thickness 1.84–2.84						
	(5 × 10^6)	"Neck" 0.81–1.44						
Leukocytes (white blood cells)	4,000–11,000 (7,500)	6–10	300–625	160–450	1.055–1.085	52–60 (56)	30–36 (33)	4–18 (11)
Granulocytes								
Neutrophils: 55–70% WBC (65%)	2–6 × 10^3 (4,875)	8–8.6 (8.3)	422–511 (467)	268–333 (300)	1.075–1.085 (1.080)	—	—	—
Eosinophils: 1–4% WBC (3%)	45–480 (225)	8–9 (8.5)	422–560 (491)	268–382 (321)	1.075–1.085 (1.080)	—	—	—
Basophils: 0–1.5% WBC (1%)	0–113 (75)	7.7–8.5 (8.1)	391–500 (445)	239–321 (278)	1.075–1.085 (1.080)	—	—	—
Agranulocytes								
Lymphocytes: 20–35% WBC (25%)	1,000–4,800 (1875)	6.75–7.34 (7.06)	300–372 (336)	161–207 (184)	1.055–1.070 (1.063)	—	—	—
Monocytes: 3–8% WBC (6%)	100–800 (450)	9–9.5 (9.25)	534–624 (579)	382–449 (414)	1.055–1.070 (1.063)	—	—	—
Thrombocytes (platelets)	(1.4 ♂), 2.14 (♀) –5 × 10^5 (2.675 × 10^5)	2–4 (3) Thickness 0.9–1.3	16–35 (25)	5–10 (7.5)	1.04–1.06 (1.05)	60–68 (64)	32–40 (36)	Neg.

[a] Normal physiologic range, with "typical" value in parentheses.
[b] Extractives include mostly minerals (ash), carbohydrates, and fats (lipids).

The primary function of erythrocytes is to aid in the transport of blood gases — about 30 to 34% (by weight) of each cell consisting of the oxygen- and carbon dioxide-carrying protein hemoglobin ($64,000 \leq MW \leq 68,000$) and a small portion of the cell containing the enzyme carbonic anhydrase, which catalyzes the reversible formation of carbonic acid from carbon dioxide and water. The primary function of leukocytes is to endow the human body with the ability to identify and dispose of foreign substances such as infectious organisms) that do not belong there — agranulocytes (lymphocytes and monocytes) essentially doing the "identifying" and granulocytes (neutrophils, basophils, and eosinophils) essentially doing the "disposing." The primary function of platelets is to participate in the blood clotting process.

Removal of all hematocytes from blood centrifugation or other separating techniques leaves behind the aqueous (91% water by weight, 94.8% water by volume), saline (0.15 N) suspending medium called *plasma* — which has an average mass density of 1.035 ± 0.005 g/cm^3 and a viscosity $1\frac{1}{2}$ to 2 times that of water. Some 6.5 to 8% by weight of plasma consists of the plasma proteins, of which there are three major types — albumin, the globulins, and fibrinogen — and several of lesser prominence (Table 1.2).

The primary functions of albumin are to help maintain the osmotic (oncotic) transmural pressure differential that ensures proper mass exchange between blood and interstitial fluid at the capillary level and to serve as a transport carrier molecule for several hormones and other small biochemical constituents (such as some metal ions). The primary function of the globulin class of proteins is to act as transport carrier molecules (mostly of the α and β class) for large biochemical substances, such as fats (lipoproteins) and certain carbohydrates (muco- and glycoproteins) and heavy metals (mineraloproteins), and to work together with leukocytes in the body's immune system. The latter function is primarily the responsibility of the γ class of immunoglobulins, which have antibody activity. The primary function of fibrinogen is to work with thrombocytes in the formation of a blood clot — a process also aided by one of the most abundant of the lesser proteins, prothrombin ($MW \simeq 62,000$).

Of the remaining 2% or so (by weight) of plasma, just under half (0.95%, or 983 mg/dl plasma) consists of minerals (inorganic ash), trace elements, and electrolytes, mostly the cations sodium, potassium, calcium, and magnesium and the anions chlorine, bicarbonate, phosphate, and sulfate — the latter three helping as buffers to maintain the fluid at a slightly alkaline pH between 7.35 and 7.45 (average 7.4). What is left, about 1087 mg of material per deciliter of plasma, includes (1) mainly (0.8% by weight) three major types of fat, that is, cholesterol (in a free and esterified form), phospholipid (a major ingredient of cell membranes), and triglyceride, with lesser amounts of the fat-soluble vitamins (A, D, E, and K), free fatty acids, and other lipids, and (2) "extractives" (0.25% by weight), of which about two-thirds includes glucose and other forms of carbohydrate, the remainder consisting of the water-soluble vitamins (B-complex and C), certain enzymes, nonnitrogenous and nitrogenous waste products of metabolism (including urea, creatine, and creatinine), and many smaller amounts of other biochemical constituents — the list seeming virtually endless.

Removal from blood of all hematocytes and the protein fibrinogen (by allowing the fluid to completely clot before centrifuging) leaves behind a clear fluid called *serum*, which has a density of about 1.018 ± 0.003 g/cm^3 and a viscosity up to $1\frac{1}{2}$ times that of water. A glimpse of Table 1.1 and Table 1.2, together with the very brief summary presented above, nevertheless gives the reader an immediate appreciation for why blood is often referred to as the "river of life." This river is made to flow through the vascular piping network by two central pumping stations arranged in series: the left and right sides of the human heart.

1.2 The Pumping Station: The Heart

Barely the size of the clenched fist of the individual in whom it resides — an inverted, conically shaped, hollow muscular organ measuring 12 to 13 cm from base (top) to apex (bottom) and 7 to 8 cm at its widest point and weighing just under 0.75 lb (about 0.474% of the individual's body weight, or some 325 g) — the human heart occupies a small region between the third and sixth ribs in the central portion of the thoracic cavity of the body. It rests on the diaphragm, between the lower part of the two lungs, its

TABLE 1.2 Plasma

Constituent	Concentration range (mg/dl plasma)	Typical plasma value (mg/dl)	Molecular weight range	Typical value	Typical size (nm)
Total protein, 7% by weight	6400–8300	7245	21,000–1,200,000	—	—
Albumin (56% TP)	2800–5600	4057	66,500–69,000	69,000	15 × 4
α_1-*Globulin* (5.5% TP)	300–600	400	21,000–435,000	60,000	5–12
α_2-*Globulin* (7.5% TP)	400–900	542	100,000–725,000	200,000	50–500
β-*Globulin* (13% TP)	500–1230	942	90,000–1,200,000	100,000	18–50
γ-*Globulin* (12% TP)	500–1800	869	150,000–196,000	150,000	23 × 4
Fibrinogen (4% TP)	150–470	290	330,000–450,000	390,000	(50–60) × (3–8)
Other (2% TP)	70–210	145	70,000–1,000,000	200,000	(15–25) × (2–6)
Inorganic ash, 0.95% by weight	930–1140	983	20–100	—	— (Radius)
Sodium	300–340	325	—	22.98977	0.102 (Na^+)
Potassium	13–21	17	—	39.09800	0.138 (K^+)
Calcium	8.4–11.0	10	—	40.08000	0.099 (Ca^{2+})
Magnesium	1.5–3.0	2	—	24,30500	0.072 (Mg^{2+})
Chloride	336–390	369	—	35.45300	0.181 (Cl^-)
Bicarbonate	110–240	175	—	61.01710	0.163 (HCO_3^-)
Phosphate	2.7–4.5	3.6	—	95.97926	0.210 (HPO_4^{2-})
Sulfate	0.5–1.5	1.0	—	96.05760	0.230 (SO_4^{2-})
Other	0–100	80.4	20–100	—	0.1–0.3
Lipids (fats), 0.80% by weight	541–1000	828	44,000–3,200,000	= Lipoproteins	Up to 200 or more
Cholesterol (34% TL)	12–105 "free"	59	386.67	Contained mostly in intermediate to LDL β-lipoproteins; higher in women	
	72–259 esterified, 84–364 "total"	224 283			
Phospholipid (35% TL)	150–331	292	690–1,010	Contained mainly in HDL to VHDL α_1-lipoproteins	
Triglyceride (26% TL)	65–240	215	400–1,370	Contained mainly in VLDL α_2-lipoproteins and chylomicrons	
Other (5% TL)	0–80	38	280–1,500	Fat-soluble vitamins, prostaglandins, fatty acids	
Extractives, 0.25% by weight	200–500	259	—	—	—
Glucose	60–120, fasting	90	—	180.1572	0.86 D
Urea	20–30	25	—	60.0554	0.36 D
Carbohydrate	60–105	83	180.16–342.3	—	0.74–0.108 D
Other	11–111	61	—	—	—

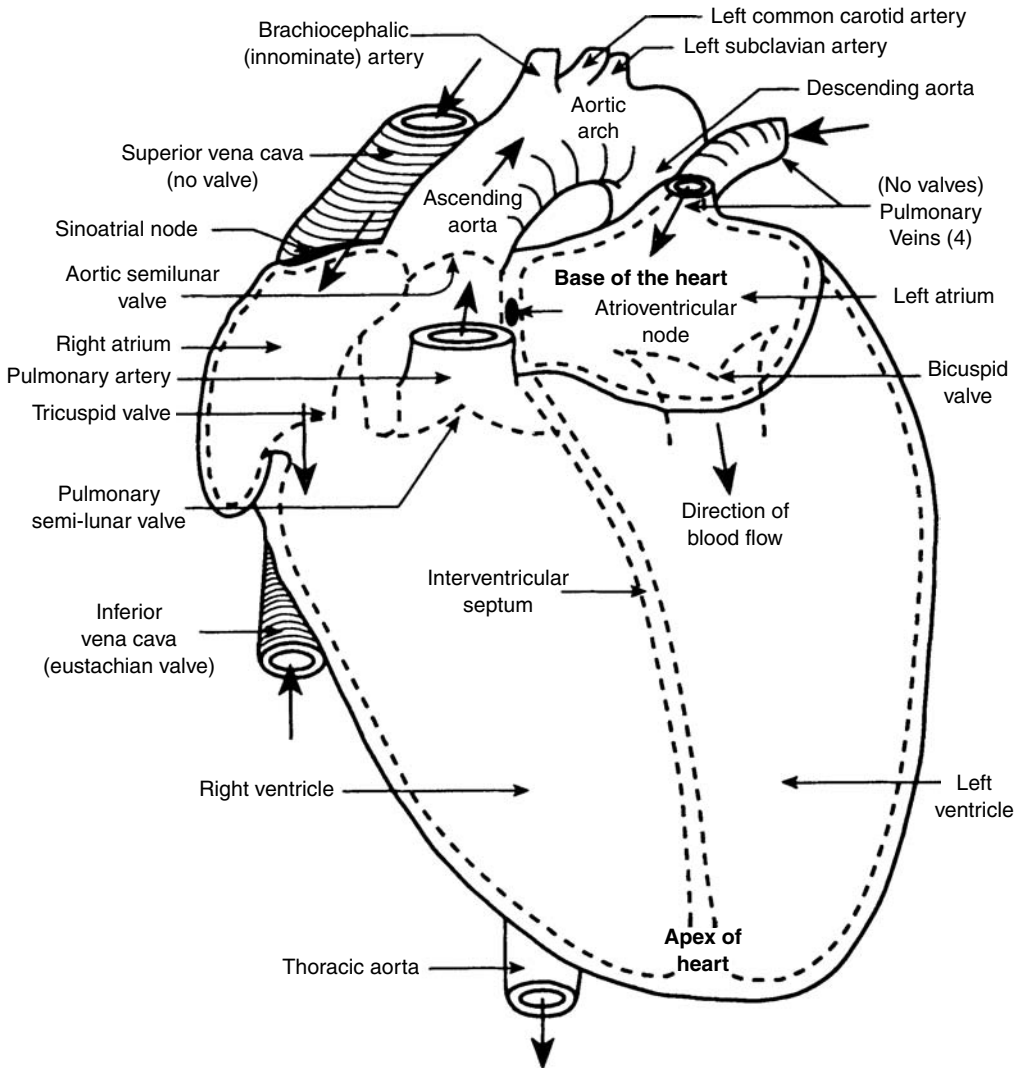
base-to-apex axis leaning mostly toward the left side of the body and slightly forward. The heart is divided by a tough muscular wall — the interatrial-interventricular septum — into a somewhat crescent-shaped right side and cylindrically shaped left side (Figure 1.1), each being one self-contained pumping station, but the two being connected in series. The left side of the heart drives oxygen-rich blood through the aortic semilunar outlet valve into the *systemic circulation*, which carries the fluid to within a differential neighborhood of each cell in the body — from which it returns to the right side of the heart low in oxygen and rich in carbon dioxide. The right side of the heart then drives this oxygen-poor blood through the pulmonary semilunar (pulmonic) outlet valve into the *pulmonary circulation*, which carries the fluid to the lungs — where its oxygen supply is replenished and its carbon dioxide content is purged before it returns to the left side of the heart to begin the cycle all over again. Because of the anatomic proximity of the heart to the lungs, the right side of the heart does not have to work very hard to drive


FIGURE 1.1   Anterior view of the human heart showing the four chambers, the inlet and outlet valves, the inlet and outlet major blood vessels, the wall separating the right side from the left side, and the two cardiac pacing centers — the **sinoatrial node** and the **atrioventricular node**. Boldface arrows show the direction of flow through the heart chambers, the valves, and the major vessels.

blood through the pulmonary circulation, so it functions as a low-pressure ($P \leq 40$ mmHg gauge) pump compared with the left side of the heart, which does most of its work at a high pressure (up to 140 mmHg gauge or more) to drive blood through the entire systemic circulation to the furthest extremes of the organism.

Each cardiac (heart) pump is further divided into two chambers: a small upper receiving chamber, or atrium (auricle), separated by a one-way valve from a lower discharging chamber, or ventricle, which is about twice the size of its corresponding atrium. In order of size, the somewhat spherically shaped left atrium is the smallest chamber — holding about 45 ml of blood (at rest), operating at pressures on the order of 0 to 25 mmHg gauge, and having a wall thickness of about 3 mm. The pouch-shaped right atrium is next (63 ml of blood, 0 to 10 mmHg gauge of pressure, 2-mm wall thickness), followed by the conical/cylindrically shaped left ventricle (100 ml of blood, up to 140 mmHg gauge of pressure, variable wall thickness up to 12 mm) and the crescent-shaped right ventricle (about 130 ml of blood,

up to 40 mmHg gauge of pressure, and a wall thickness on the order of one-third that of the left ventricle, up to about 4 mm). All together, then, the heart chambers collectively have a capacity of some 325 to 350 ml, or about 6.5% of the total blood volume in a "typical" individual — but these values are nominal, since the organ alternately fills and expands, contracts, and then empties as it generates a *cardiac output*.

During the 480-msec or so filling phase — diastole — of the average 750-msec cardiac cycle, the inlet valves of the two ventricles (3.8-cm-diameter tricuspid valve from right atrium to right ventricle; 3.1-cm-diameter bicuspid or mitral valve from left atrium to left ventricle) are open, and the outlet valves (2.4-cm-diameter pulmonary valve and 2.25-cm-diameter aortic semilunar valve, respectively) are closed — the heart ultimately expanding to its end-diastolic-volume (EDV), which is on the order of 140 ml of blood for the left ventricle. During the 270-msec emptying phase — systole — electrically induced vigorous contraction of **cardiac muscle** drives the intraventricular pressure up, forcing the one-way inlet valves closed and the unidirectional outlet valves open as the heart contracts to its end-systolic-volume (ESV), which is typically on the order of 70 ml of blood for the left ventricle. Thus the ventricles normally empty about half their contained volume with each heart beat, the remainder being termed the *cardiac reserve volume*. More generally, the difference between the *actual* EDV and the *actual* ESV, called the *stroke volume* (SV), is the volume of blood expelled from the heart during each systolic interval, and the ratio of SV to EDV is called the *cardiac ejection fraction*, or *ejection ratio* (0.5–0.75 is normal, 0.4–0.5 signifies mild cardiac damage, 0.25–0.40 implies moderate heart damage, and <0.25 warms of severe damage to the heart's pumping ability). If the stroke volume is multiplied by the number of systolic intervals per minute, or heart (HR), one obtains the total cardiac output (CO):

$$CO = HR \times (EDV - ESV) \tag{1.1}$$

Dawson [1991] has suggested that the cardiac output (in milliliters per minute) is proportional to the weight W (in kilograms) of an individual according to the equation

$$CO - 224 W^{3/4} \tag{1.2}$$

and that "normal" heart rate obeys very closely the relation

$$HR = 229 W^{-1/4} \tag{1.3}$$

For a "typical" 68.7-kg individual (blood volume = 5200 ml), Equation 1.1, Equation 1.2, and Equation 1.3 yield CO = 5345 ml/min, HR = 80 beats/min (cardiac cycle period = 754 msec) and SV = CO/HR = $224 W^{3/4}/229 W^{-1/4} = 0.978 W = 67.2$ ml/beat, which are very reasonable values. Furthermore, assuming this individual lives about 75 years, his or her heart will have cycled over 3.1536 billion times, pumping a total of 0.2107 billion liters of blood (55.665 million gallons, or 8134 quarts per day) — all of it emptying into the circulatory pathways that constitute the vascular system.

1.3   The Piping Network: Blood Vessels

The vascular system is divided by a microscopic capillary network into an upstream, high-pressure, efferent arterial side (Table 1.3) — consisting of relatively thick-walled, viscoelastic tubes that carry blood away from the heart — and a downstream, low-pressure, afferent venous side (Table 1.4) — consisting of correspondingly thinner (but having a larger caliber) elastic conduits that return blood back to the heart. Except for their differences in thickness, the walls of the largest arteries and veins consist of the same three distinct, well-defined, and well-developed layers. From innermost to outermost, these layers are (1) the thinnest *tunica intima*, a continuous lining (the vascular **endothelium**) consisting of a single layer of simple

TABLE 1.3 Arterial System[a]

Blood vessel type	(Systemic) typical number	Internal diameter range	Length Range[b]	Wall thickness	Systemic volume	(Pulmonary) typical number	Pulmonary volume
Aorta	1	1.0–3.0 cm	30–65 cm	2–3 mm	156 ml	—	—
Pulmonary artery	—	2.5–3.1 cm	6–9 cm	2–3 cm	—	1	52 ml
Wall morphology: Complete tunica adventitia, external elastic lamina, tunica media, internal elastic lamina, tunica intima, subendothelium, endothelium, and vasa vasorum vascular supply							
Main branches	32	5 mm–2.25 cm	3.3–6 cm	$\simeq$2 mm	83.2 ml	6	41.6 ml
(Along with the aorta and pulmonary artery, the largest, most well-developed of all blood vessels)							
Large arteries	288	4.0–5.0 mm	1.4–2.8 cm	$\simeq$1 mm	104 ml	64	23.5 ml
(A well-developed tunica adventitia and vasa vasorum, although wall layers are gradually thinning)							
Medium arteries	1152	2.5–4.0 mm	1.0–2.2 cm	$\simeq$0.75 mm	117 ml	144	7.3 ml
Small arteries	3456	1.0–2.5 mm	0.6–1.7 cm	$\simeq$0.50 mm	104 ml	432	5.7 ml
Tributaries	20,736	0.5–1.0 mm	0.3–1.3 cm	$\simeq$0.25 mm	91 ml	5184	7.3 ml
(Well-developed tunica media and external elastic lamina, but tunica adventitia virtually nonexistent)							
Small rami	82,944	250–500 μm	0.2–0.8 cm	$\simeq$125 μm	57.2 ml	11,664	2.3 ml
Terminal branches	497,664	100–250 μm	1.0–6.0 mm	$\simeq$60 μm	52 ml	139,968	3.0 ml
(A well-developed endothelium, subendothelium, and internal elastic lamina, plus about two to three 15-μm-thick concentric layers forming just a very thin tunica media; no external elastic lamina)							
Arterioles	18,579,456	25–100 μm	0.2–3.8 mm	$\simeq$20–30 μm	52 ml	4,094,064	2.3 ml
Wall morphology: More than one smooth muscle layer (with nerve association in the outermost muscle layer), a well-developed internal elastic lamina; gradually thinning in 25- to 50-μm vessels to a single layer of smooth muscle tissue, connective tissue, and scant supporting tissue							
Metarterioles	238,878,720	10–25 μm	0.1–1.8 mm	$\simeq$5–15 μm	41.6 ml	157,306,536	4.0 ml
(Well-developed subendothelium; discontinuous contractile muscle elements; one layer of connective tissue)							
Capillaries	16,124,431,360	3.5–10 μm	0.5–1.1 mm	$\simeq$0.5–1 μm	260 ml	3,218,406,696	104 ml
(Simple endothelial tubes devoid of smooth muscle tissue; one-cell-layer-thick walls)							

[a] Vales are approximate for a 68.7-kg individual having a total blood volume of 5200 ml.

[b] Average uninterrupted distance between branch origins (except aorta and pulmonary artery, which are total length).

TABLE 1.4 Venous System

Blood vessel type	(Systemic) Typical number	Internal diameter range	Length range	Wall thickness	Systemic volume	(Pulmonary) Typical number	Pulmonary volume
Postcapillary venules	4,408,161,734	8–30 μm	0.1–0.6 mm	1.0–5.0 μm	166.7 ml	306,110,016	10.4 ml
(Wall consists of thin endothelium exhibiting occasional pericytes (pericapillary connective tissue cells) which increase in number as the vessel lumen gradually increases)							
Collecting venules	160,444,500	30–50 μm	0.1–0.8 mm	5.0–10 μm	161.3 ml	8,503,056	1.2 ml
(One complete layer of pericytes, one complete layer of veil cells (veil-like cells forming a thin membrane), occasional primitive smooth muscle tissue fibers that increase in number with vessel size)							
Muscular venules	32,088,900	50–100 μm	0.2–1.0 mm	10–25 μm	141.8 ml	3,779,136	3.7 ml
(Relatively thick wall of smooth muscle tissue)							
Small collecting veins	10,241,508	100–200 μm	0.5–3.2 mm	$\simeq$30 μm	329.6 ml	419,904	6.7 ml
(Prominent tunica media of continuous layers of smooth muscle cells)							
Terminal branches	496,900	200–600 μm	1.0–6.0 mm	30–150 μm	206.6 ml	34,992	5.2 ml
(A well-developed endothelium, subendothelium, and internal elastic lamina; well-developed tunica media but fewer elastic fibers than corresponding arteries and much thinner walls)							
Small veins	19,968	600 μm–1.1 mm	2.0–9.0 mm	$\simeq$0.25 mm	63.5 ml	17,280	44.9 ml
Medium veins	512	1–5 mm	1–2 cm	$\simeq$0.50 mm	67.0 ml	144	22.0 ml
Large veins	256	5–9 mm	1.4–3.7 cm	$\simeq$0.75 mm	476.1 ml	48	29.5 ml
(Well-developed wall layers comparable to large arteries but about 25% thinner)							
Main branches	224	9.0 mm–2.0 cm	2.0–10 cm	$\simeq$1.00 mm	1538.1 ml	16	39.4 ml
(Along with the vena cava and pulmonary veins, the largest, most well-developed of all blood vessels)							
Vena cava	1	2.0–3.5 cm	20–50 cm	$\simeq$1.50 mm	125.3 ml	—	—
Pulmonary veins	—	1.7–2.5 cm	5–8 cm	$\simeq$1.50 mm	—	4	52 ml

Wall morphology: Essentially the same as comparable major arteries but a much thinner tunica intima, a much thinner tunica media, and a somewhat thicker tunica adventitia; contains a vasa vasorum

Total systemic blood volume: 4394 ml — 84.5% of total blood volume; 19.5% in arteries ($\sim$3:2 large:small), 5.9% in capillaries, 74.6% in veins ($\sim$3:1 large:small); 63% of volume is in vessels greater than 1 mm internal diameter.

Total pulmonary blood volume: 468 ml — 9.0% of total blood volume; 31.8% in arteries, 22.2% in capillaries, 46% in veins; 58.3% of volume is in vessels greater than 1 mm internal diameter; remainder of blood in heart, about 338 ml (6.5% of total blood volume).

squamous (thin, sheetlike) endothelial cells "glued" together by a polysaccharide (sugar) intercellular matrix, surrounded by a thin layer of subendothelial connective tissue interlaced with a number of circularly arranged elastic fibers to form the subendothelium, and separated from the next adjacent wall layer by a thick elastic band called the *internal elastic lamina*, (2) the thickest *tunica media*, composed of numerous circularly arranged elastic fibers, especially prevalent in the largest blood vessels on the arterial side (allowing them to expand during systole and to recoil passively during diastole), a significant amount of smooth muscle cells arranged in spiraling layers around the vessel wall, especially prevalent in medium-sized arteries and arterioles (allowing them to function as control points for blood distribution), and some interlacing collagenous connective tissue, elastic fibers, and intercellular mucopolysaccharide substance (extractives), all separated from the next adjacent wall layer by another thick elastic band called the *external elastic lamina*, and (3) the medium-sized *tunica adventitia*, an outer vascular sheath consisting entirely of connective tissue.

The largest blood vessels, such as the aorta, the pulmonary artery, the pulmonary veins, and others, have such thick walls that they require a separate network of tiny blood vessels — the vasa vasorum — just to service the vascular tissue itself. As one moves toward the capillaries from the arterial side (see Table 1.3), the vascular wall keeps thinning, as if it were shedding 15-μm-thick, onion-peel-like concentric layers, and while the percentage of water in the vessel wall stays relatively constant at 70% (by weight), the ratio of elastin to collagen decreases (actually reverses) — from 3 : 2 in large arteries (9% elastin, 6% collagen, by weight) to 1 : 2 in small tributaries (5% elastin, 10% collagen) — and the amount of smooth muscle tissue increases from 7.5% by weight of large arteries (the remaining 7.5% consisting of various extractives) to 15% in small tributaries. By the time one reaches the capillaries, one encounters single-cell-thick endothelial tubes — devoid of any smooth muscle tissue, elastin, or collagen — downstream of which the vascular wall gradually "reassembles itself," layer-by-layer, as it directs blood back to the heart through the venous system (Table 1.4).

Blood vessel structure is directly related to function. The thick-walled large arteries and main *distributing branches* are designed to withstand the pulsating 80 to 130 mmHg blood pressures that they must endure. The smaller elastic *conducting vessels* need only operate under steadier blood pressures in the range 70 to 90 mmHg, but they must be thin enough to penetrate and course through organs without unduly disturbing the anatomic integrity of the mass involved. Controlling arterioles operate at blood pressures between 45 and 70 mmHg but are heavily endowed with smooth muscle tissue (hence their being referred to as *muscular vessels*) so that they may be actively shut down when flow to the capillary bed they service is to be restricted (for whatever reason), and the smallest capillary *resistance vessels* (which operate at blood pressures on the order of 10 to 45 mmHg) are designed to optimize conditions for transport to occur between blood and the surrounding interstitial fluid. Traveling back up the venous side, one encounters relatively steady blood pressures continuously decreasing from around 30 mmHg all the way down to near zero, so these vessels can be thin-walled without disease consequence. However, the low blood pressure, slower, steady (time-dependent) flow, thin walls, and larger caliber that characterize the venous system cause blood to tend to "pool" in veins, allowing them to act somewhat like reservoirs. It is not surprising, then, that at any given instant, one normally finds about two-thirds of the total human blood volume residing in the venous system, the remaining one-third being divided among the heart (6.5%), the microcirculation (7% in systemic and pulmonary capillaries), and the arterial system (19.5 to 20%).

In a global sense, then, one can think of the human cardiovascular system — using an electrical analogy — as a voltage source (the heart), two capacitors (a large venous system and a smaller arterial system), and a resistor (the microcirculation taken as a whole). Blood flow and the dynamics of the system represent electrical inductance (inertia), and useful engineering approximations can be derived from such a simple model. The cardiovascular system is designed to bring blood to within a capillary size of each and every one of the more than 10^{14} cells of the body — but *which* cells receive blood at any given time, *how much* blood they get, the *composition* of the fluid coursing by them, and related physiologic considerations are all matters that are not left up to chance.

1.4   Cardiovascular Control

Blood flows through organs and tissues either to nourish and sanitize them or to be itself processed in some sense — for example, to be oxygenated (pulmonary circulation), stocked with nutrients (splanchnic circulation), dialyzed (renal circulation), cooled (cutaneous circulation), filtered of dilapidated red blood cells (splenic circulation), and so on. Thus any given vascular network normally receives blood according to the metabolic needs of the region it perfuses and/or the function of that region as a blood treatment plant and/or thermoregulatory pathway. However, it is not feasible to expect that our physiologic transport system can be "all things to all cells all of the time" — especially when resources are scarce and/or time is a factor. Thus the distribution of blood is further prioritized according to three basic criteria (1) how essential the perfused region is to the maintenance of life itself (e.g., we can survive without an arm, a leg, a stomach, or even a large portion of our small intestine but not without a brain, a heart, and at least one functioning kidney and lung, (2) how essential the perfused region is in allowing the organism to respond to a life-threatening situation (e.g., digesting a meal is among the least of the body's concerns in a "fight or flight" circumstance), and (3) how well the perfused region can function and survive on a decreased supply of blood (e.g., some tissues — like striated skeletal and smooth muscle — have significant anaerobic capability; others — like several forms of connective tissue — can function quite effectively at a significantly decreased metabolic rate when necessary; some organs — like the liver — are larger than they really need to be; and some anatomic structures — like the eyes, ears, and limbs — have duplicates, giving them a built-in redundancy).

Within this generalized prioritization scheme, control of cardiovascular function is accomplished by mechanisms that are based either on the inherent physicochemical attributes of the tissues and organs themselves — so-called intrinsic control — or on responses that can be attributed to the effects on cardiovascular tissues of other organ systems in the body (most notably the **autonomic nervous system** and the **endocrine system**) — so-called extrinsic control. For example, the accumulation of wastes and depletion of oxygen and nutrients that accompany the increased rate of metabolism in an active tissue both lead to an *intrinsic* relaxation of local **precapillary sphincters** (rings of muscle) — with a consequent widening of corresponding capillary entrances — which reduces the local resistance to flow and thereby allows more blood to perfuse the active region. On the other hand, the *extrinsic* innervation by the autonomic nervous system of smooth muscle tissues in the walls of arterioles allows the central nervous system to completely shut down the flow to entire vascular beds (such as the cutaneous circulation) when this becomes necessary (such as during exposure to extremely cold environments).

In addition to prioritizing and controlling the *distribution* of blood, physiologic regulation of cardiovascular function is directed mainly at four other variables: cardiac output, blood pressure, blood volume, and blood composition. From Equation 1.1 we see that cardiac output can be increased by increasing the heart rate (a **chronotropic** effect), increasing the end-diastolic volume (allowing the heart to fill longer by delaying the onset of systole), decreasing the end-systolic volume (an **inotropic** effect), or doing all three things at once. Indeed, under the extrinsic influence of the sympathetic nervous system and the adrenal glands, HR can triple — to some 240 beats/min if necessary — EDV can increase by as much as 50% — to around 200 ml or more of blood — and ESV and decrease a comparable amount (the cardiac reserve) — to about 30 to 35 ml or less. The combined result of all three effects can lead to over a sevenfold increase in cardiac output — from the normal 5 to 5.5 l/min to as much as 40 to 41 l/min or more for very brief periods of strenuous exertion.

The control of blood pressure is accomplished mainly by adjusting at the arteriolar level the downstream resistance to flow — an increased resistance leading to a rise in arterial backpressure, and vice versa. This effect is conveniently quantified by a fluid-dynamic analogue to Ohm's famous $E = IR$ law in electromagnetic theory, voltage drop E being equated to fluid pressure drop ΔP, electric current I corresponding to flow — cardiac output (CO) — and electric resistance R being associated with an analogous vascular "peripheral resistance" (PR). Thus one may write

$$\Delta P = (CO)(PR) \tag{1.4}$$

Normally, the total systemic peripheral resistance is 15 to 20 mmHg/l/min of flow but can increase significantly under the influence of the vasomotor center located in the medulla of the brain, which controls arteriolar muscle tone.

The control of blood volume is accomplished mainly through the excretory function of the kidney. For example, antidiuretic hormone (ADH) secreted by the pituitary gland acts to prevent renal fluid loss (excretion via urination) and thus increases plasma volume, whereas perceived extracellular fluid overloads such as those which result from the peripheral vasoconstriction response to cold stress lead to a sympathetic/adrenergic receptor-induced renal diuresis (urination) that tends to decrease plasma volume — if not checked, to sometimes dangerously low dehydration levels. Blood composition, too, is maintained primarily through the activity of endocrine hormones and enzymes that enhance or repress specific biochemical pathways. Since these pathways are too numerous to itemize here, suffice it to say that in the body's quest for **homeostasis** and stability, virtually nothing is left to chance, and every biochemical end can be arrived at through a number of alternative means. In a broader sense, as the organism strives to maintain life, it coordinates a wide variety of different functions, and central to its ability to do just that is the role played by the cardiovascular system in transporting mass, energy, and momentum.

Defining Terms

Atrioventricular (AV) node: A highly specialized cluster of neuromuscular cells at the lower portion of the right atrium leading to the interventricular septum; the AV node delays sinoatrial, (SA) node-generated electrical impulses momentarily (allowing the atria to contract first) and then conducts the depolarization wave to the bundle of His and its bundle branches.

Autonomic nervous system: The functional division of the nervous system that innervates most glands, the heart, and smooth muscle tissue in order to maintain the internal environment of the body.

Cardiac muscle: Involuntary muscle possessing much of the anatomic attributes of skeletal voluntary muscle and some of the physiologic attributes of involuntary smooth muscle tissue; SA node-induced contraction of its interconnected network of fibers allows the heart to expel blood during systole.

Chronotropic: Affecting the periodicity of a recurring action, such as the slowing (bradycardia) or speeding up (tachycardia) of the heartbeat that results from extrinsic control of the SA node.

Endocrine system: The system of ductless glands and organs secreting substances directly into the blood to produce a specific response from another "target" organ or body part.

Endothelium: Flat cells that line the innermost surfaces of blood and lymphatic vessels and the heart.

Homeostasis: A tendency to uniformity or stability in an organism by maintaining within narrow limits certain variables that are critical to life.

Inotropic: Affecting the contractility of muscular tissue, such as the increase in cardiac *power* that results from extrinsic control of the myocardial musculature.

Precapillary sphincters: Rings of smooth muscle surrounding the entrance to capillaries where they branch off from upstream metarterioles. Contraction and relaxation of these sphincters close and open the access to downstream blood vessels, thus controlling the irrigation of different capillary networks.

Sinoatrial (SA) node: Neuromuscular tissue in the right atrium near where the superior vena cava joins the posterior right atrium (the sinus venarum); the SA node generates electrical impulses that initiate the heartbeat, hence its nickname the cardiac "pacemaker."

Stem cells: A generalized parent cell spawning descendants that become individually specialized.

2.1 Introduction

The body, if it is to achieve optimal performance, must possess mechanisms for sensing and responding appropriately to numerous biologic cues and signals in order to control and maintain its internal environment. This complex role is effected by the integrative action of the endocrine and neural systems. The endocrine contribution is achieved through a highly sophisticated set of communication and control systems involving signal generation, propagation, recognition, transduction, and response. The signal entities are chemical messengers or hormones that are distributed through the body mainly by the blood circulatory system to their respective target sites, organs, or cells, to modify their activity in some fashion.

Endocrinology has a comparatively long history, but real advances in the understanding of endocrine physiology and mechanisms of regulation and control began in the late 1960s with the introduction of sensitive and relatively specific analytical methods; these enabled low concentrations of circulating hormones

to be measured reliably, simply, and at relatively low cost. The breakthrough came with the development and widespread adoption of competitive protein binding and radioimmunoassays that superseded existing cumbersome bioassay methods. Since then, knowledge of the physiology of individual endocrine glands and of the neural control of the pituitary gland and the overall feedback control of the endocrine system has progressed and is growing rapidly. Much of this has been accomplished by applying to endocrinological research the methods developed in cellular and molecular biology and recombinant DNA technology. At the same time, theoretical and quantitative approaches using mathematical modeling to complement experimental studies have been of value in gaining a greater understanding of endocrine dynamics.

2.2   Endocrine System: Hormones, Signals, and Communication between Cells and Tissues

Hormones are chemical messengers synthesized and secreted by specialized endocrine glands to act locally or at a distance, having been carried in the bloodstream (classic endocrine activity) or secreted into the gut lumen (lumocrine activity) to act on target cells that are distributed elsewhere in the body. Probably, to be more correct three actions should be defined, namely: endocrine action when the hormone is distributed in circulation binds to distant target cells; paracrine action in which the hormone acts locally by diffusing from its source to target cells in close proximity; and autocrine action when the hormone acts upon the cell that actually produced it.

Hormones are chemically diverse, physiologically potent molecules that are the primary vehicle for intercellular communication with the capacity to override the intrinsic mechanisms of normal cellular control. They can be classified broadly into four groups according to their physicochemical characteristics (1) steroid hormones, (2) peptide and protein hormones, (3) those derived from amino acids, principally the aromatic amino acid tyrosine, and (4) the eicosanoids (fatty acid derivatives).

1. *Steroids* are lipids, more specifically, derivatives of cholesterol produced by chemical modification. Examples include the sex steroids such as testosterone and the adrenal steroids such as cortisol. The first and rate-limiting step in the synthesis of all steroid hormones is the conversion of cholesterol to pregnenolone, which is formed on the inner membrane of cell mitochondria then transferred to the endoplasmic reticulum for further enzymatic transformations that yield the steroid hormones. Newly synthesized steroid hormones are rapidly secreted from the cell, so an increase in secretion reflects an accelerated rate of synthesis. Lipid-derived molecules, like the steroid hormones, are hydrophobic, so to improve their solubility they have to be carried in the circulation bound to specific transport proteins, though to a limited extent there is low-affinity, nonspecific binding to plasma proteins, such as plasma albumen. Binding capability and production clearance rates affect their half-life, which is comparatively long, and the rate of elimination. Steroid hormones are typically eliminated, following enzymatic inactivation in the liver, by excretion in urine and bile.

2. *Peptide and protein hormones* are synthesized in the cellular endoplasmic reticulum and then transferred to the Golgi apparatus where they are packaged into secretory vesicles for export. They can then be secreted either by regulated secretion or by constitutive secretion. In the former case, the hormone is stored in secretory granules and released in "bursts" when appropriately stimulated. This process enables cells to secrete a large amount of hormone over a short period of time. However, in the second case, the hormone is not stored within the cell, but rather it is released from the secretory vesicles as it is synthesized. As products of posttranslational modification of RNA-directed protein synthesis, they vary considerably in size, encompassing a range from that of peptides as short as three amino acids to large, multiple subunit glycoproteins. Several protein hormones are synthesized as prohormones, then subsequently modified by proteolysis to yield their active form. In other cases, the hormone is originally embedded within the sequence of a larger precursor, the active molecule being released by proteolytic cleavage of the parent molecule. The peptide and protein hormones are essentially hydrophilic and are therefore able to circulate in the blood in the free state; their half-life tends to be very short, of the order of a few minutes only.

3. *Amino acid derivatives*: There are two groups of hormones derived from the amino acid tyrosine; namely, thyroid hormones which are basically a "double" tyrosine ring incorporating three or four iodine atoms and the catecholamines that include epinephrine and norepinephrine that have the capability of functioning as both hormones and neurotransmitters. However, the two groups have highly different half-lives in the circulation, the thyroid hormones being of the order of several days, being inactivated by intracellular deiodinases, while that of the catecholamines is a few minutes only. Two other amino acids are involved in hormone synthesis: tryptophan, which is the precursor of both serotonin and the pineal hormone melatonin and glutamic acid, which is the precursor of histamine.

4. *Eicosanoids* are comprised of a large group of molecules derived from polyunsaturated fatty acids, the principal groups of the class being the prostaglandins, prostacyclins, leukotrienes, and thromboxanes. The specific eicosanoids which are synthesized by the cell is determined by a complex enzyme system within the cell following stimulation. Arachadonic acid released through the action of various lipases from cell plasma membrane lipids is the precursor for these hormones. All these hormones are rapidly metabolized and are active for a few seconds only.

2.2.1   A System View

The endocrine and nervous systems are physically and functionally linked by a specific region of the brain called the hypothalamus, which lies immediately above the pituitary gland, to which it is connected by an extension called the pituitary stalk. The integrating function of the hypothalamus is mediated by cells that possess the properties of both nerve and processes that carry electrical impulses and on stimulation can release their signal molecules into the blood. Each of the hypothalamic neurosecretory cells can be stimulated by other nerve cells in higher regions of the brain to secrete specific peptide hormones or release factors into the adenohypophyseal portal vasculature. These hormones can then specifically stimulate or suppress the secretion of a second hormone from the anterior pituitary. Figure 2.1 and Table 2.1 show, in schematic and descriptive form, respectively, details of the major endocrine glands of the body and the endocrine pathways.

The pituitary hormones in the circulation interact with their target tissues, which, if endocrine glands, are stimulated to secrete further (third) hormones that feedback to inhibit the release of the pituitary hormones. It will be seen from Figure 2.1 and Table 2.1 that the main targets of the pituitary are the adrenal cortex, the thyroid, and the gonads. These axes provide good examples of the control of pituitary hormone release by negative-feedback inhibition; for example, adrenocorticotropin (ACTH), luteinizing hormone (LH), and follicle-stimulating hormone (FSH) are selectively inhibited by different steroid hormones, as is thyrotropin (thyroid stimulating hormone [TSH]) release by the thyroid hormones.

In the case of growth hormone (GH) and prolactin, the target tissue is not an endocrine gland and thus does not produce a hormone; then the feedback control is mediated by inhibitors. Prolactin is under dopamine inhibitory control, whereas hypothalamic releasing and inhibitory factors control GH release. The two posterior pituitary (neurohypophyseal) hormones, oxytocin and vasopressin, are synthesized in the supraoptic and paraventricular nuclei and are stored in granules at the end of the nerve fibers in the posterior pituitary. Oxytocin is subsequently secreted in response to peripheral stimuli from the cervical stretch receptors or the suckling receptors of the breast. In a like manner, antidiuretic hormone (ADH, vasopressin) release is stimulated by the altered activity of hypothalamic osmoreceptors responding to changes in plasma solute concentrations.

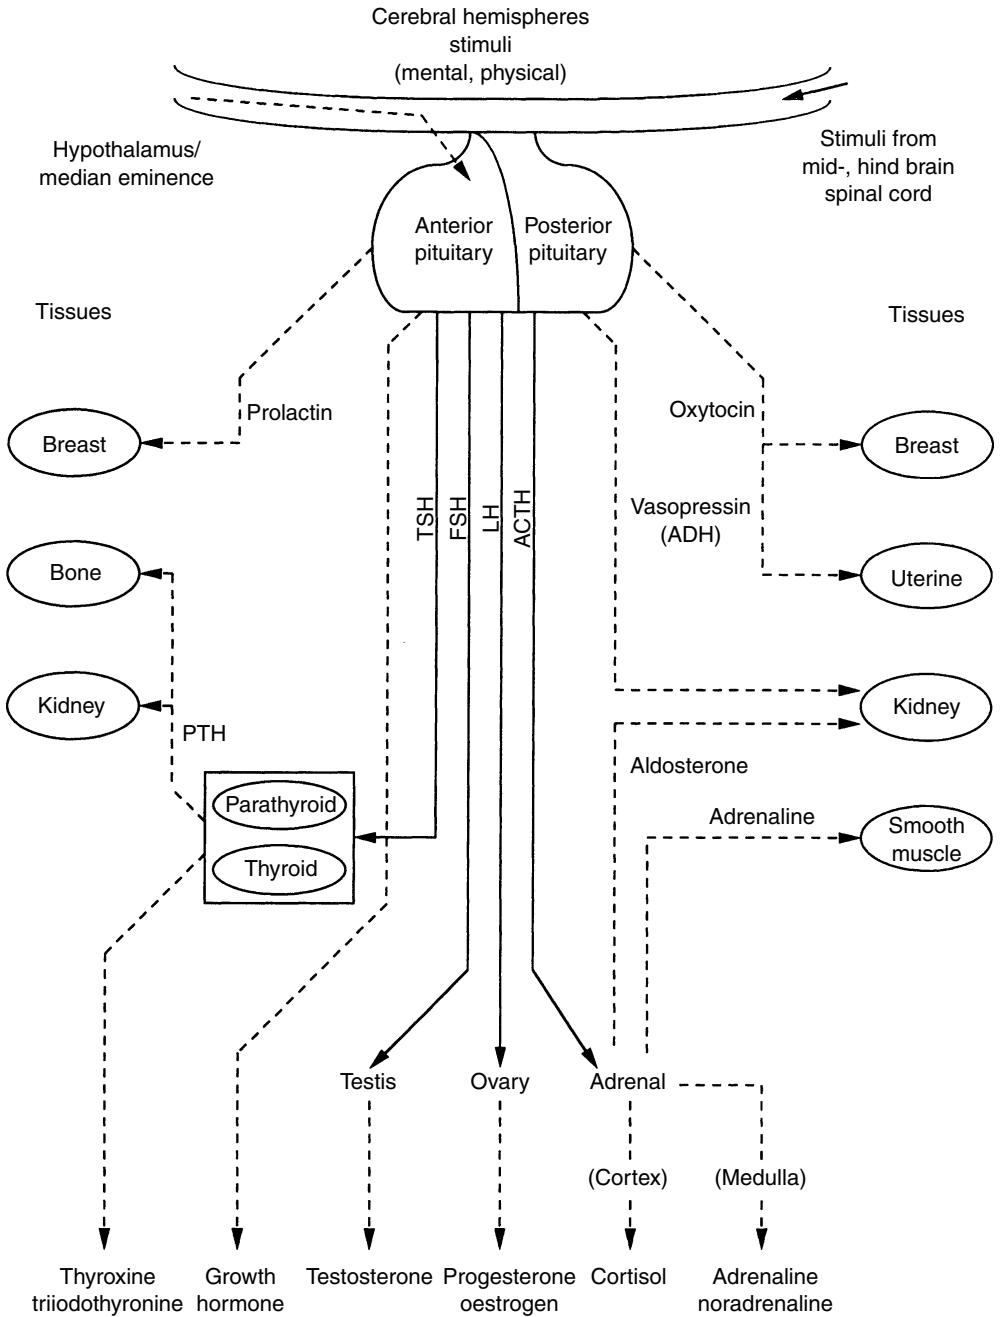
It will be noted that the whole system is composed of several endocrine axes with the hypothalamus, pituitary, and other endocrine glands together forming a complex hierarchical regulatory system. There is no doubt that the anterior pituitary occupies a central position in the control of hormone secretion and, because of its important role, was often called the "conductor of the endocrine orchestra." However, the release of pituitary hormones is mediated by complex feedback control (discussed in the following sections), so the pituitary should be regarded as having a permissive role rather than having the overall control of the endocrine system.


FIGURE 2.1 Representation of the forward pathways of pituitary and target gland hormone release and action: ——— tropic hormones; – – – – tissue-affecting hormones.

2.3 Hormone Action at the Cell Level: Signal Recognition, Signal Transduction, and Effecting a Physiological Response

The ability of target glands or tissues to respond to hormonal signals depends on the ability of the cells to recognize the signal. This function is mediated by specialized proteins or glycoproteins in or on the cell

TABLE 2.1   Main Endocrine Glands and the Hormones They Produce and Release

Gland	Hormone	Chemical characteristics
Hypothalamus/median eminence	Thyrotropin-releasing hormone (TRH)	Peptides
	Somatostatin	
	Gonadotropin-releasing hormone	Amine
	Growth hormone-releasing hormone	
	Corticotropin-releasing hormone	
	Prolactin inhibitor factor	
Anterior pituitary	Thyrotropin (TSH)	Glycoprotiens
	Luteinizing hormone	
	Follicle-stimulating hormone (FSH)	Proteins
	Growth hormones	
	Prolactin	
	Adrenocorticotropin (ACTH)	
Posterior pituitary	Vasopressin (antidiuretic hormone, ADH)	
	Oxytocin	Peptides
Thyroid	Triidothyronine (T3)	Tyrosine derivatives
	Thyroxine (T4)	
Parathyroid	Parathyroid hormone (PTH)	Peptide
Adrenal cortex	Cortisol	Steroids
	Aldosterone	
Adrenal medulla	Epinephrine	Catecolamines
	Norepinephrine	
Pancreas	Insulin	Proteins
	Glucagon	
	Somatostatin	
Gonads		
Testes	Testosterone	Steroids
Ovaries	Oestrogen	
	Progesssterone	

TABLE 2.2   Summary of Location of Receptor, Associated Classes of Hormones, and Their Principle Mechanism of Action

Location of receptors	Classes of hormones	Principal mechanism of action
Plasma membrane (cell surface)	Proteins and peptides, catecholamines and eicosanoids	Generation of second messengers that primarily modulate the activity of intracellular enzymes
Intracellular (cytoplasm and/or nucleus)	Steroids and thyroid hormones	Modification of RNA-directed protein synthesis and the transcriptional activity of responsive genes

plasma membrane that are specific for a particular hormone, able to recognize it, bind it with high affinity, and react when very low concentrations are present. Recognition of the hormonal signal and activation of the cell surface receptors initiates a flow of information to the cell interior, which triggers a chain of intracellular events in a preprogrammed fashion that produces a characteristic response. It is useful to classify the site of such action of hormones into two groups (see Table 2.2): those which act at the cell surface without, generally, traversing the cell membrane and those which actually enter the cell before effecting a response. In the study of this multistep sequence, two important events can be readily studied, namely, the binding of the hormone to its receptor, and activation of cytoplasmic effects. These events, such as receptor activation and signal generation, are an active area of research.

One technique employed in an attempt to elucidate the intermediate steps has been to use ineffective mutant receptors, which when assayed are either defective in their hormone-binding capabilities or in

effector activation and thus unable to transduce a meaningful signal to the cell. However, the difficulty with these studies has been to distinguish receptor-activation and signal-generation defects from hormone-binding and effector activation defects. A parallel technique is to explore the use of agonists, which are molecules that behave like the "normal" hormone, bind the receptor and induce all the postreceptor events that yield a physiological effect. Natural hormones are themselves agonists and, in many cases, more than one distinct hormone can bind to the same receptor. For a given receptor, different agonists can have dramatically different potencies. The corollary to this is to explore the use of antagonists, that is molecules that bind the receptor and block-binding of the agonist, but fail to trigger intracellular signaling events. Hormone antagonists have obvious pharmaceutical potential in clinical endocrinology.

The peptide and protein hormones circulate at very low concentrations relative to other proteins in the blood plasma. These low concentrations are reflected in the very high affinity and specificity of the receptor sites, which permit recognition of the relevant hormones amid the prolusion of protein molecules in the circulation. Adaptation to a high concentration of a signal ligand in a time-dependent reversible manner enables cells to respond to changes in the concentration of a ligand instead of to its absolute concentration. The number of receptors in a cell is not constant; synthesis of receptors may be induced or repressed by other hormones or even by their own hormones. Adaptation can occur in several ways. Ligand binding can inactivate a cell surface receptor either by inducing its internalization and degradation or by causing the receptor to adopt an inactive conformation. Alternatively, it may result from the changes in one of the nonreceptor proteins involved in signal transduction following receptor activation. Down regulation is the name given to the process whereby a cell decreases the number of receptors in response to intense or frequent stimulation and can occur by degradation or more temporarily by phosphorylation and sequestration. Up regulation is the process of increasing receptor expression either by other hormones or in response to altered stimulation.

2.3.1   Structure of Cell Surface Receptors

Cell surface receptors are integral membrane proteins and, as such, have regions that contribute to three basic domains:

- *Extracellular domains*: Some of the residues exposed to the outside of the cell interact with and bind the hormone — another term for these regions is the ligand-binding domain.
- *Transmembrane domains*: Hydrophobic stretches of amino acids are "comfortable" in the lipid bilayer and serve to anchor the receptor in the membrane.
- *Cytoplasmic or intracellular domains*: Tails or loops of the receptor that are within the cytoplasm react to hormone binding by interacting in some way with other molecules, leading to generation of second messengers. Cytoplasmic residues of the receptor are thus the effector region of the molecule.

Several distinctive variations in receptor structure have been identified; some receptors being simple, single-pass proteins, many growth factor receptors take this form. Others, such as the receptor for insulin, have more than one subunit. Another class, which includes the beta-adrenergic receptor, is threaded through the membrane seven times.

Receptor molecules are neither isolated nor fixed in one location of the plasma membrane. In some cases, other integral membrane proteins interact with the receptor to modulate its activity. Some types of receptors cluster together in the membrane after binding hormone. Finally, as elaborated in the following sections, interaction of the hormone-bound receptor with other membrane or cytoplasmic proteins is the key to generation of second messengers and transduction of the hormonal signal.

2.3.2   Fate of the Hormone–Receptor Complex

Normal cell function depends upon second messenger cascades being transient events. Indeed, a number of cancers are associated with receptors that continually stimulate second messenger systems. One important

part of negative regulation on hormone action is that cell surface receptors are internalized. In many cases, internalization is stimulated by hormone binding. Internalization occurs by endocytosis through structures called coated pits. The resulting endosomes may fuse with lysosomes, leading to destruction of the receptor and hormone. In other cases, it appears that the hormone dissociates and the receptor is recycled by fusion of the endosome back into the plasma membrane.

2.4   Hormones Acting at the Cell Surface

Most peptide and protein hormones are hydrophilic and thus unable to traverse the lipid-containing cell membrane and must therefore act through activation of receptor proteins on the cell surface. When these receptors are activated by the binding of an extracellular signal ligand, the ligand–receptor complex initiates a series of protein interactions within or adjacent to the inner surface of the plasma membrane, which in turn brings about changes in intracellular activity. This can happen in one of two ways. The first involves the so-called second messenger, by altering the activity of a plasma membrane-bound enzyme, which in turn increases (or sometimes decreases) the concentration of an intracellular mediator. The second involves activation of other types of cell surface receptors, which leads to changes in the plasma membrane electrical potential and the membrane permeability, resulting in altered transmembrane transport of ions or metabolites. If the hormone is thought of as the "first messenger," cyclic adenosine monophosphate (cAMP) can be regarded as the "second messenger," capable of triggering a cascade of intracellular biochemical events that can lead either to a rapid secondary response such as altered ion transport, enhanced metabolic pathway flux, steroidogenesis or to a slower response such as DNA, RNA, and protein synthesis resulting in cell growth or cell division.

2.4.1   Second Messenger Systems

Currently, four second messenger systems are recognized in cells, as summarized in Table 2.3. Note that not only do multiple hormones utilize the same second messenger system, but a single hormone can utilize more than one system. Understanding how cells integrate signals from several hormones into a coherent biological response remains a challenge.

The cell surface receptors for peptide hormones are linked functionally to a cell membrane-bound enzyme that acts as the catalytic unit. This receptor complex consists of three components (1) the receptor itself which recognizes the hormone, (2) a regulatory protein called a G-protein that binds guanine nucleotides and is located on the cytosolic face of the membrane, and (3) adenylate cyclase, which catalyzes the conversion of adenosine triphosphate (ATP) to cAMP. As the hormone binds at the receptor site, it is coupled through a regulatory protein, which acts as a transducer, to the enzyme adenyl cyclase, which catalyzes the formation of cAMP from ATP. The G-protein consists of three subunits, which in the unstimulated state form a heterotrimer to which a molecule of guanine diphosphate (GDP) is bound. Binding of the hormone to the receptor causes the subunit to exchange its GDP for a molecule of guanine triphosphate (GTP), which then dissociates from the subunits. This in turn decreases the affinity of

TABLE 2.3   Second Messenger/Examples of Hormones Which Utilize This System

Second messenger	Examples of dependent hormones
Cyclic AMP	Epinephrine and norepinephrine, glucagon, luteinizing hormone, follicle stimulating hormone, thyroid stimulating hormone, calcitonin, parathyroid hormone, antidiuretic hormone
Protein kinase	Insulin, growth hormone, prolactin, oxytocin, erythropoietin, various growth factors
Calcium ions and phosphoinositides	Epinephrine and norepinephrine, angiotensin II, antidiuretic hormone, gonadotrophin releasing hormone, thyroid releasing hormone
Cyclic GMP	Atrial natriuretic hormone, nitric oxide

the receptor for the hormone and leads to its dissociation. The GTP subunit not only activates adenylate cyclase, but also has intrinsic GTPase activity and slowly converts GTP back to GDP, thus allowing the subunits to reassociate and so regain their initial resting state. There are hormones, such as somatostatin, that possess the ability to inhibit AMP formation but still have similarly structured receptor complexes. The G-protein of inhibitory complexes consists of an inhibitory subunit complexed with a subunit thought to be identical to the subunits of the stimulatory G-protein. However, it appears that a single adenylate cyclase molecule can be simultaneously regulated by more than one G-protein enabling the system to integrate opposing inputs.

The adenylate cyclase reaction is rapid, and the increased concentration of intracellular cAMP is short-lived, since it is rapidly hydrolyzed and destroyed by the enzyme cAMP phosphodiesterase, which terminates the hormonal response. The continual and rapid removal of cAMP and free calcium ions from the cytosol makes for both the rapid increase and decrease of these intracellular mediators when the cells respond to signals. Rising cAMP concentrations affect cells by stimulating cAMP-dependent protein kinases to phosphorylate-specific target proteins.

Phosphorylation of proteins leads to conformational changes that enhance their catalytic activity, thus providing a signal amplification pathway from hormone to effector. These effects are reversible because phosphorylated proteins are rapidly dephosphorylated by protein phosphatases when the concentration of cAMP falls. A similar system involving cyclic GMP, although less common and less well studied, plays an analogous role to that of cAMP. The action of thyrotropin-releasing hormone (TRH), parathyroid hormone (PTH), and epinephrine is catalyzed by adenyl cyclase, and this can be regarded as the classic reaction.

2.4.1.1   Calcium Ion and Phosphoinositide Second Messenger Systems

However, there are variant mechanisms. In the phosphatidylinositol-diacylglycerol (DAG)/inositol triphosphate (EP3) system, some surface receptors are coupled through another G-protein to the enzyme phospholipase C, which cleaves the membrane phospholipid to form DAG and IP3 or phospholipase D which cleaves phosphatidyl choline to DAG via phosphatidic acid. DAG causes the calcium, phospholid-dependent protein kinase C to translocate to the cell membrane from the cytosolic cell compartment to become 20 times more active in the process. IP3 mobilizes calcium from storage sites associated with the plasma and intracellular membranes thereby contributing to the activation of protein kinase C as well as other calcium-dependent processes. DAG is cleared from the cell either by conversion to phosphatidic acid, which may be recycled to phospholipid, or it may be broken down to fatty acids and glycerol. The DAG derived from phosphatidylinositol usually contains arachidonic acid esterified to the middle carbon of glycerol. Arachidonic acid is the precursor of the prostaglandins and leukotrienes, which are biologically active eicosanoids. Thyrotropin and vasopressin modulate an activity of phospholipase C that catalyzes the conversion of phosphatidylinositol to diacylglycerol and inositol, 1,4,5-triphosphate, which act as the second messengers. They mobilize bound intracellular calcium and activate a protein kinase, which in turn alters the activity of other calcium-dependent enzymes within the cell.

Increased concentrations of free calcium ions affect cellular events by binding to and altering the molecular conformation of calmodulin; the resulting calcium ion–calmodulin complex can activate many different target proteins, including calcium ion-dependent protein kinases. Each cell type has a characteristic set of target proteins that are so regulated by cAMP-dependent kinases and calmodulin that it will respond in a specific way to an alteration in cAMP or calcium ion concentrations. In this fashion, cAMP or calcium ions act as second messengers in such a way as to allow the extracellular signal not only to be greatly amplified but, just as importantly, also to be made specific for each cell type.

2.4.1.2   Protein Kinase Second Messenger Systems

The hormone binds to domains exposed on the cell's surface, resulting in a conformational change that activates kinase domains located in the cytoplasmic regions of the receptor. In many cases, the receptor phosphorylates itself as part of the kinase activation process. The activated receptor phosphorylates

a variety of intracellular targets, many of which are enzymes that become activated or are inactivated upon phosphorylation. The receptors for several protein hormones are themselves protein kinases, which are switched on by binding of hormone. The kinase activity associated with such receptors results in phosphorylation of tyrosine residues on other proteins. Insulin is an example of a hormone whose receptor is a tyrosine kinase.

The action of the important hormone insulin that regulates glucose metabolism depends on the activation of the enzyme tyrosine kinase catalyzing the phosphorylation of tyrosyl residues of proteins. This effects changes in the activity of calcium-sensitive enzymes, leading to enhanced movement of glucose and fatty acids across the cell membrane and modulating their intracellular metabolism. The binding of insulin to its receptor site has been studied extensively; the receptor complex has been isolated and characterized. It was such work that highlighted the interesting aspect of feedback control at the cell level down-regulation: the ability of peptide hormones to regulate the concentration of cell surface receptors. After activation, the receptor population becomes desensitized, or "down-regulated"; leading to a decreased availability of receptors and thus a modulation of transmembrane events.

As with cAMP second messenger systems, activation of receptor tyrosine kinases leads to rapid modulation in a number of target proteins within the cell. Interestingly, some of the targets of receptor kinases are protein phosphatases, which, upon activation by receptor tyrosine kinase, become competent to remove phosphates from other proteins and alter their activity. Again, a seemingly small change due to hormone binding is amplified into a multitude of effects within the cell.

In some cases, binding of hormone to a surface receptor induces a tyrosine kinase cascade, even though the receptor is not itself a tyrosine kinase. The growth hormone receptor is one example of such a system — the interaction of growth hormone with its receptor leads to activation of cytoplasmic tyrosine kinases, with results conceptually similar to that seen with receptor kinases.

2.5 Hormones Acting within the Cell

Receptors for steroid and thyroid hormones are located inside target cells, in the cytoplasm or nucleus, and function as ligand-dependent transcription factors. That is to say, the hormone–receptor complex binds to promoter regions of responsive genes and stimulate or sometimes inhibit transcription from those genes. Thus, the mechanism of action of these hormones is to modulate gene expression in target cells. By selectively affecting transcription from a battery of genes, the concentration of those respective proteins are altered, which clearly can change the phenotype of the cell.

2.5.1 Structure of Intracellular Receptors

Steroid and thyroid hormone receptors are members of a large group of transcription factors. In some cases, multiple forms of a given receptor are expressed in cells, adding to the complexity of the response. All of these receptors are composed of a single polypeptide chain that has three distinct domains: the amino-terminus, involved in activating or stimulating transcription by interacting with components of the transcriptional machinery; the DNA-binding domain responsible for binding of the receptor to specific DNA sequences; and the carboxy-terminus or ligand-binding domain, which binds hormone. In addition to these three core domains, two other important regions of the receptor protein are a nuclear localization sequence, which targets the protein to nucleus, and a dimerization domain, responsible for latching two receptors together in a form capable of binding DNA.

2.5.2 Hormone–Receptor Binding and Interactions with DNA

Steroid hormones are small hydrophobic molecules derived from cholesterol that are solubilized by binding reversibly to specify carrier proteins in the blood plasma. Once released from their carrier proteins, they readily pass through the plasma membrane of the target cell and bind, again reversibly,

to steroid hormone receptor proteins in the cytosol. This is a relatively slow process when compared to protein hormones. The latter second messenger-mediated phosphorylation–dephosphorylation reactions modify enzymatic processes rapidly with the physiological consequences becoming apparent in seconds or minutes and are as rapidly reversed. Nuclear-mediated responses, on the other hand, lead to transcription/translation-dependent changes that are slow in onset and tend to persist since reversal is dependent on degradation of the induced proteins. The protein component of the steroid hormone–receptor complex has an affinity for DNA in the cell nucleus, where it binds to nuclear chromatin and initiates the transcription of a small number of genes. These gene products may, in turn, activate other genes and produce a secondary response, thereby amplifying the initial effect of the hormone. Each steroid hormone is recognized by a separate receptor protein, but this same receptor protein has the capacity to regulate several different genes in different target cells. This, of course, suggests that the nuclear chromatin of each cell type is organized so that only the appropriate genes are made available for regulation by the hormone–receptor complex. The thyroid hormone triiodothyronine (T3) also acts, though by a different mechanism than the steroids, at the cell nucleus level to initiate genomic transcription. The hormonal activities of GH and prolactin influence cellular gene transcription and translation of messenger RNA by complex mechanisms.

2.6 Endocrine System: Some Other Aspects of Regulation and Control

2.6.1 Control of Endocrine Activity

The physiologic effects of hormones depend largely on their concentration in blood and extracellular fluid. Almost inevitably, disease results when hormone concentrations are either too high or too low, and precise control over circulating concentrations of hormones is therefore crucial. The concentration of hormone as seen by target cells is determined by three factors:

- Rate of production: the synthesis and secretion of hormones are the most highly regulated aspect of endocrine control, which is mediated by feedback circuits, as described in the following sections
- Rate of delivery: a blood-flow-dependent factor
- Rate of degradation and elimination

2.6.2 Feedback Control of Hormone Production

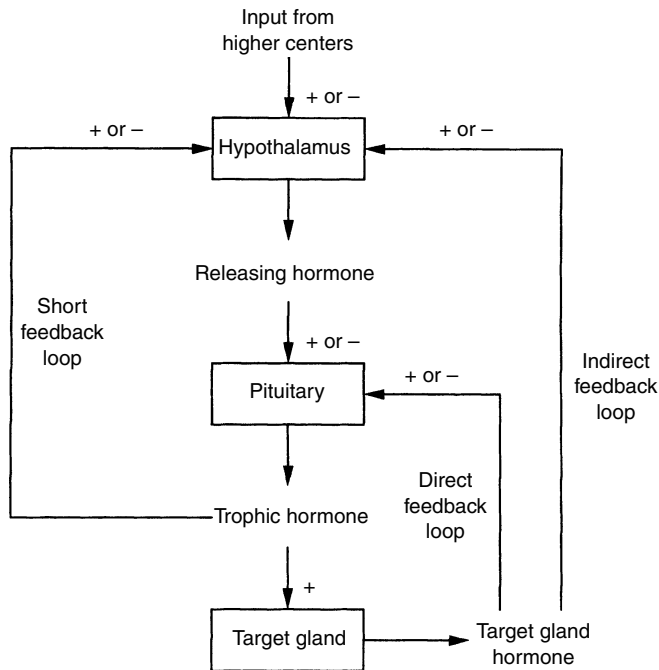
From the foregoing sections it is clear that the endocrine system exhibits complex molecular and metabolic dynamics, which involve many levels of control and regulation. At lower levels within this hierarchy, there is inherent feedback and control within the dynamics of metabolic processes themselves. Superimposed upon this there are also complex patterns of feedback and control that result from the effects of enzymes that catalyze such metabolic reactions. However, our focus here is the higher level of feedback and control resulting from hormonal dynamics. Hormones are chemical signals released from a hierarchy of endocrine glands and propagated through the circulation to a hierarchy of cell types. The integration of this system depends on a series of what systems engineers call "feedback loops"; feedback is a reflection of mutual dependence of the system variables: variable x affects variable y, and y affects x. Further, it is essentially a closed-loop system in which the feedback of information from the system output to the input has the capacity to maintain homeostasis. A diagrammatic representation of the ways in which hormone action is controlled is shown in Figure 2.2. One example of this control structure arises in the context of the thyroid hormones. In this case, TRH, secreted by the hypothalamus, triggers the anterior pituitary into the production of TSH. The target gland is the thyroid, which produces T3 and thyroxine (T4). The complexity of control includes both direct and indirect feedback of T3 and T4, as outlined in Figure 2.2, together with TSH feedback on to the hypothalamus.


FIGURE 2.2 Illustration of the complexity of hormonal feedback control ($+$ indicates a positive or augmenting effect; $-$ indicates a negative or inhibiting effect).

2.6.3 Negative Feedback

If an increase in y causes a change in x, which in turn tends to decrease y, feedback is said to be negative; in other words, the signal output induces a response that feeds back to the signal generator to decrease its output. Simply, negative feedback is seen when the output of a pathway inhibits inputs to the pathway. This is the most common form of control in physiologic systems, and examples are many. For instance, as mentioned earlier, the anterior pituitary releases trophic or stimulating hormones that act on peripheral endocrine glands such as the adrenals or thyroid or to gonads to produce hormones that act back on the pituitary to decrease the secretion of the trophic hormones. These are examples of what is called long-loop feedback (see Figure 2.2). (Note: the adjectives long and short reflect the spatial distance or proximity of effector and target sites.) The trophic hormones of the pituitary are also regulated by feedback action at the level of their releasing factors. Ultrashort-loop feedback is also described. There are numerous examples of short-loop feedback as well, the best being the reciprocal relation between insulin and blood glucose concentrations, as depicted in Figure 2.3. In this case, elevated glucose concentration (and positive rate of change, implying not only proportional but also derivative control) has a positive effect on the pancreas, which secretes insulin in response. This has an inhibiting effect on glucose metabolism, resulting in a reduction of blood glucose toward a normal concentration; in other words, classic negative-feedback control.

Feedback loops are also involved extensively to regulate secretion of hormones in the hypothalamic-pituitary axis. An important example of a negative-feedback loop is seen in control of thyroid hormone secretion. The thyroid hormones thyroxine and triiodothyronine (T4 and T3) are synthesized and secreted by thyroid glands and affect metabolism throughout the body. The negative-feedback control sequence in this system is: neurones in the hypothalamus secrete TRH, which stimulates cells in the anterior pituitary to secrete TSH. The released TSH binds to receptors on epithelial cells in the thyroid gland, stimulating synthesis and secretion of thyroid hormones, which affect probably all cells in the body. However, when the blood concentrations of thyroid hormones increase above a certain threshold, TRH-secreting neurons

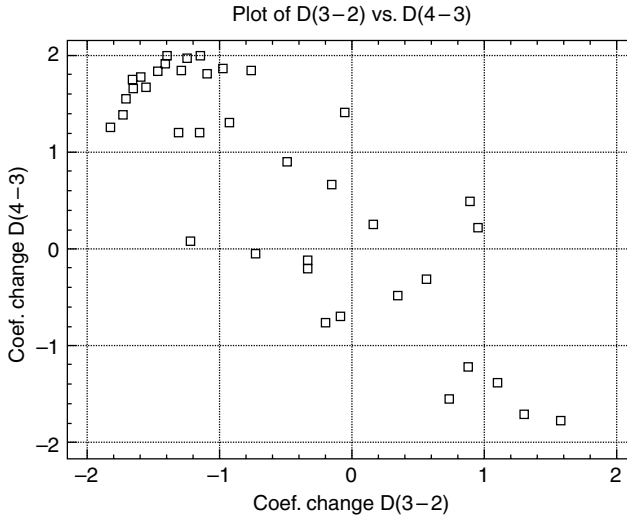
Plot of D(3−2) vs. D(4−3)


FIGURE 2.3   The interaction of insulin as an illustration of negative feedback within a hormonal control system.

in the hypothalamus are inhibited and stop secreting TRH. Inhibition of TRH secretion leads to shutoff of TSH secretion, which leads to shutoff of thyroid hormone secretion. As thyroid hormone levels decay below the threshold, negative feedback is relieved, TRH secretion starts again, leading to TSH secretion.

2.6.4 Positive Feedback

If increase in y causes a change in x, which tends to increase y, feedback is said to be positive; in other words, a further signal output is evoked by the response it induces or provokes. This is intrinsically an unstable system, but there are physiologic situations where such control is valuable. In the positive feedback situation, the signal output will continue until no further response is required. Suckling provides an example; stimulation of nipple receptors by the suckling child provokes an increased oxytocin release from the posterior pituitary with a corresponding increase in milk flow. Removal of the stimulus causes cessation of oxytocin release.

2.6.5 Pulsatile and Rhythmic Endocrine Control

An important consequence of feedback control and the limited physical half-life of hormones is that a pulsatile pattern of secretion and thus of hormone concentrations is seen over time for virtually all hormones, with variations in pulse characteristics that reflect specific physiologic states. In addition to these short-term pulses, longer-term temporal oscillations or endocrine rhythms are also commonly observed and undoubtedly important in both normal and pathologic states. Many hormone functions exhibit rhythmicity in the pulsatile release of hormones.

The most readily recognizable is the approximately 24-h cycle (circadian or diurnal rhythm). For instance, blood sampling at frequent intervals has shown that ACTH is secreted episodically, each secretory burst being followed 5 to 10 min later by cortisol secretion. These episodes are most frequent in the early morning, with plasma cortisol concentrations highest around 7 to 8 A.M. and lowest around midnight. ACTH and cortisol secretion vary inversely, and the parallel circadian rhythm is probably due to a cyclic change in the sensitivity of the hypothalamic feedback center to circulating cortisol. Longer cycles are also known, for example, the infradian menstrual cycle.

It is clear that such inherent rhythms are important in endocrine communication and control, suggesting that its physiologic organization is based not only on the structural components of the system but also on the dynamics of their interactions. The rhythmic, pulsatile nature of release of many hormones is a

means whereby time-varying signals can be encoded, thus allowing large quantities of information to be transmitted and exchanged rapidly in a way that small, continuous changes in threshold levels would not allow.

2.6.6 Coda

Inevitably, our brief exposition has been able to touch upon an enormous subject only by describing some of the salient features of this fascinating domain, but it is hoped that it may nevertheless stimulate a further interest. However, not surprisingly, the endocrinology literature is massive both in terms of the number of books and texts and an ever-increasing number of journals. It is suggested that anyone wishing to read further may initially start from one of the many excellent textbooks and go on from there.

Nervous system unlike other organ systems is primarily concerned with signals, information encoding and processing, and control rather than manipulation of energy. It acts like a communication device whose components use substances and energy in processing signals and in reorganizing them, choosing and commanding as well as in developing and learning. A central question that is often asked is how nervous systems work and what governs the principles of their operation. In an attempt to answer this question, we, at the same time, ignore other fundamental questions such as anatomical or neurochemical and molecular aspects. We rather concentrate on relations and transactions between neurons and their assemblages in the nervous system. We deal with neural signals (encoding and decoding), the evaluation and weighting of incoming signals, and the formulation of outputs. A major part of this chapter is devoted to higher aspects of the nervous system such as memory and learning rather than individual systems such as vision and audition, which are treated extensively elsewhere [1]. Finally, some known abnormalities of the nervous system including Parkinson's and Alzheimer's disease, epilepsy, and the phantom limb sensation, and pain are the subjects we deal with.

3.1   Definitions

Nervous systems can be defined as organized assemblies of nerve cells as well as nonnervous cells. Nerve cells or neurons are specialized in the generation, integration, and conduction of incoming signals from the outside world or from other neurons and deliver them to other excitable cells or to *effectors* such as muscle cells. Nervous systems are easily recognized in higher animals, but not in the lower species, since the defining criteria are difficult to apply.

3-1

A central nervous system (CNS) can be easily distinguished from a peripheral nervous system (PNS), since it contains most of the motor and the nucleated parts of neurons that innervate muscles and other effectors. The PNS contains all the sensory nerve cell bodies with some exceptions, plus local *plexuses*, local *ganglia*, and peripheral axons that make up the *nerves*. Most sensory axons go all the way into the central nervous system while the remaining relay in peripheral plexuses. Motor axons originating in the CNS innervate effector cells.

The nervous system has two major roles: first, to regulate, acting homeostatically, in restoring some conditions of the organism after some external stimulus and second, to act to alter a preexisting condition by replacing it or modifying it. In both cases — regulation or initiation of a process — learning can be superimposed. In most species, learning is more or less an adaptive mechanism, combining and timing species-characteristic acts, with a large degree of evolution toward perfection.

The nervous system is a complex structure for which realistic assumptions have led to irrelevant oversimplifications. One can break down the nervous system into four components: sensory transducers, neurons, axons, and muscle fibers. Each of these components gathers processes and transmits information impinging upon them from the outside world, usually in the form of complex stimuli. The processing is carried out by excitable tissues — neurons, axons, sensory receptors, and muscle fibers. Neurons are the basic elements of the nervous system. If, put in small assemblies or clusters, they form neuronal assemblies or neuronal networks communicating with each other either chemically via *synaptic junctions* or electrically via *tight* junctions. The main characteristics of a cell are the *cell body* or *soma*, which contains the *nucleus*, and a number of processes originating from the cell body called the *dendrites*, which reach out to the surroundings to make contacts with other cells. These contacts serve as the incoming information to the cell, while the outgoing information follows a conduction path, the axon. The incoming information is integrated in the cell body and generates the result of this at the *axon hillock*. There are two types of outputs that can be generated and therefore two types of neurons: those who generate *grated* potentials that attenuate with distance and those who generate *action* potentials. The action potential, travels through the axon, a thin long process that passively passes the action potential or rather a train of action potentials without attenuation (*all-or-none* effect). A series of action potentials is often called a *spike train*. A threshold built into the hillock, and depending on its level, allows or stops the generation of the spike train. Axons usually terminate on other neurons by means of *synaptic terminals* or *boutons* and have properties similar to those of an electric cable with varying diameters and speeds of signal transmission. Axons can be of two types, namely *myelinated* or *unmyelinated*. In the former the axon is surrounded by a thick fatty material, the myelin sheath, which is interrupted at regular intervals by gaps called the *nodes of Ranvier*. These nodes provide for the *saltatory* conduction of the signal along the axon. The axon makes functional connections with other neurons at synapses either on the cell body, the dendrites, or the axons. There exist two kinds of synapses: *excitatory* and *inhibitory* and as the name implies they either increase the *firing* frequency of the postsynaptic neurons or decrease it, respectively [5].

Sensory receptors are specialized cells that, in response to an incoming stimulus, generate a corresponding electrical signal, a graded receptor potential. Although the mechanisms by which the sensory receptors generate receptor potentials, are not exactly known, the most plausible scenario is that an external stimulus alters the membrane permeabilities. The receptor potential then is the change in intracellular potential relative to the *resting* potential.

It is important to notice here that the term receptor is used in physiology to refer not only to sensory receptors but in a different sense to proteins that bind neurotransmitters, hormones, and other substances with great affinity and specificity as a first step in starting up physiological responses. This receptor is often associated with nonneural cells that surround it and form a *sense organ*. The forms of energy converted by the receptors include mechanical, thermal, electromagnetic, and chemical energy. The particular form of energy to which a receptor is most sensitive is called its *adequate stimulus*. The problem of how receptors convert energy into action potentials in the sensory nerves has been the subject of intensive study. In the complex sense organs such as those concerned with hearing and vision there exist separate receptor cells and synaptic junctions between receptors and afferent nerves. In other cases such as the cutaneous sense organs, the receptors are specialized. Where a stimulus of constant strength is applied to a receptor

repeatedly, the frequency of the action potentials in its sensor nerve declines over a period of time. This phenomenon is known as *adaptation*; if the adaptation is very rapid then the receptors are called *phasic*, otherwise as *tonic*.

Another important issue is the *coding* of sensory information. Action potentials are similar in all nerves although there are variations in their speed of conduction and other characteristics. But if the action potentials are the same in most cells, then what makes the visual cells sensitive to light and not to sound and the touch receptors sensitive to a sensation of touch and not of smell? And how can we tell if these sensations are strong or not? These sensations depend upon the specific part of the brain called the *doctrine of specific nerve energies* and has been questioned over time by several researchers. No matter where a particular sensory pathway is stimulated along its path of connecting to the brain, the sensation produced is always referred to the location of the receptor site. This is the principle of the *law of projections*. An example of this law is the "phantom limb" where an amputee of a limb is complaining about pain or an itching sensation in that limb. This phenomenon is discussed in a greater detail later on in the chapter.

3.2 Functions of the Nervous System

The basic unit of integrated activity is the *reflex arc*. This arc consists of a sense organ, an afferent neuron, one or more synapses in a central integrating station (or sympathetic ganglion), an efferent neuron, as well as, an effector. The simplest reflex arc is the *monosynaptic* one, which only has one synapse between the afferent and efferent neuron. With more than one synapses the reflex arc is called *polysynaptic*. In each of these cases, activity is modified by both spatial and temporal facilitation, occlusion, and other effects [2,3].

In mammals, the connection between afferent and efferent somatic neurons is found either in the brain or the spinal cord. The Bell–Magendie law dictates the fact that in the spinal cord the dorsal roots are sensory while the ventral roots are motor. The action potential message that is carried by an axon is eventually fed to a muscle, or to a secretory cell, or to the dendrite of another neuron. If an axon is carrying a graded potential, its output is too weak to stimulate a muscle, but it can terminate on a secretory cell or dendrite. The latter can have as many as 10,000 inputs. If the end point is a motor neuron, which has been found experimentally in the case of fibers from the primary endings, then there is a time lag between the time when a stimulus was applied and a response obtained from the muscle. This time interval is called the *reaction time* and in humans is approximately 20 msec for a stretch reflex. The distance from the spinal cord can be measured and since the conduction velocities of both the efferent and afferent fibers are known, another important quantity can be calculated, namely the *central delay*. This delay is the portion of the reaction time that was spent for conduction to and from the spinal cord. It has been found that muscle spindles also make connections that cause muscle contraction via polysynaptic pathways, while the afferents from secondary endings make connections that excite extensor muscles. When a motor neuron sends a burst of action potentials to its skeletal muscle, the amount of contraction depends largely on the discharge frequency, but on many other factors as well, such as the history of the load on the muscle and the load itself. *The stretch error* can be calculated from the desired motion minus the actual stretch. If this error is then fed back to the motor neuron, its discharge frequency is modified appropriately. This frequency modification corresponds to one of the three feedback loops that are available locally. Another loop corrects for overstretching beyond the point at which the muscle or tendon may tear. Since a muscle can only contract, it must be paired with another muscle (*antagonist*) in order to affect the return motion. Generally speaking, a flexor muscle is paired with an extension muscle that cannot be activated simultaneously. This means that the motor neurons that affect each one of these muscles are not activated at the same time. Instead when one set of motor neurons is active, the other is inhibited and vice versa. When a movement involves two or more muscles that normally cooperate by contracting simultaneously, the excitation of one causes facilitation of the other *synergistic* members via cross connections. All of these networks form feedback loops. An engineer's interpretation of how these loops work would be to assume dynamic conditions, as is the case in all parts of the nervous system. This has little value in dealing with stationary conditions, but it provides for an ability to adjust to changing conditions.

The nervous system, as mentioned in the introduction, is a control system of processes that adjust both internal and external operations. As humans we have experiences that change our perception of events in our environment. The same is true for higher animals that besides having an internal environment, the status of which is of major importance, also share an external environment of utmost richness and variety. Objects and conditions that have direct contact with the surface of an animal directly affect the future of the animal. Information about changes at some point provides a prediction of possible future. The amount of information required to represent changing conditions increases as the required temporal resolution of detail increases. This creates a vast amount of data to be processed by any finite system. Considering the fact that the information reaching sensory receptors is too extensive and redundant, as well as modified by external interference (noise), the nervous system has a tremendously difficult task to accomplish. Enhanced responsiveness to a particular stimulus can be produced by structures that either increase the energy converging on a receptor or increase the effectiveness of coupling of a specific type of stimulus to the receptor. Different species have sensory systems that respond to stimuli that are important to them for survival. Often one nervous system responds to conditions that are not sensed by another nervous system [4,5]. The transduction, processing, and transmission of signals in any nervous system, produces a survival mechanism for an organism but only after these signals have been further modified by effector organs. Although the nerve impulses that drive a muscle as explained earlier are discrete events, a muscle twitch takes much longer to happen, a fact that allows for responses to overlap and produce a much smoother output. Neural control of motor activity of skeletal muscle is accomplished entirely by the modification of the muscle excitation, which involves changes in velocity, length, stiffness, and heat production. The importance of accurate timing of inputs, and the maintenance of this timing across several synapses, is obvious in sensory pathways of the nervous system. Cells are located next to other cells that have overlapping or adjacent receptive or motor fields. The dendrites provide important and complicated sites of interactions as well as channels of variable effectiveness for excitatory inputs, depending on their position relative to the cell body. Among the best examples are the cells of the medial superior olive in the auditory pathway. These cells have two major dendritic trees extending from opposite poles of the cell body. One receives synaptic inhibitory input from the ipsilaterial cochlear nucleus and the other from the contralateral, which normally is an excitatory input. These cells deal with the determination of the azimuth of a sound. When a sound is present at the contralateral side, most cells are excited while ipsilateral sounds cause inhibition. It has been shown that the cells can go from complete excitation to full inhibition with a difference of only a few hundred milliseconds in arrival time of the two inputs.

The question then arises: how does the nervous system put together the signals available to it so that a determination of our output takes place? To arrive at an understanding of how the nervous system intergrates incoming information at a given moment of time, we must understand that the processes that take place depend both on cellular forms and a topological architecture as well as on the physiological properties that relate input to output. That is, we have to know the *transfer* functions or *coupling* functions. Integration depends on the weighting of inputs. One of the important factors determining weighting is the area of synaptic contact. The extensive dendrites are the primary integrating structures. Electronic spread is the means of mixing, smoothing, attenuating, delaying, and summing postsynaptic potentials. The spatial distribution of input is often not random but systematically restricted. Also, the wide variety of characteristic geometries of synapses is, no doubt, important not just for the weighting of different combinations of inputs. When repeated stimuli are presented at various intervals at different junctions, higher amplitude synaptic potentials are generated, if the intervals between them are not too short or too long. This increase in amplitude is due to a phenomenon called *facilitation*. If the response lasts longer than the interval between impulses, so that the second response rises from the residue of the first, then it is called *temporal summation*. If in addition, the response increment due to the second stimulus is larger than the previous one, then it is facilitation. Facilitation is an important function of the nervous system and is found in quite different forms and durations ranging from a few milliseconds to tenths of seconds. Facilitation may grade from forms of sensitization to learning, especially at long intervals. A special case is the so-called *posttetanic potentiation* which is the result of high frequency stimulation for long periods of time (about 10 sec). The latter is an interesting case since, no effects can be seen during stimulation but

afterward any test stimulus at various intervals creates a marked increase in response up to many times more than the "tetanic" stimulus. *Antifacilitation*, is the phenomenon where a decrease of response from the neuron is observed at certain junctions, due to successive impulses. Its mechanism is less understood than facilitation. Both facilitation and antifacilitation may be observed on the same neuron but when different functions are performed.

3.3   Representation of Information in the Nervous System

Whenever information is transferred between different parts of the nervous system some communication paths have to be established, and some parameters of impulse firing relevant to communication must be set up. Since what is communicated is nothing more than impulses — spike trains — the only basic variables in a train of events are the number of and the interval between spikes. With respect to that, the nervous system acts like a pulse coded analog device since the intervals are continuously graded. There exists a distribution of interval lengths between individual spikes, which in any sample can be expressed by the shape of the interval histogram. If one examines different examples, it will be seen that their distributions markedly differ. Some histograms look like Poisson distributions, some others exhibit Gaussian or bimodal shapes. The coefficient of variation — expressed as the standard deviation over the mean — in some cases is constant while in others it varies. Some other properties depend on the sequence of longer and shorter intervals than the mean. Some neurons show no linear dependence, some others positive or negative correlations of successive intervals. If stimulus is delivered and a discharge from the neuron is observed, a *poststimulus time histogram* can be used using the onset of the stimulus as a reference point and average many responses in order to reveal certain consistent features of temporal patterns. Coding of information can then be based on the average frequency, which can represent relevant gradations of the input. Mean frequency is the code in most cases, although no definition of it has been given with respect to measured quantities such as averaging time, weighting functions, and forgetting functions. Characteristic transfer functions have been found that suggest that there are several distinct coding principles in addition to the mean frequency. Each theoretically possible code becomes a candidate code as long as there exists some evidence that is readable by the system under investigation. So, one has to first test for the availability of the code by imposing a stimulus that is considered normal. After a response has been observed, the code is considered to be available. If the input is changed to different levels of one parameter and changes are observed at the postsynaptic level, the code is called *readable*. However, only if both are formed in the same preparation and no other parameter is available and readable, can the code be said to be the *actual* code employed. Some such parameters are:

- Time of firing
- Temporal pattern
- Number of spikes in the train
- Variance of interspike intervals
- Spike delays or latencies
- Constellation code

The latter is a very important one, especially when used in conjunction with the concept of *receptive fields* of units in different sensory pathways. The unit receptors do not need to have highly specialized abilities to permit encoding of a large number of distinct stimuli. Receptive fields are topographic and overlap extensively. Any given stimulus will excite a certain constellation of receptors and is therefore encoded in the particular set that is activated. A large degree of uncertainty prevails and requires the brain to operate probabilistically. In the nervous system there exists a large amount of *redundancy* although neurons might have different thresholds. It is questionable, however, if these units are entirely equivalent although they share parts of their receptive fields. The nonoverlapping parts might be of importance and critical to sensory function. On the other hand, redundancy does not necessarily mean unspecified or

random connectivity. It rather allows for greater sensitivity and resolution, improvement of signal to noise ratio, while at the same time it provides stability of performance.

Integration of large numbers of converging inputs to give a single output can be considered as an averaging or probabilistic operation. The "decisions" made by a unit depend on its inputs or some intrinsic states and on its reaching a certain threshold. This way every unit in the nervous system can make a decision, when it changes from one state to a different one. A theoretical possibility also exists that a mass of randomly connected neurons may constitute a trigger unit and that activity with a sharp threshold can spread through such a mass redundancy. Each part of the nervous system and in particular the receiving side can be thought of as a filter. Higher-order neurons do not merely pass that information on, but instead, they use convergence from different channels, as well as divergence of the same channels and other processes, in order to modify incoming signals. Depending on the structure and coupling functions of the network, what gets through is determined. Similar networks exist at the output side. They also act as filters, but since they formulate decisions and commands with precise *spatiotemporal* properties they can be thought of as *pattern generators*.

3.4 Lateral Inhibition

Our discussion will be incomplete without the description of a very important phenomenon in the nervous system. This phenomenon called *lateral inhibition* is used by the nervous system to improve spatial resolution and contrast. The effectiveness of this type of inhibition decreases with distance. In the retina, for example, lateral inhibition is used extensively in order to improve contract. As the stimulus approaches a certain unit, it first excites neighbors of the recorded cell. Since these neighbors inhibit that unit, its response is a decreased firing frequency. If the stimulus is exactly over the recorded unit, this unit is excited and fires above its normal rate and as the stimulus moves out again the neighbors are excited while the unit under consideration fires less. If we now examine the output of all the units as a whole and at once, while half of the considered array is stimulated the other half is not, we will notice that at the point of discontinuity of the stimulus going from stimulation to nonstimulation, the firing frequencies of the two halves have been differentiated to the extreme at the stimulus edge, which has been enhanced. The neuronal circuits responsible for lateral shifts are relatively simple. Lateral inhibition can be considered to give the negative of the second spatial derivative of the input stimulus. A second layer of neurons could be constructed to perform this spatial differentiation on the input signal to detect only the edge. It is probably lateral inhibition that explains the psychophysical illusion known as *Mach bands*. It is probably the same principle that operates widely in the nervous system to enhance the sensitivity to contrast in the visual system in particular and in all other modalities in general. Through the years different models have been developed in order to describe lateral inhibition mathematically and various methods of analysis have been employed. These models include both one-dimensional examination of the phenomenon and two-dimensional treatment, where a two-dimensional array is used as a stimulus. This two-dimensional treatment is justified since most of the sensory receptors of the body form two-dimensional maps (receptive fields). In principle, if a one-dimensional lateral inhibition system is linear, one can extend the analysis to two dimensions by means of superposition. The objective is the same as that of the nervous system: to improve image sharpness without introducing too much distortion. This technique requires storage of each picture element (pixel) and lateral "inhibitory" interactions between adjacent pixels. Since a picture may contain millions of pixels, high-speed computers with large-scale memories are required.

At a higher level, similar algorithms can be used to evaluate decision-making mechanisms. In this case, many inputs from different sensory systems are competing for attention. The brain evaluates each one of the inputs as a function of the remaining ones. One can picture a decision-making mechanism resembling a "locator" of stimulus peaks. The final output depends on what weights are used at the inputs of a push–pull mechanism. Thus a decision can be made depending on the weights an individual's brain is applying to the incoming information about the situation under consideration. The most important information is heavily weighted while the rest is either totally masked or weighted very lightly.

3.5   Higher Functions of the Nervous System

3.5.1   Human Perception and Pattern Recognition

One way of understanding the human perception is to study the mechanisms of information processing in the brain. The recognition of patterns of sensory input is one function of the brain, a task accomplished by neuronal circuits, the *feature extractors*. Although such neuronal information is more likely to be processed globally, by a large number of neurons, in animals, single-unit recording is one of the most powerful tools in the hands of a physiologist. Most often, the concept of the *receptive field* is used as a method of understanding the sensory information processing. In the case of the visual system we would call the receptive field a well-defined region of the visual field, which when stimulated will change the firing rate of a neuron in the visual pathway. The response of the neuron will usually depend on the distribution of light in the receptive field. Therefore, the information collected by the brain from the outside world is transformed into spatial as well as temporal patterns of neural activity.

The question often asked is how do we perceive and recognize faces, objects, and scenes. Even in those cases where only noisy representations exist, we are still able to make some inference as to what the pattern represents. Unfortunately in humans, single-unit recording, as mentioned earlier is impossible. As a result, one has to use other kinds of measurements, such as evoked potentials (EPs) or functional imaging techniques such as functional magnetic resonance imaging (fMRI), and positron emission tomography (PET). Although physiological in nature, EPs are still far away from giving us information at the neuronal level. However, all these methods have been used extensively as a way of probing the human (and animal) brains because of their noninvasive character. EPs can be considered to be the result of integrations of the neuronal activity of many neurons somewhere in the brain. These gross potentials can be used as a measure of the response of the brain to sensory inputs.

The question then arises: Can we use this response to influence the brain in producing patterns of activity that we want? None of the efforts of the past closed that loop. How do we explain then the phenomenon of selective attention by which we selectively direct our attention to something of interest and discard the rest? And what happens with the evolution of certain species that change appearance according to their everyday needs? All of these questions tend to lead to the fact that somewhere in the brain there is a loop where previous knowledge or experience is used as a feedback to the brain itself. This feedback modifies the ability of the brain to respond in a different way to the same stimulus the next time it is presented. In a way then, the brain creates mental "images" independent of the stimulus, which tend to modify the representation of the stimulus in the brain [1].

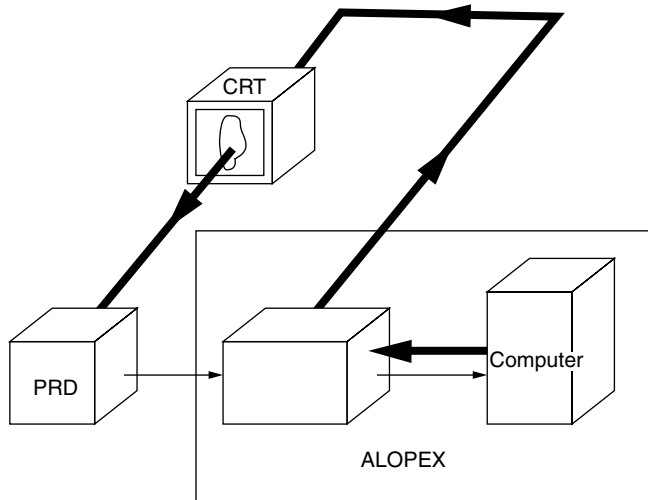
This section describes some efforts in which different methods have been used in trying to address the difficult task of feedback loops in the brain. However, no attempt will be made to explain or even postulate where these feedback loops might be located. If one considers the brain as a huge set of neural networks, then one question has been debated for many years: what is the role of the individual neuron in the net and what is the role of each network in the global processes of the brain? More specifically, does the neuron act as an analyzer or a detector of specific features or does it merely reflect the characteristic response of a population of cells of which it happens to be a member? What invariant relationships exist between sensory input and the response of a single neuron and how much can be "read" about the stimulus parameters from the record of a single EP? In turn, then, how much feedback can one use from a single EP in order to influence the stimulus and how successful can that influence be? Many physiologists express doubts that simultaneous observations of large number of individual neuronal activities can be readily interpreted. In other words, can then, a feedback process influence and modulate the stimulus patterns so that they appear as being optimal? If this were proven to be true, it would mean that we can reverse the pattern recognition process and instead of recognizing a pattern we would be able to create a pattern from a vast variety of possible patterns. It would be like creating a link between our brain and a computer, equivalent to a brain–computer system network. Figure 3.1 is a schematic representation of such a process involved in what we call the feedback loop of the system. The *pattern recognition device* (PRD) is connected to an ALOPEX system (a computer algorithm and an image processor in this case) and faces a display


FIGURE 3.1 An ALOPEX system. The stimulus is presented on the cathode ray tube (CRT). The observer or any pattern recognition device (PRD) faces the CRT; the subject's response is sent to the ALOPEX interface unit where it is recorded and integrated and the final response is sent to the computer. The computer calculates the values of the new pattern to be presented on the CRT according to the ALOPEX algorithm and the process continues until the desired pattern appears on the CRT. At this point the response is considered to be optimal and the process stops.

monitor where different intensity patterns can be shown. In this figure, thin arrows represent response information and heavy arrows represent detailed pattern information generated by the computer and relayed by an ALOPEX system to the monitor. ALOPEX is a set of algorithms described in detail elsewhere in this Handbook. If this kind of arrangement is used for the determination of visual-receptive fields of neurons, then the PRD is nothing more than the brain of the experimental animal or human. This way the neuron under investigation does its own selection of the best stimulus or trigger feature, and reverses the role of the neuron from being a feature extractor to becoming a feature generator as mentioned earlier. The idea is to find the response of the neuron to a stimulus and use this response as a positive feedback in the directed evaluation of the initially random pattern. Thus, the cell filters out the key trigger features from the stimulus and reinforces them with the feedback.

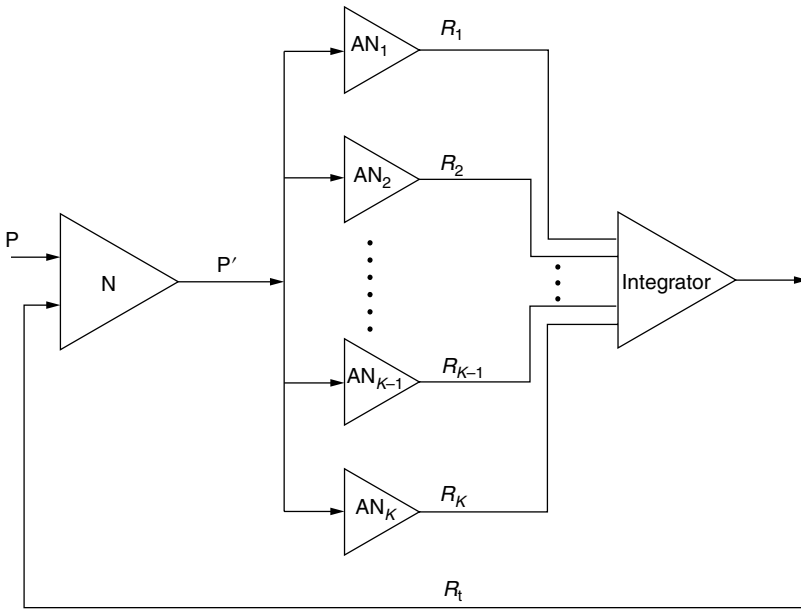
As a generalization of this process we might consider that a neuron, N, receives a visual input from a pattern, P, which is transmitted in a modified form P′ to an analyzer neuron AN (or even a complex of such neurons) as shown in Figure 3.2. The analyzer responds with a scalar variable, R, that is then fed back to the system and the pattern is modified accordingly. The process continues in small steps (iterations) until there is an almost perfect correlation between the original pattern (template) and the one that the neuron, N, indirectly created. This integrator sends the response back to the original modifier. The integrator need not be a linear one. It could take any nonlinear form, a fact that is a more realistic representation of the visual cortex. We can envision the input patterns as templates preexisting in the memory of the system, a situation that might come about with visual experience. For a "naive" system, any initial pattern will do. As experience is gained the patterns become less random. If one starts with a pattern that has some resemblance to one of the preexisting patterns, evolution will take its course. In nature, there might exist a mechanism similar to that of ALOPEX [1]. By filtering the characteristics that are most important for the survival of the species, changes would be triggered. *Perception*, therefore, could be considered to be an interaction between sensory inputs and past experience in the form of templates stored in the memory bank of the perceiver and is specific to the perceiver's needs. These templates are modifiable with time and adjusted accordingly to the input stimuli. With this approach the neural nets and ensembles of nets generate patterns that describe their thinking and memory properties. Thus, the normal flow of information is *reversed* and controls the afferent systems.


FIGURE 3.2 Schematic representation of the ALOPEX "inverse" pattern recognition scheme. Each neuron represents a feature analyzer, which responds to the stimulus with a scalar quantity R called the *response*. R is then fed back to the system and the pattern is modified accordingly. This process continues until there is an almost perfect correlation between the desired output and the original pattern.

Perception processes as well as feature extraction or suppression of images or objects can be ascribed to specific neural mechanisms due to some sensory input, or even due to some "wishful thinking" of the PRD. If it is true that the association cortex is affecting the sensitivity of the sensory cortex, then an ALOPEX mechanism is what one needs to close the loop for memory and learning.

3.5.2 Memory and Learning

If we try to define what memory is, we will face the fact that memory is not a single mental faculty but it is rather composed of multiple abilities mediated by separate and distinct brain systems. Memory for a recent event can be expressed *explicitly* as a conscious recollection, or *implicitly*, as a facilitation of test performance without conscious recollection. The major distinction between these two memories is that explicit or *declarative* memory depends on limbic and diencephalic structures and provides the basis for recollection of events, while implicit or *nondeclarative* memory, supports skills and habit learning, single conditioning, and the well-researched phenomenon of *priming* [7].

Declarative memory refers to memory of recent events and is usually assessed by tests of recall or recognition for specific single items. When the list of items becomes longer, a subject not only learns about each item on the list but also makes associations about what all these items have in common, that is, the subject learns about the category that the items belong to. Learning leads to changes that increase or decrease the effectiveness of impulses arriving at the junctions between neurons and the cumulative effect of these changes constitutes memory. Very often a particular pattern of neural activity leads to a result that occurs some time after that activity has ended. Learning then requires some means of relating the activity that is to be changed to the evaluation that can be made only by the delayed consequence. This phenomenon in physics is called *hysteresis* and refers to any modifications of future actions due to past actions. *Learning* then could be defined as change in any neuronal response resulting from previous experiences due to an external stimulus. *Memory* in turn, would be the maintenance of these changes over time. The collection of neural changes representing memory is commonly known as the *engram* and a major part of recent work has been to identify and locate engrams in the brain, since specific parts of

the nervous system are capable of specific types of learning. The view of memory that has recently emerged is that, information storage is tied to specific processing areas that are engaged during learning. The brain is organized so that separate regions of the neocortex simultaneously carry out computations on specific features or characteristics of the external stimulus, no matter how complex that stimulus might be. If the brain learns specific properties or features of the stimulus then we talk about the *nonassociative memory*. Associated with this type of learning is the phenomenon of *habituation* in which, if the same stimulus is presented repeatedly, the neurons respond less and less, while the introduction of a new stimulus increases the sensitization of the neuron. If learning includes two related stimuli then we talk about associative learning. This type of learning can be of two types: classical conditioning and operant conditioning. The former deals with relationships among stimuli while the latter deals with the relationship of the stimulus to the animal's own behavior. In humans, there exist two types of memory: short- and long-term memories. The best way to study any physiological process in humans (especially memory) is to study its pathology. The study of amnesia has provided strong evidence of distinguishing between these types of memory. Amnesic patients can keep a short list of numbers in mind for several minutes if they pay attention to the task. The difficulty comes when the list becomes longer, especially if the amount to be learned exceeds the brain capacity of what can be held in immediate memory. It could be that this happens because more systems have to be involved and that temporary information storage may occur within each brain area where stable changes in synaptic efficacy can eventually develop. *Plasticity* within existing pathways can account for most of the observations and short-term memory occurs too quickly for it to require any major modifications of neuronal pathways. The capacity of long-term memory requires the integrity of the medial temporal and diencephalic regions, in conjunction with neurons for storage of information. Within the domain of long-term memory amnesic patients demonstrate intact learning and retention of certain motor, perceptual and cognitive skills, and intact priming effects. These patients do not exhibit any learning deficits but have no conscious awareness of prior study sessions or recognition of previously presented stimuli.

Priming effects can be tested by presenting words and then providing either the first few letters of the word or the last part of the word for recognition by the patient. Normal subjects, as expected, perform better than amnesic subjects. But if these patients are instructed to "read" the incomplete word instead of memorizing it, then they perform as well as the normal. Also, amnesic patients perform well if words are cued by category names. Thus, priming effects seem to be independent of the processes of recall and recognition memory, which is also observed in normal subjects. All these evidences support the notion that the brain has organized its memory functions around fundamentally different information storage systems. In perceiving a word, a preexisting array of neurons is activated that have concurrent activities that produce perception and priming is one of these functions.

Memory is not fixed immediately after learning, but continues to grow toward stabilization over a period of time. This stabilization is called *consolidation of memory*. Memory consolidation is a *dynamic* feature of long-term memory, especially the declarative memory, but is neither an automatic process with fixed lifetime nor is it determined at the time of learning. It is rather a process of reorganization of stored information. As time passes, some not yet consolidated memories fade out by remodeling the neural circuitry that is responsible for the original representation or by establishing new representations, since the original one might be forgotten.

The problems of learning and memory are studied continuously and with increased interest these years, especially because artificial systems such as Neural Networks can be used to mimic functions of the nervous system.

3.6 Abnormalities of the Nervous System

3.6.1 Parkinson's Disease

Parkinson's disease is a slowly progressive neurodegenerative disease of the CNS (central nervous system) first described in 1817 by James Parkinson. The incidence rates ranges from 4.5 to 21/100,000 individuals

per year. At least 750,000,000 people are affected in the United States alone. Although most patients affected are over 60 years of age, as many as 10% may be less than 40.

Parkinson's disease occurs due to degeneration of the substantia nigra, a part of the brain involved in motor control, whose cells secretes the neurotransmitter dopamine to other movement-control centers known as the basal ganglia. The basal ganglia circuitry, which utilizes other neurotransmitters like gamma-aminobutyric acid and serotonin among others, is therefore affected. It is due to these other neuro-transmitters that patients may develop nonmotor symptoms later in the disease. Some of these symptoms include cognitive problems, psychiatric disorders (e.g., depression), sleep disorders (e.g., restless leg syndrome, rapid eye movement (REM), behavior disorder), and autonomic nervous system dysfunction among others [8].

A minority of patients may have a genetic disorder. Those patients know of other family members, throughout the different generations, with Parkinson's disease. But what causes the degeneration in the substantia nigra in the majority of the patients is still unknown. Multiple reports were published in the late 1970s and early 1980s of patients who developed parkinsonism induced by MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a contaminant of illicit narcotics. Some other culprits include manganese, carbon monoxide, pesticides, antidopaminergic therapy, but these are implicated only in very few cases.

The diagnosis is made clinically when the characteristic motor deficits appear. These include tremor, bradykinesia (slowed movements), rigidity, and postural instability. The tremor occurs at rest. It occasionally begins with an alternating opposition of the fingers and thumb called "pill-rolling" tremor. The characteristic frequency of the Parkinsonian tremor is of 3 to 5 cycles/sec. Symptoms usually begin on one side of the body and slowly progresses over years to decades to include the other side.

The various pharmacological treatments currently available are designed to affect the dopaminergic system. The "gold standard" is levodopa. However, long-term use of levodopa leads to motor complications, mainly dyskinesias or chorea (involuntary, uncontrolled movements of the body). Dopamine agonists appear to delay the onset of dyskinesias for a few years. Currently under study are a few nondo-paminergic drugs with the hope of improving motor symptoms, avoid motor complications, and delay neurodegeneration [10].

3.6.2 Alzheimer's Disease

Alzheimer's disease (AD) it is the most common form of dementia among elders. It is named after Alois Alzheimer, who described both the clinical features and pathologic changes in 1906. Like Parkinson's disease, it is also a progressive neurodegenerative disease. The prevalence in the United States in patients above age 65 is 10.3%, rising to 47% in those over the age of 80.

Alzheimer's disease is primarily the result of degeneration or death of nerve cells in the cerebral cortex and in areas that usually control functions such as memory, personality, logical thinking, and other. As the nerve cells become withered and small, they cause the enlargement of the ventricles of the brain. Recent events are not remembered, the individual is not able to perform calculations or make plans and decisions. Abrupt personality changes alarm family members and friends thus disabling the person from functioning normally.

The etiology of the majority of the cases still remains unknown, although it appears to be depending on multiple factors. Familial AD, although rare, can be inherited. The patients in this group have an earlier onset (age 30 to 60) than the common form of AD. The one risk factor for the more common form is a protein involved in cholesterol transport known as apolipoprotein E (apoE). The allele frequency of an isoform of apoE (apoE4) was found to be 40% in either familial or common form AD compared to 15% in patients without AD [11].

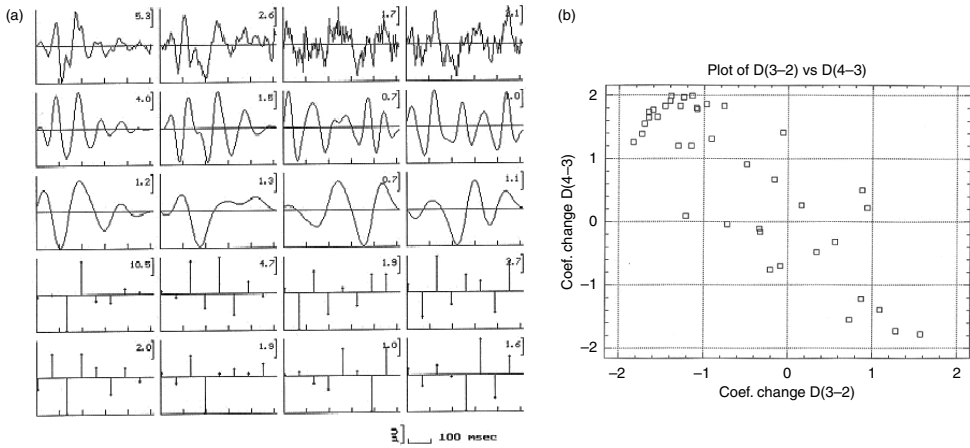
Alzheimer's disease is characterized by atrophy of the cerebral cortex, usually more severe in the frontal, parietal, and temporal lobes. The most characteristic microscopic findings are the senile plaques and neurofibrillary tangles. These are mostly found throughout the cerebral cortex and hippocampus. The activity of choline acetyltransferase, the biosynthetic enzyme of acetylcholine, has a 50 to 90% reduction in the cerebral cortex and hippocampus in AD. Therefore, cholinergic neurons are largely affected.


FIGURE 3.3 (a) A normal waveform (leftmost column) and three pathological waveforms. The 6th octave wavelet and residual signals (2nd and 3rd rows) and their Wavelet Coefficients (4th and 5th rows respectively). Vertical tickmarks indicate the vertical scale of the plots. (b) Scatter plot of D_{3-2} vs. D_{4-3}. In the scatter plot, the upper leftmost grid and its immediate right and down neighbors indicate an acceptable range of coefficient changes for the (N_{70}-P_{100}-N_{130}) complex of the pattern reversal VEP, analyzed by B-spline wavelets.

Amyloid-beta (AB) is the major substance implicated in the progression of AD. Large amounts of this peptide due to overproduction, lack of degradation, or other factors lead to the formation of senile plaques. Their presence may trigger the release of cytochrome C, which is associated with *apoptosis* (cell death) and neurodegeneration. (Parkinson's disease, also involves amyloids that aggregate and participate in the direct or indirect loss of synapses and neurons.) Other studies point to excessive amounts of glutamate in the extracellular fluid. Their presence are thought to very rapidly inhibit the transport of molecules from the cell body to the end terminal of the axon, therefore leading to the loss of synapses — the end result of AD. Thus, chemical synaptic input is stopped and the ability of the person to perform certain functions is greatly inhibited.

Since the only definite way to diagnose AD is through histopathology, clinicians can diagnose possible or probable AD depending on signs and symptoms until a brain autopsy confirms the diagnosis. Some of the symptoms include progressive worsening of memory and other cognitive functions and cognitive loss impairing social or occupational functioning and causing a significant decline from a previous level of functioning. The current therapies used for AD include cholinesterase inhibitors, estrogen, nonsteroidal anti-inflammatory drugs, and vitamin E.

A physiological approach in determining the relative severity of the pathological changes in the associative cortex is the use of EPs, mainly visual. These recordings account for the clinical finding of diminished visual interpretation skills with normal visual acuity. The most important finding and consistent abnormality with flash visual evoked potentials (VEPs) is the delayed latency of the P_{100} component and at the same time an increase in its amplitude. The later VEP peaks may also be delayed in patients with AD. Sophisticated analysis with B-spline wavelets was performed on data collected from 40 subjects, 14 of them suffering from a degenerative disease like AD. The scatter plot of Figure 3.3, shows that the VEP complex (N_{70}-P_{100}-N_{130}) in the delta–theta and alpha bands yields a negative wavelet coefficient D_{3-2} in the $[-2, -1]$ region, a positive D_{4-3} in the region $[1, 2]$, and a negative third coefficient in the sixth octave, standing for an alpha discharge, is observed for normal waveforms. Any deviations from these findings may be interpreted as abnormal behavior.

3.6.3 Epilepsy

This is a disease that affects 1% of the world's population and is characterized by a sudden malfunction of the brain. The malfunctioning might reappear and reflects the clinical signs of extensive activity of neurons

in synchrony. Two types of epilepsy have been identified: *generalized* and *focal*. The former involves the whole brain while the latter involves specific smaller well-defined regions of the brain. Symptoms associated with epilepsy include impairment of consciousness, autonomic or sensory symptoms, motor phenomena as well as psychic symptoms.

When antiepileptic medication stops affecting the patient's symptoms, surgery is recommended. However, the gold standard of the exact localization of the epileptic focus is to use electroencephalography (EEG). Depending on the individual occurrence of seizures, EEG analysis has been proven very valuable. It would be even more valuable if it could give a reliable prediction of when a seizure might occur, a fact that would be of enormous importance to the individual suffering from epilepsy. As in many other nervous system disorders, our knowledge of epilepsy comes from animal models. Despite the fact that there exists an enormous amount of literature on the subject, the main mechanisms (both physiological and chemical) are still not well understood.

A lot of work is still needed, especially in terms of understanding the content of EEGs using both linear and nonlinear techniques, the latter used lately more often. So far, research with nonlinear methods of analysis can, at best, predict a seizure only a few seconds before it happens and none of these methods have been adopted clinically.

3.6.4 Phantom Limb Sensation/Pain

Phantom limb pain (PLP) is a term that describes a class of painful phenomena that affect individuals who have undergone a traumatic amputation of a limb. These individuals experience painful sensations that are perceived to be originating from the amputated limb. In subjects with PLP the painful sensations are generated in the higher cortical areas of the CNS. This is in contrast to the normal condition in which pain signals originate in the PNS and are then passed to the higher processing centers where these signals are perceived as pain. The fact that PLP is centrally generated means that traditional pain treatments are relatively ineffective in the long-term treatment of PLP, since these treatments act on the pathway between the PNS and the CNS to stop the transmission of painful stimuli.

It has been observed that chronic PLP can lead to significant impairment in areas of daily living. Of the sufferers of PLP, 18% were unable to work, 33.5% report that PLP interferes with their ability to work, 82% have sleep disorders, 43% report that PLP impairs their social activities, and 45% of patients report an impairment in their daily activities.

Work performed in our laboratories utilized fMRI to test the hypothesis that there exists a neural construct such that higher-processing areas in the brain responsible for integrating motor, somatosensory, and visual information into a unified somatic perception expect certain cohesive patterns of input from the lower areas of the brain. More specifically, these areas expect that somatosensory and visual feedback is consistent and that it agrees with motor output. Under normal conditions these expectations are typically met. When a part of the body is amputated, however, the motor cortex is still capable of issuing motor commands to the missing limb but there is erroneous somatosensory and a complete lack of visual feedback. This inconsistency in information pertaining to the limb results in higher-processing centers receiving patterns of input that are not consistent with the neural construct. It is hypothesized that upon receiving patterns of inconsistent information the higher-associative areas that comprise the hypothetical neural construct conclude that things are not as they should be with the missing limb and that this conclusion leads to the perception of pain originating from the missing limb. One would expect that, if the hypothesis is correct, there might be found a conflict recognition center, or a region or regions of the brain that are active in response to somatosensory sensory conflict. The insula is an area of the brain that is known to be a center of multimodal sensory integration and an area whose activity is correlated with various types of pain. For these reasons, the insula is an area of great interest in the search for the hypothetical conflict recognition center.

The fMRI was used to investigate patterns of neural activation in normal subjects and amputees during experiments involving the movement and visual monitoring of intact and phantom limbs. With amputees, visual feedback was manipulated to bring visual and motor activity into closer agreement. In the normal experiments visual feedback was manipulated to create disagreement between visual and motor activity.

If the hypothesis were correct one would expect to see different patterns of activation when the motor and sensory systems are in agreement as opposed to when they are not.

Work by other laboratories support the role of insula as an integrator of information, a region associated with various forms of pain and discomfort and a region whose activity has been found to correlate with conditions being other than what they should be according to the individual. It is suggested here that it is the identification that things are not as they should be that leads to the perception of pain and that this process is mediated, in part, by the insula.

Vision System

George D. Stetten

Carnegie Mellon University

David Marr, an early pioneer in computer vision, defined vision as extracting "... from images of the external world, a description that is useful for the viewer and not cluttered with irrelevant information" [Marr, 1982]. Advances in computers and video technology in the past decades have created the expectation that artificial vision should be realizable. The nontriviality of the task is evidenced by the continuing proliferation of new and different approaches to computer vision without any observable application in our everyday lives. Actually, computer vision is already offering practical solutions in industrial assembly and inspection, as well as for military and medical applications; so it seems we are beginning to master some of the fundamentals. However, we have a long way to go to match the vision capabilities of a 4-year-old child. In this chapter, we explore what is known about how nature has succeeded at this formidable task — that of interpreting the visual world.

4.1   Fundamentals of Vision Research

Research into biologic vision systems has followed several distinct approaches. The oldest is psychophysics, in which human and animal subjects are presented with visual stimuli and their responses recorded. Important early insights also were garnered by correlating clinical observations of visual defects with known neuroanatomic injury. In the past 50 years, a more detailed approach to understanding the mechanisms of vision has been undertaken by inserting small electrodes deep within the living brain to monitor the electrical activity of individual neurons and by using dyes and biochemical markers to track the anatomic course of nerve tracts. This research has led to a detailed and coherent, if not complete, theory of a visual system capable of explaining the discrimination of form, color, motion, and depth. This theory has been confirmed by noninvasive radiologic techniques that have been used recently to study the physiologic responses of the visual system, including positron emission tomography [Zeki et al., 1991] and functional magnetic resonance imaging [Belliveau et al., 1992; Cohen and Bookheimer, 1994], although

these noninvasive techniques provide far less spatial resolution and thus can only show general regions of activity in the brain.

4.2 A Modular View of the Vision System

4.2.1 The Eyes

Movement of the eyes is essential to vision, not only allowing rapid location and tracking of objects but also preventing stationary images on the retina, which are essentially invisible. Continual movement of the image on the retina is essential to the visual system.

The eyeball is spherical and therefore free to turn in both the horizontal and vertical directions. Each eye is rotated by three pairs of mutually opposing muscles, innervated by the oculomotor nuclei in the brainstem. The eyes are coordinated as a pair in two useful ways: turning together to find and follow objects and turning inward to allow adjustment for parallax as objects become closer. The latter is called convergence.

The optical portion of the eye, which puts an image on the retina, is closely analogous to a photographic or television camera. Light enters the eye, passing through a series of transparent layers — the cornea, the aqueous humor, the lens, and the vitreous body — to eventually project on the retina.

The cornea, the protective outer layer of the eye, is heavily innervated with sensory neurons, triggering the blink reflex and tear duct secretion in response to irritation. The cornea is also an essential optical element, supplying two thirds of the total refraction in the eye. Behind the cornea is a clear fluid, the aqueous humor, in which the central aperture of the iris, the pupil, is free to constrict or dilate. The two actions are accomplished by opposing sets of muscles.

The lens, a flexible transparent object behind the iris, provides the remainder of refraction necessary to focus an image on the retina. The ciliary muscles surrounding the lens can increase the lens' curvature, thereby decreasing its focal length and bringing nearer objects into focus. This is called accommodation. When the ciliary muscles are at rest, distant objects are in focus. There are no contradictory muscles to flatten the lens. This depends simply on the elasticity of the lens, which decreases with age. Behind the lens is the vitreous humor, consisting of a semigelatinous material filling the volume between the lens and the retina.

4.2.2 The Retina

The retina coats the back of the eye and is therefore spherical, not flat, making optical **magnification** constant at 3.5 degrees of scan angle per millimeter. The retina is the neuronal front end of the visual system, the image sensor. In addition, it accomplishes the first steps in edge detection and color analysis before sending the processed information along the optic nerve to the brain. The retina contains five major classes of cells, roughly organized into layers. The dendrites of these cells each occupy no more than 1 to 2 mm^2 in the retina, limiting the extent of spatial integration from one layer of the retina to the next.

First come the receptors, which number approximately 125 million in each eye and contain the light-sensitive pigments responsible for converting photons into chemical energy. Receptor cells are of two general varieties: rods and cones. The cones are responsible for the perception of color and they function only in bright light. When the light is dim, only rods are sensitive enough to respond. Exposure to a single photon may result in a measurable increase in the membrane potential of a rod. This sensitivity is the result of a chemical cascade, similar in operation to the photomultiplier tube, in which a single photon generates a cascade of electrons. All rods use the same pigment, whereas three different pigments are found in three separate kinds of cones.

Examination of the retina with an otoscope reveals its gross topography. The yellow circular area occupying the central 5 degrees of the retina is called the macula lutea, within which a small circular pit called the fovea may be seen. Detailed vision occurs only in the fovea, where a dense concentration of cones provides visual activity to the central 1° of the visual field.

On the inner layer of the retina one finds a layer of ganglion cells, whose axons make up the optic nerve, the output of the retina. They number approximately 1 million, or less than 1% of the number of receptor cells. Clearly, some data compression has occurred in the space between the receptors and the ganglion cells. Traversing this space are the bipolar cells, which run from the receptors through the retina to the ganglion cells. Bipolar cells exhibit the first level of information processing in the visual system; namely, their response to light on the retina demonstrates "center/surround" **receptive fields**. By this I mean that a small dot on the retina elicits a response, while the area surrounding the spot elicits the opposite response. If both the center and the surround are illuminated, the net result is no response. Thus bipolar cells respond only at the border between dark and light areas. Bipolar cells come in two varieties, on-center and off-center, with the center respectively brighter or darker than the surround.

The center response of bipolar cells results from direct contact with the receptors. The surround response is supplied by the horizontal cells, which run parallel to the surface of the retina between the receptor layer and the bipolar layer, allowing the surrounding area to oppose the influence of the center. The amacrine cells, a final cell type, also run parallel to the surface but in a different layer, between the bipolar cells and the ganglion cells, and are possibly involved in the detection of motion.

Ganglion cells, since they are triggered by bipolar cells, also have center/surround receptive fields and come in two types, on- and off-center. On-center ganglion cells have a receptive field in which illumination of the center increases the firing rate and a surround where it decreases the rate. Off-center ganglion cells display the opposite behavior. Both types of ganglion cells produce little or no change in firing rate when the entire receptive field is illuminated, because the center and surround cancel each other. As in many other areas of the nervous system, the fibers of the optic nerve use frequency encoding to represent a scalar quantity.

Multiple ganglion cells may receive output from the same receptor, since many receptive fields overlap. However, this does not limit overall spatial resolution, which is maximum in the fovea, where two points separated by 0.5 min of arc may be discriminated. This separation corresponds to a distance on the retina of 2.5 mm, which is approximately the center-to-center spacing between cones. Spatial resolution falls off as one moves away from the fovea into the peripheral vision, where resolution is as low as 1 degree of arc.

Several aspects of this natural design deserve consideration. Why do we have center/surround receptive fields? The ganglion cells, whose axons make up the optic nerve, do not fire unless there is meaningful information, that is, a border, falling within the receptive field. It is the edge of a shape we see rather than its interior. This represents a form of data compression. Center/surround receptive fields also allow for relative rather than absolute measurements of color and brightness. This is essential for analyzing the image independent of lighting conditions. Why do we have both on- and off-center cells? Evidently, both light and dark are considered information. The same shape is detected whether it is lighter or darker than the background.

4.2.3 Optic Chiasm

The two optic nerves, from the left and right eyes, join at the optic chiasm, forming a hemidecussation, meaning that half the axons cross while the rest proceed uncrossed. The resulting two bundles of axons leaving the chiasm are called the optic tracts. The left optic tract contains only axons from the left half of each retina. Since the images are reversed by the lens, this represents light from the right side of the visual field. The division between the right and left optic tracts splits the retina down the middle, bisecting the fovea. The segregation of sensory information into the contralateral hemispheres corresponds to the general organization of sensory and motor centers in the brain.

Each optic tract has two major destinations on its side of the brain (1) the superior colliculus and (2) the lateral geniculate nucleus (LGN). Although **topographic mapping** from the retina is scrambled within the optic tract, it is reestablished in both major destinations so that right, left, up, and down in the image correspond to specific directions within those anatomic structures.

4.2.4 Superior Colliculus

The superior colliculus is a small pair of bumps on the dorsal surface of the midbrain. Another pair, the inferior colliculus, is found just below it. Stimulation of the superior colliculus results in contralateral eye movement. Anatomically, output tracts from the superior colliculus run to areas that control eye and neck movement. Both the inferior and superior colliculi are apparently involved in locating sound. In the bat, the inferior colliculus is enormous, crucial to that animal's remarkable echolocation abilities. The superior colliculus processes information from the inferior colliculus, as well as from the retina, allowing the eyes to quickly find and follow targets based on visual and auditory cues.

Different types of eye movements have been classified. The saccade (French, for "jolt") is a quick motion of the eyes over a significant distance. The saccade is how the eyes explore an image, jumping from landmark to landmark, rarely stopping in featureless areas. Nystagmus is the smooth pursuit of a moving image, usually with periodic backward saccades to lock onto subsequent points as the image moves by. Microsaccades are small movements, several times per second, over 1 to 2 min of arc in a seemingly random direction. Microsaccades are necessary for sight; their stabilization leads to effective blindness.

4.2.5 Lateral Geniculate Nucleus

The thalamus is often called "the gateway to the cortex" because it processes much of the sensory information reaching the brain. Within the thalamus, we find the LGN, a peanut-sized structure that contains a single synaptic stage in the major pathway of visual information to higher centers. The LGN also receives information back from the cortex, so-called reentrant connections, as well as from the nuclei in the brainstem that control attention and arousal.

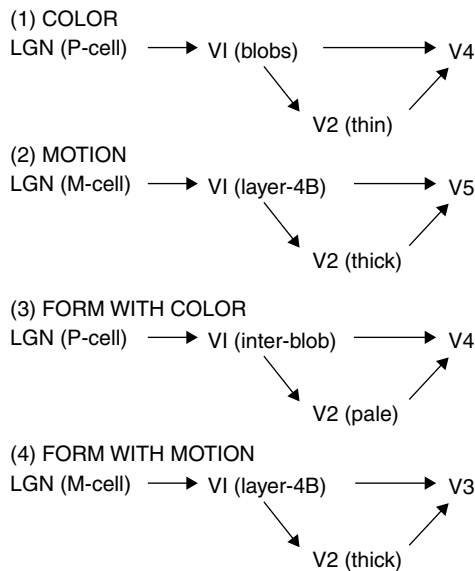
The cells in the LGN are organized into three pairs of layers. Each pair contains two layers, one from each eye. The upper two pairs consist of parvocellular cells (P cells) that respond with preference to different colors. The remaining lower pair consists of magnocellular cells (M cells) with no color preference but with transient responses that contribute to motion perception (Figure 4.1). The topographic mapping is identical for all six layers; that is, passing through the layers at a given point yields synapses responding to


FIGURE 4.1   Visual pathways to cortical areas showing the separation of information by type. The lateral geniculate nucleus (LGN) and areas V1 and V2 act as gateways to more specialized higher areas.

a single area of the retina. Axons from the LGN proceed to the primary visual cortex in broad bands, the optic radiations, preserving this topographic mapping and displaying the same center/surround response as the ganglion cells.

4.2.6   Area V1

The LGN contains approximately 1.5 million cells. By comparison, the primary visual cortex, or striate cortex, which receives the visual information from the LGN, contains 200 million cells. It consists of a thin (2-mm) layer of gray matter (neuronal cell bodies) over a thicker collection of white matter (myelinated axons) and occupies a few square inches of the occipital lobes. The primary visual cortex has been called area 17 from the days when the cortical areas were first differentiated by their **cytoarchitectonics** (the microscopic architecture of their layered neurons). In modern terminology, the primary visual cortex is often called visual area 1, or simply V1.

Destroying any small piece of V1 eliminates a small area in the visual field, resulting in scotoma, a local blind spot. Clinical evidence has long been available that a scotoma may result from injury, stroke, or tumor in a local part of V1. Between neighboring cells in V1's gray matter, horizontal connections are at most 2 to 5 mm in length. Thus, at any given time, the image from the retina is analyzed piecemeal in V1. Topographic mapping from the retina is preserved in great detail. Such mapping is seen elsewhere in the brain, such as in the somatosensory cortex [Mountcastle, 1957]. Like all cortical surfaces, V1 is a highly convoluted sheet, with much of its area hidden within its folds. If unfolded, V1 would be roughly pear shaped, with the top of the pear processing information from the fovea and the bottom of the pear processing the peripheral vision. Circling the pear at a given latitude would correspond roughly to circling the fovea at a fixed radius.

The primary visual cortex contains six layers, numbered 1 through 6. Distinct functional and anatomic types of cells are found in each layer. Layer 4 contains neurons that receive information from the LGN. Beyond the initial synapses, cells demonstrate progressively more complex responses. The outputs of V1 project to an area known as visual area 2 (V2), which surrounds V1, and to higher visual areas in the occipital, temporal, and parietal lobes as well as to the superior colliculus. V1 also sends reentrant projections back to the LGN. Reentrant projections are present at almost every level of the visual system [Edelman, 1978; Felleman and Essen, 1991].

Cells in V1 have been studied extensively in animals by inserting small electrodes into the living brain (with surprisingly little damage) and monitoring the individual responses of neurons to visual stimuli. Various subpopulations of cortical cells have thus been identified. Some, termed simple cells, respond to illuminated edges or bars at specific locations and at specific angular orientations in the visual field. The angular orientation must be correct within 10 to 20° for the particular cell to respond. All orientations are equally represented. Moving the electrode parallel to the surface yields a smooth rotation in the orientation of cell responses by about 10 degrees for each 50 mm that the electrode is advanced. This rotation is subject to reversals in direction, as well as "fractures," or sudden jumps in orientation.

Other cells, more common than simple cells, are termed complex cells. Complex cells respond to a set of closely spaced parallel edges within a particular receptive field. They may respond specifically to movement perpendicular to the orientation of the edge. Some prefer one direction of movement to the other. Some complex and simple cells are end-stopped, meaning they fire only if the illuminated bar or edge does not extend too far. Presumably, these cells detect corners, curves, or discontinuities in borders and lines. End-stopping takes place in layers 2 and 3 of the primary visual cortex. From the LGN through the simple cells and complex cells, there appears to be a sequential processing of the image. It is probable that simple cells combine the responses of adjacent LGN cells and that complex cells combine the responses of adjacent simple cells.

A remarkable feature in the organization of V1 is **binocular convergence**, in which a single neuron responds to identical receptive fields in both eyes, including location, orientation, and directional sensitivity to motion. It does not occur in the LGN, where axons from the left and right eyes are still segregated into

different layers. Surprisingly, binocular connections to neurons are present in V1 at birth. Some binocular neurons are equally weighted in terms of responsiveness to both eyes, while others are more sensitive to one eye than to the other. One finds columns containing the latter type of cells in which one eye dominates, called ocular dominance columns, in uniform bands approximately 0.5-mm wide everywhere in V1. Ocular dominance columns occur in adjacent pairs, one for each eye, and are prominent in animals with forward-facing eyes, such as cats, chimpanzees, and humans. They are nearly absent in rodents and other animals whose eyes face outward.

The topography of orientation-specific cells and of ocular dominance columns is remarkably uniform throughout V1, which is surprising because the receptive fields near the fovea are 10 to 30 times smaller than those at the periphery. This phenomenon is called magnification. The fovea maps to a greater relative distance on the surface of V1 than does the peripheral retina, by as much as 36-fold [Daniel and Whitteridge, 1961]. In fact, the majority of V1 processes only the central 10° of the visual field. Both simple and complex cells in the foveal portion can resolve bars as narrow as 2 min of arc. Toward the periphery, the resolution falls off to 1° of arc.

As an electrode is passed down through the cortex perpendicular to the surface, each layer demonstrates receptive fields of characteristic size, the smallest being at layer 4, the input layer. Receptive fields are larger in other layers due to lateral integration of information. Passing the electrode parallel to the surface of the cortex reveals another important uniformity to V1. For example, in layer 3, which sends output fibers to higher cortical centers, one must move the electrode approximately 2 mm to pass from one collection of receptive fields to another that does not overlap. An area approximately 2 mm across thus represents the smallest unit piece of V1, that is, that which can completely process the visual information. Indeed, it is just the right size to contain a complete set of orientations and more than enough to contain information from both eyes. It receives a few tens of thousands of fibers from the LGN, produces perhaps 50,000 output fibers, and is fairly constant in cytoarchitectonics whether at the center of vision, where it processes approximately 30 min of arc, or at the far periphery, where it processes 7 to 8° of arc.

The topographic mapping of the visual field onto the cortex suffers an abrupt discontinuity between the left and right hemispheres, and yet our perception of the visual scene suffers no obvious rift in the midline. This is due to the corpus collousum, an enormous tract containing at least 200 million axons, that connects the two hemispheres. The posterior portion of the corpus collousum connects the two halves of V1, linking cells that have similar orientations and whose receptive fields overlap in the vertical midline. Thus a perceptually seamless merging of left and right visual fields is achieved. Higher levels of the visual system are likewise connected across the corpus collousum. This is demonstrated, for example, by the clinical observation that cutting the corpus collousum prevents a subject from verbally describing objects in the left field of view (the right hemisphere). Speech, which normally involves the left hemisphere, cannot process visual objects from the right hemisphere without the corpus collousum.

By merging the information from both eyes, V1 is capable of analyzing the distance to an object. Many cues for depth are available to the visual system, including occlusion, parallax (detected by the convergence of the eyes), optical focusing of the lens, rotation of objects, expected size of objects, shape based on perspective, and shadow casting. **Stereopsis**, which uses the slight difference between images due to the parallax between the two eyes, was first enunciated in 1838 by Sir Charles Wheatstone and it is probably the most important cue [Wheatstone, 1838]. Fixating on an object causes it to fall on the two foveas. Other objects that are nearer become outwardly displaced on the two retinas, while objects that are farther away become inwardly displaced. About 2° of horizontal disparity is tolerated, with fusion by the visual system into a single object. Greater horizontal disparity results in double vision. Almost no vertical displacement (a few minutes of arc) is tolerated. Physiologic experiments have revealed a particular class of complex cells in V1 that are disparity tuned. They fall into three general classes. One class fires only when the object is at the fixation distance, another only when the object is nearer, and a third only when it is farther away [Poggio and Talbot, 1981]. Severing the corpus collousum leads to a loss of stereopsis in the vertical midline of the visual field.

When the inputs to the two retinas cannot be combined, one or the other image is rejected. This phenomenon is known as retinal rivalry and can occur in a piecewise manner or can even lead to blindness in one eye. The general term amblyopia refers to the partial or complete loss of eyesight not caused by abnormalities in the eye. The most common form of amblyopia is caused by strabismus, in which the eyes are not aimed in a parallel direction but rather are turned inward (cross-eyed) or outward (wall-eyed). This condition leads to habitual suppression of vision from one of the eyes and sometimes to blindness in that eye or to alternation, in which the subject maintains vision in both eyes by using only one eye at a time. Cutting selected ocular muscles in kittens causes strabismus, and the kittens respond by alternation, preserving functional vision in both eyes. However, the number of cells in the cortex displaying binocular responses is greatly reduced. In humans with long-standing alternating strabismus, surgical repair making the eyes parallel again does not bring back a sense of depth. Permanent damage has been caused by the subtle condition of the images on the two retinas not coinciding. This may be explained by the Hebb model for associative learning, in which temporal association between inputs strengthens synaptic connections [Hebb, 1961].

Further evidence that successful development of the visual system depends on proper input comes from clinical experience with children who have cataracts at birth. Cataracts constitute a clouding of the lens, permitting light, but not images, to reach the retina. If surgery to remove the cataracts is delayed until the child is several years old, the child remains blind even though images are restored to the retina. Kittens and monkeys whose eyelids are sown shut during a critical period of early development stay blind even when the eyes are opened. Physiologic studies in these animals show very few cells responding in the visual cortex. Other experiments depriving more specific elements of an image, such as certain orientations or motion in a certain direction, yield a cortex without the corresponding cell type.

4.2.7 Color

Cones, which dominate the fovea, can detect wavelengths between 400 and 700 nm. The population of cones in the retina can be divided into three categories, each containing a different pigment. This was established by direct microscopic illumination of the retina [Marks et al., 1964; Wald, 1974]. The pigments have a bandwidth on the order of 100 nm, with significant overlap, and with peak sensitivities at 560 nm (yellow–green), 530 nm (blue–green), and 430 nm (violet). These three cases are commonly known as red, green, and blue. Compared with the auditory system, whose array of cochlear sensors can discriminate thousands of different sonic frequencies, the visual system is relatively impoverished with only three frequency parameters. Instead, the retina expends most of its resolution on spatial information. Color vision is absent in many species, including cats, dogs, and some primates, as well as in most nocturnal animals, since cones are useless in low light.

By having three types of cones at a given locality on the retina, a simplified spectrum can be sensed and represented by three independent variables, a concept known as trichromacy. This model was developed by Thomas Young and Hermann von Helmholtz in the 19th century before neurobiology existed and does quite well at explaining the retina [Young, 1802; Helmholtz, 1889]. The model is also the underlying basis for red–green–blue (RGB) video monitors and color television [Ennes, 1981]. Rods do not help in discriminating color, even though the pigment in rods does add a fourth independent sensitivity peak.

Psychophysical experimentation yields a complex, redundant map between spectrum and perceived color, or hue, including not only the standard red, orange, yellow, green, and blue but hues such as pink, purple, brown, and olive green that are not themselves in the rainbow. Some of these may be achieved by introducing two more variables: saturation, which allows for mixing with white light, and intensity, which controls the level of color. Thus three variables are still involved: hue, saturation, and intensity.

Another model for color vision was put forth in the 19th century by Ewald Hering [1864]. This theory also adheres to the concept of trichromacy, espousing three independent variables. However, unlike the

Young–Helmholtz model, these variables are signed; they can be positive, negative, or zero. The resulting three axes are red–green, yellow–blue, and black–white. The Hering model is supported by the physiologic evidence for the center/surround response, which allows for positive as well as negative information. In fact, two populations of cells, activated and suppressed along the red–green and yellow–blue axes, have been found in monkey LGN. Yellow is apparently detected by a combination of red and green cones.

The Hering model explains, for example, the perception of the color brown, which results only when orange or yellow is surrounded by a brighter color. It also accounts for the phenomenon of **color constancy**, in which the perceived color of an object remains unchanged under differing ambient light conditions provided background colors are available for comparison. Research into color constancy was pioneered in the laboratory of Edwin Land [Land and McCann, 1971]. As David Hubel says, "We require color borders for color, just as we require luminance borders for black and white" [Hubel, 1998]. As one might expect, when the corpus collousum is surgically severed, color constancy is absent across the midline.

Color processing in V1 is confined to small circular areas, known as blobs, in which double-opponent cells are found. They display a center/surround behavior based on the red–green and yellow–blue axes but lack orientation selectivity. The V1 blobs were first identified by their uptake of certain enzymes, and only later was their role in color vision discovered [Livingstone and Hubel, 1984]. The blobs are especially prominent in layers 2 and 3, which receive input from the P cells of the LGN.

4.2.8 Higher Cortical Centers

How are the primitive elements of image processing so far discussed united into an understanding of the image? Beyond V1 are many higher cortical centers for visual processing, at least 12 in the occipital lobe and others in the temporal and parietal lobes. Area V2 receives axons from both the blob and interblob areas of V1 and performs analytic functions such as filling in the missing segments of an edge. V2 contains three areas categorized by different kinds of stripes: thick stripes which process relative horizontal position and stereopsis, thin stripes which process color without orientations, and pale stripes which extend the process of end-stopped orientation cells.

Beyond V2, higher centers have been labeled V3, V4, V5, etc. Four parallel systems have been delineated [Zeki, 1992], each system responsible for a different attribute of vision, as shown in Figure 4.1. This is obviously an oversimplification of a tremendously complex system.

Corroborative clinical evidence supports this model. For example, lesions in V4 lead to achromatopsia, in which a patient can only see gray and cannot even recall colors. Conversely, a form of poisoning, carbon monoxide chromatopsia, results when the V1 blobs and V2 thin stripes selectively survive exposure to carbon monoxide thanks to their rich vasculature, leaving the patient with a sense of color but not of shape. A lesion in V5 leads to akinetopsia, in which objects disappear.

As depicted in Figure 5.1, all visual information is processed through V1 and V2, although discrete channels within these areas keep different types of information separate. A total lesion of V1 results in the perception of total blindness. However, not all channels are shown in Figure 4.1, and such a "totally blind" patient may perform significantly better than expected if they were truly behind when forced to guess between colors or between motions in different directions. The patient with this condition, called blindsight, will deny being able to see anything [Weiskrantz, 1990].

Area V1 preserves retinal topographic mapping and shows receptive fields, suggesting a piecewise analysis of the image, although a given area of V1 receives sequential information from disparate areas of the visual environment as the eyes move. V2 and higher visual centers show progressively larger receptive fields and less-defined topographic mapping but more specialized responses. In the extreme of specialization, neurobiologists joke about the "grandmother cell," which would respond only to a particular face. No such cell has yet been found. However, cortical regions that respond to faces in general have been found in the temporal lobe. Rather than a "grandmother cell," it seems that face-selective neurons are members of ensembles for coding facts [Gross and Sergen, 1992].

Defining Terms

Binocular convergence: The response of a single neuron to the same location in the visual field of each eye.

Color constancy: The perception that the color of an object remains constant under different lighting conditions. Even though the spectrum reaching the eye from that object can be vastly different other objects in the field of view are used to compare.

Cytoarchitectonics: The organization of neuron types into layers as seen by various staining techniques under the microscope. Electrophysiologic responses of individual cells can be correlated with their individual layer.

Magnification: The variation in amount of retinal area represented per unit area of V1 from the fovea to the peripheral vision. Even though the fovea takes up an inordinate percentage of V1 compared with the rest of the visual field, the scale of the cellular organization remains constant. Thus the image from the fovea is, in effect, magnified before processing.

Receptive field: The area in the visual field that evokes a response in a neuron. Receptive fields may respond to specific stimuli such as illuminated bars or edges with particular directions of motion, etc.

Stereopsis: The determination of distance to objects based on relative displacement on the two retinas because of parallax.

Topographic mapping: The one-to-one correspondence between location on the retina and location within a structure in the brain. Topographic mapping further implies that contiguous areas on the retina map to contiguous areas in the particular brain structure.

5.1   Overview

Human hearing arises from airborne waves alternating 50 to 20,000 times a second about the mean atmospheric pressure. These pressure variations induce vibrations of the tympanic membrane, movement of the middle-ear ossicles connected to it, and subsequent displacements of the fluids and tissues of the cochlea in the inner ear. Biomechanical processes in the cochlea analyze sounds to frequency-mapped vibrations along the basilar membrane, and approximately 3,500 inner hair cells modulate transmitter release and spike generation in 30,000 spiral ganglion cells whose proximal processes make up the auditory nerve. This neural activity enters the central auditory system and reflects sound patterns as temporal and spatial spike patterns. The nerve branches and synapses extensively in the cochlear nuclei, the first of the central auditory nuclei. Subsequent brainstem nuclei pass auditory information to the medial geniculate and auditory cortex (AC) of the thalamocortical system.

We extract more information from sound than from any other sense. Although primates are described as "visual" animals, speech and music carry more of our cultural and societal meaning than sight or other senses, and we suffer more from deafness than with other sensory losses. Highly effective adaptations of auditory processing occur in many animals including insects, amphibians, birds, cetaceans, and bats for prey acquisition, predator avoidance, intraspecies signaling, and other tasks. This chapter surveys current understanding of the hearing process.

5.2   The Peripheral Auditory System

5.2.1   The External and Middle Ear

As shown in Figure 5.1, ambient sounds are collected by the pinna, the visible portion of the external ear, and guided to the middle ear by the external auditory meatus, or ear canal. Sounds are filtered due to the
FIGURE 5.1   The peripheral auditory system showing the external-ear structures (pinna and external meatus), the middle ear, and the inner ear. (Courtesy of Virginia Merrill Bloedel Hearing Research Center, Seattle, Washington.)

geometry of the pinna and sound shadowing effects of the head. In species with movable pinnae selective scanning of the auditory environment is possible for high frequencies [Geisler, 1998; Kinsler et al., 1999].

The bounding interface between the external and middle ear is the tympanic membrane. Pressure variations across the membrane move three ossicles, the malleus (hammer) connected to the membrane, the incus (anvil), and the stapes (stirrup) whose footplate is a piston-like structure fitting into the oval window, an opening to the fluid-filled cavities of the inner ear. Ligaments and muscles suspend the middle-ear ossicles so that they move freely. If sound reaches fluids of the inner ear directly, 99.9% of the energy is reflected [Wever and Lawrence, 1954], a 30-dB loss due to the mismatch in acoustic impedance between air and inner-ear fluids. Properties of the external meatus, middle-ear cavity, tympanic membrane, and middle-ear ossicles shape the responsiveness of a species to different frequencies.

The eustachian tube is a bony channel lined with soft tissue extending from the middle ear to the nasopharynx. In humans it is often closed, except during swallowing, and provides a means by which pressure is equalized across the tympanic membrane. The function is clearly observed with changes in altitude or barometric pressure. A second function of the eustachian tube is to aerate the tissues of the middle ear.

The volume of the air-filled middle-ear cavity inversely determines the stiffness of the tympanic membrane at low frequencies. A reduction of low-frequency impedance for some desert rodents with large middle-ear cavities [Ravicz and Rosowski, 1997] enhances detection of predators at a distance. On the other hand, the mass of the middle-ear ossicles dominates impedance at high frequencies and is related to head mass [Nummela, 1995]. For this reason small mammals generally have good high-frequency hearing, often extending above 60 kHz. As sound frequency increases, impedances decrease due to eardrum stiffness and increase due to ossicular mass leaving a middle range where sound transmission to the inner ear is most efficient, limited only by resistive forces [Geisler, 1999], resonances of the cavities, and mechanical advantages provided by the tympanic membrane, ossicles, and oval window.

Since the ear canal and middle-ear cavities are, or approximate, closed volumes, they support quarter-wavelength resonances. The human meatus has a broad resonance between 3 and 4 kHz, enhancing sound

pressure at the membrane by 12 dB [Weiner and Ross, 1946; von Békésy, 1950]. This will be modified by obstructing the meatus with headphones or a hearing aid and must be considered in system designs.

The head and external and middle-ear structures impose a transfer function on sound pressure at the tympanic membrane [Bateau, 1967; Blauert, 1997]. The monaural (single-ear) head-related transfer function (HRTF) is a function of sound-source azimuth and elevation relative to pressure waveforms at the tympanic membrane. It is complex, affecting both sound amplitudes and phases over their spectrum. Sound localization, highly dependent on binaural hearing, involves a binaural HRTF combining the left and right monaural HRTFs. Since the structures determining these functions vary, individualized HRTFs combined with head-position sensing are important for computer synthesis of realistic three-dimensional sound experiences delivered through headphones [Wightman and Kistler, 1989]. For some source locations, even the shadowing effects of the torso produce HRTF cues [Algazi et al., 2002].

Since the acoustic impedance of the atmospheric source is much less than that of the aqueous medium of the inner ear, a very inefficient energy transfer would exist without the external and middle ears. The ossicles form an impedance transformer with a mechanical advantage that passes the acoustic signal at the tympanic membrane to inner-ear fluids with low loss. Essentially air-based sounds of low-pressure and high-volume velocity are transformed to fluid displacements in the inner ear having high-pressure and low-volume velocity. Two important mechanisms promote this transfer: the area of the tympanic membrane is about 20 times that of the footplate of the stapes, and the lengths of the malleus and incus form a lever advantage from the eardrum to oval window of about 1.3 in humans [Wever and Lawrence, 1954; Geisler, 1998]. The hydraulic piston due to the areal ratio contributes about 26 dB to counteract the impedance mismatch, and the lever mechanism about 2.3 dB. These concepts of middle-ear mechanisms hold at frequencies below about 2 kHz, but the tympanic membrane does not behave as a piston at higher frequencies and can support multiple modes of vibration. Second, the mass of the ossicles becomes significant contributing to resonances. Third, connections between the ossicles are not lossless, and their stiffness cannot be ignored. Fourth, pressure variations in the middle-ear cavity can change the stiffness of the tympanic membrane, as do reflexive contractions of middle-ear muscles, especially in response to intense sounds. Fifth, the cavity of the middle ear produces resonances at acoustic frequencies. All of these factors produce variations in high-frequency acoustic transmission from the external to the inner ear specific to individuals, species, and conditions.

5.2.2 The Inner Ear

The acoustic portion of the mammalian inner ear is a spiral structure, the cochlea (snail), containing a central core, the modiolus, where fibers of the auditory nerve collect. The nerve fibers arise from spiral ganglion cells (SGCs) whose somas form the spiral ganglion in a bony canal around the modiolus. Around the modiolus spiral three fluid-filled chambers or scalae, the scala vestibule (SV), the scala media (SM), and the scala tympani (ST) as shown in Figure 5.2. At the base of the cochlea the stapes footplate displaces fluid in the SV through the oval window. At the other end of the spiral, the apex of the cochlea, the SV and the ST communicate through the helicotrema. Both are filled with perilymph, similar to extracellular fluid. The SM spirals between them and is filled with endolymph, a medium high in K+ and low in Na+ due to active processes in the stria vascularis lining the lateral wall. A positive potential of 80 mV is maintained in the SM by the metabolically driven ionic pumps of the stria vascularis. The SM is separated from the SV by Reissner's membrane, which is impermeable to ions. The SM is separated from the ST by the basilar membrane (BM) with a length of about 31 mm over 2.5 spiral turns in human [Wever and Lawrence, 1954]. Resting on the BM is the organ of Corti consisting of one row of inner hair cells (IHCs) that transduce acoustic signals into neural signals, three rows of outer hair cells (OHCs) that play an active role in the biomechanics of the cochea, cells that support the hair cells, and the tectorial membrane overlying the stereocilia of the hair cells.

Stapes displacements for tones above behavioral threshold are very small, estimates of 0.0001 nm being common [Geisler, 1998]. This can be compared to 0.1 nm for the diameter of a hydrogen atom.
FIGURE 5.2   A cross-sectional representation of one turn of the cochlea.

The structures of the inner ear transform these infinitesimal movements to neural discharges that underlie the detection of sounds.

5.2.2.1   The Basilar Membrane

The cochlear partition (BM and organ of Corti) provides the primary passive mechanical filter function of the inner ear. Alternating fluid displacements at the footplate of the stapes induce pressure differences across the partition from its base near the oval window to its apex near the helicotrema. The cochlear partition has graded mechanical properties favoring rapid movement to high frequencies near the base and slower movement to low frequencies near the apex resulting in a traveling wave motion in that order. The membrane's width varies as it traverses the cochlear duct, narrower at its basal end than at its apical end. It is stiffer at the base than at the apex, with stiffness varying by about two orders of magnitude. Pressure relief is provided for the incompressible fluids of the inner ear by the round window, a membrane-covered opening from the ST to the middle-ear cavity. A transient pressure increase (condensation) at the stapes displaces its footplate inward, a traveling wave is initiated along the BM, pressure is increased in the ST, and a compensatory outward displacement of the round window membrane occurs. A rarefaction causes the round window membrane to move inward toward the ST.

Sound decomposition into its frequency components is a major function of the cochlea. Georg von Békésy observed the traveling wave on the cochlear partitions of cadavers under stroboscopic light synchronized to high-intensity, low-frequency tones. The traveling wave reached a maximum displacement along the BM depending on the frequency of the tone indicating a roughly logarithmic mapping of increasing frequencies from the apex to the base. His experiments on the peripheral auditory system are collected in a book [von Békésy, 1950], and he was awarded the 1961 Nobel Prize in medicine for his research.

Movements of the BM are very small, in the nanometer range or less for normal hearing, and a new technique increased measurement resolution to this level [Johnstone and Boyle, 1967]. The Mössbauer technique uses Doppler shift in γ emissions from a small radioactive particle placed on the moving tissue being observed. In 1971, Rhode published Mössbauer measurements of tuning in the basal region of the living cochlea. These tuning curves were remarkably sharp (Q_{10} of 7 to 8) for pure tones at low intensities, but they degraded to broad tuning at high intensities. The slopes of the tuning curve are much greater at the high-frequency edge than at the low-frequency edge. In the absence of an explanation using passive models, these and subsequent observations came to implicate active tuning processes in the cochlea, sometimes called the "cochlear amplifier."

Measurements using laser interferometer techniques now allow displacement resolutions of less than a nanometer [Mammano and Ashmore, 1995] and have aided investigations of the cochlea's active tuning
FIGURE 5.3 A depiction of the organ of Corti and its cellular structures. TM: tectorial membrane elevated to show stereocilia, PC: inner and outer pillar cells, DC: Deiter's cells, RL: reticular lamina, SC (IHC): one row of stereocilia for IHCs, SC (OHC): three rows of stereocilia for OHCs, HC: Hensen's cells. Other abbreviations are as used in text. Synapses from SGCs are seen at the bottoms of IHCs with efferent axons to OHCs seen in the tunnel and passing between Deiters' cells.

mechanisms. It has been discovered that the cochlear amplifier operates primarily in the basal, high-frequency regions and is highly compressive, that is, large increases in high-frequency tone intensity cause small increases in the maximum displacement of the BM [Geisler, 1998].

5.2.2.2 The Organ of Corti

As shown in Figure 5.3, the organ of Corti is comprised of supporting cells, the hair cells themselves, and the tectorial membrane. The ciliated ends of both OHCs and IHCs are rigidly fixed by supporting cells, for example, Deiters cells form the reticular lamina, a rigid plate holding the upper ends of the OHCs. Pillar cells form a rigid triangular tunnel whose upper surface extends the reticular lamina. The reticular lamina and upper ends of the pillar cells and other support cells form a barrier to ions, thereby isolating the endolymph of the SM from the perilymph of the ST surrounding the lower parts of the hair cells.

Both IHCs and OHCs have precise patterns of stereocilia at the end held within the rigid plate formed by supporting cells. The tectorial membrane overlies the stereocilia, but while those of OHCs contact the tectorial membrane, the stereocilia of the IHCs do not. At the end opposite the stereocilia, IHCs synapse with the distal processes of SGCs. The proximal processes of SGCs are generally myelinated and form most of the auditory nerve. The nerve is laid down as these fibers collect from the apex and base in an orderly spiral manner. The nerve retains the frequency map of the BM, that is, it is tonotopically organized, a characteristic that carries through much of the auditory system.

5.2.2.2.1 Inner Hair Cells

The IHCs lie in a single row on the modiolar side of the organ of Corti and number between 3000 and 4000 in human [Nadol, 1988]. The IHCs' stereocilia are of graded, increasing length from the modiolar

side of the cell. Early in ontogeny, a kinocilium is positioned next to the longest stereocilia, and excitation of hair cells occurs from ciliary displacement in that direction further opening membrane channels to potassium and depolarizing the cell [Hudspeth, 1987]. The positive potential in the endolymph of the SM drives K+ ions through the gating mechanism of IHC stereocilia to the negative intracellular potential. Displacement in the other direction reduces channel opening and produces a relative hyperpolarization [Hudspeth and Corey, 1977]. These changes in intracellular potential modulate transmitter release through vesicle exocytosis at the base of the IHCs. The transmitter is related to glutamate but not glutamate itself [Gleich et al., 1990].

The IHCs are not attached to the tectorial membrane, so their response is thought to be responsive to fluid velocity over their stereocilia rather than direct displacement. Hair cells in some species exhibit frequency tuning when isolated [Crawford and Fettiplace, 1985], but mammalian hair cells do not. The tuning of the mammalian auditory system arises from the motions of the cochlear partition, and this is transferred to the IHCs and to the rest of the auditory system through their connection to SGCs. The nature of membrane channels and molecular mechanisms in auditory hair cells is being examined using a number of techniques [Hudspeth, 2000; Ashmore and Mammano, 2001].

5.2.2.2.2 Outer Hair Cells

There are about 12,000 OHCs in the human cochlea [Nadol, 1988]. They have primarily *efferent* innervation, a puzzling arrangement for many years since the cochlea was a "sensory organ." The discovery of cochlear tuning that was not readily explainable from passive mechanical properties shifted attention to the OHCs where research, over the last few decades, has focused on their cellular and molecular mechanisms.

It was discovered that electrical stimulation of isolated OHCs produced lengthening or shortening [Brownell et al., 1985]. It is generally accepted that the motility of OHCs counters viscous drag from fluids and cells of the cochlear partition. Through their contact to the tectorial membrane they sense the subnanometer displacements of the BM and feedback, in phase, to augment them. This positive feedback occurs at auditory frequencies and is responsible for cochlear amplification. It occurs, or is most obvious, at low sound intensities, so it is responsible for the incredible sensitivity of the ear and for the nonlinear compression of the dynamic range of intensity coding. It was also observed that iontophoretic application of acetylcholine to the synaptic end of OHCs causes them to shorten. Efferents to OHCs release acetylcholine and thereby modulate the mechanical properties of the cochlea. The OHCs appear to affect the response of the auditory system in several ways. They enhance the tuning characteristics of the system to sinusoidal stimuli, decreasing thresholds and narrowing the filter's bandwidth, and they likely influence the damping of the BM dynamically by actively changing its stiffness.

Before the role of OHCs was determined it was observed that sounds could be measured in the meatus, both spontaneously and in response to other sounds [Wilson, 1986]. In humans they tend to contain spectrally narrow components and vary across individuals. OHCs are strongly implicated as the source for these emissions because sounds in the opposite ear affect them (presumably through the efferent system) and aspirin, known to affect OHCs, reduces them [Geisler, 1998]. As with most positive-feedback systems, spontaneous oscillation is suggested. Otoacoustic emissions are becoming important in the clinical evaluation of cochlear function for their potential signaling of cochlear pathologies.

5.2.2.3 Spiral Ganglion Cells and the Auditory Nerve

The auditory nerve of the human contains about 30,000 afferent fibers. Most (93%) are heavily myelinated and arise from Type I SGCs whose distal processes synapse on IHCs. The rest are from smaller, more lightly myelinated Type II SGCs. Each IHC has, on average, a number of Type I SCCs that synapse with it, 8 in the human and 18 in the cat. In contrast, each Type II SGC contacts OHCs at a rate of about 10 to 60 cells per fiber. The tonotopically organized nerve (low-frequency fibers in the center and high-frequency fibers in the outer layers) exits the modiolus and enters the internal auditory meatus of the temporal bone on its path to the cochlear nuclei.

Discharge spike patterns from the nerve have typically been characterized with repeated tone bursts varied in frequency and intensity [Kiang, 1965]. Three views of the data are commonly used:

1. The temporal pattern of response to a tone burst is summarized in a peristimulus time histogram (PSTH). Auditory neurons may discharge only a few times during a brief tone burst, but if a histogram of spike events is synchronized to the onset of repeated tone bursts, a PSTH results that is more statistically representative of the neuron's response. Discharge patterns from the nerve have a primary-like pattern (see Figure 5.5).

2. A rate-level function of spike counts vs. intensity at one tonal frequency has a threshold level, where counts rise from quiet levels, and a maximum rate, often a plateau holding for further increases in intensity. The range from threshold to the maximum, or saturation, level is called the dynamic range for sound-intensity signaling by response rate changes. A spontaneous rate of discharge, ranging from 50 spikes per second to less than 10, is usually measured for subthreshold stimulus levels.

3. Fiber responses are also characterized with tuning curves, a plot of thresholds for stimulus intensity vs. frequency. Tuning curves for auditory nerve fibers have a minimum intensity (maximum sensitivity) at a characteristic frequency (CF).

Sounds are coded in nerve discharges in two major ways: the level of discharge activity within the fiber population reflects the spectrum of sounds (labeled-line or place coding), and the temporal pattern of discharges in a fiber is partially synchronized to the cycle-by-cycle timing of frequencies near its CF (temporal synchrony coding). Furthermore, complex sounds undergo nonlinear interactions in the cochlea, an example being two-tone suppression where the introduction of a new tone reduces both the discharge rate and synchrony of a fiber to CF tones [Geisler, 1998].

While these coding mechanisms were discovered with tones, Sachs and Young [1979] found that the spectra of lower-intensity vowel sounds are represented as corresponding tonotopic rate peaks in nerve activity, but for higher intensities this place code is lost as discharge rates saturate. At high intensities, spike synchrony to frequencies near CF continue to signal the relative spectral content of vowels, a temporal code. These results hold for high-spontaneous-rate fibers (over 15 spikes sec), which are numerous. Less common, low-spontaneous-rate fibers (<15 spikes sec) appear to maintain the rate code at higher intensities, suggesting different coding roles for these two fiber populations. Furthermore, it has more recently been argued that these results from the cat do not represent the human cochlea. When vowels are spectrally scaled to match the cat's cochlea, the rate code appears to remain at high intensities [Recio et al., 2002].

5.3 The Central Auditory System

The central auditory system consists of the cochlear nuclei; groups of brainstem nuclei including the superior olivary complex (SOC) , nuclei of the lateral lemniscus (LL), and inferior colliculus (IC); and the auditory thalamocortical system consisting of the medial geniculate in the thalamus and multiple areas of the cerebral cortex. Figure 5.4 schematically indicates the nuclear levels and pathways. Efferent pathways are not shown. Page constraints prevent us from providing uniform detail for all levels of the auditory system.

5.3.1 Cochlear Nuclei

Many studies have focused on the anatomy and physiology of the cochlear nucleus (CN) revealing a wealth of information. It can be subdivided into three regions, the anteroventral CN (AVCN) anterior to the nerve entry, the posteroventral CN (PVCN), and the dorsal CN (DCN), each with one or more distinctive neuron types and connections. The axon from each Type I SGC in the nerve branches to each of the three divisions in an orderly manner so that tonotopic organization is maintained. Neurons with
FIGURE 5.4 Schematic of the auditory system. Some of the major pathways and connections have been represented. The system is bilaterally symmetrical (midline as dashed line), paths are crossed and shown for one side in most cases for clarity.

common morphologic classifications are found in all three divisions, especially granule cells, which tend to receive connections from Type II SGCs.

Morphologic categories based on shapes of dendritic trees and somas include spherical bushy cells in the anterior part of the AVCN, both globular bushy cells and spherical bushy in posterior AVCN, stellate cells throughout the AVCN and in the lower layers of the DCN, octopus cells (asymmetrical dendritic tree resembling an octopus) in the PVCN, and fusiform and giant cells in DCN. In AVCN spherical bushy cells receive input from one Type I ganglion cell through a large synapse formation containing end bulbs of Held, while the globular cells receive inputs from a few afferent fibers. The AVCN is tonotopically organized, and neurons having similar CFs form layers called "isofrequency laminae" [Bourk et al., 1981], an organization repeated with variation through most auditory nuclei. The DCN is structurally the most intricate of the CN subnuclei having four or five layers in many species giving it a "cortical" structure comparable to the cerebellum [see Young, 1998; Oertel and Young, 2004]. Extracellular recording techniques, including simultaneous recording from pairs of physiologically identified DCN units and responses to tones and noise has allowed the development of conceptual models of DCN neuronal circuitry in cat [Young and Brownell, 1976; Voigt and Young, 1980, 1990; Young and Davis, 2002] and gerbil [Davis and Voigt, 1997]. Although some differences between the two species have been noted, these may well be explained by a similar underlying neural circuit model whose parameters are somewhat species specific (as opposed to completely different neuronal architectures) [Davis and Voigt, 1997].

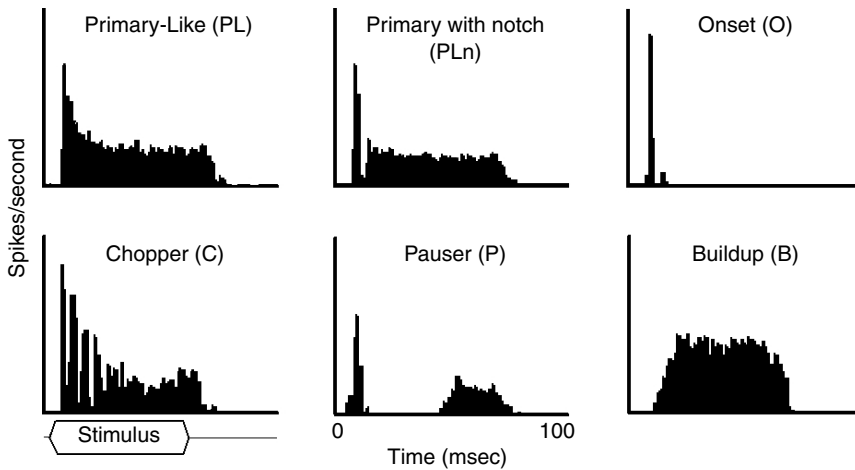
Intracellular recording in slice preparation has identified the membrane characteristics of CN neuronal types [Bal and Oertel, 2001; Manis, 1990]. Some of these characteristics have been confirmed *in vivo* [Hancock and Voigt, 2002]. The diversity of neuronal morphologic types, their participation in local


FIGURE 5.5 PSTH categories obtained for neural spike activity in the nerve and cochlear nuclei in response to brief tone bursts (stimulus envelope shown in lower left). Discharges in the nerve have the PL pattern while the others are associated with regions of the VCN and DCN and with specific morphological types.

circuits, and the emerging knowledge of their membrane biophysics are motivating detailed modeling [Babalian et al., 2003].

5.3.1.1 Spike Discharge Patterns

Tone bursts at a cell's CF and 40 dB above threshold produce PSTHs with shapes distinctive to different nuclear subdivisions and even different morphologic types. PSTH patterns provide insight into sound features exciting auditory neurons. Figure 5.5 illustrates the major PSTH pattern types obtained from the auditory nerve and CN. Auditory nerve fibers and spherical bushy cells in AVCN have primary-like patterns in their PSTHs, an elevated spike rate after tone onset, falling to a slowly adapting level until the tone burst ends. Globular bushy cells may have primary-like, pri-notch (primary-like with a brief notch after onset), or chopper patterns. Stellate cells have nonprimary-like patterns. Onset response patterns, one or a few brief peaks of discharge at onset with little or no discharges afterward, are observed in the PVCN from octopus cells. Chopper, pauser, and buildup patterns are observed in many cells of the DCN. For most CN neurons, these patterns are not necessarily stable over different stimulus intensities; a primary-like pattern may change to a pauser pattern and then to a chopper pattern as intensity is raised [Young, 1984].

Because central neurons often have inhibitory inputs, some stimuli reduce discharge probabilities, and so threshold tuning curves are extended to response-field maps. Figure 5.6 shows three response-field patterns, but many variations have been observed on these. Fibers and neurons with primary-like PSTHs generally have response maps with only an excitatory region (Figure 5.6a) although controls must be used to identify two-tone suppression. The lower edges of this region approximate the threshold-tuning curve. Octopus cells often have very broad tuning curves and extended response maps, as suggested by their frequency-spanning dendritic trees. More complex response maps are observed for some neurons, such as those in the DCN. Inhibitory regions alone, a frequency–intensity area of suppressed spontaneous discharge rates, or combinations of excitatory and inhibitory regions have been observed. Some neurons are excited only within islands of frequency–intensity combinations, demonstrating a CF but having no response to high-intensity or wide-band sounds [Spirou et al., 1999]. Response maps in the DCN containing both excitatory and inhibitory regions have been shown to arise from a convergence of inputs from neurons with only excitatory or inhibitory regions in their maps [Young and Voigt, 1981].

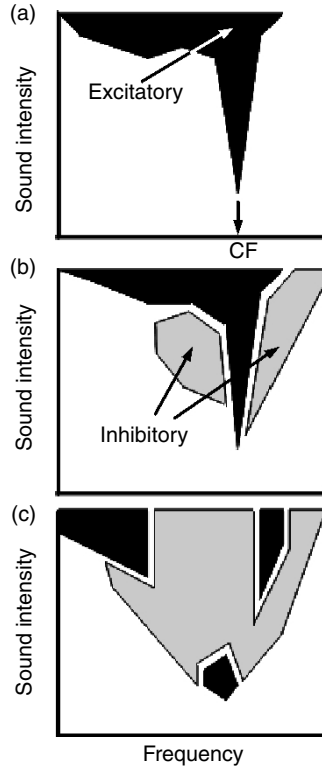
Categorization of CN neurons increasingly depends on many measures: cellular morphology, PSTH and response-field response patterns tones, responses to wide-band stimuli and binaural stimuli, membrane channel physiology, afferent and efferent connectivity, and molecular expressions and


FIGURE 5.6   Response-field maps characteristic of auditory-nerve fibers (a) and central neurons. Two-tone suppression in the cochlea, not due to inhibitory synapses, may resemble panel b maps. Maps are extracted from discharge rates sampled over the stimulus intensity–frequency parameter space. The inhibitory areas represent decreases in spontaneous or evoked discharge rates by tone bursts of the frequency and intensity under test.

responses [Spirou et al., 1999; Fujino and Oertel, 2001]. Beyond mere cellular categorization, information processing in the CN is being discovered as the functions of neuronal circuits are dissected.

Principal neurons of cats [Spirou and Young, 1991] and gerbils [Parsons et al., 2001] have shown to be sensitive to spectral notches like those appearing in HRTFs. These notches, whose center frequency changes with elevation, are thought to be cues for sounds localized in the median plane, where interaural time and intensity cues are absent. Thus, part of the function of the DCN may be to aide in median plane sound localization. The DCN, however, integrates these spectral cues with information from the somatosensory and vestibular systems, as well as from descending auditory pathways. The DCN shows signs of both long-term potentiation (LTP) and long-term depression (LTD) of some of its synapses, providing the infrastructure for learning [see Oertel and Young, 2004]. Whether these learning mechanisms are used exclusively during development (e.g., when we need to learn to associate specific spectral notch frequencies with specific median plane locations) or if they function in adults navigating within their acoustic environments remains a topic of intense interest.

In addition to the contributions to our understanding of CN function gained through anatomy, physiology, pharmacology, and behavioral approaches, computational modeling of the neuronal circuitry of the CN has also contributed to our understanding of CN function. Auditory nerve models have provided the front ends to CN models [Carney, 1993]. Single CN neurons [Kim et al., 1994, Hewitt and Meddis, 1995] as well as neural populations have been modeled [Voigt and Davis, 1996; Hancock and Voigt, 1999]. A major reason for computational modeling of the neuronal circuitry is to verify the behavior of the model, compare it to the known physiology, and to predict behavior of the model to novel stimuli [see Hancock et al., 1997; Nelkin et al., 1997].

5.3.2 Superior Olivary Complex

The SOC contains ten or more subdivisions in some species. It is the first major site at which connections from the two ears converge and is therefore a center for binaural processing that underlies sound localization. There are large differences in the subdivisions between mammalian groups such as bats, primates, cetaceans, and burrowing rodents that utilize vastly different binaural cues. Binaural cues to the locus of sounds include interaural level differences (ILDs), interaural time differences (ITDs), and detailed spectral differences for multispectral sounds due to head and pinna filtering characteristics. These are summarized in the binaural HRTF [Tollin and Yin, 2001].

The medial superior olive (MSO) and lateral superior olive (LSO) process ITDs and ILDs, respectively. A neuron in the MSO receives projections from spherical bushy cells of the CN from both sides and thereby the precise timing and tuning cues of nerve fibers passed through the large synapses mentioned. The temporal accuracy of the pathways and the comparison precision of MSO neurons permit the discrimination of changes in ITD of a few tens of microseconds. MSO neurons project to the ipsilateral IC through the LL. Globular bushy cells of the CN project to the medial nucleus of the trapezoid body (MNTB) on the contralateral side, where they synapse on one and only one neuron in a large, excitatory synapse, the calyx of Held. MNTB neurons send inhibitory projections to neurons of the LSO on the same side, which also receives excitatory input from spherical bushy cells and probably other neurons in the AVCN on the same side [Doucet and Ryugo, 2003]. Sounds reaching the ipsilateral side will excite discharges from an LSO neuron, while those reaching the contralateral side will inhibit its discharge. The relative balance of excitation and inhibition is a function of ILD resulting in this cue being encoded in LSO discharge rates.

One of the subdivisions of the SOC, the dorsomedial periolivary nucleus (DMPO), is a source of efferent fibers that reach the contralateral cochlea in the crossed olivocochlear bundle (COCB). Neurons of the DMPO receive inputs from collaterals of globular bushy cell axons of the contralateral ACVN that project to the MNTB and from octopus cells on both sides. The functional role of the feedback from the DMPO to the cochlea is not well understood.

5.3.3 Nuclei of the Lateral Lemniscus

The LL consists of ascending axons from the CN and LSO. The nuclei of the lateral lemniscus (NLL) lie within this tract, and some, such as the dorsal nucleus LL (DNLL), are known to process binaural information [Burger and Pollak, 2001], but less is known about these nuclei as a group than others, partially due to their relative inaccessibility.

5.3.4 Inferior Colliculi

The IC are paired structures lying on the surface of the upper brainstem. Each colliculus has a large central nucleus, the ICC, a surface cortex, and paracentral nuclei. Each colliculus receives afferents from a number of lower brainstem nuclei, projects to the medial geniculate body (MGB) through the brachium, and communicates with the other colliculus through a commissure. The ICC is the major division and has distinctive isofrequency laminae formed from cells with disk-shaped dendritic trees and afferent fibers. The terminal endings of afferents form fibrous layers between laminae. The remaining neurons in the ICC are stellate cells that have dendritic trees spanning laminae. Axons from these two cell types make up much of the ascending ICC output.

Both monaural and binaural information converge at the IC through direct projections from the CN and from the SOC and NLL. Crossed CN inputs and those from the ipsilateral MSO are excitatory. Inhibitory synapses in the ICC arise from the DNLL, mediated by gamma-amino-butyric acid (GABA), and from the ipsilateral LSO, mediated by glycine [Faingold et al., 1991].

These connections provide an extensive base for identifying sound direction at this midbrain level, but due to their convergence, it is difficult to determine what binaural processing occurs at the IC as opposed to being passed from the SOC and NLL. Many neurons in the IC respond differently depending on binaural parameters. Varying ILDs for clicks or high-frequency tones often indicate that contralateral

sound is excitatory. Ipsilateral sound may have no effect on responses to contralateral sound, classifying the cell as E0, or it may inhibit responses, in which case the neuron is classified as EI, or maximal excitation may occur for sound at both ears, classifying the neuron as EE. Neurons responding to lower frequencies are influenced by ITDs, specifically the phase difference between sinusoids at the ears. Spatial receptive fields for sounds are not well documented in the mammalian IC, but barn owls, who use the sounds of prey for hunting at night, have sound-based spatial maps in the homologous structure [Knudsen and Knudsen, 1983; Bala et al., 2003]. In mammals and owls the superior colliculus, situated just rostral to the IC and largely visual in function, has spatial auditory receptive field maps.

5.3.5 Thalamocortical System

5.3.5.1 Medial Geniculate

The MGB and AC form the auditory thalamocortical system. As with other sensory systems, extensive projections to and from the cortical region exist in this system. The MGB has three divisions, the ventral, dorsal, and medial. The ventral division is the largest and has the most precise tonotopic organization. Almost all its input is from the ipsilateral ICC through the brachium of the IC. Its large bushy cells have dendrites oriented so as to lie in isofrequency layers, and the axons of these neurons project to the AC.

5.3.5.2 Auditory Cortex

As suggested previously, it is inaccurate to view central auditory pathways as a frequency-mapped sensory conduit to higher centers. The auditory system, indeed the entire brain operates to ensure survival by promoting effective behaviors and storing experience in memory for future decisions. In essence, audition identifies critical sound events and associates them with appropriate responses. This is evident in many observations at the cerebral cortex, but examples for bats and human speech suggest the range and complexity of processing in auditory pathways.

5.3.5.2.1 Bat Cortex
Bats of the suborder Microchiroptera use echos from cries they emit to locate and capture prey, usually insects. A well-studied species, the mustached bat (Pteronotus parnellii) emits brief sounds with a fundamental continuous frequency (CF) around 30 kHz with a short downward frequency-modulated (FM) sweep at the end. This cry has strong harmonics, so much of the returning energy is at multiples of the fundamental. This CF–FM sound is just one strategy used by various Microchiroptera, but the role of the AC in the mustached bat has been extensively studied. Figure 5.7 shows responsive regions in this bat's cortex. In an expanded region of a tonotopic map is the Doppler-shifted CF (DSCF) area with responses to the second harmonic of the 30-kHz chirp the bat emits. Cochlear specializations in this bat's inner ear greatly emphasize frequency resolution in the 60-kHz region. Specifically, returning CF sounds are mapped so precisely that the Doppler shift produced by insect wing flutters will cause the site of maximum activity to vary. Another area, the CF/CF area, compares the frequency of the returning CF signal with that of the emitted signal, a cue for the relative velocity of the prey. The FM–FM region responds to the time difference between the emitted and returning FM cry components as a cue to the distance of the prey [Suga, 1990].

   To illustrate the variation in cortical function, it is noted that other species of bats process sound differently in their auditory cortices. The pallid bat uses echolocation for obstacle avoidance and passive listening to locate prey [Razak and Fuzessery, 2002]. As with the mustached bat, echolocation uses frequencies above 30 kHz, but prey location uses frequencies below 20 kHz, and neuron responses differ accordingly over the tonotopic map at cortex.

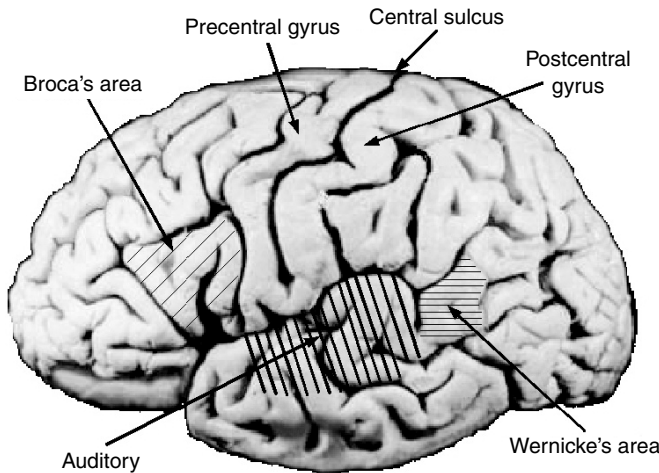
5.3.5.2.2 Human Cortex
The understanding and production of speech has evolved in human-ancestral primates over the last two hundred thousand years and are mediated by the primary AC and surrounding areas. The primary AC is tonotopically organized, but surrounding areas implicated in higher-level language functions are not
FIGURE 5.7 Auditory cortical areas of the mustached bat showing selective processing in different cortical areas for the emitted and returning components of the CF-FM echolocation cry. (Adapted from Suga [1990]. *Sci. Am.* 262: 60–68.)


FIGURE 5.8 Cortical areas in human involved with hearing and language. The auditory areas are located on the temporal lobe, the primary area (A1) being on the dorsal surface within the Sylvan sulcus (not visible). Broca and Wernicke's areas are involved with the production and understanding of language.

easily analyzed. Studies of stroke and injury have helped differentiate the roles of these areas. In most individuals these functions are limited to the left side of the brain.

Figure 5.8 shows the major regions of auditory and language processing relative to common cortical landmarks. The primary auditory area is on the upper surface of the temporal lobe (not shown), but supplementary areas are located on the lateral temporal lobe. Broca's area is located in the posterior portion of the frontal lobe near the auditory regions in the temporal lobe. Wernicke's area is in the

posterior part of the temporal lobe. Regions surrounding these also participate in language, but it is difficult to define many of the functions involved because they involve mixtures of speech production and understanding with subtle grammatical and logical relationships.

Two clinical conditions arising from stroke or injury have been studied extensively, Broca's and Wernicke's aphasias. Damage to Broca's area will often lead to labored but generally correct speech production, but spoken sentences with complex grammars will not be understood. The concept that Broca's area provides short-term working memory for the comparison of sentence components has been suggested. In contrast, patients with damage to Wernicke's area will often speak effortlessly but with many lexical errors, and they generally do not understand sentences spoken by others. Wernicke's area, once thought to underlie "speech comprehension" is now considered a link between areas for concept and meaning with those for word choice and grammar. Wernicke's area is often grouped with the supramarginal gyrus (SMG) just above it. A third clinical syndrome, conduction aphasia, results from damage to neural pathways linking Wernicke's to the SMG and Broca's area. Speech production and understanding is less affected in conduction aphasia, but it has distinctive features including an inability to repeat sentences accurately and difficulty in naming things.

Significant variations arise over the range of clinical damage to cortical and white matter surrounding these areas, especially the SMG, and if tissue damage is restricted to a small area, the aphasia may be transient. Auditory input at the cortical level goes far beyond tonotopic organization to complexities of language, and when it is absent other sensory input may take over. An example of the generality of function is the disruption of signing by a deaf patient during electrical stimulation of these areas during awake brain surgery for temporal lobe epilepsy [Corina et al., 1999]. Tissues normally involved with understanding and producing speech switch to visual cues with deafness.

5.4 Pathologies

Hearing loss results from conductive and neural deficits. Conductive hearing loss due to attenuation in the outer or middle ear often can be alleviated by amplification provided by hearing aids and may be subject to surgical correction. Sensorineural loss due to the absence of IHCs results from genetic deficits, biochemical insult, and exposure to intense sound, or aging (presbycusis). For some cases of sensorineural loss, partial hearing function can be restored with the cochlear prosthesis, direct electrical stimulation of remaining SGCs using small arrays of electrodes inserted into the ST (see chapter on cochlear implants) As of 2004, an estimated 70,000 people have received cochlear implants.

Lesions of the nerve and central structures occur due to trauma, tumor growth, and vascular accidents. These may be subject to surgical intervention to prevent further damage and promote functional recovery. In patients having no auditory nerve due to tumor removal, direct electrical stimulation of the CN has been used to provide auditory sensation.

5.5 Further Topics

In a brief survey it is not possible to cover many important topics for the auditory system. Excellent books treat these in detail. A great deal of attention has been and is being paid to plasticity in neural and behavioral mechanisms of hearing [Parks et al., 2004]. Likewise, little has been said about perceptual mechanisms and the techniques for assessing the behavioral limits of hearing [Hartmann, 1998].

Gastrointestinal System

Berj L. Bardakjian
University of Toronto

6.1 Introduction

The primary function of the gastrointestinal system (Figure 6.1) is to supply the body with nutrients and water. The ingested food is moved along the alimentary canal at an appropriate rate for digestion, absorption, storage, and expulsion. To fulfill the various requirements of the system, each organ has adapted one or more functions. The esophagus acts as a conduit for the passage of food into the stomach for trituration and mixing. The ingested food is then emptied into the small intestine, which plays a major role in the digestion and absorption processes. The chyme is mixed thoroughly with secretions and it is propelled distally (1) to allow further gastric emptying, (2) to allow for uniform exposure to the absorptive mucosal surface of the small intestine, and (3) to empty into the colon. The vigor of mixing and the rate of propulsion depend on the required contact time of chyme with enzymes and the mucosal surface for efficient performance of digestion and absorption. The colon absorbs water and electrolytes from the chyme, concentrating and collecting waste products that are expelled from the system at appropriate times. All of these motor functions are performed by contractions of the muscle layers in the gastrointestinal wall (Figure 6.2).
FIGURE 6.1   The gastrointestinal tract.

6.2   Gastrointestinal Electrical Oscillations

6.2.1   Main Features

Gastrointestinal motility is governed by myogenic, neural, and chemical control systems. The myogenic control system is manifest by rhythmic depolarizations of the smooth muscle cells, which constitute electrical oscillations called the electrical control activity (ECA) or slow waves [Daniel and Chapman, 1963]. The properties of this myogenic system and its electrical oscillations dictate to a large extent the contraction patterns in the stomach, small intestine, and colon [Szurszewski, 1987]. The ECA controls the contractile excitability of smooth muscle cells since the cells may contract only when depolarization of the membrane voltage exceeds an excitation threshold. The normal spontaneous amplitude of ECA depolarization does not exceed this excitation threshold except when neural or chemical excitation is present. The myogenic system affects the frequency, direction, and velocity of the contractions. It also affects the coordination or lack of coordination between adjacent segments of the gut wall. Hence, the electrical activities in the gut wall provide an electrical basis for gastrointestinal motility.

In the distal stomach, small intestine, and colon, there are intermittent bursts of rapid electrical oscillations, called the electrical response activity (ERA) or spike bursts. The ERA occurs during the depolarization plateaus of the ECA if a cholinergic stimulus is present and it is associated with muscular contractions (Figure 6.3). Thus, neural and chemical control systems determine whether contractions will occur or not, but when contractions are occurring, the myogenic control system (Figure 6.4) determines the spatial and temporal patterns of contractions.
FIGURE 6.2   The layers of the gastrointestinal wall.
FIGURE 6.3   The relationships between ECA, ERA, and muscular contractions. The ERA occurs in the depolarized phase of the ECA. Muscular contractions are associated with the ERA, and their amplitude depends on the frequency of response potentials within an ERA burst.

There is also a cyclical pattern distally propagating ERA that appears in the small intestine during the fasted state [Szurszewski, 1969], called the migrating motility complex (MMC). This pattern consists of four phases [Code and Marlett, 1975]: Phase I has little or no ERA, phase II consists of irregular ERA bursts, phase III consists of intense repetitive ERA bursts where there is an ERA burst on each ECA cycle, and phase IV consists of irregular ERA bursts but is usually much shorter than phase II and may not be always present. The initiation and propagation of the MMC is controlled by enteric cholinergic neurons in the intestinal wall (Figure 6.2). The propagation of the MMC may be modulated by inputs from extrinsic nerves or circulating hormones [Sarna et al., 1981]. The MMC keeps the small intestine clean of residual food, debris, and desquamated cells.

FIGURE 6.4 The Gastrointestinal ECA and ERA, recorded in a conscious dog from electrode sets implanted subserosally on stomach (S), duodenum (D), jejunum (J), proximal ascending colon (A), distal ascending colon (AC), transverse colon (TC), and descending colon (DC), respectively. Each trace is of 2 min duration.

6.2.2 Intercellular Communication

Interstitial cells of Cajal (ICC) pace gastrointestinal smooth muscle by initiating slow waves in both longitudinal and circular muscle layers, and they appear to be preferred sites for reception of neurotransmitters [Ward et al., 2001; Sanders et al., 2002; Daniel, 2004]. ICC of the myenteric plexus play a crucial role in pacing slow waves and contractions while intramuscular ICC appear to play a role in receiving neural messages [Ward et al., 2001; Sanders et al., 2002]. Coupling between ICC and smooth muscle networks is essential for entrainment of ECA to obtain coordinated muscle contraction. Gap junctions play an important role in intercellular communication since they provide direct electrical and metabolic coupling between cytoplasm of neighboring cells [Chanson and Spray, 1995], but cells are also coupled by a variety of other structures [Daniel et al., 1976; Huizinga et al., 1992]. ICC may be coupled to smooth muscle by gap junctions as found at the inner border of the circular muscle layer in the canine colon [Berezin et al., 1988], but at other sites, such as between ICC and the muscle layers of the mouse small intestine, gap junctions were not found; however, there was an abundance of close apposition junctions [Thuneberg, 1982]. Within certain muscle layers no gap junctions can be recognized by electron microscopic techniques such as in the longitudinal muscle of the intestine and colon of a variety of species [Zamir and Hanani, 1990; Liu et al., 1998]. In such tissues, close apposition junctions are always observed. Such contacts may contain small groups of connexons, which would allow electrical and metabolic communication although it could not be identified as a gap junction; only a large aggregate of connexons can be recognized as a gap junction by electron microscopy. Nevertheless, electrical communication other than purely resistive is likely to occur.

One type of conspicuous contact is the peg-and-socket junction, where an extrusion of one cell forms a peg, which penetrates a neighboring cell and fits into an intrusion that forms a socket with an intracellular gap of 20 nm. This extrusion can be up to 10 μm long, undergo a 90° bend upon entering a cell, and be up to 1.5 μm in diameter [Thuneberg et al., 1998]. The abundance of these structures in areas of no demonstrable gap junctions and their absence in areas that have many gap junctions suggest that they may provide an intercellular communication pathway other than a direct low-resistance pathway as provided by a gap junction.

Daniel [2004] reviewed communication between ICC and gastrointestinal smooth muscle and he considered structural, theoretical, and experimental difficulties with the possible role of gap junctions

in pacing and in neurotransmission. Furthermore, he considered the following alternate possibilities for transmission of ICC pacing and neural messages (a) The production of an electric field potential in narrow clefts between cells, such as in close apposition junctions, which was shown to be sufficient to allow electrical coupling [Sperelakis et al., 1977; Vigmond and Bardakjian, 1995; Sperelakis, 2002; Sperelakis and McConnell, 2002; Sperelakis and Ramasamy, 2002] and (b) Potassium accumulation in the narrow clefts, such as in peg-and-socket junctions, which was shown to facilitate electrical coupling without gap junctions [Sperelakis et al., 1984; Vigmond and Bardakjian, 2000].

6.2.3   Coupled Nonlinear Oscillators

There is an extensive literature on the mathematical modeling of the generation of oscillations, their coupling, their entrainment, and frequency pulling [Fitzhugh, 1961; Pavlidis, 1973; Plant and Kim, 1976; Winfree, 1980; Ermentrout and Kopell, 1984; Grasman, 1984; Rinzel, 1987; Sherman and Rinzel, 1991; Bardakjian and Diamant, 1994]. The entrainment of coupled oscillators is governed by both intrinsic oscillator properties and coupling mechanisms. The theory of second-order relaxation oscillators, as "traditionally" formulated was qualitative in nature. Two types of oscillators were described (a) Van der Pol type oscillators [Van der Pol and Van der Mark, 1928], which were generalized [Fitzhugh, 1961] to exhibit neuronal-like features and (b) Winfree-type oscillators [Winfree, 1980, 1989], which focused on rate processes of phase and amplitude of oscillation and they were helpful in elucidating the nature of "phase-resetting" phenomena in biological oscillators. Furthermore, quantitative fourth-order models of the Hodgkin-Huxley type [Hodgkin and Huxley, 1952; Plant and Kim, 1976] have been described that closely reproduce neuronal transmembrane voltages. However, development of these quantitative oscillator models requires a full biophysical description of ionic transport mechanisms through membrane channels, pumps, and exchangers. A simpler alternative is the leaky integrate-and-fire model [Stein, 1967], which can only reproduce basic spiking behavior and it is mostly useful for investigation of large networks where the focus is not on individual cells.

On the other hand, the mapped clock oscillator (MCO) [Bardakjian and Diamant, 1994] is a multiportal generalization of the Winfree-type oscillator that is quantitative in nature and exhibits refractory properties. Its parameters are the coefficients of the Fourier series representation of the intrinsic transmembrane voltage oscillation. Hence, they can be obtained directly from the Fourier analysis of the biologically measured intrinsic waveform of the isolated oscillator (e.g., in experiments where segments of an organ are isolated from each other by transaction). Each oscillator consists of, first, a dynamic nonlinearity represented by two nonlinear simultaneous differential equations that govern the state variables of the system and, second, a static nonlinearity that maps the two state variables onto the observable output. The dynamic nonlinearity represents the clock mechanism of the oscillator. The values of its state variables can be modified by three input "portals," each of which correspond to a different type of coupling pathway (gap junctions, field effects, and membrane receptors). The static nonlinearity represents the cellular membrane. This mapper can be changed to represent the waveform of the specific cell being modeled. The MCO can represent transmembrane voltage oscillations in different systems (e.g., neurons, cardiac cells, gastrointestinal muscle, and pancreatic beta cells).

6.3   A Historical Perspective

6.3.1   Minute Rhythms

Alvarez and Mahoney [1922] reported the presence of a rhythmic electrical activity (which they called "action currents") in the smooth muscle layers of the stomach, small intestine, and colon. Their data was acquired from cat (stomach and small intestine), dog (stomach, small intestine, and colon), and rabbit (small intestine and colon). They also demonstrated the existence of frequency gradients in excised stomach and bowel. Puestow [1933] confirmed the presence of a rhythmic electrical activity (which he called "waves of altered electrical potential") and a frequency gradient in isolated canine

small intestinal segments. He also demonstrated the presence of an electrical spiking activity (associated with muscular contractions) superimposed on the rhythmic electrical activity. He implied that the rhythmic electrical activity persisted at all times, whereas the electrical spike activity was of an intermittent nature. Bozler [1938, 1939, 1941] confirmed the occurrence of an electrical spiking activity associated with muscular contractions both *in vitro* in isolated longitudinal muscle strips from guinea pig (colon and small intestine) and rabbit (small intestine), and *in situ* in exposed loops of small intestine of anesthetized cat, dog, and rabbit as well as in cat stomach. He also suggested that the strength of a spontaneous muscular contraction is proportional to the frequency and duration of the spikes associated with it.

The presence of two types of electrical activity in the smooth muscle layers of the gastrointestinal tract in several species had been established [Milton and Smith, 1956; Bulbring et al., 1958; Burnstock et al., 1963; Daniel and Chapman, 1963; Bass, 1965; Gillespie, 1962; Duthie, 1974; Christensen, 1975; Daniel, 1975; Sarna, 1975a]. The autonomous electrical rhythmic activity is an omnipresent myogenic activity [Burnstock et al., 1963] whose function is to control the appearance in time and space of the electrical spiking activity (an intermittent activity associated with muscular contractions) when neural and chemical factors are appropriate [Daniel and Chapman, 1963]. Neural and chemical factors determine whether or not contractions will occur, but when contractions are occurring, the myogenic control system determines the spatial and temporal patterns of contractions.

Isolation of a distal segment of canine small intestine from a proximal segment (using surgical transection or clamping) had been reported to produce a decrease in the frequency of both the rhythmic muscular contractions [Douglas, 1949; Milton and Smith, 1956] and the electrical rhythmic activity [Milton and Smith, 1956] of the distal segment, suggesting frequency entrainment or pulling of the distal segment by the proximal one. It was demonstrated [Milton and Smith, 1956] that the repetition of the electrical spiking activity changed in the same manner as that of the electrical rhythmic activity, thus confirming a one-to-one temporal relationship between the frequency of the electrical rhythmic activity, the repetition rate of the electrical spiking activity, and the frequency of the muscular contractions (when all are present at any one site). Nelson and Becker [1968] suggested that the electrical rhythmic activity of the small intestine behaves like a system of coupled relaxation oscillators. They used two forward coupled relaxation oscillators, having different intrinsic frequencies, to demonstrate frequency entrainment of the two coupled oscillators. Uncoupling of the two oscillators caused a decrease in the frequency of the distal oscillator simulating the effect of transection of the canine small intestine.

The electrical rhythmic activity in canine stomach [Sarna et al., 1972], canine small intestine [Nelson and Becker, 1968; Diamant et al., 1970; Sarna et al., 1971], human small intestine [Robertson–Dunn and Linkens, 1974], human colon [Bardakjian and Sarna, 1980], and human rectosigmoid [Linkens et al., 1976] has been modeled by populations of coupled nonlinear oscillators. The interaction between coupled nonlinear oscillators is governed by both intrinsic oscillator properties and coupling mechanisms.

6.3.2 Hour Rhythms

The existence of periodic gastric activity in the fasted state in both dog [Morat, 1882] and man [Morat, 1893] has been reported. The occurrence of a periodic pattern of motor activity, comprising bursts of contractions alternating with "intervals of repose," in the gastrointestinal tracts of fasted animals was noted early in the 20th century by Boldireff [1905]. He observed that (1) the bursts recurred with a periodicity of about 1.5 to 2.5 h, (2) the amplitude of the gastric contractions during the bursts were larger than those seen postprandially, (3) the small bowel was also involved, and (4) with longer fasting periods, the bursts occurred less frequently and had a shorter duration. Periodic bursts of activity were also observed in (1) the lower esophageal sphincter, [Cannon and Washburn, 1912], and (2) the pylorus [Wheelon and Thomas, 1921]. Further investigation of the fasting contractile activity in the upper small intestine was undertaken in the early 1920s with particular emphasis on the coordination between the stomach and duodenum [Wheelon and Thomas, 1922; Alvarez and Mahoney, 1923]. More

recently, evidence was obtained [Itoh et al., 1978] that the cyclical activity in the lower esophageal sphincter noted by Cannon and Washburn [1912] was also coordinated with that of the stomach and small intestine.

With the use of implanted strain gauges, it was possible to observe contractile activity over long periods of time and it was demonstrated that the cyclical fasting pattern in the duodenum was altered by feeding [Jacoby et al., 1963]. The types of contractions observed during fasting and feeding were divided into four groups [Reinke et al., 1967; Carlson et al., 1972]. Three types of contractile patterns were observed in fasted animals (1) quiescent interval, (2) a shorter interval of increasing activity, and (3) an interval of maximal activity. The fourth type was in fed animals and it consisted of randomly occurring contractions of varying amplitudes. With the use of implanted electrodes in the small intestine of fasted dogs, Szurszewski [1969] demonstrated that the cyclical appearance of electrical spiking activity at each electrode site was due to the migration of the cyclical pattern of quiescence, increasing activity, and maximal electrical activity down the small intestine from the duodenum to the terminal ileum. He called this electrical pattern the migrating myoelectric complex (MMC). Grivel and Ruckebusch [1972] demonstrated that the mechanical correlate of this electrical pattern, which they called the migrating motor complex, occurs in other species such as sheep and rabbits. They also observed that the velocity of propagation of the maximal contractile activity was proportional to the length of the small intestine. Code and Marlett [1975] observed the electrical correlate of the cyclical activity in dog stomach that was reported by Morat [1882; 1893] and they demonstrated that the stomach MMC was coordinated with the duodenal MMC.

The MMC pattern has been demonstrated in other mammalian species [Ruckebusch and Fioramonti, 1975; Ruckebusch and Bueno, 1976], including humans. Bursts of distally propagating contractions have been noted in the gastrointestinal tract of man [Beck et al., 1965], and their cyclical nature was reported by Stanciu and Bennet [1975]. The MMC has been described in both normal volunteers [Vantrappen et al., 1977; Fleckenstein, 1978; Thompson et al., 1980; Kerlin and Phillips, 1982; Rees et al., 1982] and in patients [Vantrappen et al., 1977; Thompson et al., 1982; Summers et al., 1982].

6.3.3 Terminology

A nomenclature to describe the gastrointestinal electrical activities has been proposed to describe the minute rhythm [Sarna, 1975b] and the hour rhythm [Carlson et al., 1972; Code and Marlett, 1975].

Control cycle is one depolarization and repolarization of the transmembrane voltage. Control wave (or slow wave) is the continuing rhythmic electrical activity recorded at any one site. It was assumed to be generated by the smooth muscle cells behaving like a relaxation oscillator at that site. However, recent evidence [Hara et al., 1986; Suzuki et al. 1986; Barajas–Lopez et al., 1989; Serio et al., 1991] indicates that it is generated by a system of interstitial cells of Cajal (ICC) and smooth muscle cells at that site. ECA is the totality of the control waves recorded at one or several sites. Response Potentials (or spikes) are the rapid oscillations of transmembrane voltage in the depolarized state of smooth muscle cells. They are associated with muscular contraction and their occurrence is assumed to be in response to a control cycle when acetylcholine is present. ERA is the totality of the groups of response potentials at one or several sites.

Migrating motility complex (MMC) is the entire cycle, which is composed of four phases. Initially, the electrical and mechanical patterns were referred to as the migrating myoelectric complex and the migrating motor complex, respectively. Phase I is the interval during which fewer than 5% of ECA have associated ERA and no or very few contractions are present. Phase II is the interval when 5 to 95% of the ECA has associated ERA, and intermittent contractions are present. Phase III is the interval when more than 95% of ECA have associated ERA and large cyclical contractions are present. Phase IV is a short and waning interval of intermittent ERA and contractions. Phases II and IV are not always present and are difficult to characterize, whereas phases I and III are always present. MMC cycle time is the interval from the end of one phase III to the end of a subsequent phase III at any one site. Migration time is the time taken for the MMC to migrate from the upper duodenum to the terminal ileum.

6.4   The Stomach

6.4.1   Anatomical Features

The stomach is somewhat pyriform in shape with its large end directed upward at the lower esophageal sphincter and its small end bent to the right at the pylorus. It has two curvatures, the greater curvature which is four to five times as long as the lesser curvature, and it consists of three namely, regions: the fundus, the corpus (or body), and the antrum, respectively. It has three smooth muscle layers. The outermost layer is the longitudinal muscle layer, the middle is the circular muscle layer, and the innermost is the oblique muscle layer. These layers thicken gradually in the distal stomach toward the pylorus, which is consistent with stomach function since trituration occurs in the distal antrum. The size of the stomach varies considerably among subjects. In an adult male, its greatest length when distended is about 25 to 30 cm and its widest diameter is about 10 to 12 cm [Pick and Howden, 1977].

The structural relationships of nerve, muscle, and interstitial cells of Cajal in the canine corpus indicated a high density of gap junctions indicating very tight coupling between cells. Nerves in the corpus are not located close to circular muscle cells but are found exterior to the muscle bundles, whereas ICCs have gap junction contact with smooth muscle cells and are closely innervated [Daniel and Sakai, 1984].

6.4.2   Gastric ECA

In the canine stomach, the fundus does not usually exhibit spontaneous electrical oscillations, but the corpus and antrum do exhibit such oscillations. In the intact stomach, the ECA is entrained to a frequency of about 5 cpm (about 3 cpm in humans) throughout the electrically active region with phase lags in both the longitudinal and circumferential directions [Sarna et al., 1972]. The phase lags decrease distally from corpus to antrum.

There is a marked intrinsic frequency gradient along the axis of the stomach and a slight intrinsic frequency gradient along the circumference. The intrinsic frequency of gastric ECA in isolated circular muscle of the orad and midcorpus is the highest (about 5 cpm) compared to about 3.5 cpm in the rest of the corpus, and about 0.5 cpm in the antrum. Also, there is an orad to aborad intrinsic gradient in resting membrane potential, with the terminal antrum having the most negative resting membrane potential, about 30 mV more negative than the fundal regions [Szurszewski, 1987]. The relatively depolarized state of the fundal muscle may explain its electrical inactivity since the voltage-sensitive ionic channels may be kept in a state of inactivation. Hyperpolarization of the fundus to a transmembrane voltage of -60 mV produces fundal control waves similar to those recorded from mid and orad corpus.

The ECA in canine stomach was modeled [Sarna et al., 1972] using an array of 13 bidirectionally coupled relaxation oscillators. The model featured (1) an intrinsic frequency decline from corpus to the pylorus and from greater curvature to the lesser curvature, (2) entrainment of all coupled oscillators at a frequency close to the highest intrinsic frequency, and (3) distally decreasing phase lags between the entrained oscillators. A simulated circumferential transection caused the formation of another frequency plateau aboral to the transection. The frequency of the orad plateau remained unaffected while that of the aborad plateau was decreased. This is consistent with the observed experimental data.

6.4.3   The Electrogastrogram

In a similar manner to other electrophysiological measures such as the electrocardiogram (EKG) and the electroencephalogram (EEG), the electrogastrogram (EGG) was identified [Stern and Koch, 1985; Chen and McCallum, 1994]. The EGG is the signal obtained from cutaneous recording of the gastric myoelectrical activity by using surface electrodes placed on the abdomen over the stomach. Although the first EGG was recorded in the early 1920s [Alvarez, 1922], progress *vis-à-vis* clinical applications has been relatively slow, in particular when compared to the progress made in EKG, which also started in the early 1920s. Despite many attempts made over the decades, visual inspection of the EGG signal has not led to the identification of waveform characteristics that would help the clinician to diagnose

functional or organic diseases of the stomach. Even the development of techniques such as time–frequency analysis [Qiao et al., 1998] and artificial neural network-based feature extraction [Liang et al., 1997; Wang et al., 1999] for computer analysis of the EGG did not provide clinically relevant information about gastric motility disorders. It has been demonstrated that increased EGG frequencies (1) were seen in perfectly healthy subjects [Pffafenbach et al., 1995] and (2) did not always correspond to serosally recorded tachygastria in dogs [Mintchev and Bowes, 1997]. As yet, there is no effective method of detecting a change in the direction or velocity of propagation of gastric ECA from the EGG.

6.5 The Small Intestine

6.5.1 Anatomical Features

The small intestine is a long hollow organ, which consists of the duodenum, jejunum, and ileum, respectively. Its length is about 650 cm in humans and 300 cm in dogs. The duodenum extends from the pylorus to the ligament of Treitz (about 30 cm in humans and dogs). In humans, the duodenum forms a C-shaped pattern, with the ligament of Treitz near the corpus of the stomach. In dogs, the duodenum lies along the right side of the peritoneal cavity, with the ligament of Treitz in the pelvis. The duodenum receives pancreatic exocrine secretions and bile. In both humans and dogs, the jejunum consists of the next one third whereas the ileum consists of the remaining two thirds of the intestine. The major differences between the jejunum and ileum are functional in nature, relating to their absorption characteristics and motor control. The majority of sugars, amino acids, lipids, electrolytes, and water are absorbed in the jejunum and proximal ileum, whereas bile acids and vitamin B12 are absorbed in the terminal ileum.

6.5.2 Small Intestinal ECA

In the canine small intestine, the ECA is not entrained throughout the entire length [Diamant and Bortoff, 1969a; Sarna et al., 1971]. However, the ECA exhibits a plateau of constant frequency in the proximal region whereby there is a distal increase in phase lag. The frequency plateau (of about 20 cpm) extends over the entire duodenum and part of the jejunum. There is a marked intrinsic frequency gradient in the longitudinal direction with the highest intrinsic frequency being less than the plateau frequency. When the small intestine was transected *in vivo* into small segments (15 cm long), the intrinsic frequency of the ECA in adjacent segments tended to decrease aborally in an exponential manner [Sarna et al., 1971]. A single transection of the duodenum caused the formation of another frequency plateau aboral to the transection. The ECA frequency in the orad plateau was generally unaffected, while that in the aborad plateau was decreased [Diamant and Bortoff, 1969b; Sarna et al., 1971]. The frequency of the aborad plateau was either higher than or equal to the highest intrinsic frequency distal to the transection, depending on whether the transection of the duodenum was either above or below the region of the bile duct [Diamant and Bortoff, 1969b].

The ECA in canine small intestine was modeled using a chain of 16 bidirectionally coupled relaxation oscillators [Sarna et al., 1971]. Coupling was not uniform along the chain, since the proximal oscillators were strongly coupled and the distal oscillators were weakly coupled. The model featured (1) an exponential intrinsic frequency decline along the chain, (2) a frequency plateau which is higher than the highest intrinsic frequency, and (3) a temporal variation of the frequencies distal to the frequency plateau region. A simulated transection in the frequency plateau region caused the formation of another frequency plateau aboral to the transection, such that the frequency of the orad plateau was unchanged whereas the frequency of the aborad plateau decreased.

The ECA in human small intestine was modeled using a chain of 100 bidirectionally coupled relaxation oscillators [Robertson-Dunn and Linkens, 1976]. Coupling was nonuniform and asymmetrical. The model featured (1) a piecewise linear decline in intrinsic frequency along the chain, (2) a piecewise linear decline in coupling similar to that of the intrinsic frequency, (3) forward coupling which is stronger than

backward coupling, and (4) a frequency plateau in the proximal region, which is higher than the highest intrinsic frequency in the region.

6.5.3 Small Intestinal MMC

The MMCs in canine small intestine have been observed in intrinsically isolated segments [Sarna et al., 1981; 1983], even after the isolated segment has been stripped of all extrinsic innervation [Sarr and Kelly, 1981] or removed in continuity with the remaining gut as a Thiry Vella loop [Itoh et al., 1981]. This intrinsic mechanism is able to function independently of extrinsic innervation, since vagotomy [Weisbrodt et al., 1975; Ruckebusch and Bueno, 1977] does not hinder the initiation of the MMC. The initiation of the small intestinal MMC is controlled by integrative networks within the intrinsic plexuses utilizing nicotinic and muscarinic cholinergic receptors [Ormsbee et al., 1979; El-Sharkawy et al., 1982].

When the canine small intestine was transected into four equal strips [Sarna et al., 1981, 1983], it was found that each strip was capable of generating an independent MMC that would appear to propagate from the proximal to the distal part of each segment. This suggested that the MMC could be modeled by a chain of coupled relaxation oscillators. The average intrinsic periods of the MMC for the four segments were reported to be 106.2, 66.8, 83.1, and 94.8 min, respectively. The segment containing the duodenum had the longest period, while the subsequent segment containing the jejunum had the shortest period. However, in the intact small intestine, the MMC starts in the duodenum and not the jejunum. Bardakjian et al. [1981, 1984] have demonstrated that both the intrinsic frequency gradients and resting level gradients have major roles in the entrainment of a chain of coupled oscillators. In modeling the small intestinal MMC with a chain of four coupled oscillators, it was necessary to include a gradient in the intrinsic resting levels of the MMC oscillators (with the proximal oscillator having the lowest resting level) in order to entrain the oscillators and allow the proximal oscillator to behave as the leading oscillator [Bardakjian and Ahmed, 1992].

6.6   The Colon

6.6.1   Anatomical Features

In humans, the colon is about 100 cm in length. The ileum joins the colon approximately 5 cm from its end, forming the cecum, which has a worm-like appendage — the appendix. The colon is sacculated and the longitudinal smooth muscle is concentrated in three bands (the taeniae). It lies in front of the small intestine against the abdominal wall and it consists of the ascending (on the right side), transverse (across the lower stomach), and descending (on the left side) colon. The descending colon becomes the sigmoid colon in the pelvis as it runs down and forward to the rectum. Major functions of the colon are (1) to absorb water, certain electrolytes, short chain fatty acids, and bacterial metabolites; (2) to slowly propel its luminal contents in the caudad direction; (3) to store the residual matter in the distal region; and (4) to rapidly move its contents in the caudad direction during mass movements [Sarna, 1991]. In dogs, the colon is about 45 cm in length and the cecum has no appendage. The colon is not sacculated, and the longitudinal smooth muscle coat is continuous around the circumference [Miller et al., 1968]. It lies posterior to the small intestine and it consists mainly of ascending and descending segments with a small transverse segment. However, functionally it is assumed to consist of three regions, each of about 15 cm in length, representing the ascending, transverse, and descending colon, respectively.

6.6.2   Colonic ECA

In the human colon, the ECA is almost completely phase-unlocked between adjacent sites as close as 1 to 2 cm apart and its frequency (about 3 to 15 cpm) and amplitude at each site vary with time [Sarna et al., 1980]. This results in short duration contractions that are also disorganized in time and space. The disorganization of ECA and its associated contractions is consistent with the colonic function of extensive

mixing, kneading, and slow net distal propulsion [Sarna, 1991]. In the canine colon, the reports about the intrinsic frequency gradient were conflicting [Vanasin et al., 1974; Shearin et al., 1978; El-Sharkawy, 1983].

The human colonic ECA was modeled [Bardakjian and Sarna, 1980] using a tubular structure of 99 bidirectionally coupled nonlinear oscillators arranged in 33 parallel rings where each ring contained three oscillators. Coupling was nonuniform and it increased in the longitudinal direction. The model featured (1) no phase-locking in the longitudinal or circumferential directions, (2) temporal and spatial variation of the frequency profile with large variations in the proximal and distal regions and small variations in the middle region, and (3) waxing and waning of the amplitudes of the ECA, which was more pronounced in the proximal and distal regions. The model demonstrated that the "silent periods" occurred because of the interaction between oscillators and they did not occur when the oscillators were uncoupled. The model was further refined [Bardakjian et al., 1990] such that when the ECA amplitude exceeded an excitation threshold, a burst of ERA was exhibited. The ERA bursts occurred in a seemingly random manner in adjacent sites because (1) the ECA was not phase-locked and (2) the ECA amplitudes and waveshapes varied in a seemingly random manner.

6.7   Epilogue

The ECA in stomach, small intestine, and colon behaves like the outputs of a population of coupled nonlinear oscillators. The populations in the stomach and the proximal small intestine are entrained, whereas those in the distal small intestine and colon are not entrained. There are distinct intrinsic frequency gradients in the stomach and small intestine but their profile in the colon is ambiguous.

The applicability of modeling of gastrointestinal ECA by coupled nonlinear oscillators has been reconfirmed [Daniel et al., 1994] and a novel nonlinear oscillator, the mapped clock oscillator, was proposed [Bardakjian and Diamant, 1994] for modeling the cellular ECA. The oscillator consists of two coupled components: a clock, which represents the interstitial cells of Cajal and a mapper, which represents the smooth muscle transmembrane ionic transport mechanisms [Skinner and Bardakjian, 1991]. Such a model accounts for the mounting evidence supporting the role of the interstitial cells of Cajal as a pacemaker for the smooth muscle transmembrane voltage oscillations [Hara et al., 1986; Suzuki et al., 1986; Barajas–Lopez et al., 1989; Serio et al., 1991; Sanders, 1996; Sanders et al., 2002; Daniel, 2004].

Modeling of the gastrointestinal ECA by populations of coupled nonlinear oscillators [Bardakjian, 1987] suggests that gastrointestinal motility disorders associated with abnormal ECA can be effectively treated by (1) electronic pacemakers to coordinate the oscillators, (2) surgical interventions to remove regional ectopic foci, and (3) pharmacotherapy to stimulate the oscillators. Electronic pacing has been demonstrated in canine stomach [Kelly and LaForce, 1972; Sarna and Daniel, 1973; Bellahsene et al., 1992] and small intestine [Sarna and Daniel, 1975c; Becker et al., 1983]. Also, pharmacotherapy with prokinetic drugs such as Domperidone and Cisapride has demonstrated improvements in the coordination of the gastric oscillators.

Respiratory System

Arthur T. Johnson
University of Maryland

Christopher G. Lausted
The Institute for Systems Biology

Joseph D. Bronzino
Trinity College

As functioning units, the lung and heart are usually considered as a single complex organ, but because these organs contain essentially two compartments — one for blood and one for air — they are usually separated in terms of the tests conducted to evaluate heart or pulmonary function. This chapter focuses on some of the physiologic concepts responsible for normal function and specific measures of the lung's ability to supply tissue cells with enough oxygen while removing excess carbon dioxide.

7.1 Respiration Anatomy

The respiratory system consists of the lungs, conducting airways, pulmonary vasculature, respiratory muscles, and surrounding tissues and structures (Figure 7.1). Each plays an important role in influencing respiratory responses.

7.1.1 Lungs

There are two lungs in the human chest; the right lung is composed of three incomplete divisions called lobes, and the left lung has two, leaving room for the heart. The right lung accounts for 55% of total gas volume and the left lung for 45%. Lung tissue is spongy because of the very small (200–300×10^{-6} m diameter in normal lungs at rest) gas-filled cavities called **alveoli**, which are the ultimate structures for gas exchange. There are 250–350 million alveoli in the adult lung, with a total alveolar surface area of 50–100 m^2 depending on the degree of lung inflation [Johnson, 1991].

7-1
FIGURE 7.1   Schematic representation of the respiratory system.

7.1.2   Conducting Airways

Air is transported from the atmosphere to the alveoli beginning with the oral and nasal cavities, through the pharynx (in the throat), past the glottal opening, and into the trachea or windpipe. Conduction of air begins at the larynx, or voice box, at the entrance to the trachea, which is a fibromuscular tube 10–12 cm in length and 1.4–2.0 cm in diameter [Kline, 1976]. At a location called the carina, the trachea terminates and divides into the left and right bronchi. Each bronchus has a discontinuous cartilaginous support in its wall. Muscle fibers capable of controling airway diameter are incorporated into the walls of the bronchi, as well as in those of air passages closer to the alveoli. Smooth muscle is present throughout the respiratory bronchiolus and alveolar ducts but is absent in the last alveolar duct, which terminates in one to several alveoli. The alveolar walls are shared by other alveoli and are composed of highly pliable and collapsible squamous epithelium cells.

The bronchi subdivide into subbronchi, which further subdivide into bronchioli, which further subdivide, and so on, until finally reaching the alveolar level. Table 7.1 provides a description and dimensions of the airways of adult humans. A model of the geometric arrangement of these air passages is presented in Figure 7.2. It will be noted that each airway is considered to branch into two subairways. In the adult human there are considered to be 23 such branchings, or generations, beginning at the trachea and ending in the alveoli.

Movement of gases in the respiratory airways occurs mainly by bulk flow (convection) throughout the region from the mouth to the nose to the fifteenth generation. Beyond the fifteenth generation, gas diffusion is relatively more important. With the low gas velocities that occur in **diffusion**, dimensions of the space over which diffusion occurs (alveolar space) must be small for adequate oxygen delivery into the walls; smaller alveoli are more efficient in the transfer of gas than are larger ones. Thus animals with high levels of oxygen consumption are found to have smaller-diameter alveoli compared with animals with low levels of oxygen consumption.

TABLE 7.1   Classification and Approximate Dimensions of Airways of Adult Human Lung (Inflated to about 3/4 of TLC)[a]

Common name	Numerical order of generation	Number of each	Diameter, mm	Length, mm	Total cross-sectional area, cm^2	Description and comment
Trachea	0	1	18	120	2.5	Main cartilaginous airway; partly in thorax
Main bronchus	1	2	12	47.6	2.3	First branching of airway; one to each lung; in lung root; cartilage
Lobar bronchus	2	4	8	19.0	2.1	Named for each lobe; cartilage
Segmental bronchus	3	8	6	7.6	2.0	Named for radiographical and surgical anatomy; cartilage
Subsegmental bronchus	4	16	4	12.7	2.4	Last generally named bronchi; may be referred to as medium-sized bronchi; cartilage
Small bronchi	5–10	1,024[b]	1.3[b]	4.6[b]	13.4[b]	Not generally named; contain decreasing amounts of cartilage. Beyond this level airways enter the lobules as defined by a strong elastic lobular-limiting membrane
Bronchioles	11–13	8,192[b]	0.8[b]	2.7[b]	44.5[b]	Not named; contain no cartilage, mucus-secreting elements, or cilia. Tightly embedded in lung tissue
Terminal bronchioles	14–15	32,768[b]	0.7[b]	2.0[b]	113.0[b]	Generally 2 or 3 orders so designated; morphology not significantly different from orders 11–13
Respiratory bronchioles	16–18	262,144[b]	0.5[b]	1.2[b]	534.0[b]	Definite class; bronchiolar cuboidal epithelium present, but scattered alveoli are present giving these airways a gas exchange function. Order 165 often called first-order respiratory bronchiole; 17, second-order; 18, third-order
Alveolar ducts	19–22	4,194,304[b]	0.4[b]	0.8[b]	5,880.0[b]	No bronchial epithelium; have no surface except connective tissue framework; open into alveoli
Alveolar sacs	23	8,388,608	0.4	0.6	11,800.0	No reason to assign a special name; are really short alveolar ducts
Alveoli	24	300,000,000	0.2			Pulmonary capillaries are in the septae that form the alveoli

[a] The number of airways in each generation is based on regular dichotomous branching. [b] Numbers refer to last generation in each group.

FIGURE 7.2 General architecture of conductive and transitory airways. In the conductive zone air is conducted to and from the lungs while in the respiration zone, gas exchange occurs. (Used with permission from Weibel [1963].)

7.1.3 Alveoli

Alveoli are the structures through which gases diffuse to and from the body. To ensure that gas exchange occurs efficiently, alveolar walls are extremely thin. For example, the total tissue thickness between the inside of the alveolus to pulmonary capillary blood plasma is only about 0.4×10^{-6} m. Consequently, the principal barrier to diffusion occurs at the plasma and red blood cell level, not at the alveolar membrane [Ruch and Patton, 1966]. Molecular diffusion within the alveolar volume is responsible for mixing of the enclosed gas. Due to small alveolar dimensions, complete mixing probably occurs in less than 10 msec, fast enough that alveolar mixing time does not limit gaseous diffusion to or from the blood [Astrand and Rodahl, 1970].

Of particular importance to proper alveolar operation is a thin surface coating of surfactant. Without this material, large alveoli would tend to enlarge and small alveoli would collapse. It is the present view that surfactant acts like a detergent, changing the stress–strain relationship of the alveolar wall and thereby stabilizing the lung [Johnson, 1991].

7.1.4 Pulmonary Circulation

There is no true pulmonary analogue to the systemic arterioles, since the **pulmonary circulation** occurs under relatively low pressure [West, 1977]. Pulmonary blood vessels, especially capillaries and venules, are very thin walled and flexible. Unlike systemic capillaries, pulmonary capillaries increase in diameter, and pulmonary capillaries within alveolar walls separate adjacent alveoli with increases in blood pressure or decreases in alveolar pressure. Flow, therefore, is significantly influenced by elastic deformation. Although pulmonary circulation is largely unaffected by neural and chemical control, it does respond promptly to hypoxia.

There is also a high-pressure systemic blood delivery system to the bronchi that is completely independent of the pulmonary low-pressure ($\sim$3330 N/m^2) circulation in healthy individuals. In diseased states, however, bronchial arteries are reported to enlarge when pulmonary blood flow is reduced, and some arteriovenous shunts become prominent [West, 1977].

Total pulmonary blood volume is approximately 300–500 cm^3 in normal adults, with about 60–100 cm^3 in the pulmonary capillaries [Astrand and Rodahl, 1970]. This value, however, is quite variable, depending on such things as posture, position, disease, and chemical composition of the blood [Kline, 1976].

Since pulmonary arterial blood is poor in oxygen and rich in carbon dioxide, it exchanges excess carbon dioxide for oxygen in the pulmonary capillaries, which are in close contact with alveolar walls. At rest, the transit time for blood in the pulmonary capillaries is computed as

$$t = V_c / \dot{V}_c$$

where t is blood transit time, sec; V_c is capillary blood volume, m^3; $\dot{V}_c$ is total capillary blood flow (cardiac output, m^3/sec); and is somewhat less than 1 sec, while during exercise it may be only 500 msec or even less.

7.1.5 Respiratory Muscles

The lungs fill because of a rhythmic expansion of the chest wall. The action is indirect in that no muscle acts directly on the lung. The diaphragm, the muscular mass accounting for 75% of the expansion of the chest cavity, is attached around the bottom of the thoracic cage, arches over the liver, and moves downward like a piston when it contracts. The external intercostal muscles are positioned between the ribs and aid **inspiration** by moving the ribs up and forward. This, then, increases the volume of the thorax. Other muscles are important in the maintenance of thoracic shape during breathing. For details, see Ruch and Patton [1966] and Johnson [1991].

Quiet **expiration** is usually considered to be passive; that is, pressure to force air from the lungs comes from elastic expansion of the lungs and chest wall. During moderate to severe exercise, the abdominal and internal intercostal muscles are very important in forcing air from the lungs much more quickly than would otherwise occur. Inspiration requires intimate contact between lung tissues, pleural tissues (the **pleura** is the membrane surrounding the lungs), and chest wall and diaphragm. This is accomplished by reduced intrathoracic pressure (which tends toward negative values) during inspiration.

Viewing the lungs as an entire unit, one can consider the lungs to be elastic sacs within an airtight barrel — the thorax — which is bounded by the ribs and the diaphragm. Any movement of these two boundaries alters the volume of the lungs. The normal breathing cycle in humans is accomplished by the active contraction of the inspiratory muscles, which enlarges the thorax. This enlargement lowers intrathoracic and interpleural pressure even further, pulls on the lungs, and enlarges the alveoli, alveolar ducts, and bronchioli, expanding the alveolar gas and decreasing its pressure below atmospheric. As a result, air at atmospheric pressure flows easily into the nose, mouth, and trachea.

7.2 Lung Volumes and Gas Exchange

Of primary importance to lung functioning is the movement and mixing of gases within the respiratory system. Depending on the anatomic level under consideration, gas movement is determined mainly by diffusion or convection.

Without the thoracic musculature and rib cage, as mentioned above, the barely inflated lungs would occupy a much smaller space than they occupy *in situ*. However, the thoracic cage holds them open. Conversely, the lungs exert an influence on the thorax, holding it smaller than should be the case without the lungs. Because the lungs and thorax are connected by tissue, the volume occupied by both together is between the extremes represented by relaxed lungs alone and thoracic cavity alone. The resting volume VR, then, is that volume occupied by the lungs with glottis open and muscles relaxed.
FIGURE 7.3   Lung capacities and lung volumes.

Lung volumes greater than resting volume are achieved during inspiration. Maximum inspiration is represented by inspiratory reserve volume (IRV). IRV is the maximum additional volume that can be accommodated by the lung at the end of inspiration. Lung volumes less than resting volume do not normally occur at rest but do occur during exhalation while exercising (when exhalation is active). Maximum additional expiration, as measured from lung volume at the end of expiration, is called expiratory reserve volume (ERV). Residual volume is the amount of gas remaining in the lungs at the end of maximal expiration.

Tidal volume VT is normally considered to be the volume of air entering the nose and mouth with each breath. Alveolar **ventilation** volume, the volume of fresh air that enters the alveoli during each breath, is always less than tidal volume. The extent of this difference in volume depends primarily on the anatomic **dead space**, the 150- to 160-ml internal volume of the conducting airway passages. The term dead is quite appropriate, since it represents wasted respiratory effort; that is, no significant gas exchange occurs across the thick walls of the trachea, bronchi, and bronchiolus. Since normal tidal volume at rest is usually about 500 ml of air per breath, one can easily calculate that because of the presence of this dead space, about 340–350 ml of fresh air actually penetrates the alveoli and becomes involved in the gas exchange process. An additional 150–160 ml of stale air exhaled during the previous breath is also drawn into the alveoli.

The term volume is used for elemental differences of lung volume, whereas the term capacity is used for combination of lung volumes. Figure 7.3 illustrates the interrelationship between each of the following lung volumes and capacities:

1. *Total lung capacity (TLC)*: The amount of gas contained in the lung at the end of maximal inspiration.
2. *Forced vital capacity (FVC)*: The maximal volume of gas that can be forcefully expelled after maximal inspiration.
3. *Inspiratory capacity (IC)*: The maximal volume of gas that can be inspired from the resting expiratory level.
4. ***Functional residual capacity (FRC)***: The volume of gas remaining after normal expiration. It will be noted that FRC is the same as the resting volume. There is a small difference, however, between resting volume and FRC because FRC is measured while the patient breathes, whereas resting volume is measured with no breathing. FRC is properly defined only at end-expiration at rest and not during exercise.

TABLE 7.2   Typical Lung Volumes for Normal, Healthy Males

Lung volume	Normal values	
Total lung capacity (TLC)	6.0×10^{-3} m^3	(6,000 cm^3)
Residual volume (RV)	1.2×10^{-3} m^3	(1,200 cm^3)
Vital capacity (VC)	4.8×10^{-3} m^3	(4,800 cm^3)
Inspiratory reserve volume (IRV)	3.6×10^{-3} m^3	(3,600 cm^3)
Expiratory reserve volume (ERV)	1.2×10^{-3} m^3	(1,200 cm^3)
Functional residual capacity (FRC)	2.4×10^{-3} m^3	(2,400 cm^3)
Anatomic dead volume (V_D)	1.5×10^{-4} m^3	(150 cm^3)
Upper airways volume	8.0×10^{-5} m^3	(80 cm^3)
Lower airways volume	7.0×10^{-5} m^3	(70 cm^3)
Physiologic dead volume (V_D)	1.8×10^{-3} m^3	(180 cm^3)
Minute volume ($\dot{V}_e$) at rest	1.0×10^{-4} m^3/sec	(6,000 cm^3/min)
Respiratory period (T) at rest	4 sec	
Tidal volume (V_T) at rest	4.0×10^{-4} m^3	(400 cm^3)
Alveolar ventilation volume (V_A) at rest	2.5×10^{-4} m^3	(250 cm^3)
Minute volume during heavy exercise	1.7×10^{-3} m^3/sec	(10,000 cm^3/min)
Respiratory period during heavy exercise	1.2 sec	
Tidal volume during heavy exercise	2.0×10^{-3} m^3	(2,000 cm^3)
Alveolar ventilation volume during exercise	1.8×10^{-3} m^3	(1,820 cm^3)

These volumes and specific capacities, represented in Figure 7.3, have led to the development of specific tests (that will be discussed below) to quantify the status of the pulmonary system. Typical values for these volumes and capacities are provided in Table 7.2.

7.3   Perfusion of the Lung

For gas exchange to occur properly in the lung, air must be delivered to the alveoli via the conducting airways, gas must diffuse from the alveoli to the capillaries through extremely thin walls, and the same gas must be removed to the cardiac atrium by blood flow. This three-step process involves (1) alveolar ventilation, (2) the process of diffusion, and (3) ventilatory **perfusion**, which involves pulmonary blood flow. Obviously, an alveolus that is ventilated but not perfused cannot exchange gas. Similarly, a perfused alveolus that is not properly ventilated cannot exchange gas. The most efficient gas exchange occurs when ventilation and perfusion are matched.

There is a wide range of ventilation-to-perfusion ratios that naturally occur in various regions of the lung [Johnson, 1991]. Blood flow is somewhat affected by posture because of the effects of gravity. In the upright position, there is a general reduction in the volume of blood in the thorax, allowing for larger lung volume. Gravity also influences the distribution of blood, such that the perfusion of equal lung volumes is about five times greater at the base compared with the top of the lung [Astrand and Rodahl, 1970]. There is no corresponding distribution of ventilation; hence the ventilation-to-perfusion ratio is nearly five times smaller at the top of the lung (Table 7.3). A more uniform ventilation-to-perfusion ratio is found in the supine position and during exercise [Jones, 1984b].

Blood flow through the capillaries is not steady. Rather, blood flows in a halting manner and may even be stopped if intraalveolar pressure exceeds intracapillary blood pressure during diastole. Mean blood flow is not affected by heart rate [West, 1977], but the highly distensible pulmonary blood vessels admit more blood when blood pressure and cardiac output increase. During exercise, higher pulmonary blood pressures allow more blood to flow through the capillaries. Even mild exercise favors more uniform perfusion of the lungs [Astrand and Rodahl, 1970]. Pulmonary artery systolic pressures increases from 2670 N/m^2 (20 mmHg) at rest to 4670 N/m^2 (35 mmHg) during moderate exercise to 6670 N/m^2 (50 mmHg) at maximal work [Astrand and Rodahl, 1970].

TABLE 7.3 Ventilation-to-Perfusion Ratios from the Top to Bottom of the Lung of Normal Man in the Sitting Position

7.4 Gas Partial Pressure

The primary purpose of the respiratory system is gas exchange. In the gas-exchange process, gas must diffuse through the alveolar space, across tissue, and through plasma into the red blood cell, where it finally chemically joins to hemoglobin. A similar process occurs for carbon dioxide elimination.

As long as intermolecular interactions are small, most gases of physiologic significance can be considered to obey the ideal gas law:

$$pV = nRT$$

where p is pressure; N/m^2; V is volume of gas, m^3; n is number of moles, mol; R is gas constant, $(N \times m)/(mol \times K)$; and T is the absolute temperature, K.

The ideal gas law can be applied without error up to atmospheric pressure; it can be applied to a mixture of gases, such as air, or to its constituents, such as oxygen or nitrogen. All individual gases in a mixture are considered to fill the total volume and have the same temperature but reduced pressures. The pressure exerted by each individual gas is called the **partial pressure** of the gas.

Dalton's law states that the total pressure is the sum of the partial pressures of the constituents of a mixture:

$$p = \sum_{i=1}^{N} p_i$$

where p_i is the partial pressure of the ith constituent, N/m^2 and N is the total number of constituents.

Dividing the ideal gas law for a constituent by that for the mixture gives

$$\frac{P_i V}{PV} = \frac{n_i R_i T}{nRT}$$

so that

$$\frac{p_i}{p} = \frac{n_i R_i}{nR}$$

TABLE 7.4   Molecular Masses, Gas Constants, and Volume Fractions
for Air and Constituents

Constituent	Molecular mass, kg/mol	Gas constant, $N \cdot m/(mol \cdot K)$	Volume fraction in air, m^3/m^3
Air	29.0	286.7	1.0000
Ammonia	17.0	489.1	0.0000
Argon	39.9	208.4	0.0093
Carbon dioxide	44.0	189.0	0.0003
Carbon monoxide	28.0	296.9	0.0000
Helium	4.0	2078.6	0.0000
Hydrogen	2.0	4157.2	0.0000
Nitrogen	28.0	296.9	0.7808
Oxygen	32.0	259.8	0.2095

Note: Universal gas constant is 8314.43 $N \cdot m/kg \cdot mol \cdot K$.

which states that the partial pressure of a gas may be found if the total pressure, mole fraction, and ratio of gas constants are known. For most respiratory calculations, p will be considered to be the pressure of 1 atmosphere, 101 kN/m^2. Avogadro's principle states that different gases at the same temperature and pressure contain equal numbers of molecules:

$$\frac{V_1}{V_2} = \frac{nR_1}{nR_2} = \frac{R_1}{R_2}$$

Thus

$$\frac{p_i}{p} = \frac{V_i}{V}$$

where V_i/V is the volume fraction of a constituent in air and is therefore dimensionless. Table 7.4 provides individual gas constants, as well as volume fractions, of constituent gases of air.

Gas pressures and volumes can be measured for many different temperature and humidity conditions. Three of these are body temperature and pressure, saturated (**BTPS**); ambient temperature and pressure (ATP); and standard temperature and pressure, dry (**STPD**). To calculate constituent partial pressures at STPD, total pressure is taken as barometric pressure minus vapor pressure of water in the atmosphere:

$$p_i = (V_i/V)(p - pH_2O)$$

where p is total pressure, kN/m^2; pH_2O is vapor pressure of water in atmosphere, kN/m^2; and V_i/V as a ratio does not change in the conversion process.

Gas volume at STPD is converted from ambient condition volume as

$$V_i = V_{amb}[273/(273 + \Theta)][(p - pH_2O)/101.3]$$

where V_i is volume of gas i corrected to STPD, m^3; V_{amb} is volume of gas i at ambient temperature and pressure, m^3; Θ is ambient temperature, $°C$; p is ambient total pressure, kN/m^2; and pH_2O is the vapor pressure of water in the air, kN/m^2.

Partial pressures and gas volumes may be expressed in BTPS conditions. In this case, gas partial pressures are usually known from other measurements. Gas volumes are converted from ambient conditions by

$$V_i = V_{amb}[310/(273 + \Theta)][(p - pH_2O)/p - 6.28]$$

Table 7.5 provides gas partial pressure throughout the respiratory and circulatory systems.

TABLE 7.5   Gas Partial Pressures (kN/m^2) Throughout the Respiratory and
Circulatory Systems

7.5 Pulmonary Mechanics

The respiratory system exhibits properties of resistance, compliance, and inertance analogous to the
electrical properties of resistance, capacitance, and inductance. Of these, inertance is generally considered
to be of less importance than the other two properties.

Resistance is the ratio of pressure to flow:

$$R = P/V$$

where R is resistance, $N \times sec/m^5$; P is pressure, N/m^2; and V is the volume flow rate, m^3/sec.

Resistance can be found in the conducting airways, in the lung tissue, and in the tissues of the chest wall.
Airways exhalation resistance is usually higher than airways inhalation resistance because the surrounding
lung tissue pulls the smaller, more distensible airways open when the lung is being inflated. Thus airways
inhalation resistance is somewhat dependent on lung volume, and airways exhalation resistance can be
very lung-volume-dependent [Johnson, 1991]. Respiratory tissue resistance varies with frequency, lung
volume, and volume history. Tissue resistance is relatively small at high frequencies but increases greatly at
low frequencies, nearly proportional to $1/f$. Tissue resistance often exceeds airway resistance below 2 Hz.
Lung tissue resistance also increases with decreasing volume amplitude [Stamenovic et al., 1990].

Compliance is the ratio of lung volume to lung pressure:

$$C = V/P$$

where C is compliance, m^5/N; V is lung volume/m^3; and P is the pressure, N/m^2.

As the lung is stretched, it acts as an expanded balloon that tends to push air out and return to its
normal size. The static pressure–volume relationship is nonlinear, exhibiting decreased static compliance
at the extremes of lung volume [Johnson, 1991]. As with tissue resistance, dynamic tissue compliance does
not remain constant during breathing. Dynamic compliance tends to increase with increasing volume and
decrease with increasing frequency [Stamenovic et al., 1990].

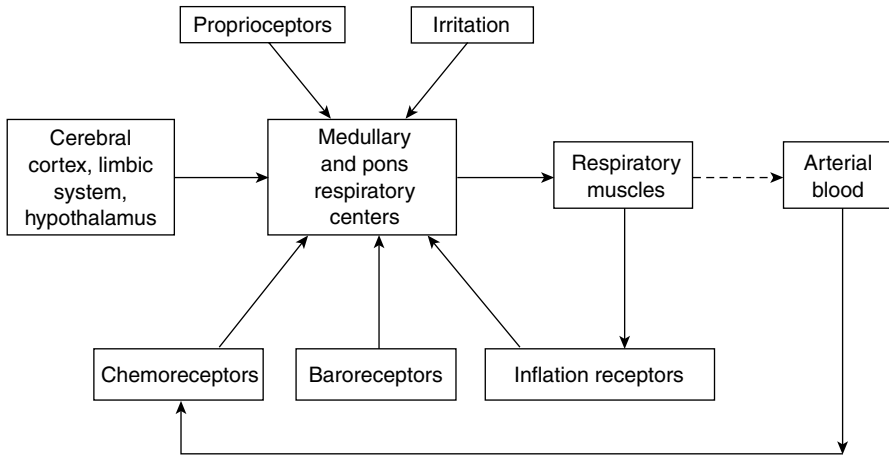
Two separate approaches can be used to model lung tissue mechanics. The traditional approach places
a linear viscoelastic system in parallel with a plastoelastic system. A linear viscoelastic system consists of
ideal resistive and compliant elements and can exhibit the frequency dependence of respiratory tissue.
A plastoelastic system consists of dry-friction elements and compliant elements and can exhibit the volume
dependence of respiratory tissue [Hildebrandt, 1970]. An alternate approach is to utilize a nonlinear
viscoelastic system that can characterize both the frequency dependence and the volume dependence of
respiratory tissue [Suki and Bates, 1991].


FIGURE 7.4   General scheme of respiratory control.

Lung tissue hysteresivity relates resistance and compliance:

$$\omega R = \eta / C_{\text{dyn}}$$

where ω is frequency, rad/sec; R is resistance, $\text{N} \times \text{sec/m}^5$; η is hysteresivity, unitless; and C_{dyn} is the dynamic compliance, m^5/n.

Hysteresivity, analogous to the structural damping coefficient used in solid mechanics, is an empirical parameter arising from the assumption that resistance and compliance are related at the microstructural level. Hysteresivity is independent of frequency and volume. Typical values range from 0.1 to 0.3 [Fredberg and Stamenovic, 1989].

7.6   Respiratory Control

Control of respiration occurs in many different cerebral structures [Johnson, 1991] and regulates many things (Hornbein, 1981). Respiration must be controled to produce the respiratory rhythm, ensure adequate gas exchange, protect against inhalation of poisonous substances, assist in maintenance of body pH, remove irritations, and minimize energy cost. Respiratory control is more complex than cardiac control for at least three reasons:

1. Airways airflow occurs in both directions
2. The respiratory system interfaces directly with the environment outside the body
3. Parts of the respiratory system are used for other functions, such as swallowing and speaking

As a result, respiratory muscular action must be exquisitely coordinated; it must be prepared to protect itself against environmental onslaught, and breathing must be temporarily suspended on demand.

All control systems require sensors, controllers, and effectors. Figure 7.4 presents the general scheme for respiratory control. There are **mechanoreceptors** throughout the respiratory system. For example, nasal receptors are important in sneezing, apnea (cessation of breathing), bronchodilation, bronchoconstriction, and the secretion of mucus. Laryngeal receptors are important in coughing, apnea, swallowing, bronchoconstriction, airway mucus secretion, and laryngeal constriction. Tracheobronchial receptors are important in coughing, pulmonary hypertension, bronchoconstriction, laryngeal constriction, and mucus production. Other mechanoreceptors are important in the generation of the respiratory pattern and are involved with respiratory sensation.

Respiratory **chemoreceptors** exist peripherally in the aortic arch and carotic bodies and centrally in the ventral medulla oblongata of the brain. These receptors are sensitive to partial pressures of CO_2 and O_2 and to blood pH.

The respiratory controller is located in several places in the brain. Each location appears to have its own function. Unlike the heart, the basic respiratory rhythm is not generated within the lungs but rather in the brain and is transmitted to the respiratory muscles by the phrenic nerve.

Effector organs are mainly the respiratory muscles, as described previously. Other effectors are muscles located in the airways and tissues for mucus secretion. Control of respiration appears to be based on two criteria (1) removal of excess CO_2 and (2) minimization of energy expenditure. It is not the lack of oxygen that stimulates respiration but increased CO_2 partial pressure that acts as a powerful respiratory stimulus. Because of the buffering action of blood bicarbonate, blood pH usually falls as more CO_2 is produced in the working muscles. Lower blood pH also stimulates respiration.

A number of respiratory adjustments are made to reduce energy expenditure during exercise: respiration rate increases, the ratio of inhalation time to exhalation time decreases, respiratory flow waveshapes become more trapezoidal, and expiratory reserve volume decreases. Other adjustments to reduce energy expenditure have been theorized but not proven [Johnson, 1991].

7.7   The Pulmonary Function Laboratory

The purpose of a pulmonary function laboratory is to obtain clinically useful data from patients with respiratory dysfunction. The pulmonary function tests (PFTs) within this laboratory fulfill a variety of functions. They permit (1) quantification of a patient's breathing deficiency, (2) diagnosis of different types of pulmonary diseases, (3) evaluation of a patient's response to therapy, and (4) preoperative screening to determine whether the presence of lung disease increases the risk of surgery.

Although PFTs can provide important information about a patient's condition, the limitations of these tests must be considered. First, they are nonspecific in that they cannot determine which portion of the lungs is diseased, only that the disease is present. Second, PFTs must be considered along with the medical history, physical examination, x-ray examination, and other diagnostic procedures to permit a complete evaluation. Finally, the major drawback of some PFTs is that they require a full patient cooperation and for this reason these tests cannot be conducted on critically ill patients. Consider some of the most widely used PFTs: spirometry, body **plethysmography**, and diffusing capacity.

7.7.1   Spirometry

The simplest PFT is the spirometry maneuver. In this test, the patient inhales to TLC and exhales forcefully to residual volume. The patient exhales into a displacement bell chamber that sits on a water seal. As the bell rises, a pen coupled to the bell chamber inscribes a tracing on a rotating drum. The spirometer offers very little resistance to breathing; therefore, the shape of the spirometry curve (Figure 7.5) is purely a function of the patient's lung compliance, chest compliance, and airway resistance. At high lung volumes, a rise in intrapleural pressure results in greater expiratory flows. However, at intermediate and low lung volumes, the expiratory flow is independent of effort after a certain intrapleural pressure is reached.

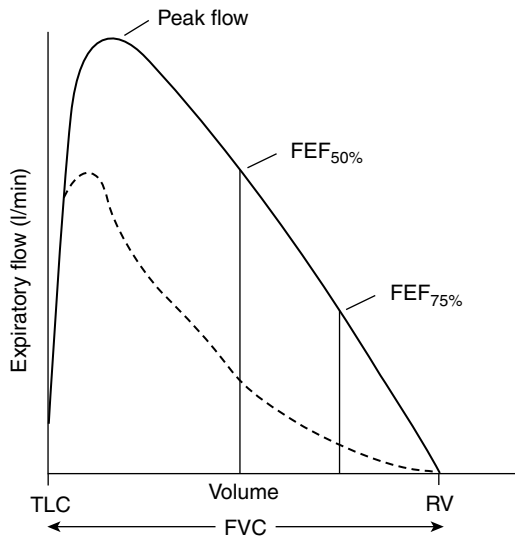
Measurements made from the spirometry curve can determine the degree of a patient's ventilatory obstruction. FVC, forced expiratory volumes (FEVs), and forced expiratory flows (FEFs) can be determined. The FEV indicates the volume that has been exhaled from TLC for a particular time interval. For example, FEV0.5 is the volume exhaled during the first half-second of expiration, and FEV1.0 is the volume exhaled during the first second of expiration; these are graphically represented in Figure 7.5. Note that the more severe the ventilatory obstruction, the lower are the timed volumes (FEV0.5 and FEV1.0). The FEF is a measure of the average flow (volume/time) over specified portions of the spirometry curve and is represented by the slope of a straight line drawn between volume levels. The average flow over the first quarter of the forced expiration is the FEF0–25%, whereas the average flow over the middle 50% of
FIGURE 7.5 Typical spirometry tracing obtained during testing; inspiratory capacity (IC), tidal volume (TV), forced vital capacity (FVC), forced expiratory volume (FEV), and forced expiratory flows. Dashed line represents a patient with obstructive lung disease; solid line represents a normal, healthy individual.


FIGURE 7.6 Flow-volume curve obtained from a spirometry maneuver. Solid line is a normal curve; dashed line represents a patient with obstructive lung disease.

the FVC is the FEF25–75%. These values are obtained directly from the spirometry curves. The less steep curves of obstructed patients would result in lower values of FEF0–25% and FEF25–75% compared with normal values, which are predicted on the basis of the patient's sex, age, and height. Equations for normal values are available from statistical analysis of data obtained from a normal population. Test results are then interpreted as a percentage of normal.

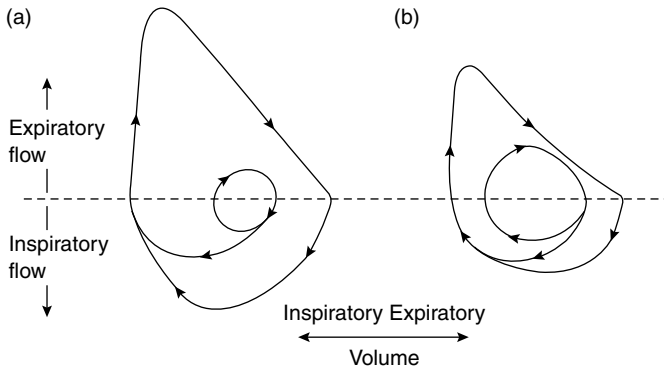
Another way of presenting a spirometry curve is as a flow-volume curve. Figure 7.6 represents a typical flow-volume curve. The expiratory flow is plotted against the exhaled volume, indicating the maximum flow that may be reached at each degree of lung inflation. Since there is no time axis, a time must mark the FEV0.5 and FEV1.0 on the tracing. To obtain these flow-volume curves in the laboratory, the patient usually exhales through a **pneumotach**. The most widely used pneumotach measures a pressure drop


FIGURE 7.7 Typical flow-volume loops. (a) Normal flow-volume loop. (b) Flow-volume loop of patient with obstructive lung disease.

across a flow-resistive element. The resistance to flow is constant over the measuring range of the device; therefore, the pressure drop is proportional to the flow through the tube. This signal, which is indicative of flow, is then integrated to determine the volume of gas that has passed through the tube.

Another type of pneumotach is the heated-element type. In this device, a small heated mass responds to airflow by cooling. As the element cools, a greater current is necessary to maintain a constant temperature. This current is proportional to the airflow through the tube. Again, to determine the volume that has passed through the tube, the flow signal is integrated.

The flow-volume loop in Figure 7.7 is a dramatic representation displaying inspiratory and expiratory curves for both normal breathing and maximal breathing. The result is a graphic representation of the patient's reserve capacity in relation to normal breathing. For example, the normal patient's tidal breathing loop is small compared with the patient's maximum breathing loop. During these times of stress, this tidal breathing loop can be increased to the boundaries of the outer ventilatory loop. This increase in ventilation provides the greater gas exchange needed during the stressful situation. Compare this condition with that of the patient with obstructive lung disease. Not only is the tidal breathing loop larger than normal, but also the maximal breathing loop is smaller than normal. The result is a decreased ventilatory reserve, limiting the individual's ability to move air in and out of the lungs. As the disease progresses, the outer loop becomes smaller, and the inner loop becomes larger.

The primary use of spirometry is in detection of obstructive lung disease that results from increased resistance to flow through the airways. This can occur in several ways:

1. Deterioration of the structure of the smaller airways that results in early airways closure.
2. Decreased airway diameters caused by bronchospasm or the presence of secretions increases the airway's resistance to airflow.
3. Partial blockage of a large airway by a tumor decreases airway diameter and causes turbulent flow.

Spirometry has its limitations, however. It can measure only ventilated volumes. It cannot measure lung capacities that contain the residual volume. Measurements of TLC, FRC, and RV have diagnostic value in defining lung overdistension or restrictive pulmonary disease; the body plethysmograph can determine these absolute lung volumes.

7.7.2 Body Plethysmography

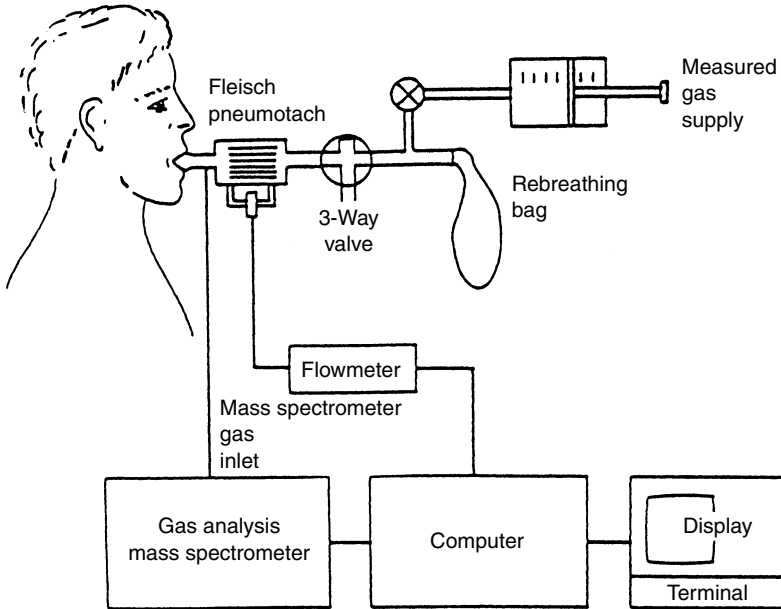
In a typical plethysmograph, the patient is put in an airtight enclosure and breathes through a pneumotach. The flow signal through the pneumotach is integrated and recorded as tidal breathing. At the end of a normal expiration (at FRC), an electronically operated shutter occludes the tube through which the patient is breathing. At this time the patient pants lightly against the occluded airway. Since there is no


FIGURE 7.8 Typical system configuration for the measurement of rebreathing pulmonary diffusing capacity.

flow, pressure measured at the mouth must equal alveolar pressure. But movements of the chest that compress gas in the lung simultaneously rarify the air in the plethysmograph, and vice versa. The pressure change in the plethysmograph can be used to calculate the volume change in the plethysmograph, which is the same as the volume change in the chest. This leads directly to determination of FRC.

At the same time, alveolar pressure can be correlated to plethysmographic pressure. Therefore, when the shutter is again opened and flow rate is measured, airway resistance can be obtained as the ratio of alveolar pressure (obtainable from plethysmographic pressure) to flow rate [Carr and Brown, 1993]. Airway resistance is usually measured during panting, at a nominal lung volume of FRC and flow rate of ± 1 l/sec.

Airway resistance during inspiration is increased in patients with asthma, bronchitis, and upper respiratory tract infections. Expiratory resistance is elevated in patients with emphysema, since the causes of increased expiratory airway resistance are decreased driving pressures and the airway collapse. Airway resistance also may be used to determine the response of obstructed patients to bronchodilator medications.

7.7.3 Diffusing Capacity

So far the mechanical components of airflow through the lungs have been discussed. Another important parameter is the diffusing capacity of the lung, the rate at which oxygen or carbon dioxide travel from the alveoli to the blood (or vice versa for carbon dioxide) in the pulmonary capillaries. Diffusion of gas across a barrier is directly related to the surface area of the barrier and inversely related to the thickness. Also, diffusion is directly proportional to the solubility of the gas in the barrier material and inversely related to the molecular weight of the gas.

Lung diffusing capacity (Dl) is usually determined for carbon monoxide but can be related to oxygen diffusion. The popular method of measuring carbon monoxide diffusion utilizes a rebreathing technique in which the patient rebreathes rapidly in and out of a bag for approximately 30 sec. Figure 7.8 illustrates the test apparatus. The patient begins breathing from a bag containing a known volume of gas consisting of 0.3–0.5% carbon monoxide made with heavy oxygen, 0.3–0.5% acetylene, 5% helium, 21% oxygen, and

a balance of nitrogen. As the patient rebreathes the gas mixture in the bag, a modified **mass spectrometer** continuously analyzes it during both inspiration and expiration. During this rebreathing procedure, the carbon monoxide disappears from the patient-bag system; the rate at which this occurs is a function of the lung diffusing capacity.

The helium is inert and insoluble in lung tissue and blood, and equilibrates quickly in unobstructed patients, indicating the dilution level of the test gas. Acetylene, on the other hand, is soluble in blood and is used to determine the blood flow through the pulmonary capillaries. Carbon monoxide is bound very tightly to hemoglobin and is used to obtain diffusing capacity at a constant pressure gradient across the alveolar-capillary membrane.

Decreased lung diffusing capacity can occur from the thickening of the alveolar membrane or the capillary membrane as well as the presence of interstitial fluid from edema. All these abnormalities increase the barrier thickness and cause a decrease in diffusing capacity. In addition, a characteristic of specific lung diseases is impaired lung diffusing capacity. For example, fibrotic lung tissue exhibits a decreased permeability to gas transfer, whereas pulmonary emphysema results in the loss of diffusion surface area.

Defining Terms

Alveoli: Respiratory airway terminals where most gas exchange with the pulmonary circulation takes place.

BTPS: Body temperature (37°C) and standard pressure (1 atm), saturated (6.28 kN/m^2).

Chemoreceptors: Neural receptors sensitive to chemicals such as gas partial pressures.

Dead space: The portion of the respiratory system that does not take part in gas exchange with the blood.

Diffusion: The process whereby a material moves from a region of higher concentration to a region of lower concentration.

Expiration: The breathing process whereby air is expelled from the mouth and nose. Also called exhalation.

Functional residual capacity: The lung volume at rest without breathing.

Inspiration: The breathing process whereby air is taken into the mouth and noise. Also called inhalation.

Mass spectrometer: A device that identifies relative concentrations of gases by means of mass-to-charge ratios of gas ions.

Mechanoreceptors: Neural receptors sensitive to mechanical inputs such as stretch, pressure, irritants, and so on.

Partial pressure: The pressure that a gas would exert if it were the only constituent.

Perfusion: Blood flow to the lungs.

Plethysmography: Any measuring technique that depends on a volume change.

Pleura: The membrane surrounding the lung.

Pneumotach: A measuring device for airflow.

Pulmonary circulation: Blood flow from the right cardiac ventricle that perfuses the lung and is in intimate contact with alveolar membranes for effective gas exchange.

STPD: Standard temperature (0°C) and pressure (1 atm), dry (moisture removed).

Ventilation: Airflow to the lungs.

Physiological Modeling, Simulation, and Control

Joseph L. Palladino
Trinity College

THE COMPLEXITIES OF PHYSIOLOGICAL SYSTEMS often lead to the creation of new models to aid in the understanding of measured experimental data and to predict new features of the system under study. Models may serve to compactly summarize known system properties, including biomechanical, chemical, and electrical phenomena. Experiments performed on the model yield new information that casts light on unknown mechanisms underlying these properties and stimulate the formulation of new questions and the design of new experiments. Further, such quantitative description often leads to a better understanding of the physical mechanisms underlying both normal and altered (diseased) system performance. Ultimately, modeling may facilitate clinical diagnosis of system failure at an early stage of disease development.

Models begin conceptually; for example, the concept that a blood vessel behaves as a fluid-filled pipe. Concepts may be developed into physical models, for example, using a latex tube to describe a blood vessel, upon which experiments are performed. Often, concepts are realized as mathematical models, whereby the concept is described by physical laws, transformed into a set of mathematical equations, and solved via computer. Simulations, distinct from models, are descriptions that mimic the physiological system. The quantitative nature of physiological models allows them to be employed as components of systems for the study of physiological control, illustrated in several of this section's chapters.

Chapter 8 describes the iterative process of physiological modeling and presents three recent, widely different, modeling approaches in cardiovascular dynamics. The first is a compact model of the canine left ventricle. Its modular design permits application to study the greater human cardiovascular system, or the specific study of flow during closed chest CPR. Next, a large-scale, distributed muscle model shows how mechanical description of muscle structure can predict a molecular mechanism responsible for heart muscle's complex mechanical function, that is, structure predicts function. Finally, an approach for predicting ventricular hypertrophy based on cardiac function is presented, with function predicting structure.

Chapter 9 shows how compartmental models may be used to describe physiological systems, for example, pharmacokinetics. The production, distribution, transport, and interaction of exogenous materials, such as drugs or tracers, and endogenous materials, such as hormones, are described. Examples of both linear and nonlinear compartmental models are presented, as well as parameter estimation, optimal experiment design, and model validation.

Chapter 10 demonstrates the importance of cardiovascular modeling in designing closed-loop drug delivery systems, such as intravenous infusion pumps for pharmacological agents. The chapter begins with an extensive review of segmental and transmission line models of the arterial system and time-varying elastance descriptions of the left ventricle. The author makes an argument for employing nonlinear cardiovascular-linked pharmacological models to aid in controller design since data from these models can improve, and reduce the number of, animal and human experiments, and can be used to simulate human conditions not easily produced in animals.

Chapter 11 presents models used to study the continual interaction of the respiratory mechanical system and pulmonary gas exchange. Traditionally, the respiratory system is described as a chemostat — ventilation increases with increased chemical stimulation. Alternatively, the author proposes that quantitative description of the "respiratory central pattern generator," a network of neuronal clusters in the brain, is a much more sophisticated and realistic approach. Study of this dynamic, optimized controller of a nonlinear plant is interesting from both physiological and engineering perspectives, the latter due to applications of these techniques for new, intelligent control system design.

Chapter 12 introduces the use of neural network techniques and their application in modeling physiological control systems. As their name implies, neural networks are computational algorithms based upon the computational structure of the nervous system, and are characterized as distributed processing and adaptive. Neural networks have been used to describe the control of arm movements with electrical stimulation and the adaptive control of arterial blood pressure.

Chapter 13 surveys methods of system identification in physiology, the process of extracting models or model components from experimental data. Identification typically refers to model specification or model estimation, where unknown parameters are estimated within the specified model using experimental data and advanced computational techniques. Estimation may be either parametric, where algebraic or difference equations represent static or dynamic systems, or nonparametric, where analytical (convolution), computational (look-up tables), or graphical (phase-space) techniques characterize the system. This chapter closes with a recent hybrid modular approach.

Chapter 14 shows how modeling can propose mechanisms to explain experimentally observed oscillations in the cardiovascular system. A control system characterized by a slow and delayed change in resistance due to smooth muscle activity is presented. Experiments on this model show oscillations in the input impedance frequency spectrum, and flow and pressure transient responses to step inputs consistent with experimental observations. This autoregulation model supports the theory that low-frequency oscillations in heart rate and blood pressure variability spectra (Mayer waves) find their origin in the intrinsic delay of flow regulation.

Chapter 15 presents models to describe the control of human movement, primarily the dynamics of human extremities. Presented are the challenges associated with description of the extremities as rigid bodies using laws of mechanics such as D'Alembert's principle, the Newton–Euler method, and the LaGrange equations. Analytic limb models are presented first, described by sets of ordinary differential equations. Next, the complexities of limb movement control are described by nonanalytic models, for example an expert system denoted "artificial reflex control," learning algorithms and fuzzy logic. Finally, hybrid controller models combining analytic and nonanalytic techniques are discussed.

Chapter 16 describes physiological models of the fast eye movement, or saccade, that enables the eye to move quickly from one image to another. This common eye movement is encountered when scanning from the end of one line of printed text to the start of another. Early quantitative models helped define important characteristics of saccades. Increasingly complex models of the oculomotor plant were derived using improved models of the rectus eye muscle. Finally, application of system control theory and simulation methods led to a saccade generator model in close agreement with experimental data.

Chapter 17 adopts a comparative approach using biological scaling laws to compare the cardiovascular systems of different mammals. Allometry, the change of proportions with increase of size, and dimensional analysis is used to develop allometric relations for important cardiovascular parameters such as stroke volume, peripheral resistance, and heart efficiency. Optimal cardiovascular design is also discussed.

Chapter 18 presents a biomedical analysis of cardiopulmonary resuscitation. This work begins by characterizing open and closed chest techniques. The authors then review the broad range of adjuvant techniques, such as MAST augmented or impulse CPR. The chapter proposes a modeling based approach suggesting that CPR as a technique should reestablish cardiac valvular function to be effective.

8.1 Introduction

A model, in the broad sense, is a representation of something, be it a physical or cerebral representation. In the sciences, models often begin as conceptual interpretations of experimental observations (Figure 8.1). Experimental observations (stage 1) lead to a qualitative concept (stage 2) and additional questions, which then require additional experiments (stage 3). At some point, sufficient knowledge is gained that quantitative representations, or models, arise (stage 4). Such models may take the form of physical models, for example, where a network of elastic tubes represent the arterial circulation. Commonly in medicine, the term model refers to an animal model, with the assumption that a particular animal's physiology is similar to that of a human.

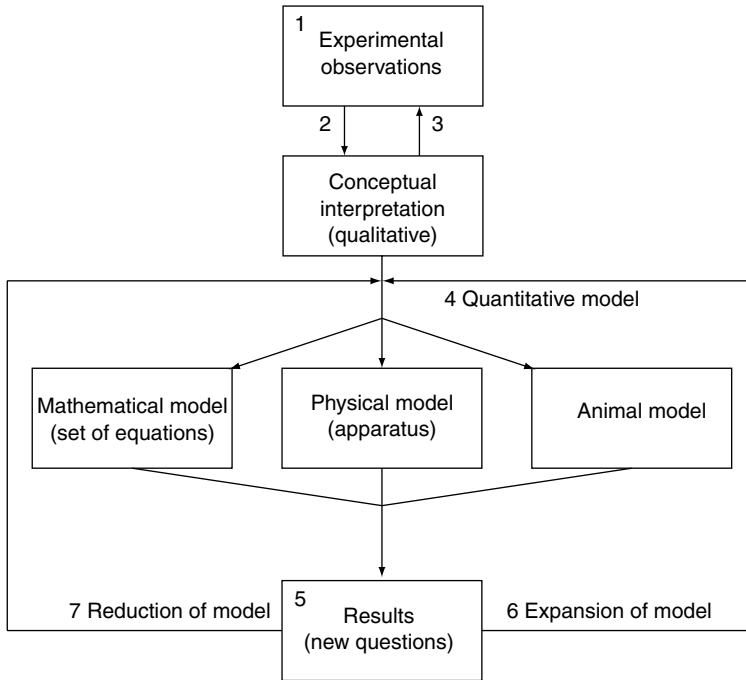
This chapter focuses on mathematical models, where equations of motion are developed and solved to describe the physiological system of interest. In physics and chemistry, a multitude of experimental observations can be captured in a small number of concepts, often referred to as laws. A law is a statement of the relation between quantities, which, as far as is known, is invariable within a range of conditions. For example, Ohm's law expresses the ratio between the voltage difference across and the current through an object as a constant. In physiology, experimental observations can likewise be ordered by relating them to natural laws, if expanded with features peculiar to living beings, such as control phenomena,


FIGURE 8.1   A schematic depicting the iterative inter-relationships between models and experiments. Stages 1 to 7 are described in the text.

especially homeostasis. The life sciences guide application of these natural laws. Common natural laws originally developed for inanimate materials must also be rewritten for living materials. In such complex systems, several laws may play their part, and the process is then referred to as development of a model. Model design, therefore, must meet stringent requirements and serves to rein in undisciplined speculation. Modeling attempts to identify the mechanism(s) responsible for experimental observations and is fundamentally distinct from simulation, in which anything that reproduces the experimental data is acceptable.

A successful mathematical model provides guidance to new experiments, which may modify or generalize the model, in turn suggesting additional new experiments. This iterative process is illustrated in Figure 8.1. The quest for understanding of a body of experimental observations leads to a tentative conceptual interpretation, which is transformed into quantitative statements by invoking established natural laws. The resulting mathematical model consists of a set of equations, which are solved, generally with the aid of a computer. The equation solutions (stage 5) are quantitative statements about experimental observations, some of which were not part of the original body of experiments, extending knowledge about the system under study. Consequently, new experiments become specified, adding to the store of experimental data. The enlarged body of experimental observations may cause modification in the investigator's conceptual interpretation, which in turn may give reason to modify the model. This iterative process should weed out flawed experiments and misconceptions in the mathematical model. If the entire effort is successful, a comprehensive, quantitative, and verified interpretation of the relevant experimental observations will result. Sometimes, the resulting model is expanded (stage 6) to incorporate new discoveries. Alternatively, the model may be systematically reduced (stage 7) to eliminate minor features, and is often then used as a building block for incorporation into a larger-scale system model. Model reduction is based on understanding, allowing intelligent separation of major and minor effects. Model simplification, on the other hand, implies arbitrary action based on intuition.

The iterative process in model building was described by Popper in 1959 [1]. He points out that no model is perfect, in fact, he proposes that models must exhibit "falsifiability." Clearly, models possess the inherent danger of refinement beyond which no new information is gained. Another potential pitfall is the balance between experiments and model development. Collecting experimental data without a framework of understanding, or postulating model results without experimental verification may be equally hazardous. Model refinement may continue until its complexity increases without any increase in knowledge. Kuhn takes this idea one step further, proposing that scientific developments sometimes stagnate until a "revolution" occurs [2]. One recent example is the study of wave transmission in blood vessels. For many years, investigators focused on description of a single tube, with limited results. It was only when the novel approach of including arterial branching arose that a wide range of previously unexplained experimental observations could be understood [3,4]. For example, experiments showed that the arterial flow pulse decreases moving away from the heart, as expected for a passive network. The arterial pressure pulse, however, increases, seemingly in violation of energy conservation. This paradox was explained via wave reflection in the new (revolutionary) branching model.

The first case study of this chapter outlines the development of a model of left ventricular pumping. The model is devised from canine experiments and represents the left ventricle as a time, volume, and outflow-dependent pressure generator. In the course of model development, a new analytical method of measuring ventricular elastance emerges, with the potential of clarifying issues with previous elastance measurements. One application is a slight model expansion to study the cardiac pump theory of cardiopulmonary resuscitation (CPR).

A major challenge in the biosciences today is integration of a large body of molecular level information, with the ultimate goal of understanding organ function. Two different, novel modeling approaches to this goal are next presented. The first shows how a model based on muscle structure can predict a molecular mechanism responsible for muscle's mechanical properties (function). The second presents an approach for predicting ventricular hypertrophy (structure) based on cardiac metabolic function. Due to space constraints, discussion is limited to the main points; however, details are available in the original research papers cited.

8.2 Modeling Heart Dynamics

8.2.1 Introduction

Mechanical performance of the heart, more specifically the left ventricle, is typically characterized by estimates of ventricular elastance. The heart is an elastic bag that stiffens and relaxes with each heartbeat. Elastance is a measure of stiffness, classically defined as the differential relation between pressure and volume:

$$E_v = \frac{\mathrm{d}p_v}{\mathrm{d}V_v} \tag{8.1}$$

Here, p_v and V_v denote ventricular pressure and volume, respectively. For any instant in time, ventricular elastance E_v is the differential change in pressure with respect to volume. Mathematically, this relation is clear. Measurement of E_v is much less clear.

Equation 8.1 was estimated using the ratio of finite changes in ventricular pressure and volume [5]:

$$E_v = \frac{\Delta p_v}{\Delta V_v} \tag{8.2}$$

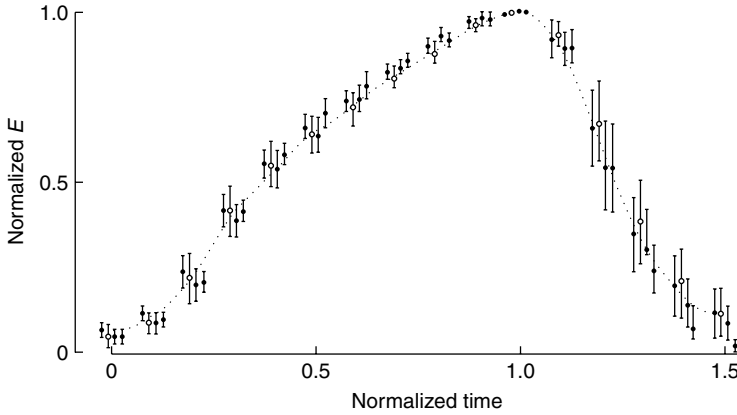
This approach leads to physically impossible results. For example, before the aortic valve opens, the left ventricle is generating increasing pressure while there is not yet any change in volume. The ratio in Equation 8.2 gives an infinite elastance when the denominator is zero. Integration of Equation 8.1 leads


FIGURE 8.2 Time-varying ventricular elastance curves measured using the definition in Equation 8.3. Measured elastance curves are distinctive in shape. (Adapted from Suga, H. and Sagawa, K. 1974. Instantaneous pressure–volume relationship under various end-diastolic volume. *Circ. Res.* 35: 117–126.)

to time-varying elastance definitions of the form

$$E_v(t) = \frac{p_v(t)}{V_v(t) - V_d} \tag{8.3}$$

an equation with extensive application [6,7]. In this equation, V_d is a dead volume that remains constant. Now all other terms are allowed to be varying with time. Ventricular elastance measured in this way leads to elastance curves as depicted in Figure 8.2. These curves show wide variation, as suggested by the large error bars. The distinctive asymmetric shape leads to a puzzle. Equation 8.3 shows that under isovolumic conditions ventricular pressure p_v must have the same shape as elastance $E_v(t)$. However, experiments show that isovolumic pressure curves are symmetric, unlike Figure 8.2. A further complication is the requirement of ejecting beats for measuring $E_v(t)$, which requires not only the heart but also a circulation. Ventricular pressure is a strong function of both volume contained and time

$$p_v = p_v(V_v, t) \tag{8.4}$$

Hence, an incremental change in pressure requires

$$\Delta p_v = \frac{\partial p_v}{\partial V_v} \Delta V_v + \frac{\partial p_v}{\partial t} \Delta t \tag{8.5}$$

which leads to

$$\frac{\Delta p_v}{\Delta V_v} = \frac{\partial p_v}{\partial V_v} + \frac{\partial p_v}{\partial t} \frac{\Delta t}{\Delta V_v} \tag{8.6}$$

$\Delta t / \Delta V_v$ in the second term of the right-hand side is equal to $-1/Q_v$, inverse ejection outflow. Consequently, elastance definitions such as Equation 8.2 and Equation 8.3 are not measures purely of ventricular elastance but also include arterial effects. This may explain why such models have difficulty in accurately predicting flow [8]. Consequently, a new measure of the heart's mechanical properties was developed.

8.2.2 Left Ventricular Dynamics

A new ventricle model was developed using isolated canine heart experiments [10,11]. Experiments began with measurement of isovolumic ventricular pressure [10]. For each experiment, the isolated left ventricle

was filled with an initial volume (end-diastolic) and the aorta was clamped to prevent outflow of blood. The ventricle was stimulated and the generated ventricular pressure was measured and recorded. The ventricle was then filled to a new end-diastolic volume and the experiment repeated. As in the famous experiments of Otto Frank [12], isovolumic pressure is directly related to filling.

These isovolumic pressure curves were then described by the following equation. Ventricular pressure p_v is a function of time t and ventricular volume V_v according to

$$p_v = a(V_v - b)^2 + (cV_v - d)\left[\frac{(1 - e^{-(t/\tau_c)^\alpha})e^{-((t-t_b)/\tau_r)^\alpha}}{(1 - e^{-(t_p/\tau_c)^\alpha})e^{-((t_p-t_b)/\tau_r)^\alpha}}\right] \tag{8.7}$$

or written more compactly,

$$p_v(t, V_v) = a(V_v - b)^2 + (cV_v - d)f(t) \tag{8.8}$$

where $f(t)$ is the activation function in square brackets in Equation 8.7. The function $f(t)$ describes the time course of active force generation, a product of contraction and relaxation exponentials related to myofilament crossbridge bond formation and detachment, respectively, and is given by

$$f(t) = \begin{cases} \dfrac{(1 - e^{-(t/\tau_c)^\alpha})}{(1 - e^{-(t_p/\tau_c)^\alpha})e^{-((t_p-t_b)/\tau_r)^\alpha}}, & 0 \leq t \leq t_b \\[3ex] \dfrac{(1 - e^{-(t/\tau_c)^\alpha})e^{-((t-t_b)/\tau_r)^\alpha}}{(1 - e^{-(t_p/\tau_c)^\alpha})e^{-((t_p-t_b)/\tau_r)^\alpha}}, & t_b < t < 1 \end{cases} \tag{8.9}$$

t_b is derived from α, τ_c, τ_r, and t_p [11]. The constants a, b, c, d, t_p, τ_c, τ_r, and α were experimentally derived. Figure 8.3 shows a set of isovolumic pressure curves computed for a normal canine left ventricle.
FIGURE 8.3 Isovolumic canine ventricular pressure curves described by Equation 8.8. Initial volumes range from 25 to 50 ml.

TABLE 8.1 Ventricle Model Quantities
Measured from Animal Experiments and Adapted
for the Human Analytical Model

Constant	Canine (measured)	Human (adapted)
a	0.003 (mmHg/ml^2)	0.0007
b	1.0 (ml)	20.0
c	3.0 (mmHg/ml)	2.5
d	20.0 (mmHg)	80.0
τ_c	0.164 (sec)	0.264
t_p	0.271 (sec)	0.371
τ_r	0.199 (sec)	0.299
t_b	0.233 (sec)	0.258
α	2.88	2.88
FIGURE 8.4 Equivalent systemic arterial load. Circuit elements are described in the text.

Equation 8.8 depicts the ventricle as a time- and volume-dependent pressure generator. The term to the left of the plus sign (including constants a and b) describes the ventricle's passive elastic properties. a is a measure of diastolic ventricular elastance. b corresponds to diastolic volume at zero pressure. The term to the right (including c and d) describes its active elastic properties, arising from the active generation of force in the underlying heart muscle. c and d are directly related to volume-dependent and -independent components of actively developed pressure, respectively. Representative model quantities derived from canine experiments are given in Table 8.1. This model was adapted to describe the human left ventricle using quantities in the right-hand column [11].

The most widely used arterial load is the three-element modified windkessel shown in Figure 8.4. The model appears as an electrical circuit due to its origin prior to the advent of the digital computer. Z_0 is the characteristic impedance of the aorta, in essence the aorta's flow resistance. C_s is transverse arterial compliance and describes the stretch of the arterial system in the radial direction. R_s is the peripheral resistance, describing the systemic arteries' flow resistance downstream of the aorta. The left ventricle model was coupled this reduced arterial load model and allowed to eject blood. Model parameter values for a normal arterial load are given in Table 8.2. Figure 8.5 shows results for a normal canine left ventricle ejecting into a normal arterial system. The solid curves (left ordinate) describe ventricular pressure p_v and root aortic pressure as functions of time. Root arterial pulse pressure is about 120/65 mmHg. The dashed curve (right ordinate) shows ventricular outflow. The ventricle was filled with an end-diastolic volume of 45 ml and it ejected 30 ml (stroke volume), giving an ejection fraction of 66%, which is about normal for this size animal.

The same ventricle may be coupled to a pathological arterial system, for example, one with doubled peripheral resistance R_s. As expected, increased peripheral resistance raises arterial pulse pressure (to 140/95 mmHg) and impedes the ventricle's ability to eject blood (Figure 8.6). The ejection fraction decreases to 50% in this experiment. Other experiments, such as altered arterial stiffness, may be performed. The model's flexibility allows description of heart pathology as well as changes in blood vessels. This one equation (Equation 8.8) with one set of measured parameters is able to describe the wide range of hemodynamics observed experimentally [11].

TABLE 8.2 Representative Systemic Arterial Model Element Values

Model element	Symbol	Control value
Characteristic aorta impedance	Z_0	0.1 mmHg sec/ml
Systemic arterial compliance	C_s	1.5 ml/mmHg
Peripheral arterial resistance	R_s	1.0 mmHg sec/ml
FIGURE 8.5 Ventricular and root aortic pressures (solid curves, left ordinate) and ventricular outflow (dashed curve, right ordinate) computed using the model of Equation 8.8 for a normal canine left ventricle pumping into a normal arterial circulation. The topmost solid curve corresponds to a clamped aorta (isovolumic). This ventricle has initial volume of 45 ml and pumps out 30 ml, for an ejection fraction of 66%, about normal.

Since ventricular pressure is now defined as an analytical function (Equation 8.7), ventricular elastance, E_v, defined in the classical sense as $\partial p_v / \partial V_v$, may be calculated as

$$E_v(t, V_v) = 2a(V_v - b) + c \left[\frac{(1 - e^{-(t/\tau_c)^\alpha})e^{-((t-t_b)/\tau_r)^\alpha}}{(1 - e^{-(t_p/\tau_c)^\alpha})e^{-((t_p-t_b)/\tau_r)^\alpha}} \right] \quad (8.10)$$

or

$$E_v(t, V_v) = 2a(V_v - b) + cf(t) \quad (8.11)$$

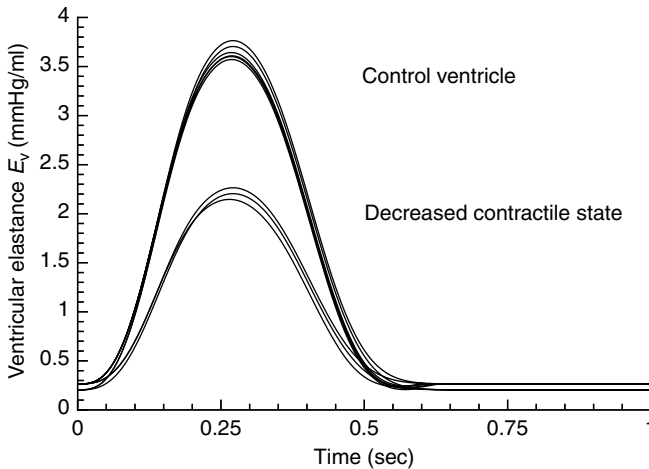
Figure 8.7 shows ventricular elastance curves computed using Equation 8.10. Elastance was computed for a wide range of ventricular and arterial states, including normal and pathological ventricles, normal and pathological arterial systems, and isovolumic and ejecting beats. These elastance curves are relatively invariant and cluster in two groups — either a normal or a weakened ventricle contractile state. Consequently, this new measure of elastance may now effectively assess the health of the heart alone, separate from blood vessel pathology.
FIGURE 8.6 The same normal canine ventricle of Figure 8.5 now pumping into an arterial system with doubled peripheral (flow) resistance. As expected, increased resistance, corresponding to narrowed vessels, leads to increased arterial pulse pressure. Ejection fraction is reduced from 66 to 50%.


FIGURE 8.7 Ventricular elastance curves computed using the new analytical function of Equation 8.10. Elastance curves computed in this way are representative of the ventricle's contractile state.

8.2.3 The Ejection Effect

Experiments show that when the left ventricle ejects blood, ventricular pressure is somewhat different than expected. As depicted in Figure 8.8, early during ejection the ventricle generates less pressure than expected, denoted pressure *deactivation*. Later in systole the heart generates greater pressure, denoted *hyperactivation*. These two variations with flow have been termed the *ejection effect* [13]. The ejection effect was incorporated into Equation 8.8 by adding a flow-dependent term:

$$p_v(t, V_v, Q_v) = a(V_v - b)^2 + (cV_v - d)F(t, Q_v) \tag{8.12}$$
FIGURE 8.8 The ejection effect, showing that early during blood ejection (systole) the heart generates somewhat less pressure than expected, denoted *deactivation* (down arrows). Later in systole, the heart generates greater pressure, denoted *hyperactivation*. Curves 1 and 2 are ventricular pressures for initial and ejected volumes, respectively. Curve 3 is the measured ejecting pressure curve. Curve 4 is root aortic pressure.

with F replacing the time function f in Equation 8.8:

$$F(t, Q_v) = f(t) - k_1 Q_v(t) + k_2 Q_v^2(t - \tau), \quad \tau = \kappa t \qquad (8.13)$$

and k_1, k_2, and κ are additional model constants. The ventricle is now depicted as a time-, volume- and flow-dependent pressure generator. Figure 8.9 shows computed pressures and flows for this formulation (top), compared to the results minus the ejection effect (below). The ejection effect tends to change the shape of both pressure and flow curves to more closely resemble experimental curves.

Addition of the ejection effect modifies the computed ventricular elastance curves, as depicted in Figure 8.10. All curves are computed using the new function of Equation 8.10. The dashed curve, minus the ejection effect, is symmetric, as in Figure 8.7. Addition of the ejection effect (solid) makes ventricular elastance asymmetrically skewed to the right, much like the measured curves depicted in Figure 8.2 using the time-varying elastance definition of Equation 8.3. As expected, the mechanical process of ejecting blood has a direct effect on the heart's elastance.

The left ventricle model of Equation 8.8 was used to describe each of the four chambers of the human heart, depicted in Figure 8.11 [14]. This complete model of the circulatory system displays a broad range of cardiovascular physiology with a small set of equations and parameters. Figure 8.12 shows computed left and right ventricle work loops for a normal heart ejecting into a normal (control) circulatory system, depicted by solid curves. Figure 8.12 also shows the same two work loops for a weakened left ventricle (dashed curves). As expected, the left ventricle work loop is diminished in size. This work loop also shifts to the right on the volume axis. Since the weaker ventricle ejects less blood, more remains to fill the heart more for the subsequent beat (EDV of 194 instead of 122 ml). This increased filling partially compensates for the weakened ventricle via Starling's law.

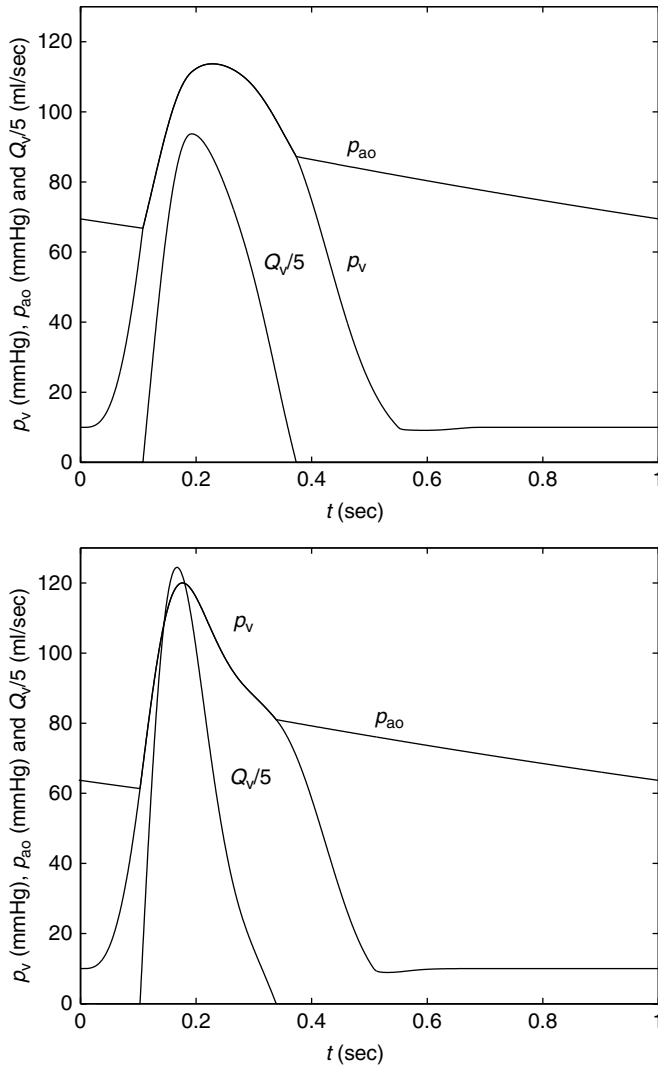
Changing only one model constant, c, in Equation 8.8 is sufficient to vary chamber contractile state. For example, Table 8.3 shows examples of congestive heart failure, resulting from decreases in c for the left ventricle and for the right ventricle. Decreasing left ventricular contractile state to one third of the control


FIGURE 8.9 The ejection effect incorporated in the ventricle model (top) with the uncorrected ventricular pressure and outflow curves for the same conditions (below) for comparison. Ventricular outflow Q_v is normalized by 1/5 to use the same numeric scale as for ventricular pressure.

value ($c = 1.0$) lowers left ventricular ejection fraction from 53 to 25%, and root aortic pulse pressure decreases from 133/70 to 93/52 mmHg. Left ventricular stroke volume decreases less, from 64 to 48 ml, since it is compensated by the increased left end-diastolic volume (194 ml) via Starling's law. Decreasing left ventricular contractile state produces left congestive heart failure. Consequently, pulmonary venous volume increases from 1347 to 1981 ml (not shown), indicating pulmonary congestion for this case.

Similar changes are noted when the right ventricle's contractile state is halved ($c = 0.5$). The right ventricular ejection fraction drops from 46 to 24%, root pulmonary artery pulse pressure decreases from 49/15 to 29/12 mmHg, and right stroke volume decreases from 64 to 44 ml, with an increased end-diastolic volume of 164 ml, from 141 ml. Conversely, c can be increased in any heart chamber to depict administration of an inotropic drug. Although not plotted, pressures, flows, and volumes are available at any circuit site, all as functions of time.

Changes in blood vessel properties may be studied alone or in combination with altered heart properties. Other system parameters such as atrial performance, as well as other experiments, may be examined. The

modular form of this model allows its expansion for more detailed studies of particular sites in the circulatory system.

8.2.4 Predictive Power: Application to CPR

The left ventricle may be described as a time-, volume- and flow-dependent pressure generator. A small number of experimentally derived parameters is sufficient to describe the wide range of observed cardiovascular dynamics. This approach links experiment and theory, leading to new ideas and experiments.

Control	64	64	122	141	53	46	133/70	49/15
Weak LV	48	48	194	129	25	38	93/52	49/21
Weak RV	44	44	102	164	49	24	109/59	29/12

Note: SV denotes stroke volume, EDV denotes end-diastolic volume, EF is ejection fraction and p_{AO} and p_{PU} are root aorta and root pulmonary artery pressures, respectively, for the left (LV) and right (RV) ventricles. Note that SV left and right are equal under all conditions.

This ventricle model permits computation of ventricular elastance, and may resolve difficulties with previous time-varying elastance definitions. Work is currently underway to devise a new measure of cardiovascular health using this model. In essence, it is thought that the magnitude of the observed ejection effect for a particular heart should be directly related to its health.

The ventricle model of Equation 8.12 was expanded to study closed-chest CPR [15]. The left ventricle was filled by a constant pressure source, and was coupled to the three-element modified windkessel arterial load, with mitral and aortic valves. Equation 8.12 includes a new term, $p_e(t)$, the external pressure applied directly to the ventricle during asystole and application of CPR:

$$p_v(V_v, t, Q_v) - p_e(t) = a(V_v - b)^2 + (cV_v - d)F(t, Q_v) \tag{8.14}$$

The main results of this predictive study are twofold. First, the normal circulation, including the mitral and aortic valves, can effectively circulate blood (with a reduced stroke volume) via external compression. This result supports the cardiac pump theory proposed by Kouwenhoven et al. [16]. Second, if the valves are removed or made incompetent no significant net flow is circulated, for either the normally beating ventricle, or the asystolic ventricle subjected to external compressions. The small (8 ml/sec) net outflow

observed in both cases results from the venous pressure contributed by the constant pressure filling source. Sloshing of blood (large net backflow) is evident with each beat. As a result, net downstream circulation is ineffective [15].

8.3   Modeling Muscle Dynamics

8.3.1   Introduction

Description of muscle contraction has essentially evolved into two separate approaches — lumped whole muscle models and specialized crossbridge models of the sarcomere. The former seek to interpret muscle's complex mechanical properties with a single set of model elements. Muscle experiments measure muscle force and length subjected to isometric (fixed length) conditions, isotonic (fixed load) conditions, and transient analysis where either length or load is rapidly changed.

Muscle force generation is believed to arise from the formation of crossbridge bonds between thick and thin myofilaments within the basic building block of muscle, the sarcomere. These structures, in the nanometer to micrometer range, must be viewed by electron microscopy or x-ray diffraction, limiting study to fixed, dead material. Consequently, muscle contraction at the sarcomere level must be described by models that integrate metabolic and structural information.

Mayow [17] proposed that muscle contraction arises from changes in its constituent elastic fibers as a by-product of respiration, introducing the concept of muscle as an elastic material that changes due to metabolic processes. Weber [18] viewed muscle as an elastic material, or spring, whose stiffness depends on whether it is in a passive or active state. In 1890, Chauveau and Laulanié [19,20] also considered muscle as an elastic spring with time-dependent stiffness, and proposed that velocity of shortening plays a role in force production. Fick [21] and Blix [22] refuted a purely elastic description on thermodynamic grounds, finding that potential energy stored during stretching a strip of muscle was less than the sum of energy released during shortening as work and heat. Blix also noticed that at the same muscle length, muscle tension produced during stretch was greater than that during release. Tension would be the same during stretch and release for a simple spring. Further, Blix reported that he was unable to describe stress relaxation and creep in muscle with a viscoelastic model.

Hill [23] coupled the spring with a viscous medium, thereby reintroducing viscoelastic muscle models, after noticing that external work done accelerating an inertial load was inversely related to shortening velocity. A two-element viscoelastic model is objectionable on mechanical grounds: in series (Maxwell body), length is unbounded for a step change in force; in parallel (Voight body), force is infinite for a step change in length. Further, Fenn [24] reported that energy released by the muscle differs for isometric or shortening muscle. Subsequently, Hill [25] developed the *contractile element*, embodied as an empirical hyperbolic relation between muscle force and shortening velocity. The contractile element was combined with two standard springs, denoted the parallel and series elastic elements. Current whole muscle models have, in general, incorporated Hill's contractile element, an empirically derived black-box force generator, in networks of traditional springs and dashpots [26]. Since model elements are not directly correlated to muscle structure, there is no logical reason to stop at three elements — models with at least nine have been proposed [27].

This approach can be criticized on the following grounds: there exists little, if any, correlation between model elements and muscle anatomical structures. No single model has been shown to comprehensively describe different muscle-loading conditions, for example, isometric, isotonic, and so on. Models tend to focus on description of a single type of experiment, and are typically based on a force–velocity relation measured under specific loading conditions. These models give little or no insight into the mechanism of contraction at the sarcomere level. Energy considerations, including the fundamental necessity of a biochemical energy source, have been ignored.

Crossbridge models focus on mechanics at the sarcomere level. Prior to actual observation of crossbridge bonds, Huxley [28] proposed a model whereby contractile force is generated by the formation of crossbridge bonds between myofilaments. This model was subsequently shown unable to describe

muscle's transient mechanical properties. Extension of Huxley's ideas to multiple-state crossbridges has been very limited in scope, for example, the Huxley and Simmons [29] two-state model does not include crossbridge attachment, detachment or filament sliding, but rather describes only the mechanics of a single set of overlapping actin and myosin filaments. In general, crossbridge models dictate bond attachment and detachment by probability or rate functions. This approach has shifted emphasis away from muscle mechanics toward increasingly complex rate functions [30].

8.3.2 Distributed Muscle Model

A large-scale, distributed muscle model was developed based on ultrastructural kinetics and possessing direct anatomic and physiologic relevance [31]. This model describes all of muscle's fundamental mechanical properties with a single set of assumptions: isometric and isotonic contractions and force transients resulting from rapid changes in muscle length during contraction. Variations in muscle properties with current loading conditions arise from the dynamic model structure, rather than adaptation of a particular force–velocity curve to describe the contractile element, or of a particular bond attachment or detachment function as for previous models. The following assumptions define the model:

- The sarcomere consists of overlapping thick and thin filaments connected by crossbridge bonds, which form during activation and detach during relaxation.
- The mass of the myofilaments is taken into account.
- Crossbridge bonds have viscoelastic properties [29] and thus may exhibit stress relaxation and creep.
- In passive muscle, thick filaments exist in stable suspension at the center of the sarcomere, which contributes to the muscle's passive elastic properties [32].
- Calcium ions serve as a trigger, which allows bond formation between filaments. Bonds formed are stretched via biochemical energy, thereby converting chemical to potential energy and developing force. This stretching results from crossbridge motion [29].
- The number of bonds formed depends upon the degree of thick–thin filament overlap [33].
- Asynchrony in bond formation and unequal numbers of bonds formed in each half sarcomere, as well as mechanical disturbances such as shortening and imposed length transients, cause movement of thick with respect to thin filaments. Since myofilament masses are taken into account these movements take the form of damped vibrations. Such vibrations occur with a spectrum of frequencies due to the distributed system properties.
- When the stress in a bond goes to zero the bond detaches [29].
- Myofilament motion and bond stress relaxation lead to bond detachment and therefore produce relaxation.

Crossbridge bonds are described as linear viscoelastic material, each represented by a three-element spring-dashpot model (Figure 8.13). During activation, the attached crossbridge head rotates, stretching the bond and generating force. A passive sarcomere is mechanically represented as myofilament masses interconnected by a matrix of permanently attached passive viscoelastic bonds. During activation, dynamically attached active bonds are formed as calcium ion and energy (ATP) allows.

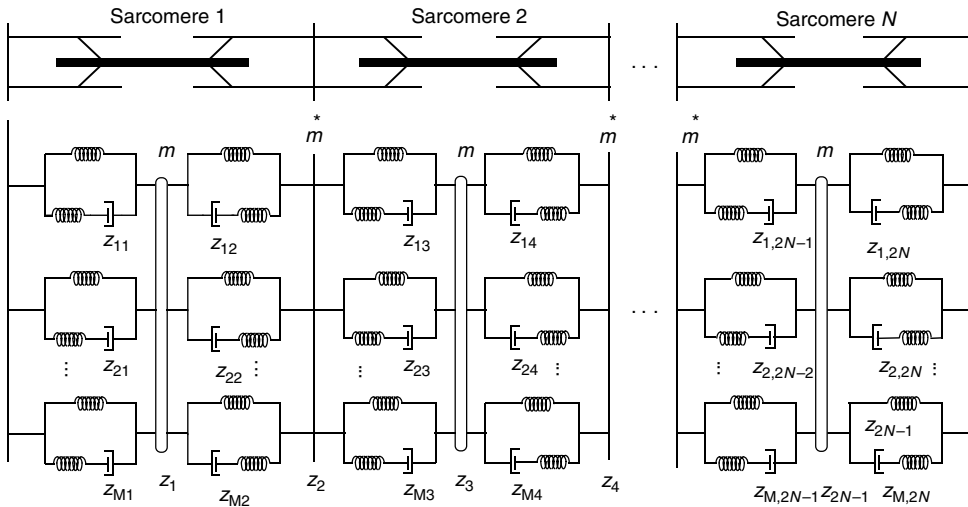
The sarcomere model is extended to a muscle fiber by taking N sarcomeres in series each with M parallel pairs of active bonds. The model currently consists of 50 series sarcomeres, each with 50 parallel pairs of crossbridges. Bond formation is taken to be distributed in two dimensions due to muscle's finite electrical propagation speed and the finite diffusion rate of calcium ions from the sarcoplasmic reticulum. The large set of resulting differential equations (5300) is solved by digital computer. Since the instantaneous number of crossbridge bonds, and therefore the model system equations, is continuously changing, the resulting model is strongly nonlinear and time-varying, despite its construction from linear, time-invariant components. Crossbridge bonds are added in a raster pattern due to the distributed system properties. After all bonds have been added, no further conditions are imposed. Crossbridge bonds subsequently


FIGURE 8.13 Schematic representation of a muscle fiber composed of N series sarcomeres each with M parallel pairs of active, viscoelastic bonds. Each bond is described by a three-element viscoelastic model. (Adapted from Palladino, J.L. and Noordergraaf, A. 1998. Springer-Verlag, New York, pp. 33–57.)

detach simply from the small internal movements of myofilaments. Consequently, the model relaxes without separate assumptions.

This model was subjected to a wide range of loading conditions. A single set of model parameters is sufficient to describe the main features of isometric, isotonic, and quick release and stretch experiments. The model is sensitive to mechanical disturbances, consistent with experimental evidence from muscle force curves [34], aequorin measurements of free calcium ion [35], and high-speed x-ray diffraction studies [36]. The model is also consistent with sarcomere length feedback studies [29] where reduced internal motion delays relaxation.

The outermost curve of Figure 8.14 depicts an isometric contraction computed from the muscle fiber model. At each Δt available bonds are attached, adding their equations to the model, and force is generated via bond stretching. For the twitch contractions in Figure 8.14 and Figure 8.15, bonds are attached from $t = 0$ to 0.5 sec. Since bond formation is not perfectly symmetrical, due to the raster attachment pattern, small force imbalances within thick–thin units develop, leading to small myofilament motions that tend to detach bonds as their force goes to zero. Consequently, at each Δt of solution, bonds are added during activation and detach continuously. Despite this very dynamic state, Figure 8.14 shows that the net isometric fiber force generated smoothly rises during muscle activation. Peak isometric force of 250 nN is in close agreement with recent experimental measurements on isolated guinea pig myocytes [34].

The time of peak force corresponds to the end of bond attachment. Physiologically, this point is associated with a lack of available bond attachment sites. This may be due to lack of calcium ion for the release of steric inhibition of actin–myosin interaction by troponin/tropomyosin, lack of myosin heads in a state necessary for attachment, or some other mechanism. Force relaxation then results simply from bond detachment due to the same internal myofilament motion mechanism. Net force smoothly recovers to the resting force level, in contrast to the dynamic motions of individual bonds and myofilaments. Surprisingly, this smooth relaxation occurs without the added feature of crossbridge recycling, that is, bond reattachment after detachment.

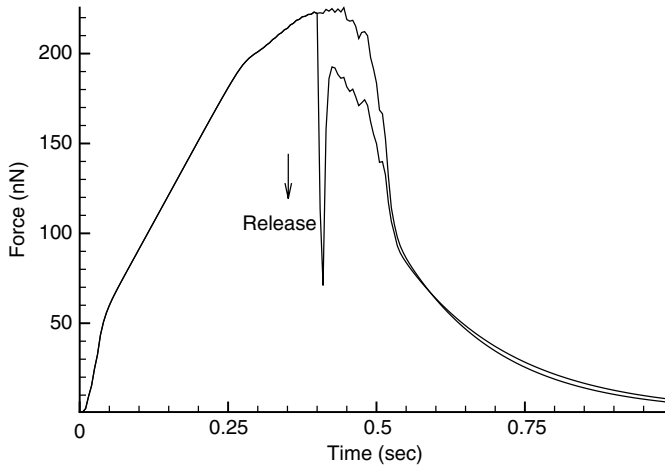
Transient response to quick length change is a critical test of any muscle model. This distributed model predicts that rapid length changes enhance system vibration and thereby promote bond detachment and muscle relaxation, underlying muscle's force deactivation phenomenon. Figure 8.14 also shows force deactivation following quick release during an otherwise isometric twitch contraction. This particular release corresponds to 0.2% of sarcomere length over 10 msec. Quick release corresponding to 2% of


FIGURE 8.14 Outermost curve describes an isometric contraction computed from the distributed muscle fiber model. Also plotted is force computed during a quick release experiment, showing significant force deactivation. (Adapted from Palladino, J.L. and Noordergraaf, A. 1998. Springer-Verlag, New York, pp. 33–57.)
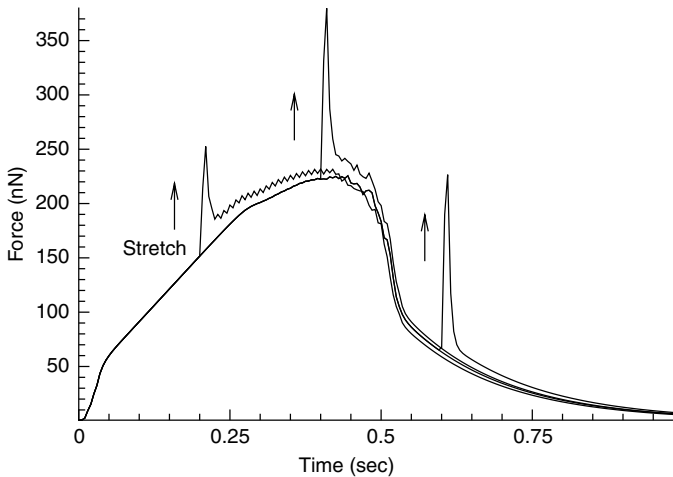

FIGURE 8.15 Quick stretches computed from the distributed muscle fiber model. (Adapted from Palladino, J.L. and Noordergraaf, A. 1998. Springer-Verlag, New York, pp. 33–57.)

sarcomere length applied during 10 msec was sufficient to bring fiber force to zero (not shown). Slower releases produce less force deactivation. These curves compare favorably with quick release transients measured on whole muscle strips and more recent experiments on isolated frog myocytes [37,38], and for ferret papillary muscles [39].

Figure 8.15 shows quick stretches computed for the distributed fiber model. Stretches corresponding to 0.2% of sarcomere length were performed over 10 msec. Curves show rapid force overshoot, followed by rapid recovery and slow recovery back to the isometric force levels. Quick stretch response is in agreement with classic studies on muscle strip and recent studies on ferret papillary muscles [39].

8.3.3 Reduced Muscle Model

The large-scale distributed muscle model can be reduced to a compact model analogous to the ventricle model previously presented (Equation 8.8). Muscle fibers (cells), or strips, can be described as force

TABLE 8.4 Model
Constant Values and Units

Constant	Value	Unit
a	2	mN/mm^2
b	8	mm
c	20	mN/mm
d	160	mN
τ_c	0.264	sec
τ_r	0.299	sec
t_p	0.371	sec
t_b	0.258	sec
α	2.88	—
FIGURE 8.16 Isometric contractions for muscle strip computed from Equation 8.15 for different initial muscle lengths l_m = 8.5, 9.0, 9.5, and 10.0 mm (topmost).

generators that are time, muscle length, and velocity of shortening dependent:

$$f_m(t, \ell_m) = a(\ell_m - b)^2 + (c\ell_m - d)f(t) \tag{8.15}$$

where f_m is muscle force and ℓ_m is muscle length. The model parameters a, b, c, and d are determined from muscle strip experiments, as is the activation function $f(t)$. $f(t)$ has the same form as in Equation 8.9. Model constant values are presented in Table 8.4. t_b is derived from α, τ_c, τ_r, and t_p [40]. Muscle elastance, E_m, may now be defined as $\partial f_m/\partial l_m$. This muscle strip model was subjected to a wide range of loading conditions.

Figure 8.16 shows isometric force curves computed from the muscle model for initial muscle lengths l_m = 8.5 to 10.0 mm. The curve shapes and magnitudes compare favorably with experimental curves in the literature, for example [41].

Figure 8.17 shows computed isotonic contractions for different fixed loads. Although not shown, this muscle model exhibits an inverse relation between isotonic load and amount of shortening, and a direct relation between initial length and shortening (Starling's law). Results are also consistent with experiments, for example [42].

Figure 8.18 shows computed initial muscle shortening velocity plotted as a function of isotonic load, which resembles Hill's hyperbolic force–length relation for tetanized skeletal muscle. This curve closely resembles the experimental $F - v$ curves of Brady from cardiac twitch contractions [43].
FIGURE 8.17   Isotonic contractions for muscle strip computed from Equation 8.15 for three intermediate and one isometric load. Top shows muscle length (right y-axis).
FIGURE 8.18   Initial muscle shortening velocity computed as a function of isotonic load.

Muscle force transients arising from rapid (but small) changes in muscle length during otherwise isometric contractions may be described by expanding the model as the ventricle model was expanded to incorporate the ejection effect:

$$f_{\mathrm{m}}(t, \ell_{\mathrm{m}}, v_{\mathrm{m}}) = a(\ell_{\mathrm{m}} - b)^2 + (c\ell_{\mathrm{m}} - d)F(t, v_{\mathrm{m}}) \tag{8.16}$$

with muscle velocity of lengthening or shortening, v_{m}, and F replacing the time function f in Equation 8.15:

$$F(t, v_{\mathrm{m}}) = f(t) - k_1 v_{\mathrm{m}}(t) + k_2 v_{\mathrm{m}}^2(t - \tau), \quad \tau = \kappa t \tag{8.17}$$
FIGURE 8.19 Quick releases of 10% of muscle length over 10 msec computed from the reduced muscle model (Equation 8.16) at three different times during contraction.

and k_1, k_2, and κ are additional model constants. In summary, muscle is a time-, length- and velocity-dependent force generator. Figure 8.19 shows computed quick releases of 10% of muscle length over 10 msec for three different times during otherwise isometric contractions. The outer envelope of force depicts isometric force at the initial length, and the inner at the new released length. As for muscle, developed force is initially much less than expected, a result of deactivation, and subsequently recovers via hyperactivation. Figure 8.20 shows the inverse experiment with computed quick stretches. Initial transient force is higher than expected, with subsequent quick drop and then isometric recovery. These results compare favorably with muscle experiments in the literature [43].

8.3.4 Predictive Power: Muscle Contraction

The idea for this distributed muscle fiber model arose in 1990 [44]. At that time, muscle fibers were assumed to be functionally similar to muscle strips. Recently, experiments on isolated muscle fibers show this to be the case. Predictions from the model have recently been borne out, for example, the magnitude of computed peak isometric force compared to that measured on isolated guinea pig myocytes [34]. Peak isometric stress measured on isolated rabbit myocytes (5.4 mN/mm^2) is very close to peak stress from rabbit papillary muscle strips (6.4 mN/mm^2) [45]. The distributed model generates peak isometric stress of 2.5 mN/mm^2. Other muscle phenomena measured on the isolated fiber include: a quadratic force–length relation [45], inotropic changes in contractile state [37], quick release and stretch [37,39], and isotonic contractions [46], all in agreement with model predictions.

Physiological modeling strives to create a framework that integrates experimental observations. A great strength of modeling is its capacity for predicting new experiments and physiological phenomena (Figure 8.1). The distributed muscle fiber model predicts that mechanical external vibration of muscle should enhance its internal vibration and promote bond detachment and therefore relaxation. To test this hypothesis, ultrasound was used to vibrate muscle. A single millisecond pulse of ultrasound delivered to the *in vivo* frog heart during systole was observed to reduce developed aortic pressure [47,48]. Experiments were designed to eliminate heating effects. Ultrasound pulses applied late in the twitch had particularly strong effects. After peak muscle force is generated, bond attachment ends so detachment via vibration has no mechanism for recovery. This force (pressure) deactivation was
FIGURE 8.20   Quick stretches of 10% of muscle length over 10 msec computed using Equation 8.16.
FIGURE 8.21   Premature ventricular contraction following ultrasound irradiation, during diastole, of the *in vivo* frog heart. The top trace is aortic pressure and below is the ECG. A lithotripter pulse of 20 MPa, 5 msec duration, is delivered at the vertical arrow. (Adapted from Dalecki, D., Raeman, C.H., Child, S.Z., and Carstensen, E.L. 1997. *Ultrasound Med. Biol.* 23: 275–285.)

reproducible and not permanently damaging as beats without irradiation produced normal pressure magnitudes and time courses. A mechanical effect is likely since moving the heart slightly out of the ultrasound beam produced no deactivation effect, despite having the same electrical environment. Ultrasound delivered during diastole was found to produce a premature ventricular contraction, as depicted in Figure 8.21, an unexpected result. These experiments suggest that medical ultrasound may have strong effects on living tissues, and demonstrates how modeling can lead to the discovery of new physiological phenomena.

8.4   Modeling Heart Function during Hypertrophy

8.4.1   Integration of Micro- and Macro-Dynamics

Modeling methodology often relies on the availability of structural parameters that have been determined from prior physical and quantitative experimentation. Alternatively, it is of vital interest to understand how a given structure arises, that is, to understand nature's design. To accomplish this, it is necessary to allow the system to adapt to its external functional demands. Due to adaptive processes, a biological system may be undergoing synthesis and desynthesis simultaneously. The balance of these opposing mechanisms results in a structure that meets the system's current functional demand. The advantage of this type of modeling approach is that it obviates measurement of every parameter. This enables the physiological modeler to provide theoretical insight outside the realm of conventional experimentation.

Often models become increasingly complex in the attempt to study smaller levels of structural detail. Ultimately, there may be a minimum level of structure at which the function is known and relatively constant, for example, a cell or a cardiac sarcomere. This structure is denoted the *micro-unit*. The assembly of such units comprises the biological system and is denoted the *macro-unit*. The macro-unit function may also be known, characterized, for example, by ventricular pressure and flow. It is the arrangement and interaction of multiple micro-units that introduces complexity in modeling. To resolve this problem, the micro-unit function is integrated while structure is varied to identify structural rules. The resulting rules are usually simple and thereby offer a special advantage to the integrative approach.

The concept of integrating micro-level function to solve for the macro-level of physiological function and overall geometry has been discussed earlier by Taylor and Weibel [49]. These researchers stated in qualitative terms that an organ system achieves "a state of structural design commensurate to functional needs resulting from regulated morphogenesis, whereby the formation of structural elements is regulated to satisfy but not exceed the requirements of the functional system." This process has been termed symorphosis.

8.4.2   Integrative Modeling

In its simplest form, this method matches function at two different levels of structure. A match is achieved by varying the macro-structure until energy utilization of the system is minimized. Structural variation can be accomplished analytically, or in the case of discontinuous or nonlinear functions by means of a computer. Energy is then minimized in terms of the micro-unit. Since the time frame for the adaptive process tends to be long, it may be difficult to accumulate experimental results. Alternatively, it would be difficult to design an "integrative experiment" whereby the macro-structure is actually altered. For example, it is not easy to add or subtract selected cardiac myocytes to or from an intact cardiac ventricle without trauma to the animal. Usually, the same heart is observed over long time periods for its response to various external loading conditions. A theoretical approach can overcome some of these difficulties.

Integrative modeling begins by identifying a minimal level of structure at which its function is known. For an organ, this could be at the cellular level or, even lower, at the molecular level. The function of interest must be defined in terms of a physical quantity, such as electrical, mechanical, chemical, and so on. The physical quantity of interest may also be time dependent, but the function of the micro-unit must be independent of change in the geometry of the macro-structure. For normal physiological conditions, this rule is valid, but it may break down in the case of a disease process. Pathological conditions further require an analysis of how the micro-unit function alters with time, for example, how myocyte function deteriorates over time in heart failure. The dimensions of the micro-unit must be defined. Since the micro-unit is chosen to be the smallest structural element, its mean dimensions are often treated as constants.

The macro-unit, for example, the structure at the organ level, consists of a group of organized micro-dynamic units. Macro-unit function must be defined in terms of the physical quantities of interest. The physical quantities at the two structural levels must be of the same type, for example, myocyte force and ventricular wall tension define force at different structural levels. Once the macro-function is

defined, it must be independent of variation in the macro-structure, that is, unchanged by the adaptive process over long time periods. Since the macro-function is important to the survival of the animal, it may be independent of a disease process as well. This is generally true until structural changes cannot accommodate the deterioration of micro-function at a sufficiently rapid pace.

The organization of the micro-units defines the macro-structure. If the structure is a simple geometry that models the anatomic shape, analytical expressions can be obtained. Use of the actual anatomical shape forces the modeling to be computational. Once the geometry is prescribed, the physical equilibrium equations can be derived that relate the micro-function to the macro-function. This is accomplished by mathematically integrating the micro-function over the entire geometry, hence the name integrative modeling. For example, the myocardial force is integrated over the ventricle in order to relate it to wall tension. The final equations contain the geometric dimensions of the model and are unknowns at the onset.

8.4.3 Energy Considerations

The micro-unit is the smallest building block employed to assemble the overall structure. The dimensions of the micro-unit therefore represent the limit of resolution for any physical quantity computed from the model. Of particular interest is the energy required by the micro-unit. When the micro-unit is fixed in dimensions, on average, it provides a gauge of energy consumption that is size independent. While the macro-unit is varied in size, the effect on the energy at the micro-unit level can then be observed. Energy considerations for biological systems are typically more complex than for standard engineering systems. For example, care must be taken to include the energy required for the basal tissue metabolism as well as the energy consumption necessary to accomplish functional tasks. This differs from a nonliving structure where only physical energy considerations suffice.

The final analysis solves for the dimensions of the macro-structure, accomplished by examining the micro-unit energy consumption, while the dimensions are varied. A solution is then obtained by solving for a zero derivative of energy with respect to each dimension and minimum in energy. Specific problems may require variance from the above procedure. For example, additional information may be available to assist in finding the solution or in placement of physiological constraints. This is particularly useful when a completely analytical approach is not possible. Lastly, it is not always necessary to obtain the solution relative to the micro-unit energy. Energy was chosen here because of its generality to all systems, but other physical quantities may be used. Whichever quantity is chosen it must be evaluated for the smallest functional unit. Ultimately, the resulting dimensions represent the optimal solution for the structure in terms of its smallest functional building block. These integrative modeling concepts are illustrated in the next section in a study of cardiac hypertrophy.

8.4.4 Predictive Power: Cardiac Hypertrophy

Current thinking dictates that the left ventricle attempts to normalize its peak wall stress values during systole and diastole by altering its dimensions [50]. There are several reasons to doubt the validity of this concept. First, anatomical locations of systolic and diastolic stress transducers have not been identified. Second, the value of wall stress cannot be determined from basic physical knowledge. Instead, wall stress is assumed to be regulated by an unknown mechanism. Last, this theory cannot explain ventricular size alterations due to metabolic disturbance, as opposed to a mechanical disturbance. Alternatively, integrative modeling is applied to the problem of cardiac hypertrophy.

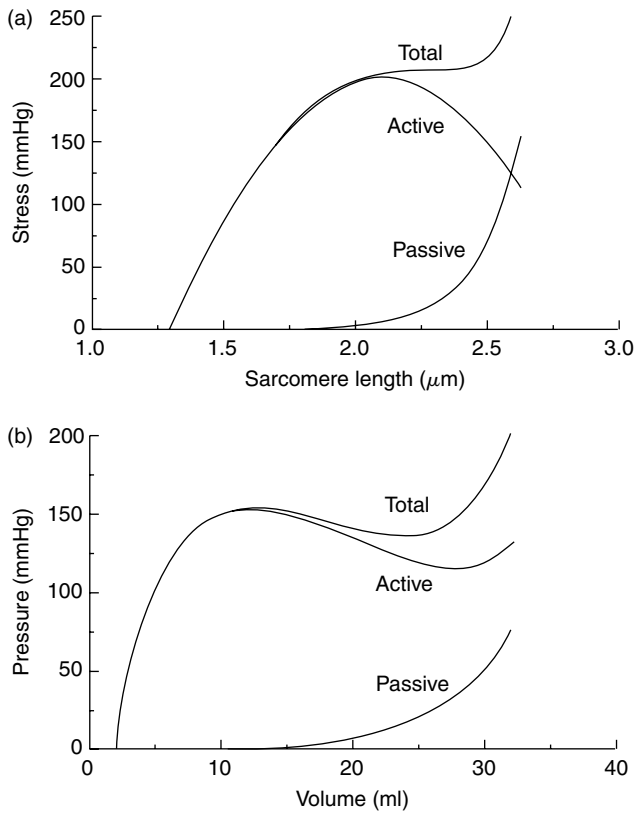
It was hypothesized that cardiac size can be determined from energetics at the sarcomere level of structure, that is, the micro-unit [51]. The cardiac sarcomere was redefined as a *sarcounit* (Figure 8.22), a constant volume structure capable of axial stress generation. The function of the sarcounit was defined by its active and passive stress–length curves (Figure 8.23), with the active function corresponding to maximal activation. Maximal stress was modulated by a periodic time function, which was zero during diastole.
FIGURE 8.22 Cardiac sarcounit (upper right) and structural arrangement to form a cylindrical left ventricle. (Adapted from Drzewiecki, G.M., Karam, E., Li, J.K.-J., and Noordergraaf, A. 1992. *Am. J. Physiol.* 263: H1054–H1063.)


FIGURE 8.23 (a) Active and passive stress–length curves describing the sarcounit. (b) Active and passive pressure–volume curves for the initial cylindrical left ventricle model. (Adapted from Drzewiecki, G.M, Karam, E., and Welkowitz, W. 1989. *J. Theor. Biol.* 139: 465–486.)

A cylindrical approximation to the geometry of the ventricle was chosen (Figure 8.22). Thus, its structure was described by the length, diameter (D), and wall thickness (W) of the cylinder [52]. The sarcounits were arranged in series and parallel so that ventricular diameter is determined by the number of series units and ventricular wall thickness and length by the number of parallel units.

Macro-function was defined by the mean aortic pressure and afterload impedance, using a modified windkessel arterial load. Preload was treated as a constant filling pressure in series with a constant flow resistance. Ventricular function was then equated with micro-function by integrating the stress and length of the sarcounits over the cylindrical structure. This yielded ventricular pressure and volume at any instant of time for given sarcounit stress and length at the corresponding time (Figure 8.23). Heart rate was allowed to vary as necessary to maintain constant mean aortic pressure. The sarcounit energetics were evaluated from the rate of myocardial oxygen consumption (MVO_2). MVO_2 was computed by assuming a proportional relationship with the area of the stress–length loop of the sarcounit per unit time. All quantities were then computed numerically, allowing several cycles to achieve steady state. Each quantity was measured at the final steady-state beat.

To solve for the dimensions of the ventricle, ventricular diameter and wall thickness were varied while evaluating all quantities, including MVO_2. Results show that MVO_2 is minimized only at a specific shape of the cylinder, or W/D ratio (Figure 8.24). Additionally, the level of MVO_2 varied with the overall size of the ventricle. When MVO_2 is also equated with the amount of oxygen supplied by the coronary circulation, a unique solution for left ventricular size and shape is obtained.

The above model was further employed to study observed patterns of cardiac hypertrophy. First, the initial size of the ventricle was consistent with that of a normal dog. Second, a pressure overload was created by raising mean aortic pressure. The model was then used to recompute ventricular size for the new afterload condition. Results show the classic wall thickening and increased wall thickness-to-diameter ratio (W/D), consistent with observed *concentric hypertrophy*. Third, volume overload was imposed by elevating cardiac output. In this case, the model predicted an increase in diameter with relatively little increase in the W/D ratio, referred to as *eccentric hypertrophy*. Lastly, the sarcomere function was impaired and its effect on the ventricle evaluated. An eccentric form of hypertrophy resulted. The diameter-to-length
FIGURE 8.24   Sarcounit myocardial oxygen consumption (MVO_2) vs. the circumference (C) and wall thickness (W) of the ventricle model. (Adapted from Drzewiecki, G.M., Karam, E., Li, J.K.-J., and Noordergraaf, A. 1992. *Am. J. Physiol.* 263: H1054–H1063.)

ratio was found to increase along with the degree of myocardial dysfunction [53]. This was consistent with observations that show the ventricle assuming a progressively more spherical shape with further myocardial failure [54].

In conclusion, modeling by means of integrating micro- and macro-function was applied to the study of cardiac hypertrophy. This approach matches the functional information available at two different levels of structure. The ability to predict macro-structure dimensions is a result of achieving this match. The cardiac growth model suggests the conclusion that the ventricular shape can be determined by the regulation of a single quantity, MVO_2, at the sarcomere level. This modeling approach is more general than the wall stress theory as it can predict growth response to metabolic anomaly, as well as to mechanical overloads. As a primary benefit, this approach permits theoretical analysis that may be impractical to realize experimentally.

8.5   Summary

This chapter presents modeling as a tool to identify and quantify the mechanism(s) responsible for observed phenomena in physiology, illustrated with recent examples from cardiovascular dynamics. The rather strict rules to which the modeling process is subject generally lead to the formulation of new, specific experiments, thereby broadening the pool of experimental data, and the database for modeling. On occasion, this process leads to areas of experimentation and the development of concepts originally judged to lie outside the scope of the original problem definition. Consequently, successful modeling aids in deepening a researcher's insight and breadth of view.

9.1 Introduction

Compartmental models are a class of dynamic, that is, differential equation, models derived from mass balance considerations, which are widely used for quantitatively studying the kinetics of materials in physiologic systems. Materials can be either exogenous, such as a drug or a tracer, or endogenous, such as a substrate or a hormone, and kinetics include processes such as production, distribution, transport, utilization, and substrate–hormone control interactions.

Compartmental modeling was first formalized in the context of isotopic tracer kinetics. Over the years it has evolved and grown as a formal body of theory [Carson et al. 1983; Godfrey, 1983; Jacquez 1996; Cobelli et al., 2000].

Compartmental models have been widely employed for solving a broad spectrum of physiologic problems related to the distribution of materials in living systems in research, diagnosis, and therapy both at whole-body, organ, and cellular level. Examples and references can be found in books [Gibaldi and Perrier, 1982; Carson et al., 1983; Jacquez, 1996; Cobelli et al., 2000; Carson and Cobelli, 2001]

and reviews [Carson and Jones, 1979; Cobelli, 1984; Cobelli and Caumo, 1998]. Purposes for which compartmental models have been developed include:

- Identification of system structure, that is, models to examine different hypotheses regarding the nature of specific physiologic mechanisms.
- Estimation of unmeasurable quantities, that is, estimating internal parameters and variables of physiologic interest.
- Simulation of the intact system behavior where ethical or technical reasons do not allow direct experimentation on the system itself.
- Prediction and control of physiologic variables by administration of therapeutic agents, that is, models to predict an optimal administration of drug in order to keep one or more physiologic variables within desirable limits.
- Cost/effectiveness optimization of dynamic clinical tests, that is, models to obtain maximal information from the minimum number of blood samples withdrawn from a patient.
- Diagnosis, that is, models to augment quantitative information from laboratory tests and clinical symptoms, thus improving the reliability of diagnosis.
- Teaching, that is, models to aid in the teaching of many aspects of physiology, clinical medicine, and pharmacokinetics.

The use of compartmental models of physiologic systems has been greatly facilitated by the availability of specific software packages for PC [SAAMII, 1998; AdaptII, 1997], which can be used both for simulation and identification.

9.2   Definitions and Concepts

Let us start with some definitions. A *compartment* is an amount of material that acts as though it is well-mixed and kinetically homogeneous. A *compartmental model* consists of a finite number of compartments with specified interconnections among them. The interconnections represent fluxes of material which physiologically represent transport from one location to another or a chemical transformation, or both, or control signals. An example of a simple two-compartment model is illustrated in Figure 9.1 where the compartments are represented by circles and the interconnections by arrows.

Given the introductory definitions, it is useful before explaining *well-mixed* and *kinetic homogeneity* to consider possible candidates for compartments. Consider the notion of a compartment as a physical space. Plasma is a candidate for a compartment; a substance such as plasma glucose could be a compartment.
FIGURE 9.1   A two-compartment model. The substance enters *de novo* compartment 1 (arrow entering a compartment from "outside") and irreversibly leaves from compartment 2 (arrow leaving a compartment to the "outside"). Material exchanges occur between compartments 2 and 1 and compartments 1 and 2 and are represented by arrows. Compartment 1 is the accessible compartment; test input and measurement (output) are denoted by a large arrow and a dashed line with a bullet, respectively.

Zinc in bone could be a compartment also as could thyroxine in the thyroid. In some experiments, different substances could be followed in plasma: plasma glucose, lactate, and alanine provide examples. Thus in the same experiment, there can be more than one plasma compartment, one for each of the substances being studied. This notion extends beyond plasma. Glucose and glucose-6-phosphate could be two different compartments inside a liver cell. Thus a physical space may actually represent more than one compartment.

In addition, one must distinguish between compartments that are accessible and nonaccessible for measurement. Researchers often try to assign physical spaces to the nonaccessible compartments. This is a very difficult problem that is best addressed once one realizes that the definition of a compartment is actually a theoretical construct, which may in fact lump material from several different physical spaces in a system; to equate a compartment with a physical space depends upon the system under study and assumptions about the model.

With these notions of what might constitute a compartment, it is easier to define the concepts of well-mixed and kinetic homogeneity. What *well-mixed* means is that any two samples taken from the compartment at the same time would have the same concentration of the substance being studied and therefore be equally representative. Thus the concept of well-mixed relates to uniformity of information contained in a single compartment.

Kinetic homogeneity means that every particle in a compartment has the same probability of taking the pathways leaving the compartment. Since, when a particle leaves a compartment, it does so because of metabolic events related to transport and utilization, it means that all particles in the compartment have the same probability of leaving due to one of these events.

The notion of a compartment, that is, lumping material with similar characteristics into collections that are homogeneous and behave identically, is what allows one to reduce a complex physiologic system into a finite number of compartments and pathways. The required number of compartments depends both on the system being studied and on the richness of the experimental configuration. A compartmental model is clearly unique for each system studied, since it incorporates known and hypothesized physiology and biochemistry. It provides the investigator with insights into the system structure and is as good as the assumptions that are incorporated in the model.

9.3 The Compartmental Model

9.3.1 Theory

Figure 9.2 represent the ith compartment of an n-compartment model; $q_i \geq 0$ denotes the mass of the compartment. The arrows represent fluxes into and out of the compartment: the input flux into the compartment from outside the system, for example, *de novo* synthesis of material and exogenous test
FIGURE 9.2 The ith compartment of an n-compartment model.

input, is represented by $u_i \geq 0$; the flux to the environment and therefore out of the system by f_{0i}; the flux from compartment i to j by f_{ji}, and the flux from compartment j to i by f_{ij}. All fluxes are greater than or equal to zero. The general equations for the compartmental model are obtained by writing the mass balance equation for each compartment:

$$\dot{q}_i = \sum_{\substack{j=1 \\ j \neq i}}^{n} f_{ij} - \sum_{\substack{j=1 \\ j \neq i}}^{n} f_{ji} - f_{0i} + u_i, \quad q_i(0) = q_{i0} \tag{9.1}$$

The input fluxes u_i are generally constant or functions of only time. The fluxes f_{ji}, f_{ij}, and f_{0i} can be functions of $q_1, \ldots, q_n$ and sometimes also of time (for the sake of simplicity, we will ignore this dependence). It is always possible to write:

$$f_{ij}(\mathbf{q}) = k_{ij}(\mathbf{q})q_j \tag{9.2}$$

where $\mathbf{q} = [q_1, \ldots, q_n]^{\mathrm{T}}$ is the vector of the compartmental masses. As a result, Equation 9.1 can be written as:

$$\dot{q}_i = \sum_{\substack{j=1 \\ j \neq i}}^{n} k_{ij}(\mathbf{q})q_j - \left(\sum_{\substack{j=1 \\ j \neq i}}^{n} k_{ji}(\mathbf{q}) + k_{0i}(\mathbf{q}) \right) q_i + u_i, \quad q_i(0) = q_{i0} \tag{9.3}$$

The k_{ij}'s are called *fractional transfer coefficients*. Equation 9.3 describes the generic *nonlinear* compartmental model. If the k_{ij}'s do not depend on the compartmental masses q_i's, the model becomes *linear*.

Defining $k_{ii}(\mathbf{q}) = -\left(\sum_{\substack{j=1 \\ j \neq i}}^{n} k_{ji}(\mathbf{q}) + k_{0i}(\mathbf{q}) \right)$ we can now write Equation 9.3 as:

$$\dot{q}_i = \sum_{j=1}^{n} k_{ij}(\mathbf{q})q_j + u_i, \quad q_i(0) = q_{i0} \tag{9.4}$$

and the model of the whole system as

$$\dot{\mathbf{q}} = \mathbf{K}(\mathbf{q})\mathbf{q} + \mathbf{u}, \quad \mathbf{q}(0) = \mathbf{q}_0 \tag{9.5}$$

where $\mathbf{K}$ is the $n \times n$ *compartmental matrix* (hereafter, let us drop the dependence on $\mathbf{q}$, for simplicity of notation) and $\mathbf{u} = [u_1, \ldots, u_n]^{\mathrm{T}}$ is the vector of input fluxes into the compartments from outside the system.

For the linear case, $\mathbf{K}$ is constant and one has:

$$\dot{\mathbf{q}} = \mathbf{K}\mathbf{q} + \mathbf{u}, \quad \mathbf{q}(0) = \mathbf{q}_0 \tag{9.6}$$

The entries of the compartmental matrix $\mathbf{K}$, for both the nonlinear 9.5 and the linear 9.6 model, satisfy

$$k_{ii} \leq 0, \quad \text{for all } i \tag{9.7}$$

$$k_{ij} \geq 0, \quad \text{for all } i \neq j \tag{9.8}$$

$$\sum_{i=1}^{n} k_{ij} = \sum_{\substack{i=1 \\ i \neq j}}^{n} k_{ij} + k_{jj} = -k_{0j} \leq 0, \quad \text{for all } j \tag{9.9}$$
FIGURE 9.3   The linear compartmental model of glucose kinetics by Cobelli et al. [1984b].

K is thus a (column) diagonally dominant matrix. This is a very important property, and in fact the stability properties of compartmental models are closely related to the diagonal dominance of the compartmental matrix. For instance for the linear model, Equation 9.6, one can show that all eigenvalues have nonpositive real parts and that there are no purely imaginary eigenvalues: this means that all solutions are bounded and if there are oscillations they are damped. The qualitative theory of linear and nonlinear compartmental models have been reviewed in Jacquez and Simon [1993], where some stability results on nonlinear compartmental models are also presented.

9.3.2 The Linear Model

The linear model, Equation 9.6, has become very useful in applications due to an important result: the kinetics of a tracer in a constant steady-state system, linear or nonlinear, are linear with constant coefficients. An example is shown in Figure 9.3 where the three-compartment model by Cobelli et al. [1984b] for studying tracer glucose kinetics in steady state at the whole-body level is depicted. Linear compartmental models in conjunction with tracer experiments have been extensively used in studying distribution of materials in living systems both at whole-body, organ and cellular level. Examples and references can be found in Carson et al. [1983], Jacquez [1996], and Cobelli et al. [2000], Carson and Cobelli [2001].

An interesting application of linear compartmental models at the organ level is in describing the exchange of materials between blood, interstitial fluid, and cell of a tissue from multiple tracer indicator dilution data. Compartmental models provide a finite difference approximation in the space dimension of a system described by partial differential equations, which may be easier resolvable from the data. These models are discussed in Jacquez [1996] and an example of a model describing glucose transport and metabolism in the human skeletal muscle can be found in Saccomani et al. [1996].

9.3.3 The Nonlinear Model

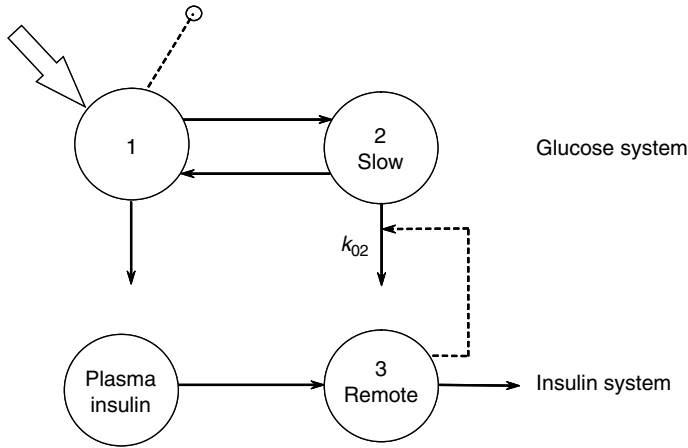
Almost all the biological models are nonlinear dynamic systems, including for example saturation or threshold processes. In particular, nonlinear compartmental models, Equation 9.5, are frequently found in biomedical applications. For such models the entries of **K** are functions of **q**, most commonly k_{ij} is a function of only few components of **q**, often q_i or q_j. Examples of k_{ij} function of q_i or q_j are the Hill and


FIGURE 9.4 The nonlinear compartmental model of insulin control on glucose distribution and metabolism by Caumo and Cobelli [1993]. The dashed line denotes a control signal.

the Langmuir nonlinearities described respectively by:

$$k_{ij}(q_j) = \frac{\alpha q_j(t)^{h-1}}{\beta + q_j(t)^h} \tag{9.10}$$

$$k_{ij}(q_i) = 1 - \frac{q_i}{\gamma} \tag{9.11}$$

where α, β, γ are positive reals, and h is a positive integer. For $h = 1$, Equation 9.10 turns into the widely used Michaelis–Menten equation.

Other interesting examples arise in describing substrate–hormone control systems. For instance the model of Figure 9.4 has been proposed [Caumo and Cobelli, 1993; Vicini et al., 1997] to describe the control of insulin on glucose distribution and metabolism during a glucose perturbation which brings the system out of steady state. The model assumes compartmental descriptions for glucose and insulin kinetics, interacting via a control signal, which emanates from the remote insulin compartment and affects the transfer rate coefficient, k_{02}, responsible for insulin-dependent glucose utilization. In this case one has:

$$k_{02}(q_3) = \delta + q_3 \tag{9.12}$$

where δ is a constant.

Additional examples and references on nonlinear compartmental models can be found in Carson et al. [1983], Godfrey [1983], Jacquez [1996], and Carson and Cobelli [2001].

9.3.4 Use in Simulation and Indirect Measurement

Models such as those described by Equation 9.5 can be used for *simulation*. Assuming that both the matrix **K** and initial state **q**(0) are known, it is possible to predict the behavior of the state vector **q** for any possible input function **u**.

A major use of compartmental models is in the *indirect measurement* of physiologic parameters and variables. For instance, given data obtained from m compartments which are accessible to measurement (usually m is a small fraction of the total number of compartments n), the model is used to estimate not directly measurable parameters and predict quantities related to nonaccessible compartments. In this case **K** is unknown and input–output experiments are performed to generate data to determine **K**. These data

can be usually described by a linear algebraic equation

$$\mathbf{y} = \mathbf{Cq} \tag{9.13}$$

where $\mathbf{y} = [y_1, \ldots, y_m]^T$ is the vector of the m model outputs and $\mathbf{C}$ is the $m \times n$ observation matrix. If model outputs are concentrations, the entries of $\boldsymbol{C}$ are the inverse of the volumes of the m compartments accessible to measurement. Real data are noisy, thus an error term $\mathbf{v}$ is usually added to $\mathbf{y}$ in Equation 9.13 to describe the actual measurements $\mathbf{z}$

$$\mathbf{z} = \mathbf{y} + \mathbf{v} \tag{9.14}$$

$\mathbf{v}$ is usually given a probabilistic description, for example, errors are assumed to be independent and often Gaussian. Equation 9.13 and Equation 9.14 together with Equation 9.5 or Equation 9.6 define the compartmental model of the system, that is, the model structure and the input–output experimental configuration.

The identification techniques described in the following section are aimed to determine the entries of $\mathbf{K}$ (and often also those of $\mathbf{C}$) from the data vector $\mathbf{z}$ of Equation 9.14.

9.4 A Priori Identifiability

Let us assume that a compartmental model structure has been postulated to describe the physiologic system, that is, the number of compartments and the connections among them have been specified. This is the most difficult step in compartmental model building.

The structure can reflect a number of facts: there may be some a priori knowledge about the system, which can be incorporated in the structure; one can make specific assumptions about the system, which are reflected in the structure; by testing via simulation one can arrive at a structure that is needed to fit the data. The result at this stage is a nonlinear, Equation 9.5, or linear, Equation 9.6, where parameters of the compartmental matrix $\mathbf{K}$ and those of the observation matrix $\mathbf{C}$, Equation 9.13, are usually unknown. Before performing the experiment or, if the experiment was already completed, before numerically estimating the model parameters from the experimental data, the following question arises: does the data contain enough information to unequivocally estimate (e.g., via least squares or maximum likelihood) all the unknown parameters of the postulated model structure? This question, set in the ideal context of error-free model structure and noise-free measurements, is usually referred to as the a priori *global identifiability*. Despite its theoretical nature, it is an essential, but often overlooked, prerequisite for model parameter estimation from real data. In particular, if it turns out in such an ideal context that some model parameters are not identifiable from the data, there is no way that the parameters can be identified in a real situation, with errors in the model structure and noise in the data.

A priori identifiability thus examines whether, given the ideal noise-free data $\mathbf{y}$, Equation 9.13, and the error-free compartmental model structure, Equation 9.5 or Equation 9.6, it is possible to make unique estimates of all the unknown model parameters. A model can be *uniquely (globally) identifiable* — that is all its parameters have one solution — or *nonuniquely (locally) identifiable* — that is, one or more of its parameters has more than one but a finite number of possible values — or *nonidentifiable* — that is, one or more of its parameters has an infinite number of solutions. For instance, the model of Figure 9.1 is uniquely identifiable, while that of Figure 9.3 is *nonidentifiable.*

A priori identifiability is also crucial in qualitative experiment design [Saccomani and Cobelli, 1992], which studies the input–output configuration necessary to ensure unique estimation of the unknown parameters. In fact, it allows to distinguish among those experiments that cannot succeed and those that might and, among the latter, may help in determining the minimal input-output configuration to ensure estimation of the unknown parameters. This is of particular relevance for physiological systems, where

the number and sites of application of inputs and outputs are severely constrained by ethical and technical reasons.

The identifiability problem is in general a difficult task, since it requires to solve a system of nonlinear algebraic equations with a number of terms and nonlinearity degree increasing with the model order. For linear compartmental models various specific methods, for example, based on transfer function, similarity transformation and graph topology, have been developed [Cobelli and DiStefano, 1980; Walter, 1982; Carson et al., 1983; Godfrey, 1983; Jacquez, 1996]. Explicit identifiability results on catenary and mamillary compartmental models [Cobelli et al., 1979] and on the three-compartmental model [Norton, 1982] are available. The introduction of computer algebraic algorithms has allowed to considerably simplifying the complexity of the problem [Audoly et al., 1998].

For nonlinear compartmental models the problem is more difficult and very few results are available, for example, based on the similarity transformation [Chappell and Godfrey, 1992] and on the output series expansion [Pohjanpalo, 1978]. When applied to large models, these methods involve nonlinear algebraic equations difficult to be solved, even by resorting to symbolic algebraic manipulative languages (e.g., Reduce, Maple). Given the relevance of identifiability of nonlinear models in biological studies, the above difficulties have stimulated new approaches to study global identifiability based on differential algebra tools. In particular, the introduction of concepts of differential algebra has been an important factor for addressing identifiability of nonlinear (compartmental and noncompartmental) models previously thought to be intractable [Ollivier, 1990; Ljung and Glad, 1994; Audoly et al., 2001]. However, the construction of an efficient algorithm still remains a difficult task. Recently a new differential algebra algorithm to test identifiability of nonlinear models with given initial conditions has been developed [Saccomani et al., 2003]. This algorithm integrates the different strategies proposed before and broadens their domain of applicability. In particular, it is a very useful tool for biological and physiological systems that often exhibit nongeneric initial conditions, for example, a model of radiotracer kinetics is characterized by zero initial conditions.

From the above considerations, it follows that if a model is a priori uniquely identifiable, then identification techniques can be used to estimate from the noisy data **z**, Equation 9.14, the numerical values of the unknown parameters. Conversely, if a model is either a priori nonuniquely identifiable or nonidentifiable, numerical estimation may lead to parametric values which are ambiguous and thus not informative about the biological system under study; this is particularly critical when dealing with physiological systems where a different numerical estimate can characterize a pathological from a normal state. In this case, to solve the problem, different strategies can be used, for example, derivation of bounds for nonidentifiable parameters [DiStefano, 1983], model reparametrization (parameter aggregation), incorporation of additional knowledge, or design of a more informative experiment. An example on the use of some of these approaches for dealing with the nonidentifiable model of glucose kinetics of Figure 9.3 is given in Cobelli and Toffolo [1987].

In conclusion, a priori unique identifiability is a prerequisite for well posedness of parameter estimation and for reconstructability of state variables in compartments not accessible to measurement. It is a necessary but not sufficient condition to guarantee successful estimation of model parameters from real input–output data.

9.5 Parameter Estimation

Given an uniquely identifiable compartmental model, one can proceed by estimating the values of the unknown parameters from the experimental data. Assuming, for the sake of simplicity, that the model is linear and that only one output variable is observed, that is, $m = 1$, by integrating Equation 9.6 one can obtain the explicit solution for the model output, that is, $y(t) = g(t, \boldsymbol{\theta})$, where $\boldsymbol{\theta}$ is a p-dimension vector which contains the p unknown parameters of the model. For instance, if the model of Figure 9.1 is used to describe the kinetics of a tracer after the administration of a pulse of known amplitude D (i.e., $u(t) = D\delta(t)$ and $q_1(0) = q_2(0) = 0$), the vector $\boldsymbol{\theta}$ is a 4-dimension vector containing the fractional

transfer coefficients k_{01}, k_{12}, k_{21}, and the volume V of the accessible compartment, while the accessible tracer concentration profile $y(t)$ is

$$y(t) = g(t, \boldsymbol{\theta}) = \frac{D}{V} \left(\frac{k_{21} + k_{01} + \sqrt{(k_{12} + k_{21} + k_{01}) + 4k_{12}k_{01}}}{2\sqrt{(k_{12} + k_{21} + k_{01}) + 4k_{12}k_{01}}} e^{-(k_{12} + k_{21} + k_{01} + \sqrt{(k_{12} + k_{21} + k_{01}) + 4k_{12}k_{01}})t} \right.$$

$$\left. + \frac{k_{12} + k_{01} + \sqrt{(k_{12} + k_{21} + k_{01}) + 4k_{12}k_{01}}}{2\sqrt{(k_{12} + k_{21} + k_{01}) + 4k_{12}k_{01}}} e^{-(k_{12} + k_{21} + k_{01} - \sqrt{(k_{12} + k_{21} + k_{01}) + 4k_{12}k_{01}})t} \right)$$

$$(9.15)$$

In practical cases, experimental data are collected at N discrete time instants $t_1, \ldots, t_N$, so that discrete time measurements $y(t_k) = g(t_k, \boldsymbol{\theta})$ are available. Letting $\mathbf{z} = [z(t_1), \ldots, z(t_N)]^T$ to denote the vector of the noisy samples of the output, according to Equation 9.14 one has:

$$\mathbf{z} = \mathbf{g}(\boldsymbol{\theta}) + \mathbf{v} \qquad (9.16)$$

where $\mathbf{g}(\boldsymbol{\theta}) = [g(t_1, \boldsymbol{\theta}), \ldots, g(t_N, \boldsymbol{\theta})]^T$, while $\mathbf{v} = [v(t_1), \ldots, v(t_N)]^T$ denotes the vector of the (additive) measurement error samples. Moreover, explicit solution of Equation 9.5 or Equation 9.6 is often non available. Thus $\mathbf{g}(\boldsymbol{\theta})$ is obtained by numerical integration of Equation 9.5 or Equation 9.6.

Estimates of $\boldsymbol{\theta}$ can be determined by several methods. These methods can be divided in two major categories. In the so-called Fisher estimation approach, only the data vector $\mathbf{z}$ of Equation 9.16 is supplied to the estimator in order to estimate the unknown model parameters $\boldsymbol{\theta}$. The second approach, known as the Bayes estimation approach, takes into account not only $\mathbf{z}$ but also some statistical information that is a priori available on the unknown parameter vector $\boldsymbol{\theta}$.

9.5.1 Fisher Approach

In the Fisher approach, parameter estimates can be obtained by nonlinear least squares or maximum likelihood together with their precision, such as, a measure of a posteriori or numerical identifiability. Details and references on parameter estimation of physiologic system models can be found in Carson et al. [1983] and Landaw and DiStefano [1984]. Weighted nonlinear least squares is mostly used, in which an estimate $\hat{\boldsymbol{\theta}}$ of the model parameter vector $\boldsymbol{\theta}$ is determined as

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}} [\mathbf{z} - \mathbf{g}(\boldsymbol{\theta})]^T \mathbf{W} [\mathbf{z} - \mathbf{g}(\boldsymbol{\theta})] \qquad (9.17)$$

where $\mathbf{W}$ is a $N \times N$ matrix of weights. In order to numerically solve Equation 9.17, both direct and gradient-type search methods are implemented in estimation schemes.

A correct knowledge of the error structure is needed in order to have a correct summary of the statistical properties of the estimates. This is a difficult task. Measurement errors are usually independent, and often a known distribution, for example, Gaussian, is assumed. Many properties of least squares hold approximately for a wide class of distributions if weights are chosen optimally, that is, equal to the inverse of the variances of the measurement errors, or at least inversely proportional to them if variances are known up to a proportionality constant, that is, $\mathbf{W}^{-1}$ is equal or proportional to $\boldsymbol{\Sigma_v}$, the $N \times N$ covariance matrix of the measurement error $\mathbf{v}$. Under these circumstances, an asymptotically correct approximation of the covariance matrix of the estimation error $\tilde{\boldsymbol{\theta}} = \boldsymbol{\theta} - \hat{\boldsymbol{\theta}}$ can be used to evaluate the precision of parameter estimates:

$$\text{cov}(\tilde{\boldsymbol{\theta}}) \cong \sigma^2 (\mathbf{S}^T \mathbf{W} \mathbf{S})^{-1} \qquad (9.18)$$

where matrix $\mathbf{S}$ is the N×p Jacobian matrix of $\mathbf{g}(\boldsymbol{\theta})$ calculated at $\hat{\boldsymbol{\theta}}$ and σ^2 is the scale factor (possibly estimated a posteriori) such that $\boldsymbol{\Sigma_v} = \sigma^2 \mathbf{W}^{-1}$. The approximation of Equation 9.18 becomes exact for a sufficiently large sample size and decreasing variances of the measurement error. If measurement errors

are Gaussian, then this approximation is the Cramer–Rao lower bound (inverse of the Fisher information matrix), that is, the optimally weighted least squares estimator is equivalent to the maximum likelihood estimator. Care must be taken in not using lower-bound variances as true parameter variances. Several factors corrupt these variances, for example, inaccurate knowledge of error structure, limited data set. Monte Carlo studies are needed to assess robustness of Cramer–Rao lower bound in specific practical applications.

To examine the quality of model predictions to observed data, in addition to visual inspection, various statistical tests on residuals are available to check for presence of systematic misfitting, nonrandomness of the errors, and accordance with assumed experimental noise. Model order estimation, that is, number of compartments in the model, is also relevant here, and for linear compartmental models, criteria such as F-test, and those based on the parsimony principle such as the Akaike and Schwarz criteria, can be used if measurement errors are Gaussian.

9.5.2 Bayes Approach

Bayes estimators assume that the parameter vector is the realization of a random vector $\boldsymbol{\theta}$, the a priori probability distribution of which $p_{\boldsymbol{\theta}}(\boldsymbol{\theta})$ is available, for example, from preliminary population studies. Starting from the knowledge of both the model of Equation 9.16 and the probability distribution of the noise vector $\mathbf{v}$, one can calculate the likelihood function $p_{\mathbf{z}|\boldsymbol{\theta}}(\mathbf{z}|\boldsymbol{\theta})$ (i.e., the probability distribution of the measurement vector in dependence of the parameter vector). From $p_{\boldsymbol{\theta}}(\boldsymbol{\theta})$ and $p_{\mathbf{z}|\boldsymbol{\theta}}(\mathbf{z}|\boldsymbol{\theta})$, the a posteriori probability distribution $p_{\theta|z}(\boldsymbol{\theta}|\mathbf{z})$ (i.e., the probability distribution of the parameter vector given the data vector) can be determined by exploiting the Bayes theorem:

$$p_{\boldsymbol{\theta}|\mathbf{z}}(\boldsymbol{\theta}|\mathbf{z}) = \frac{p_{\mathbf{z}|\boldsymbol{\theta}}(\mathbf{z}|\boldsymbol{\theta})p_{\boldsymbol{\theta}}(\boldsymbol{\theta})}{\int p_{\mathbf{z}|\boldsymbol{\theta}}(\mathbf{z}|\boldsymbol{\theta})p_{\boldsymbol{\theta}}(\boldsymbol{\theta})\,\mathrm{d}\boldsymbol{\theta}} \tag{9.19}$$

From the function of Equation 9.19 several estimators can be defined. For instance, the Maximum a Posteriori (MAP) estimate is found by determining the value of $\boldsymbol{\theta}$, which renders $p_{\boldsymbol{\theta}|\mathbf{z}}(\boldsymbol{\theta}|\mathbf{z})$ maximum, while the Mean Square (MS) estimate is defined as the expected value of θ, given the data vector:

$$\hat{\boldsymbol{\theta}} = \mathrm{E}[\boldsymbol{\theta}|\mathbf{z}] = \int \boldsymbol{\theta} p_{\boldsymbol{\theta}|\mathbf{z}}(\boldsymbol{\theta}|\mathbf{z})\,\mathrm{d}\boldsymbol{\theta} \tag{9.20}$$

When $\mathbf{v}$ and $\boldsymbol{\theta}$ are uncorrelated and Gaussian, both the MS and MAP estimates are given by

$$\hat{\boldsymbol{\theta}} = \arg \min_{\boldsymbol{\theta}}[\mathbf{z} - \mathbf{g}(\boldsymbol{\theta})]^{\mathrm{T}}\boldsymbol{\Sigma}_{\mathbf{v}}^{-1}[\mathbf{z} - \mathbf{g}(\boldsymbol{\theta})] + [\boldsymbol{\theta} - \boldsymbol{\mu}_{\boldsymbol{\theta}}]^{\mathrm{T}}\boldsymbol{\Sigma}_{\boldsymbol{\theta}}^{-1}[\boldsymbol{\theta} - \boldsymbol{\mu}_{\boldsymbol{\theta}}] \tag{9.21}$$

where $\boldsymbol{\mu}_{\boldsymbol{\theta}}$ and $\boldsymbol{\Sigma}_{\boldsymbol{\theta}}$ are, respectively, the a priori expected value (size p) and covariance matrix (size $p \times p$) of vector $\boldsymbol{\theta}$. The concepts previously considered in the Fisher approach, that is, determination of a confidence interval of the parameter estimates and choice of model order, can be addressed in the Bayes approach as well. Bayes estimation can be of relevant interest, since when statistical information on the unknown parameters of the model is a prior available and exploited, a possibly significant improvement in the parameter estimates precision with respect to Fisher estimation can be obtained, see for example, Cobelli et al. [1999] and Sparacino et al. [2000] for an example of application. However, in most cases the handling of $p_{\boldsymbol{\theta}|\mathbf{z}}(\boldsymbol{\theta}|\mathbf{z})$ and its integration in Equation 9.20 is analytically intractable and the sophisticate but computationally demanding numerical simulation techniques called Markov chain Monte Carlo must be used to determine Bayesian parameter estimates and their confidence intervals, see for example, Pillonetto et al. [2002] and Magni et al. [2001] for two recent applications.

9.5.3 Population Approaches

So far, even if homogenous experimental data sets in M different individuals were available, for example, because the same input–output experiment to identify a compartmental model with a given structure was repeated in M homogenous individuals, model identification in each individual is attacked independently. In the literature, alternative parameter estimation approaches, called "population" approaches, have also been devised to identify simultaneously the M individual models starting from the ensemble of the M sets of experimental data. Both deterministic and Bayesian approaches are available [Beal and Sheiner, 1982; Steimer et al., 1984; Davidian and Giltinan, 1995; Sheiner and Wakefield, 1999; Lunn et al., 2002]. Albeit complicated, both theoretically and algorithmically, they are particularly appealing when only few or particularly noisy data are available for each of the subjects under study, as it often happens in pharmacokinetic/pharmacodynamic research or epidemiological studies. In fact, thanks to the fact that "poor" individual data sets can borrow strength from the others, population parameter estimation approaches often allow to achieve results more satisfactory than standard single-subject parameter estimation approaches, see for example, the compartmental model applications recently made in Vicini et al. [1998], Vicini and Cobelli [2001], and Bertoldo et al. [2004].

9.6 Optimal Experiment Design

At this point one has a compartmental model structure, a description of the measurement error, and a numerical value of the parameters together with the precision with which they can be estimated. It is now appropriate to address the optimal experiment design issue. The rationale of optimal experiment design is to act on design variables such as number of test input and outputs, form of test inputs, number of samples and sampling schedule, and measurement errors so as to maximize, according to some criterion, the precision with which the compartmental model parameters can be estimated [DiStefano, 1981; Carson et al., 1983; Landaw and DiStefano, 1984; Walter and Pronzato, 1990].

In the Fisher approach, the Fisher information matrix J, which is the inverse of the lower bound of the covariance matrix, is treated as a function of the design variables and usually the determinant of J (this is called D-optimal design) is maximized in order to maximize precision of parameter estimates, and thus numerical identifiability.

The optimal design of sampling schedules, that is, the determination of the number and location of discrete-time points where samples are collected, has received much attention as it is the variable which is less constrained by the experimental situation. Theoretical and algorithmic aspects have been studied, and software is available, for both the single- and multioutput case [DiStefano, 1981; Cobelli et al., 1985; Landaw and DiStefano, 1984]. Optimal sampling schedules are usually obtained in an iterative manner: one starts with the model obtained from pilot experiments and the program computes optimal sampling schedules for subsequent experimentation. An important result for single-output linear compartmental models is that D-optimal design usually consists of independent replicates at P distinct time points, where P is the number of parameters to estimate.

Optimal sampling schedule design has been shown for example, to improve precision as compared to schedules designed by intuition or other convention and to optimize the cost effectiveness of a dynamic clinical test by reducing the number of blood samples withdrawn from a patient without significantly deteriorating their precision [Cobelli and Ruggeri, 1989; 1991].

The optimal input design problem has been relatively less studied, but some results are available on optimal equidose rectangular inputs (including the impulse) for parameter estimation in compartmental models [Cobelli and Thomaseth, 1987; 1988a, b].

In a Bayes estimation context, optimal experiment design is a more difficult task (see [Walter and Pronzato, 1990] for a survey). Applications have thus been less than those with a Fisher approach, also because the numerical implementation of the theoretical results is much more demanding.

Finally, some results on optimal experiment design in a population parameter estimation context have also been recently presented [Hooker et al., 2003].

9.7 Validation

Validation involves assessing whether or not the compartmental model is adequate for its purpose. This is a difficult and highly subjective task in modeling of physiologic systems, because intuition and understanding of the system play an important role. It is also difficult to formalize related issues such as model credibility, that is, the use of the model outside its established validity range. Some efforts have been made however to provide some formal aids for assessing the value of models of physiologic systems [Carson et al., 1983; Cobelli et al., 1984a]. A set of validity criteria have been explicitly defined, such as empirical, theoretical, pragmatic and heuristic validity, and validation strategies have been outlined for two classes of models, broadly corresponding to simple and complex models. This operational classification is based on a priori identifiability and leads to clearly defined strategies as both complexity of model structure and extent of available experimental data are taken into account. For simple models quantitative criteria based on identification, for example, a priori identifiability, precision of parameter estimates, residual errors, can be used in addition to physiologic plausibility. In contrast with simple models, complex simulation models are essentially incomplete, as there will naturally be a high degree of uncertainty with respect to both structure and parameters. Therefore validation will necessarily be based on less solid grounds. The following aids have been suggested: increasing model testability through model simplification; improved experimental design and model decomposition; adaptive fitting based on qualitative and quantitative feature comparison and time-course prediction; model plausibility.

Cardiovascular Models and Control

Fernando Casas
The Cleveland Clinic Foundation

William D. Timmons
EnteraTech, Inc.

This chapter reviews cardiovascular (CV) modeling for use in controller design, especially for closed-loop drug delivery systems (IV infusions of vasodilators, inotropes, anesthetics, neoplastic agents, and so on) and other pharmacologic applications. This first section describes the advantages and disadvantages of employing CV models for design and control and presents a brief history of CV modeling. The next section describes the basic principles and techniques for modeling the CV system, as well as the uptake, distribution, and action of cardio- and vasoactive pharmaceuticals. The chapter ends with a sample of modeling applications. A short, annotated bibliography follows the reference section for those interested in further reading.

10.1 Advantages and Disadvantages of Desktop Patients

More and more industries are coming to rely on computer simulations to increase productivity and decrease costs as well as to increase reliability and safety of resulting products. The defense, automotive, and aerospace industries come most quickly to mind, but the medical field is rapidly gaining ground in this area, too. Recent ARPA initiatives for defense technology conversion are probably most responsible for the recent surge in computer-aided health care. Today, computerized simulators teach medical students everything from basic anatomy to techniques in radial keratotomy, and skilled surgeons design, evaluate, and practice new and risky procedures without ever cutting into a single patient. Thanks to the ARPA initiative, telesurgery will soon be viable, so that in the near future, surgeons may operate on patients from half a world away. From the calculation of simple-dosage regimens to the design of sophisticated blood

pressure controllers, cardiovascular medicine also benefits from this technology. CV models can be used to prove initial feasibility, reduce development time, decrease costs, and increase reliability and safety of cardiovascular devices and therapeutics.

The increasing speed and decreasing costs of computers are having an enormous impact on controller design. There is a veritable explosion in the number of control designs as well as the theory to go with them. The ready availability of powerful computer workstations and sophisticated engineering design packages (e.g., MATLAB, LabView, MATRIXx) allow for the interactive design of high-performance, robust controllers. Engineers can tweak a controller or perturb a system, then immediately assess the effect. When combined with modern visualization techniques, these tools allow one to readily see problems and solutions that might otherwise have taken years to find and solve. Furthermore, such capabilities allow for exhaustive testing and debugging, so that the transition from the workbench to the field becomes smooth. Many companies and agencies have reported flawless transitions from the simulator to the field, most notably NASA, with its many satellites and probes that have had to work right the first time. Various companies are using simulations to improve or correct equipment and systems already in the field. A recent example is BAE Automated Systems Inc. of Dallas, Texas, which is using simulations to help debug and correct the troubled baggage system at the new Denver International Airport [Geppert, 1994].

The risk of failure or the fear of malpractice often precludes the design and evaluation of controllers in live humans, so that devices and treatments are often tested on computer and animal models first. In the past, animals have been the preferred choice, but this approach is continually being reevaluated. Whereas most researchers readily agree that animal experimentation has been and will continue to be necessary for the advancement of medical science, most would welcome methods and procedures that might reduce or even eliminate the use of animals. Furthermore, animals are rarely perfect models of human diseases and conditions. Thus, there has been and will continue to be a demand for alternative models and procedures. Tissue cultures are beginning to fill some of this need, and it is likely that computer modeling and simulation may also fill this need.

Desktop patients, if used to complement animal studies, can actually increase the reliability and applicability of certain animal tests, while also reducing the number of required experiments. In certain instances, computer modeling may be the only way to test a device prior to human use, since some human conditions are extremely difficult if not impossible to reproduce in animals. Indeed, as computers become more powerful and models become better, it may be that some day computers will be used in place of certain animal and human trials. Meanwhile, computer models can be used to (1) demonstrate feasibility, (2) increase confidence in controller designs by complementing animal studies, (3) help design better animal and clinical experiments, and (4) reduce the number of required animal and human experiments.

The disadvantage of using computer simulation is that available models will almost certainly need to be tailored to the application at hand. Since there is generally no predefined method for modeling or for modifying an existing model, the accuracy and reliability of the resulting model will depend heavily on the skill of the modeler, the appropriateness of the modifications, and the model's intended scope. Furthermore, modeling typically requires a good understanding of the physics of the problem, and this in turn requires supporting data and experimentation. Thus, modifications to include new pharmaceuticals may be problematic, since their mechanisms may only be poorly understood. And, even if supporting data are available, if a basic model does not yet exist, a significant time commitment may be required to develop one. Despite this up-front cost, model development may save tremendous time and costs later in the development process.

Fortunately, there are a large number of CV models to pick from, and experienced modelers can determine which, if any, is best for a given application. Once determined, the model can usually be converted easily to a form compatible with the development platform. Once converted, model integrity and suitability must be checked. Modifications can then be made, after which the model integrity must again be checked to ensure that it has not been compromised. Once a model is obtained and suitably modified, adequate thought must be given to program flow. Ideally, program flow should be designed such that the controller code is the same for real time and for simulation. This may be facilitated by treating all facets of data acquisition as part of the controlled system, instead of as part of the controller.

With this approach, all software for I/O and calibration would be bundled separately from the controller software. Windows-based systems facilitate this separation even further by allowing the controller and plant software to be compiled and run as two separate programs.

Other issues that must be considered involve the practical aspects of computer simulation. Even if a well-designed and validated model exists, many factors can affect the accuracy of the simulation. Stiffness, machine precision, program coding, integration method, step size, and even computer language can affect the results. Probably more insidious than all these factors is the operation of the model in regions outside its scope. This happens most often in large, complex programs when a variable takes on values outside its intended range. For example, a sudden increased cardiac preload may shift the end diastolic volume of the heart into a nonlinear region of the diastolic pressure-volume relationship. If the nonlinear behavior is not included in the model, misleading results might be produced. Finally, even in the best commercial code (let alone home-brewed code), bugs may affect simulation accuracy. For example, many commercial simulation packages are particularly poor at handling discrete events (such as a bolus infusion of a drug) when variable step-size algorithms are used to integrate continuous time models [Gustafsson, 1993].

10.2 History of Cardiovascular Modeling

William Harvey in the early 17th century was probably the first to clearly and convincingly demonstrate the role of the heart as a pump which caused the blood to flow in a unidirectional closed circuit through the systemic and pulmonary circulations. Prior to Harvey, the Galenic viewpoint from the 2d century ad predominated, namely, that the blood ebbed to and fro in the veins to provide nutrition to the rest of the body, that the arteries (from the Greek arteria, meaning windpipe) carried air, that the lungs cooled the heart and removed sooty impurities from new blood as it entered from the intestines, and that the heart contained pores to allow spirit or gaseous exchange across the septum [Acierno, 1994].

It was Stephen Hales in his Statistical Essays nearly a century later who considered arterial elasticity and postulated its buffering effect on the pulsatile nature of blood flow [Hales, 1733]. He likened the depulsing effect to the fire engines of his day, in which a chamber with an air-filled dome ("inverted globe") acted to cushion the bolus from the inlet water pump so that "a more nearly equal spout" flowed out the nozzle. This analogy became the basis of the first modern cardiovascular models and antedated the ARPA movement by quite a few decades! In the translation from English to German, Hales's inverted globe became a windkessel (air kettle); his idea later became known as the Windkessel theory when it was more formally developed and propounded by the German physiologist Otto Frank (of the Frank–Starling law of the heart) near the beginning of our century [Noordergraaf, 1978].

Frank was initially a strong proponent of the Windkessel theory, and his work spawned the interest of many subsequent investigators and led to a proliferation of modified Windkessel-type models. A critical review of these early models can be found in Aperia [1940]. The development of the analog computer shortly after World War II lead to another burst in CV modeling, based on more sophisticated segmental and transmission line theories. Grodins [1959] was probably one of the first to use these new machines to simulate cardiovascular hemodynamics. Interestingly, another early analog computer model, PHYSBE [McLeod, 1966], became a popular benchmark that is still used today to evaluate computers and simulation languages. About the mid-1970s, the advent of the inexpensive digital computer led to another revolution in CV modeling, which has continued to the present with ever-increasingly detail and scope. As Rideout [1991] observed, model complexity seems to have been limited only by computer technology. If this trend continues, we can expect to see highly detailed models emerging within the next few years as parallel computers become economical.

The major criticism of the pure Windkessel theory is that it does not allow for finite wave propagation and reflection in the arteries. Whereas blood flow in the arterial vasculature is more properly formulated in terms of space and time, the Windkessel theory ignores spacial considerations and instead lumps all the vasculature into a single point, or compartment, in space. Attempts to correct this shortcoming include adding inertial and damping factors as well as collapsible components. In addition, the great arteries

can be partitioned into sections to produce segmental models, or, when electrical network theory is invoked, transmission line models. Frank himself realized that the Windkessel theory was flawed, and so he too added modifications to include traveling waves and reflections [Noordergraaf, 1978; Milnor, 1989; Rideout, 1991].

Despite its flaws, the pure Windkessel theory is still useful as a teaching tool because of its simplicity and clear, intuitive imagery. Furthermore, as mean pressure accounts for approximately 90% of the power in the arterial pressure waveform, it performs surprisingly well and displays many of the interesting phenomena seen in the vasculature. Add to this the fact that the equations are readily extended to include spacial effects (the segmental and transmission line models), and one can see why the theory has persisted into the late 20th century. Of course, one must keep in mind that any of these approaches is only an approximation; the segmental and transmission line approaches are in many ways only a mathematical convenience that allows one to fit an arbitrarily high-order model to observed data. These approaches do not necessarily lend themselves to extrapolations and predictions regarding the physiology.

Even before Frank, there was great interest in the pure mathematics of blood flow in distensible vessels. Many a famous mathematician and scientist explored wave propagation, reflection, and pressure-flow relations in blood vessels, including: Bernoulli, Euler, Young (of Young's modulus), Poiseuille, Navier and Stokes, the Weber brothers, Resal, Moens and Korteweg, Lamb, and Witzig; more recent investigators including Morgan and Kiely, and Womersley and McDonald [Noordergraaf, 1978; Fung, 1984; Milnor, 1989]. Womersley and McDonald's students continue to be influential in cardiovascular modeling today. Early studies of theoretical hemodynamics greatly influenced the field of fluid mechanics and paved the way for modern pulse-wave propagation and reflection models of the vasculature. These models are treated in the texts by Noordergraaf [1978], Fung [1985], Li [1987], and Milnor [1989].

The hydrodynamic pulse-wave CV models are not without criticisms either. For example, they are limited to short segments of the arterial or venous tree for which input and terminal impedances must be supplied. This restriction makes them currently impractical for the analysis of long-acting pharmaceutical agents and their feedback effects on the cardiovascular system. Pharmaceuticals with vaso- and cardio-active effects usually require the tracking of drug concentrations throughout the body, which, for these models, would require an exceedingly large number of components and would result in huge programs requiring large computers, with the simulations invariably being slow and cumbersome. Furthermore, numerical techniques such as the finite-element method must be used to solve many of the hydrodynamic equations, which over extended periods might incur significant round-off and integration errors. Nevertheless, this approach will certainly form the basis of future pharmacologically linked CV models as faster and more sophisticated computers and algorithms are developed.

Because of the current shortfall in computational technology, most pharmacologic simulations requiring a CV model employ simplified or reduced-order models mentioned earlier. Besides the segmental and transmission line approaches, purely black box models are also used. The reduced segmental and transmission line models are probably most appropriate for simulations of fast-acting CV pharmaceuticals, whereas compartmental models (see Chapter 9) are more appropriate for slower-acting drugs.

The distinction between segmental and transmission line models has become increasingly blurred, especially as elements of both are often combined into the same model. Transmission line models were used as early as 1905 by Frank, although Westerhof and Noordergraaf [1969] were probably most influential in promoting the transmission line approach. As a result, these models are often called Westkessel models. They employ black box, two-terminal circuits (Westkessel terminations) to reproduce the input impedances of lumped vascular trees. Segmental models, however, are generally three terminal circuits, with two terminals representing inertial flows and viscous resistances and the third representing the compliance of the segment with respect to an external reference (typically atmospheric pressure). The segmental approach is described in more detail below.

As mentioned above, reduction in model order is typically achieved by combining segmental and transmission line models. The idea here is to represent critical, nonlinear components by segments, while the less critical, more linear components are lumped together and represented by Westkessel terminations.

Unfortunately, the black box Westkessel sections lose their physiologic meaning, which may present a problem in certain applications.

The highly simplified black box models are even worse in this regard. They are less concerned with the physiology than with the input-output relationships of the system and typically employ linear dynamics fit to observed patient responses. Though easy to implement, once defined, physiologically relevant perturbations may be difficult to produce. Furthermore, these models should not be used to infer properties or behaviors outside the range of the data sets. This is a potentially crippling drawback, especially when designing and evaluating CV controllers. However, if the goal is to generate clinically observed behaviors irrespective of the pathophysiology, then these models make an excellent choice.

Another potential drawback, which applies to both simplified and reduced-order models, is the loss of phenomena associated with pulse propagation and its effects on cardiac-arterial coupling and energetics. These effects are usually considered minor from a pharmacologic point of view, but their omission may lead to potentially serious design flaws when the resulting controller is used in certain patient populations. For example, isolated systolic hypertension (ISH) significantly contributes to strokes and heart disease in the elderly, and O'Rourke [1993] suggests that the therapy of choice, as well as the goal of treatment, should be different for ISH than for diastolic and mean arterial hypertension. It may be prudent, then, for control applications aimed at this population to be evaluated on more detailed models.

10.3 Cardiovascular Modeling

In this section, the concepts behind the segmental CV approach are described. Neurohumoral controls are also briefly discussed, as is the inclusion of pharmacokinetics and pharmacodynamics for drug uptake, distribution, and action.

10.3.1 An Idealized Segment of Artery

A short segment of artery can be modeled by an elastic, isobaric chamber attached to a rigid inlet and outlet tube (Figure 10.1). The ability of the chamber to store fluid depends on its compliance, C, which is defined as

$$C = \frac{\mathrm{d}V_c}{\mathrm{d}P_c} \tag{10.1}$$

where V_c is total segment (chamber) volume and P_c is chamber pressure. Many modelers prefer to use the reciprocal of compliance (termed stiffness, S, or elastance, E). Here, viscoelastic (stress relaxation) effects are assumed negligible, so that compliance is not an explicit function of time. Thus, compliance
FIGURE 10.1 Idealized segment of artery approximated by an elastic, isobaric chamber attached to a rigid inlet and outlet tube. P_{in}, P_{out}, and P_c are inlet, outlet, and chamber pressures; f_{in} and f_{out} are flows; L_{in} and L_{out} are inertances; R_{in} and R_{out} are viscous resistances to flow; and V_c is total segment (chamber) volume. Compliance C is defined in the text.
FIGURE 10.2   Static pressure–volume (P–V) relationship of a segment of artery.

becomes an instantaneous variable which can be obtained from the experimentally determined, steady-state pressure–volume (P–V) relationship of the segment. Furthermore, model order can now be reduced, as pressure can be mathematically represented as an empirical function of volume, either by a piecewise linear approximation, a polynomial quotient, or some other function fit to the P–V relationship. A typical P–V curve is illustrated in Figure 10.2, along with its piecewise linear approximation.

In arteries, pressure is usually positive with small oscillations about a nominal operating point (point A in Figure 10.2). Hence the piecewise linear approximation can be reduced to a single line with constant slope $1/C$:

$$P_c = \frac{(V_c - V_{cu})}{C} \tag{10.2}$$

where V_{cu} is the unstressed volume (the idealized zero-pressure volume intercept). Of course, if pressure fluctuates outside this region, then additional straight-line sections should be included.

Assuming that blood is incompressible and newtonian, that the flow profile is parabolic and unchanging with axial distance along a straight rigid tube, then flow (poisenillean) is linearly proportional to the pressure gradient across the ends of the tube. Hence, flow into and out of the chamber in Figure 10.1 may be calculated given P_{in} and P_{out} (the inlet and outlet pressures); P_c; L_{in} and L_{out} (the inertances due to fluid mass); and R_{in} and R_{out} (the resistances due to viscous drag)

$$L_{in}\frac{df_{in}}{dt} + R_{in}f_{in} = P_{in} - P_c$$
$$L_{out}\frac{df_{out}}{dt} + R_{out}f_{out} = P_c - P_{out} \tag{10.3}$$

where f_{in} and f_{out} are the flows into and out of the segment. Volume can now be calculated from the difference between the inlet and outlet flows:

$$\frac{dV_c}{dt} = f_{in} - f_{out} \tag{10.4}$$

P_c, V_c, f_{in}, and f_{out} can now be uniquely determined at any time given P_{in}, P_{out}, and the initial conditions of the segment. Determination of the parameters L and R are more problematic. They can be derived analytically, although probably because the modeling assumptions are not completely correct, an empirical fit generally produces better segmental properties.

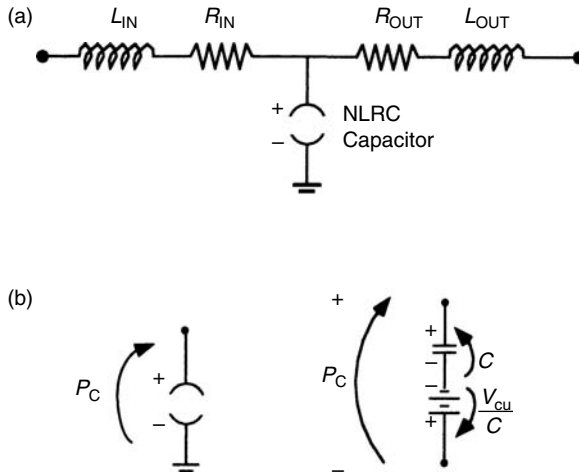
The simplified segmental structure can be represented as an RLC circuit as shown in Figure 10.3a. Tsitlik et al. [1992] remind us that each capacitor should contain a residual charge to simulate the respective


FIGURE 10.3 (a) The idealized segment of artery from Figure 10.1 as an RLC circuit. (b) The nonlinear residual charge capacitor in (a). (After Tsitlik J.E. et al. 1992. *Ann. Biomed. Eng.* 20: 595.)

segment's unstressed volume (V_{cu}). This can be achieved most easily by inserting a battery between a standard capacitor and ground (Figure 10.3b) [Tsitlik et al., 1992]. Or, if the unstressed volume for the segment remains constant (say, because the pharmacologic drug of interest has little effect on it), then the unstressed volume (and the battery) can be eliminated by subtracting it from the total vascular blood volume. The segment will then contain the stressed volume only ($V_c - V_{cu}$), so that an ordinary capacitor will suffice (again assuming operation near point A on the $P-V$ curve).

10.3.2 An Idealized Segment of Vein

In most of the venous circulation, the pressure inside the vessels is greater than the external pressure, so that the pressure-flow relationship is like that in the arteries. However, in the vena cava, in certain organs such as the lungs and during certain procedures such as resuscitation or measurement of blood pressure using a cuff, venous collapse may occur [Fung, 1984]. Thus, in contrast to an artery in which only one condition normally exists, two additional conditions must be considered for a vein.

The first condition occurs when the inlet and outlet transmural pressures are positive. [Transmural pressure is defined as the pressure gradient across the vessel wall ($P_{inside} - P_{outside}$).] In this instance, the vein can be treated as discussed above for an artery. A second condition occurs when the inlet and outlet transmural pressures are negative. In this instance, the vein will collapse, and flow will stop or be greatly reduced.

The third condition occurs when the inlet transmural pressure is positive and the outlet transmural pressure is negative. In this instance, blood flows into the chamber but not out because the outlet will be collapsed. As blood flows in, the pressure inside rises until it exceeds the external pressure, forcing the outlet open and allowing blood to flow out. But, as blood flows out, the internal pressure decreases, so that the outlet transmural pressure may become negative again, collapsing the outlet, and commencing the next cycle. This cycling is called flutter, and the collapsing at the outlet, choking. Besides flutter, a limited steady-state flow is also possible if the outlet is not completely choked off [Fung, 1984]. Limited flow is the predominant (and likely the only) effect occurring under physiologic conditions [Noordergraaf, 1978].

Purmutt et al. [1962] described this effect as a vascular waterfall. Water flowing over a falls depend only on conditions at the top, not on the length of the drop. In 1994 Holt used the term flow regulator for this effect in his seminal work on the collapsible penrose tube, and Conrad in 1969 called it a negative impedance conduit [Noordergraaf, 1978]. Starling in 1915 also made use of this concept when he used a collapsible tube, now known as a Starling resistor, to control peripheral resistance in his heart–lung
FIGURE 10.4   (a) A segmented, arbitrary length of vessel. (b) The equivalent RLC circuit.

preparations. Once flutter was found to be absent in the human physiology, Brower in 1970, Brower and Noordergraaf in 1973, and Griffiths in 1975 developed simplified equations of the pressure–flow relationship [Noordergraaf, 1978]. Snyder and Rideout [1969] also developed a model of collapsible vein. They employed a two-line approximation of the $P–V$ curve — one for the uncollapsed region and one for the collapsed region. Then, based on modifications of the Navier–Stokes equations for an elliptical tube (the cross-sectional shape of a collapsing vessel), and assuming a flat flow profile, they were able to relate flow to pressure and volume in terms of nonlinear inertances, resistances, and compliances in Equation 10.2 and Equation 10.3. They also included the effects of gravity and external pressures in the model.

10.3.3 Arterial and Venous Trees

By using the output of one segment as the input to a second, and the output of the second as the input to a third, and so on, differential equations for arbitrary lengths of vessel can be constructed (Figure 10.4a). This method also allows bifurcations to be added. Another approach can be used to derive these same equations. First, partial differential equations are formulated to define flow along the desired length of vessel. The spacial differentials are then changed to finite differences, leaving only time derivatives [Noordergraaf, 1978].

Similar to an arterial section, the resulting lumped model of the vascular tree can be represented as an electrical circuit if desired (Figure 10.4b), and nearby resistors and inductances can be combined to form Γ, T, or PI sections. A similar approach can be used for the venous circulation. To prevent ringing and other problems due to sudden impedance changes, it is often useful to add intermediate segments to taper the impedances between the heart and the capillaries [Rideout, 1991]. That is, the impedances of the large arteries should be tapered to match the higher resistive impedances of the arterioles and capillary beds and then reduced back again from the capillary beds to the large veins.

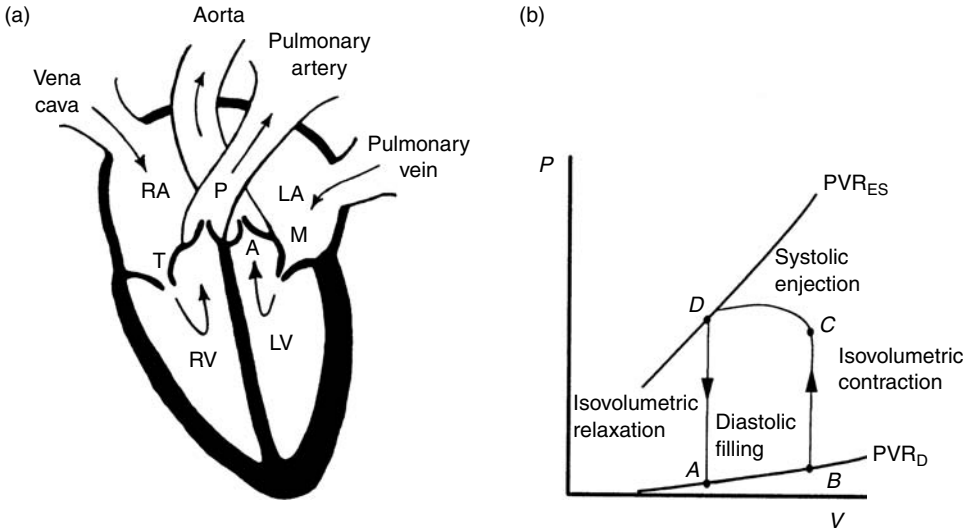
Arterial and venous branching can be roughly grouped by vessel size (large, medium, and small arteries, arterioles, capillaries, etc.) or by organ system (heart, head, legs, liver, fat, skin, muscle, etc.). Vessel grouping is useful when the model needs to track drug concentrations at whole-body effector sites, such as nitroprusside concentration in the systemic arteriolar and venous compartments. Organ grouping is useful when the model needs to track drug concentrations in certain organs, such as insulin in the liver,


FIGURE 10.5 (a) The chambers and valves of the heart. LV, left ventricle; RV, right ventricle; LA, left atrium; RA, right atrium; M, mitral valve; A, aortic valve; T, tricuspid valve; P, pulmonary valve. (b) The left ventricular cardiac cycle in the P–V plane. See text.

glucose in the pancreas, or antineoplastic agents in diseased tissues. Note that within each organ, the flows can be broken down further by vessel size or by regional or conceptual intraorgan blood flows. Once the desired organs and vessels are described, Westkessel-type impedances can be used for the rest of the vasculature.

10.3.4 Models of the Heart

The heart is a muscular pump with four chambers intimately linked into one organ (Figure 10.5a). Nevertheless, in modeling the heart, each chamber is usually modeled independently of the others. Each is typically set up as an elastic compartment with inertance and resistance similar to an artery or vein (see above). The differences are (1) that valves are included to constrain flow to one direction, and (2) that elastance (the inverse of compliance) is treated as a time-varying parameter.

The valves are straightforward and are often implemented as ideal diodes (for electrical circuit models) or as IF-THEN-ELSE statements (for algorithmic models) to keep all flows nonnegative. Defects in the valves can be added to simulate heart defects (e.g., leaky diodes for regurgitation). Other types of heart defects are just as easily simulated. For example, Blackstone et al. [1976] placed an impedance between the atrial chambers to simulate a septal opening.

Mathematical representation of the time-varying elastance is more complicated and is generally based on the characterization of the cardiac work cycle in the pressure-volume plane. In the P–V diagram in Figure 10.5b, the time course of the left ventricular cardiac cycle proceeds as follows.

During diastolic filling (A to B), ventricular pressure is below atrial and aortic pressures, so the mitral valve (between the left atrium and the left ventricle) is open, and the aortic valve (between the left ventricle and the aorta) is closed. Blood therefore flows from the atrium into the ventricle, based on the pressure gradient and the inertances and resistances of the inlet. Note that the pressure gradient will decrease as the ventricle fills due to the passive compliance of the chamber and the drop in pressure in the atrium.

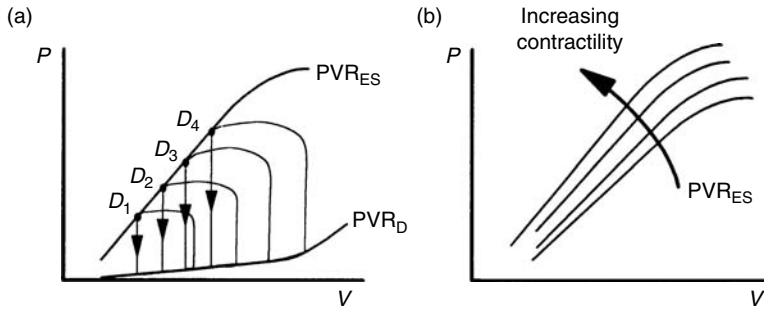
After diastole, the ventricle is stimulated to contract so that pressure rises above the atrial pressure, closing the mitral valve. In this state, pressure is too low for the aortic valve to open, so that both valves are closed and no blood flow occurs. Meanwhile, the ventricle continues to contract, raising ventricular


FIGURE 10.6 (a) Heart cycles with varying preload and afterload. (b) The end-systolic $P-V$ curve with increasing contractility of the heart.

pressure. This period (B to C) is termed isovolumetric contraction. Here, the muscle contraction can be thought of as decreasing the compliance of the chamber.

Once ventricular pressure exceeds the pressure in the aorta, the aortic valve opens and systolic ejection commences (C to D). Blood flows out from the ventricle into the aorta based on the pressure gradient, the inertances, and the resistances of the outlet. The muscle continues to contract until the cardiac action potentials have run their course.

As the muscle begins to relax, pressure will drop until it falls below the aortic pressure. At this time, the aortic valve closes, and again blood flow ceases. Meanwhile, the ventricle continues to relax, decreasing the ventricular pressure. This period (D to A) is termed isovolumetric relaxation. Here, muscle relaxation can be thought of as increasing the compliance of the chamber. Finally, ventricular pressure falls below atrial pressure, the mitral valve opens, and the cycle begins anew.

Suga and Sagawa [1972, 1974] identified and characterized several key properties of the time-varying compliance in the pressure-volume plane. In their experiments, they varied preload, afterload, stroke volume, cardiac contractility, and heart rate for both ejecting beats (heart valves patent) and isovolumic beats (heart valves sewn shut). Four observations should be noted. First, the $P-V$ point at the end of systole (Figure 10.6a, points D_1-D_4) nearly always lies along the static $P-V$ curve for activated myocardium. Second, the end systolic $P-V$ curve is unaffected by changes in preload and afterload (Figure 10.6a); however, it is affected by changes in cardiac contractility (Figure 10.6b). Third, t_{max}, the time to end systole (point D), is also unaffected by changes in preload and afterload; however, it is affected by changes in cardiac contractility and heart rate. And fourth, the ventricular filling phase allows the static $P-V$ curve for relaxed myocardium, as expected. There are some deviations from these observations, but over normal ranges these behaviors are fairly reliable [Sunagawa and Sagawa, 1982; Maughan et al., 1984].

Based on these observations, a continuum of static $P-V$ relationships can be visualized as spanning the space between the fully relaxed and the fully contracted curves, say, as a linear combination of the two. The active curve at any time could then be construed as a function of the activity level of the myocardium, α, which itself could be a function of time and t_{max}, and which would range from zero (inactive) to one (fully active):

$$\text{PVR}(\alpha(t, t_{max})) = \alpha(t, t_{max}) \cdot \text{PVR}_{ES} + (1 - \alpha(t, t_{max})) \cdot \text{PVR}_{D} \qquad (10.5)$$

Here, PVR (pressure–volume relationship) is the active $P-V$ curve, and PVR_{ES} and PVR_{D} are the end systolic and diastolic $P-V$ curves, respectively. Using this approach, the PVR_{ES} curve would be parameterized in terms of the inotropic state of the myocardium, and t_{max} would be a function of inotropic state and heart rate.

Suga and Sagawa [1972] originally approximated the two curves, PVR_{ES} and PVR_{D}, with two straight lines that intersected in a common point on the volume axis (V_d, the unstressed, or dead, volume). This was a reasonable approximation, since, in their original experiments, the nonlinear portions of the $P-V$ curves were not encountered. Based on this approach, the elastance E as a function of time becomes

greatly simplified:

$$E(t) = \frac{P(t)}{V(t) - V_d} \tag{10.6}$$

With this formulation, $\alpha(t, t_{max})$ maps to $E(t)$ by the relation

$$E(t) = \alpha(t, t_{max}) \cdot E_{max} + (1 - \alpha(t, t_{max})) \cdot E_{min} \tag{10.7}$$

where E_{min} and E_{max} are the minimum and maximum elastances. E_{max} sets the inotropic state, and E_{min} sets the diastolic filling curve. A later modification allowed each curve to have its own dead volume [Sunagawa and Sagawa, 1982].

A common definition of $\alpha(t, t_{max})$ is a squared sine wave, time scaled and shifted to fit its first half-period into the systolic time interval, and zeroed elsewhere, for example, see Martin et al. [1986]. Another common definition uses the first half-period of a sine wave, time-scaled and shifted to fit into the systolic interval. It is sometimes clipped and sometimes modified with a second harmonic to skew the waveform, for example, see Rideout [1991]. Still others have approximated $\alpha(t, t_{max})$ as a square wave [Warner, 1959], a triangle wave [McLeod, 1966; Katona et al., 1967], a sum of charging and discharging exponentials [Sun and Chiaramida, 1992], and even as a sum of gaussian (bell-shaped) exponentials [Chung et al., 1994].

Pulsations can likewise be added to the other heart chambers, although the shape of the elastance curves are somewhat different [Sunagawa and Sagawa, 1982]. In the left ventricle, $E(t)$ appears more like a skewed sine wave while $V_d(t)$ is fairly constant during ejection; in the right ventricle, $E(t)$ appears more like a squared sine wave with a larger E_{max}, while $V_d(t)$ varies continuously throughout the systolic period; in the right atrium, $E(t)$ and $V_d(t)$ behave as in the right ventricle. A common simplification of this relationship was employed by Leaning et al. [1983]. They used the same function for each chamber's elastance (in this case a sine wave), but with a different E_{min}, E_{max}, and t_{max} for each, as well as a different time shift to contract them when appropriate, for example, the atria prior to the ventricles. As is common, they also made V_d constant, though each chamber was provided with a different value.

Since the activation function is typically time-scaled to fit within the heart period, the effect of a changing heart rate, say, due to neural reflexes, can be explored. However, this requires that the heart period itself be partitioned into diastolic and systolic intervals. Various partitioning schemes exist. For the left ventricle, some fix the duration of systole [Grodins, 1959] or set it to a percentage of the heart period, with diastole taking up the rest of the period [Rideout, 1991]. A general clinic rule allocates one-third to systole and two-thirds to diastole. However, Beneken and DeWit [1967], after summarizing several publications, suggest that ventricular systole is better approximated by one-fifth the heart period plus 0.16 sec. Likewise, they determined the duration of atrial systole as 9/100 the heart period plus 0.1 sec. These formulae have gained considerable popularity, for example, see Leaning et al. [1983] and Rideout [1991].

In many drug-delivery applications, the time constants of interest are on the order of minutes to hours. In these situations, a pulsatile heart is not needed and can be traded advantageously for a mean flow model. Mean flow models are based either on the Frank–Starling law of the heart or on the pulsatile model above. In the Frank–Starling approach, a family of flow curves is constructed based on experimental observations of the heart under various conditions of preload and afterload (Figure 10.7) [Sagawa, 1967]. These are then used to calculate stroke volume for each beat. In the other approach, the stroke volume is derived analytically from the equations of the pulsatile heart [Rideout, 1991]. When using the Frank-Starling law, attenuation factors are used to impose the effects of inotropic state and heart rate. Examples of nonpulsatile heat models include those by Sagawa [1967], Greenway [1982], Möller et al. [1983], and Tham et al. [1990]. The Guyton–Coleman model [Guyton et al., 1972, 1980] is also nonpulsatile heart, though it uses a very different approach (see below).

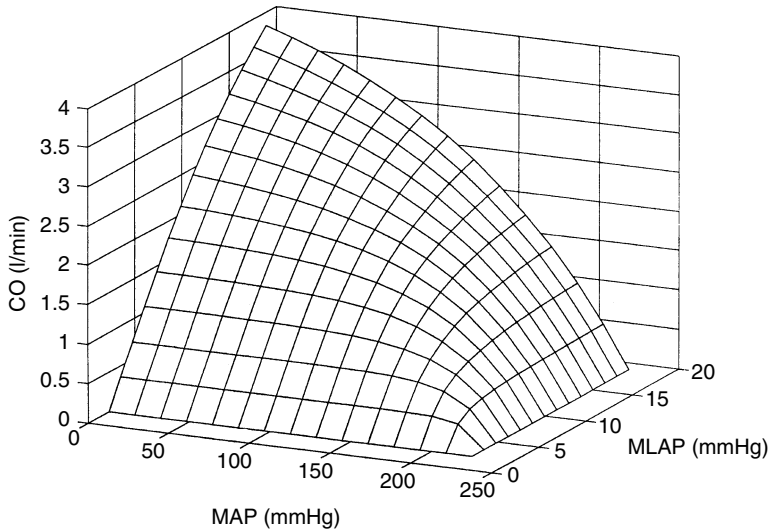
Some models of the uptake and distribution of slow-acting drugs do not explicitly use a heart, or, for that matter, a circulation. These fall under the category of purely compartmental models. In these


FIGURE 10.7   The Frank-Starling law of the heart; 3-D of Sagawa's [1967] left-ventricle equation for a 10-kg dog; CO, cardiac output; MAP, mean arterial pressure; MLAP, mean left arterial pressure.

models, the heart and circulation are subsumed into an assumption that each compartment in the model is uniformly mixed (see Chapter 9).

10.3.5 Models of Combined Heart and Circulation

Whole-body CV models couple a model of the heart to models of the vasculature. The complexity of the coupling depends on the particular need and can give rise to nonpulsatile left side (*left side* meaning the systemic circulation) only, nonpulsatile left and right side (*right side* meaning the pulmonary circulation), and pulsatile left and right side models [Rideout, 1991].

Left-side-only models are justified when the pharmaceutical agents of interest have little effect on the pulmonary circulation. In these cases, the right side is considered a follower circuit and hence can be eliminated to provide computational savings. Even if the agents of interest to affect the pulmonary circulation, an occamistic left-side-only model may still suffice. This approach may work for two reasons: either the model order is high enough that the right-side effects are inadvertently captured in the left-side model, or the drug effects are essentially the same on both sides. Keep in mind that these models have limited scope and hence should be used with care.

As an example of the modeling considerations for drug delivery, consider the following two drugs: propranolol, a beta blocker; and sodium nitroprusside (SNP), a vasodilator. Propranolol has a time constant on the order of 33 min, primarily affects the heart, and has only minor effects on the pulmonary circulation (although it may constrict the airways) [Ewy and Bressler, 1992; Gilman et al., 1993]. Hence, for propranolol, a nonpulsatile left-side-only model should be adequate for controller design. SNP, however, has a transport delay of 0.5 min and a time constant between 0.25 and 0.50 min. It affects the arterioles, the venous unstressed volume, and venous compliance. It also significantly decreases pulmonary wedge pressure [Ewy and Bressler, 1992; Gilman et al., 1993; Greenway, 1982]. Hence, for SNP, a nonpulsatile model is questionable, though it may be adequate. Furthermore, a two-sided model should be used, since SNP may have a significant effect on the pulmonary circulation. Greenway's [1982] two-sided nonpulsatile model seems to function adequately, although other investigators have switched to two-sided pulsatile models, for example, see Yu et al., 1990.

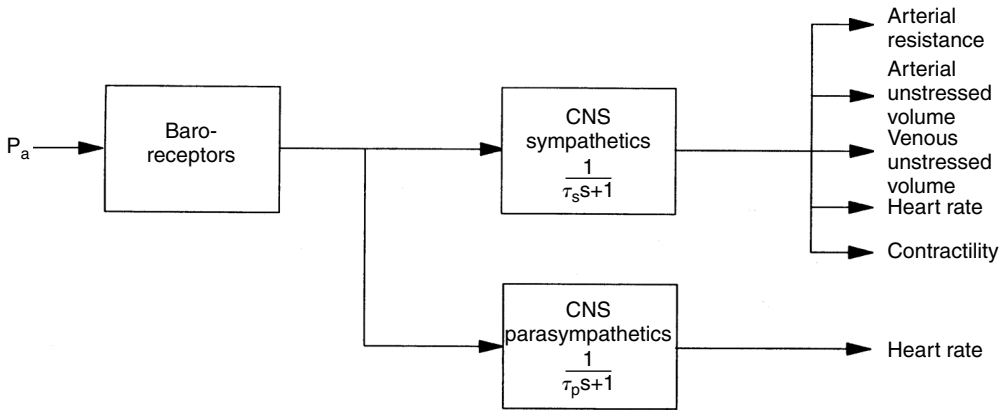
Interestingly, Martin et al. [1986] may have finessed the field of nonpulsatile models by overcoming the speed limitations associated with pulsatile models. They did this by solving the pulsatile model equations


FIGURE 10.8   Baroreceptor firing rate is passed through a low-pass filter representing the CNS and then mapped back to changes in heart rate, contractility, vascular resistances, and vascular unstressed volumes.

semi-analytically, and were thus able to significantly reduce simulation time. Their model currently makes an attractive choice for studying and designing automated drug-delivery systems.

Despite the emphasis here on nonlinear CV-based modeling, probably the most used model for the design of blood pressure controllers is the model by Slate and Sheppard [1982]. It is based on a linear, first-order impulse response of the effects of nitroprusside on mean arterial blood pressure. The model includes a recirculation effect, as well as an occasionally observed nonlinear reflex (possibly due to the chemoreceptors). It has gained wide acceptance probably because of its simplicity. Nevertheless, it has severe limitations: it lumps the effects of the primary neural and humoral reflexes as well as the patient drug sensitivity into one gain; it does not account for the effect of changing cardiac output on drug transport; and it is not easily extended to include additional drugs or disease states.

10.3.6   Neural and Humoral Control

Once the heart and vasculature are linked, neural and hormonal controls need to be added. These include the baroreflex, the chemoreflex, the renin-angiotensin reflex, capillary fluid shift, autoregulation, stress relaxation, and renal–body-fluid balance (water intake and urine output).

Baroreceptors monitor the pressure in the carotid sinuses, the aortic arch, and other large systemic arteries and increase their firing rate when the pressure increases. Their response is nonlinear and depends on whether they are exposed to mean pressure only, pulsatile pressure only, or a combination of both. Katona et al. [1967] developed a model of baroreceptor feedback that has become the basis for many CV neural control models. The output of the baroreceptor model is often passed through a low pass filter representing the CNS and then mapped back to changes in heart rate, contractility, vascular resistances, and vascular unstressed volumes through the sympathetic and parasympathetic nervous systems (Figure 10.8), for example, see Yu et al. [1990].

In addition to baroreceptors, chemoreceptors may also mediate a strong CV response, especially when systemic arterial pressure falls below 80 mmHg [Guyton et al., 1972; see also Dampney, 1994]. This reflex, through the CNS, increases cardiac activity and peripheral resistance. Strangely, few models include this effect, although Slate and Sheppard [1982] may have inadvertently included it in their simplified black box model.

The renin-angiotensin reflex is mediated hormonally through the kidneys. When pressure falls below normal, renin is secreted into the blood stream by the kidneys, which then causes the release of free angiotensin. Angiotensin causes marked vasoconstriction and thus increases peripheral resistance and arterial pressure. This reflex is often included in models because it plays an important role in many forms of hypertension and heart failure.

The other CV control reflexes are only sometimes included, although these and others are elucidated and modeled by Guyton et al. [1972, 1980]. In his elaborate model, there are five main empirically derived physiologic function blocks with many subcomponents. The model has nearly 400 parameters and is quite remarkable in its scope. Given current computer technology, however, it is somewhat cumbersome for drug delivery applications, although it promises to have great utility in the future.

10.3.7 Combined CV and Pharmacologic Models

For pharmacologic control studies, CV models readily lend themselves to the calculation of drug uptake and distribution to the various parts of the body (pharmacokinetics). Once the transport model has been built, models of drug action (pharmacodynamics) then need to be linked and related back to the CV model. Other models must also be linked if necessary. For example, models of inhalational anesthetic uptake, distribution, and effect on the respiratory and CV systems require not only a CV and pharmacologic model but also a lung model. Combined models such as these are known as multiple models, a term coined by Rideout's group [Beneken and Rideout, 1968; Rideout, 1991]. Again, the time course of the agents and their effects on the heart and circulation determine whether a pulsatile or nonpulsatile model is needed, as well as the requisite level of vascular detail.

To calculate drug uptake and transport, mass balance equations can be set up for each segment and compartment in the CV model. Additional compartments, such as a tissue or an effects compartment, can also be added (see Chapter 9). For example, given a particular compartment (or segment), the mass of drug in the compartment is calculated as follows:

$$\frac{\mathrm{d}q_i}{\mathrm{d}t} = f_{in,i}c_{i-1} - f_{\mathrm{out},i}c_i \tag{10.8}$$

where i identifies the compartment, q is the mass of drug, c is its concentration, f_{in} is the rate of blood flow into the compartment (normally equal to the flow out of the previous compartment), and f_{out} is the rate of blood flow out of the compartment. The instantaneous concentration in any compartment can then be calculated based on drug mass and total volume of the compartment (stressed plus unstressed volumes);

$$c_i = \frac{q_i}{V_i} \tag{10.9}$$

Once the concentration is known at the effector site, a pharmacodynamic model is used to describe its action. Saturation may need to be built into the effect, as well as a possible threshold concentration. Hill's sigmoidal equation can accommodate both:

$$\mathrm{EFF} = \frac{c_e^n}{c_{50}^n + c_e^n} \tag{10.10}$$

where EFF is the normalized pharmacologic effect ($0 \leq \mathrm{EFF} \leq 1$), c_e is the concentration at the effector site, c_{50} is the half-matrix concentration, and n parameterizes the steepness of the sigmoid. Hill's equation becomes the Michaelis–Menten equation when $n = 1$.

Once calculated, the drug effect can be used to modify the parameters in the CV model, much like the neural and humoral reflexes. Resistances, compliances (including the unstressed volumes) of each segment, neural and humoral feedback gains, heart rate, and contractility are all typically modified by drugs. For example, sodium nitroprusside causes vasodilation and blood pooling; therefore it would be made to primarily increase the compliance and unstressed volume of the veins, as well as to decrease arteriolar (peripheral) resistance [Greenway, 1982; Yu et al., 1990].

10.3.8   Modeling Applications

Stand-alone CV models and their development have been somewhat disconnected from other modeling applications, in particular artificial cardiovascular assist devices. Models of ventricular assist devices (VADs), total artificial hearts (TAHs), and other blood pumping devices such as cardio pulmonary bypass (CPB) pumps usually concentrate on describing the behavior and performance of the device itself. Computer modeling packages exist for designing rotary pumps as well as for testing their hydraulic performance using computational fluid dynamics (CFD). Additional computer modeling software is available for designing automatic control strategies. With the advent of increased computer processing power, the next modeling step is to integrate all these components into a comprehensive desktop patient where cardiovascular pathologies could be simulated along with the mechanical assist device, its control architecture, and its behavior with changing vascular dynamics and pharmacological effects.

Currently, modeling techniques are being used in academia, medical research, and industry. Some of their uses include describing the behavior and predicting the performance of VADs and TAHs along with their respective control strategies [Fu, 1997; Veres, 1997; Xu, 1997; Golding, 1998; Zhou, 1999; Vitale, 2001; Casas, 2004], description of not only systemic dynamics but also pulmonary venous function [Thomas, 1997], understanding of the mechanical interdependences of cardiac muscle and their implications in cardiac pathologies and treatments [McCulloch, 2001; Guccione, 2003], modeling of blood pressure and regulation of heart rate [Zhang, 2001], and effects of pharmacological treatments in cardiovascular pathologies [Popovic, 2004].

An example of simulation techniques used in the development of VADs and TAHs is presented in [Vitale, 2001] where a comprehensive dynamic model of the Cleveland Clinic Foundation — Foster Miller Technologies MagScrew blood pump was used to find the maximum device efficiency by optimizing the magnetic pitch of the noncontacting magnetic thread of the driver system. This model and corresponding numerical simulation incorporated and considered blood pump operating conditions and physiological factors such as inlet and outlet pressures and device beat rate, magnetic field strength of MagScrew and motor magnets at different dimensions, mechanical factors such as plunger motion, friction within the actuation mechanism, and electrical factors such as actuator motor bridge path resistances and supply voltages.

Results from this modeling effort not only provided information on peak efficiency operating conditions but also provided insight into other device parameters such as motor current and MagScrew forces, among others important variables, keys to the design process, and understanding of experimental tests results.

10.4   Conclusions

For designing controllers to automate cardiovascular therapeutics, the nonlinear, cardiovascular-linked pharmacologic models are well worth the added effort and time needed to construct and interface them to the design platform. Not only can they help prove initial feasibility, but they can also speed up the overall design process. For example, they can be used for interactive controller design; they can be used to design improved animal and human experiments, which can potentially reduce the total number of experiments; and they can be used to simulate human conditions that are not easily produced in animals.

The reduced compartmental and combined segmental and transmission line models are probably the most practical model form at this time given current computer technology. However, as computer technology grows, we can expect to see increasingly detailed pharmacologic models that include additional cardiovascular features such as pulse wave propagation and reflection as well as multiple short- and long-term neurohumoral feedback loops.

Further Information

The text by Rideout [1991] has a particularly good tutorial on cardiovascular modeling and even includes ACSL source code. McDonald's [1974] and Noordergraaf's [1978] texts are classics, thoroughly reviewing cardiovascular physiology and the physical principles useful in modeling it. More recent texts on the

cardiovascular system with a bioengineering slant include those by Milnor [1989], Li [1987], and Fung [1984]. Also, Guyton's 1980 text provides a detailed review of his model and its application for the analysis of hypertension and is well worth reading. Along this same line, Safar and O'Rourke's [1993] text, as well as O'Rourke's earlier work [1982], are also worth reading and provide many insights into hypertension and cardiovascular modeling. Melchior, Srinivasan, and Charles [1992] also present an overview of cardiovascular modeling, though with an emphasis on orthostatic response.

For historical interest, The History of Cardiology by Acierno [1994] provides fascinating reading, going back beyond even the early Greeks. In more recent history, a review of early CV models (early 1900s up to 1940) can be found in Aperia's monograph (1940), and a review of the post-World War II era models (late 1950s to early 1970s) that set the tone for almost all modern CV models can be found in Sagawa [1973].

For those interested in pharmacologic modeling, along with examples using the CV system, Carson, Cobelli, and Finkelstein's 1983 text is a good source. Middleman's 1972 text specifically targets in transport in the CV system, but it is somewhat dated. The current understanding of the anatomic and functional organization of the neurohumoral regulation pathways can be found in Dampney [1994].

For a survey of blood pressure controllers, the reader is referred to the recent article by Isaka and Sebald [1993]. Linkens and Hacisalihzade [1990], Katona [1988], and Westenskow [1986] also survey blood pressure controllers as well as other CV control applications. Further examples of modeling applications incorporating assist devices could be found in ASAIO [2004], Kosaka [2004], and Reesink [2004].

Respiratory Models and Control

Chi-Sang Poon
Massachusetts Institute of Technology

The respiratory system is a complex neurodynamical system. It exhibits many interesting characteristics that are akin to other physiologic control systems. However, the respiratory system is much more amenable to modeling analysis than many other systems for two reasons. First, the respiratory system is dedicated to a highly specific physiologic function, namely, the exchange of O_2 and CO_2 through the motor act of breathing. This physiologic function is readily distinguishable from extraneous disturbances arising from behavioral and other functions of the respiratory muscles. Second, the respiratory control system is structurally well organized, with well-defined afferent and efferent neural pathways, peripheral controlled processes, and a central controller. The functional and structural specificity of the respiratory system — and the diverse neurodynamic behaviors it represents — make it an ideal model system to illustrate the basic principles of physiologic control systems in general.

Like any closed-loop system, the behavior of the respiratory control system is defined by the continual interaction of the controller and the peripheral processes being controlled. The latter include the respiratory mechanical system and the pulmonary gas exchange process. These peripheral processes have been extensively studied, and their quantitative relationships have been described in detail in previous reviews. Less well understood is the behavior of the respiratory controller and the way in which it processes afferent inputs. A confounding factor is that the controller may manifest itself in many different ways, depending on the modeling and experimental approaches being taken. Traditionally, the respiratory control system has been modeled as a closed-loop *feedback/feedforward regulator* whereby homeostasis of arterial blood gas and pH is maintained. Alternatively, the respiratory controller may be viewed as a

central pattern generator in which rhythmic respiratory activity is produced in response to phasic afferent feedback. Finally, there is increasing evidence that the respiratory controller may function as an *adaptive self-tuning regulator* which optimizes breathing pattern and ventilation according to certain performance measure.

Each modeling approach reveals a separate "law" of a multifaceted controller. However, these control laws must be somehow related to one another because they are governed by the same neural network that forms the respiratory controller. It is therefore instructive to examine not only how the various models work but also how they might be fit together to encompass the myriad of response behaviors of the respiratory control system.

11.1 Structure of the Respiratory Control System

The respiratory control system is a nonlinear, multioutput, delayed-feedback dynamic system which is constantly being perturbed by unknown physiologic and pathologic disturbances (Figure 11.1). Rhythmic respiratory activity is produced by a respiratory central pattern generator (RCPG) which consists of a network of neuronal clusters in the medulla oblongata and pons areas of the brain stem. The RCPG forms the kernel of the respiratory controller. The control problem is defined by the characteristics of the controlled processes (plants) and the control objective.

11.1.1 Chemical Plant

11.1.1.1 Pulmonary Gas Exchange

The chemical plant is propelled by the ventilation of the lung, $\dot{V}_E$ which determines the alveolar PCO_2 and PO_2 according to the following mass-balance equations:

$$V_L CO_2 \cdot \frac{d}{dt} P_A CO_2 = \dot{V}_E \left(1 - \frac{V_D}{V_T}\right)(P_l CO_2 - P_A CO_2) + 863 \dot{V} CO_2 \tag{11.1}$$

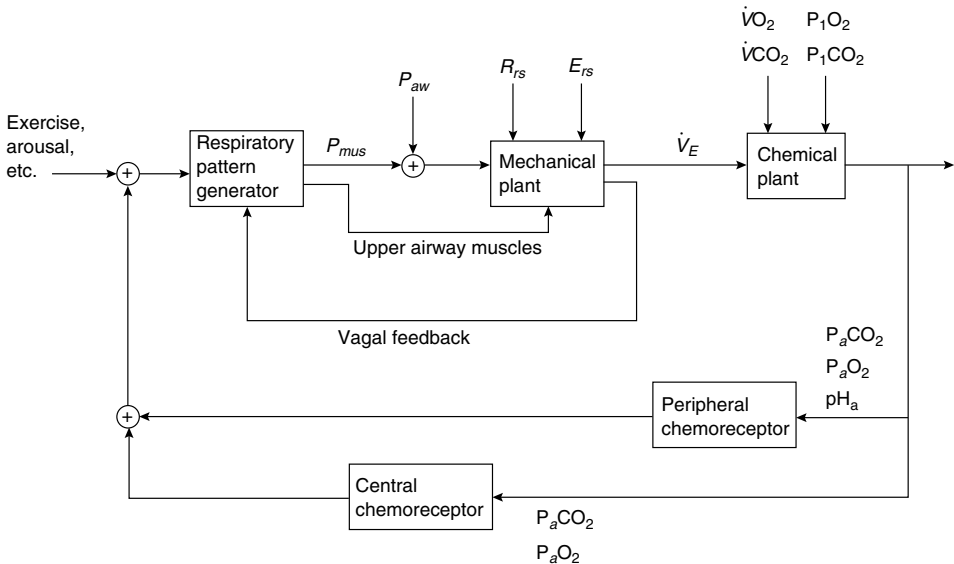
$$V_L O_2 \cdot \frac{d}{dt} P_A O_2 = \dot{V}_E \left(1 - \frac{V_D}{V_T}\right)(P_l O_2 - P_A O_2) - 863 \dot{V} O_2 \tag{11.2}$$


FIGURE 11.1   Block diagram of the respiratory control system.

The input–output relationships of the chemical plants are subject to several endogenous and exogenous disturbances. For example, increases in the metabolic production of CO_2 during muscular exercise, PCO_2 in the inspired air, and respiratory dead space during rebreathing — all contribute to an increase in CO_2 load to the lung. The added CO_2 is eliminated by an increase in pulmonary ventilation, but the effectiveness of the control action in restoring P_ACO_2 varies considerably with the type of disturbance. The input–output sensitivity $S_{pco_2} \neq \delta P_ACO_2/\delta \dot{V}_E$ of the plant is highest with metabolic CO_2 load and lowest with inhaled CO_2 load, whereas the plant dynamics is slowest with dead space load.

In pulmonary disease the efficiency of the plant in removing CO_2 is further decreased because of pulmonary ventilation/perfusion maldistribution [Poon, 1987a]. Another source of disturbance is metabolic acidosis and alkalosis which alter arterial blood gas tensions and pH through acid–base buffering in blood. All these disturbances interact nonlinearly with the plant and are not directly sensed. How does the controller cope with such variety of disturbances effectively if its only means is to alter $\dot{V}_E$? Not surprisingly, the controller responds quite differently to the various forms of CO_2 disturbance and their combinations [Oren et al., 1981; Juratsch et al., 1982; Poon and Greene, 1985; Poon, 1989a, b, 1992b; Sidney and Poon, 1995].

11.1.1.2 Chemosensory Feedback

The peripheral (arterial) chemoreceptors response to changes in P_aCO_2 may be modeled by linear first-order dynamics [Bellville et al., 1979]

$$\tau_p \cdot \frac{d}{dt}A_p = -A_p + G_p[P_aCO_2(t - T_p) - I_p] \tag{11.3}$$

where τ_p, G_p, I_p, are the time constant, gain, threshold of the peripheral chemoreceptor, and T_p is the lung-to-chemoreceptor transit delay of blood flow. Similarly, the central (intracranial) chemoreceptor is responsive to brain tissue PCO_2

$$A_c = G_c\{P_bCO_2 - I_c\} \tag{11.4}$$

where the brain tissue PCO_2 is given by

$$V_bCO_2 \cdot \frac{d}{dt}P_bCO_2 = \dot{Q}_b\{P_aCO_2(t - T_c) - P_bCO_2\} + \frac{\dot{M}_bCO_2}{KCO_2} \tag{11.5}$$

and the cerebral blood flow [Vis and Folgering, 1980] is given by

$$\dot{Q}_b(t) = \dot{Q}_0 + \Delta\dot{Q}_b(t) \tag{11.6}$$

$$\tau_b \cdot \frac{d}{dt}\Delta\dot{Q}_b = -\Delta\dot{Q}b + G_b \cdot P_aCO_2(t - T_c) \tag{11.7}$$

The central chemoreceptor normally has a greater sensitivity than the peripheral chemoreceptors (which may be silenced by hyperoxia). Their combined effects are presumably additive at low to moderate stimulation levels [Heeringa et al., 1979] but may become progressively saturated at higher levels [Eldridge et al., 1981]. The peripheral chemoreceptors have a shorter response time constant and delay than the central chemoreceptor, presumably due to their proximity to the lung and arterial blood gases. They are generally thought to be more responsive to rapid changes in blood chemistry; although the central chemoreceptor may also contribute substantially to the transient respiratory response to breath-to-breath fluctuations in chemical input during eupneic breathing in wakefulness [Bruce et al., 1992].

The dynamic response of the peripheral chemoreceptors to P_aO_2 may be modeled in a similar fashion but the steady-state response is hyperbolic [Cunningham et al., 1986]. Furthermore, hypoxia and hypercapnia have a multiplicative effect on carotid chemoreceptor discharge [Fitzgerald and Lahiri, 1986],

although the effect of changes in pH is presumably additive [Cunningham et al., 1986]. Prolonged hyp-oxia has a depressant effect on central respiratory neurons [Neubauer et al., 1990] which may offset the stimulatory effect of peripheral chemosensitivity.

Inputs from the peripheral chemoreceptors are temporally gated throughout the respiratory cycle. Stimuli are effective only if they are delivered during the second half of the inspiratory or expiratory cycle [Hildebrandt, 1977; Teppema et al., 1985; Eldridge and Millhorn, 1986]. The effect of such stimuli on medullary respiratory neurons is excitatory during the inspiratory phase and inhibitory during the expiratory phase [Lipski and Voss, 1990]. The gating effect may be modeled by a gated time function

$$A_{epg} = \text{gate}\{A_p(t)\} \tag{11.8}$$

where gate $\{\cdot\}$ is a windowing function which reflects the phasic activity of peripheral chemoreceptor inputs.

The intrinsic transient delay and nonlinearity in the transduction of chemical signals are undesirable from an automatic control perspective. On the other hand, they may represent neural preprocessing in the sensory nervous system. Such transformations in the feedback path may have important bearing on the controller's ability to achieve the control objective.

11.1.2 Mechanical Plant

11.1.2.1 Respiratory Mechanics

Pulmonary ventilation results from tidal expansion and relaxation of the lung. The equation of motion is:

$$R_{rs} \cdot \frac{dV}{dt} = -E_{rs} \cdot V + P_{aw}(t) - P_{mus}(t) \tag{11.9}$$

Both R_{rs} and E_{rs} may be nonlinear. The mechanical load of the respiratory muscles is increased by airway constriction or lung restriction in pulmonary disease, or by the imposition of external resistance and elastance which cause a back pressure P_{aw} at the airway opening. Increases in ventilatory load may elicit a compensatory response in P_{mus} so that $\dot{V}_E$ is largely restored [Poon, 1987b, 1989a, b] except under severe ventilatory loading. Reverse compensatory responses are observed during ventilatory unloading [Ward et al., 1982; Poon et al., 1987a, b].

11.1.2.2 Respiratory Muscles

The mechanical plant is propelled by the respiratory muscles which serve as a mechanical pump. Normally, P_{mus} is sustained by the inspiratory muscles (principally the diaphragm and, to a lesser extent, the external intercostal and parasternal muscles). During hyperpnea or with increased expiratory load the expiratory muscles may be recruited [Marroquin, 1991], as are accessory muscles which may contribute significantly to the generation of P_{mus} in paraplegics.

Paradoxically, the respiratory muscles may also act to reduce ventilation. During quiet breathing some postinspiratory inspiratory activity may persist during the early expiratory phase, retarding lung emptying [Poon et al., 1987b]. In disease states inspiratory activity may also be recruited during the expiratory phase to prevent lung collapse [Stark et al., 1987] or overinflation. The upper airways abductor muscles may be activated by the controller or higher brain centers to increase R_{rs} in disease states [Stark et al., 1987] or in sleep [Phillipson and Bowes, 1986]. In awake states, respiration may be interrupted by behavioral, emotional, or defensive activities which compete for the respiratory apparatus under cortical or somatic sensory commands.

The mechanical efficiency of the respiratory muscles is limited by the force-velocity and force-length relationships which may be modeled as linear "active" resistance and elastance, respectively [Milic-Emili and Zin, 1986]. Neuromechanical efficiency may be impaired in respiratory muscle fatigue or muscle weakness, resulting in diminished P_{mus} for any given neural drive.

Thus the respiratory pump is equipped with various types of actuators to regulate V_F in the face of many exogenous and endogenous mechanical disturbances. Such disturbances are detected by mechanoafferents originating in the lungs, thorax, and airways.

11.1.2.3 Mechanosensory Feedback

Among the various types of mechanoafferents, vagal slowly adapting pulmonary stretch receptors (SAR) input exerts the greatest influence on respiration by inhibiting inspiratory activity and facilitating expiratory activity (Hering-Breurer reflex). Vagal SAR volume feedback is crucial for the compensatory response of the RCPG to mechanical disturbances.

The SAR characteristic is liner at low lung volumes but may exhibit saturation nonlinearity at elevated volumes. Also, at any given lung volume SAR discharge increases with increasing rate of lung inflation [Pack et al., 1986]. To a first approximation vagal volume feedback may be modeled by

$$\text{vag}(t) = \text{sat}\{a_0 + a_1 V(t) + a_2 \dot{V}(t)\} \tag{11.10}$$

where $\text{sat}\{\cdot\}$ is a saturation function; a_0 denotes tonic vagal activity [Phillipson, 1974]; and a_1, a_2 are sensitivity parameters.

11.1.3 Control Object

It is generally assumed that the prime function of respiration is to meet the metabolic demand by the exchange of O_2 and CO_2. The control problem is to accomplish this objective within some prescribed tolerance, subject to the physical as well as environmental constraints of the respiratory apparatus. Various models of the controller have been proposed as possible solutions to the control problem [Petersen, 1981], each representing a separate control strategy and degree of modeling abstraction. In what follows we provide a synopsis of the various modeling approaches and their physiologic significance.

11.2 Chemoreflex Models

The simplest controller model is a proportional controller [Grodins and Yamashiro, 1978; Cunningham et al., 1986]. In this approach attention is focused on the control of the chemical plant; the RCPG and the mechanical plant are lumped together to form a constant-gain controller. The control signal is taken to be $\dot{V}_E$, and the effects of the breathing pattern and vagal feedback are often neglected. Thus the controller is assumed to be a fixed relay station that regulates $\dot{V}_E$ via the chemoreflex loop. These simplification allow quantitative closed-loop analyses of the chemoreflex system.

11.2.1 Feedback Control

In the chemoreflex model the respiratory control system acts like a chemostat. This is consistent with the well-known experimental observation that ventilation increases with increasing chemical stimulation. The steady-state ventilatory response to CO_2 inhalation is given by:

$$\dot{V}_E = \alpha(P_a CO_2 - \beta) \tag{11.11}$$

This empirical relationship is in agreement with the chemoreflex model which assumes that ventilatory output is proportional to the sum of chemosensory feedback:

$$\dot{V}_E = G_0(A_c + A_p) \tag{11.12}$$

Equation 11.11 follows from the steady-state solutions to the model Equation 11.3 to Equation 11.7 and Equation 11.12, provided that the effect of changes in cerebral blood flow may be neglected. The effects of hypoxia and hypoxic–hypercapnic interaction may be modeled in a similar fashion by a hyperbolic relation [Cunningham et al., 1986].

A comprehensive model of the dynamical chemoreflex system is due to the classic work of Grodins and coworkers [1967]. The dynamical response to CO_2 is given by the transient solutions of the system equations. Equation 11.3 to Equation 11.7 and Equation 11.12. Under closed-loop conditions system dynamics is also influenced by the nonlinear dynamical response of the chemical plant, Equation 11.1, as well as CO_2 uptake in body tissues. Therefore, measurement of the CO_2 response curve, Equation 11.8, is often a slow and tedious procedure. Open-loop conditions may be achieved by dynamic forcing of end-tidal PCO_2 with servo-control of P_tCO_2 which obviates the nonlinearity and slow equilibration of the lung and other body tissue stores. This technique has been used to experimentally estimate the model parameters in normal and peripheral-chemoreceptor denervated subjects by means of system identification techniques [Bellville et al., 1979]. Another open-loop technique is the CO_2 rebreathing procedure [Read, 1967] which causes a metabolically induced ramp increase in P_aCO_2 and, hence, a similar increase in $\dot{V}_F$ by way of chemoreflex. The rebreathing technique is much simpler to use than dynamic end-tidal PCO_2 forcing and is therefore suitable for clinical applications. However, this technique may not accurately determine the steady-state CO_2 response, presumably because of the variability in cerebral blood flow induced by changing P_aCO_2. More reliable techniques using pulse-step [Poon and Olson, 1985] or step-ramp [Dahan, 1990] P_tCO_2 forcings have been proposed for rapid determination of the steady-state CO_2 response with minimal experimental requirements.

Stability of the chemoreflex model may be studied by linearization of the system about some nominal state. Instability may occur if the loop gain and phase shift exceed unity and 180°, respectively. This may explain the periodic breathing phenomena found in hypoxia or high altitude where peripheral chemoreceptor gain is increased and congestive heart failure in which transit delay is prolonged [Khoo et al., 1982]. However, chemical instability alone does not account for the periodic episodes in obstructive sleep apnea which may also be influenced by fluctuation in arousal state [Khoo et al., 1991]. A technique for estimation of chemoreflex loop gain using pseudorandom binary CO_2 forcing has been proposed [Ghazanshahi and Khoo, 1997].

11.2.2 Feedforward Control

The chemoreflex model provides a satisfactory explanation for the chemical regulation of ventilation as well as respiratory instability. However, it fails to explain a fundamental aspect of ventilatory control experienced by everyone in everyday life: the increase in ventilation during muscular exercise. Typically, $\dot{V}_E$ increases in direct proportion to the metabolic demand ($\dot{V}CO_2$, $\dot{V}O_2$) such that the outputs of the chemical plant, Equation 11.1 and Equation 11.2, are well regulated at constant levels from rest to exercise. As a result, homeostasis of arterial blood chemistry is closely maintained over a wide range of work rates. The dilemma is: if increases in metabolic rate are not accompanied by corresponding increases in chemical feedback, then what causes exercise hyperpnea?

One possible explanation of exercise hyperpnea is the so-called set-point hypothesis [Defares, 1964; Oren et al., 1981] which stipulates that P_aCO_2 and P_aO_2 are regulated at constant levels by the chemoreflex controller. However, a set point is not evident during hypercapnic and hypoxic challenges where the homeostasis of P_aCO_2 and P_aO_2 is readily abolished. Furthermore, to establish a set point the controller gain must be exceedingly high, but this is not found experimentally in the hypercapnic and hypoxic ventilatory sensitivities. Finally, from a control systems perspective a high gain controller is undesirable because it could drive the system into saturation or instability.

Another possible explanation of exercise hyperpnea is that the proportional controller may be driven by two sets of inputs: a chemical feedback component via the chemoreflex loop and a feedforward component induced by some exercise stimulus [Grodins and Yamashiro, 1978]. The "feedforward–feedback control" hypothesis offers a simple remedy of the chemoreflex model, but its validity can be verified only if the

postulated "exercise stimulus" is identified. Unfortunately, although many such signals have been proposed as possible candidates [Wasserman et al., 1986], none of them has so far been unequivocally shown to represent a sufficient stimulus for exercise.

Among the variously proposed mechanisms of exercise hyperpnea, the "PCO_2 oscillation" hypothesis of Yamamoto [1962] has received widespread attention. According to this hypothesis, the controller may be responsive not only to the mean value of chemical feedback but also to its oscillatory waveform which is induced by the tidal rhythm of respiration. This hypothesis is supported by the experimental finding that alterations of the temporal relationship of the P_ACO_2 waveform could profoundly modulate the exercise hyperpnea response [Poon, 1992b].

Regardless of the origin (or even existence) of the exercise stimulus, there is evidence that exercise and chemical signals are processed by the controller in a multiplicative fashion [Poon and Greene, 1985; Poon, 1989a, b]. The input–output relationship of the controller may therefore be written as

$$\dot{V}_E = G_0(A_c + A_p)A_{ex} + G_{ex}A_{ex} \tag{11.13}$$

Note that $\dot{V}_E$ vanishes when A_{ex} is reduced to zero, in agreement with the finding of Phillipson and colleagues [1981].

11.3 Models of Respiratory Central Pattern Generator

Although the chemoreflex model is useful in studying the closed-loop control of ventilation and the chemical plant, it is lacking as to the control of breathing pattern and the mechanical plant. Models of the RCPG are often studied under open-loop conditions with chemical feedbacks being held constant while vagal volume feedback is experimentally manipulated. Modeling and analysis of the RCPG in closed-loop form are difficult because the input-output relationships of the RCPG and the mechanism of pattern generation are poorly understood. Several modeling approaches have been used to characterize its behavior under specific conditions.

11.3.1 Phase-Switching Models

The breathing cycle consists of two distinct phases: inspiration and expiration. It is therefore natural to model each phase separately and then combine them with a model of phase switching (for review, see Younes and Remmers [1981]). Each phase is controlled by a separate "center" which generates ramp-like central inspiratory and expiratory activity, respectively. The resulting lung expansion and collapse are sensed by SAR, which causes the RCPG to switch from inspiration phase to expiration phase, or vice versa, when the volume–time relationship reaches some inspiratory or expiratory off-switch threshold. The off-switch mechanisms are dependent on both the threshold values and the corresponding volume-time histories. Also, inspiratory and expiratory off-switches may be mechanically linked, as suggested by the correlation between inspiratory and expiratory durations in consecutive breaths. Both the rate of rise of inspiratory activity and the inspiratory off-switch threshold increase with increasing chemical stimulation. Throughout the inspiratory phase, vagal volume feedback exerts graded and reversible inhibition on inspiratory activity until immediately before the inspiratory off-switch where inspiratory termination becomes irreversible [Younes et al., 1978]. Perturbations of the mechanical plant, such as increases in ventilatory load, alter respiratory rhythm by changing the volume–time profiles and off-switch thresholds (Figure 11.2). These effects are abolished by vagotomy such that the RCPG always oscillates with a fixed rhythm. Various neuronal models of phase switching have been proposed [Cohen and Feldman, 1977], and putative phase-switching neurons in the medulla have been identified [Oku et al., 1992].

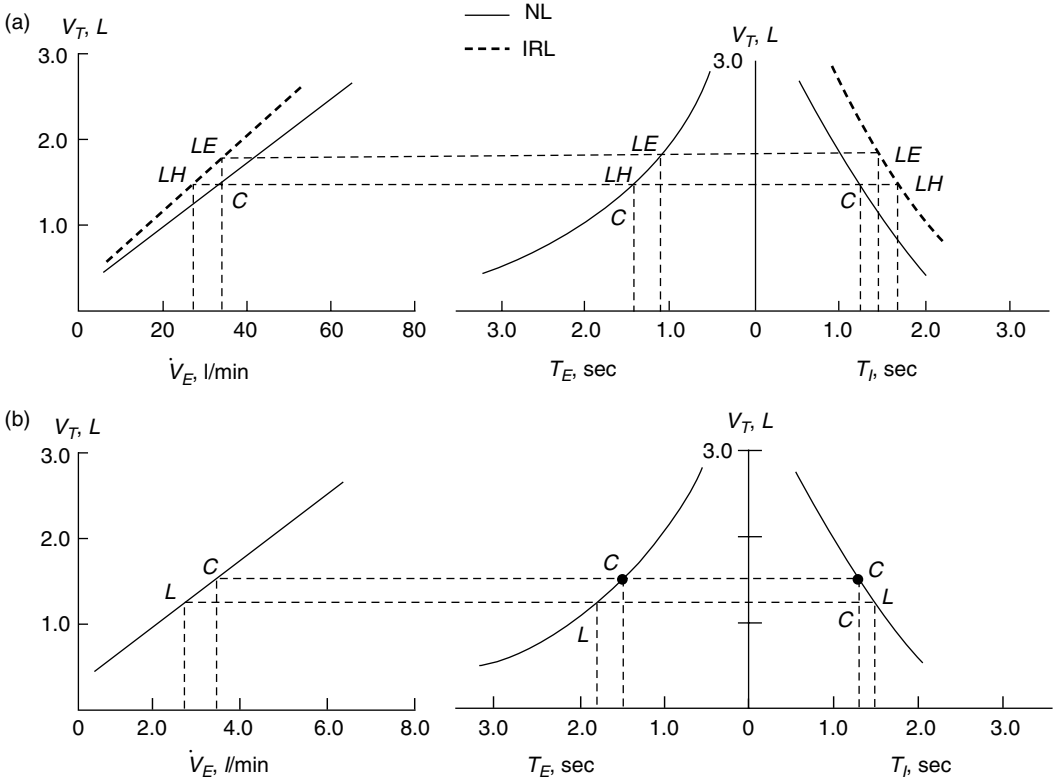
The two-phase respiratory cycle may be expanded into three phases if the expiratory phase is subdivided into an early postinspiratory inspiratory phase (stage I) and a late expiration phase (stage II). Vagal feedback has differential effects on neural activities during the two stages of expiration [St. John and Zhou, 1990].


FIGURE 11.2 Stylized diagrams illustrating the Hey plots (*left*) and respiratory phase-switching curves (*right*) for subjects breathing normally (NL) or (a) under an inspiratory resistive load (IRL), (b) under an inspiratory elastic load (IEL) at rest or during exercise. In (a), IRL causes the normal operating point (C) to move to a new point *LE* if the inspirate is free of CO_2, or to a point *LH* if CO_2 is added. In (b), IEL moves the operating point to the same point *L* whether CO_2 is present in the inspirate. Thus, the consequence of load compensation is highly dependent on the background CO_2 and the type of load. Relative scales only are shown on all axes. (From Poon, C.-S. 1989a. *J. Appl. Physiol.* 66:2400; Poon, C.-S. 1989b. *J. Appl. Physiol.* 66:2391. With permission.)

An important link between RCPG and chemoreflex models is the Hey plot [Hey et al., 1966] which suggests that $\dot{V}_E$ and V_T are linearly related except when V_T approaches vital capacity. The slope of the Hey plot is altered by resistive loads but not elastic loads to ventilation (Figure 11.2).

11.3.2 Neural Network Models

Respiratory rhythmicity is an emergent property of the RCPG resulting from mutual inhibition of inspiratory and expiratory related neurons. A minimal model due to Duffin [1991] postulated the early-burst inspiratory (*I*) neurons and Bötzinger complex expiratory (*E*) neurons to be the mutually inhibiting pair. Adaptation of the *I* neurons (e.g., by calcium-activated potassium conductance) results in sustained relaxation oscillation in the network under constant chemical excitation. Both neuron groups are assumed to have monosynaptic inhibitory projections to bulbospinal inspiratory (I_R) output neurons (Figure 11.3). The model equations are:

$$
T_t \frac{\mathrm{d}x_t}{\mathrm{d}t} - x_i = R_i - E_i + \sum C_n y_n
$$

$$
T_f \frac{\mathrm{d}x_f}{\mathrm{d}t} + x_f = R_f + C_f x_1
$$

(11.14)
FIGURE 11.3 A minimal neural network model of RCPG. I and E denote respectively the early-burst inspiratory neurons and Bötzinger complex expiratory neurons; F is a fictive adaptation neuron; S is an excitation neuron or pacemaker cell. Not shown is the bulbospinal output neuron (I_g). Numbers denote connection strengths. (From Masakazu and coworkers [1998]. With permission.)

where $y_i \equiv g(x_i - H_i)$; $g(X) \equiv \max(0, X)$; T_i, R_i, E_i, H_i are respectively the membrane time constant, resting activity, excitation, and threshold of the ith neuron; C_{ij} is the connection strength between the ith and jth neurons; and x_1, x_2, x_3, x_f correspond respectively to the activities of the I, E, I_R neurons and a fictive (F) neuron which represents the adaptation effect.

The two-phase Duffin model may be extended to a three-phase pattern by incorporating other respiratory-related neurons. Richter and coworkers [Richter et al., 1986; Ogilvie et al., 1992] have proposed a three-phase RCPG model with mutual inhibition between I neurons and postinspiratory, late-inspiratory, and E neurons, all with adaptations. Botros and Bruce [1990] have described several variants of the Richter model with varying connectivity patterns, with and without adaptation.

Balis and coworkers [1994] proposed a RCPG model comprised of distributed populations of spiking neurons which are described by the Hodgkin–Huxley equations. Based on extensive spike-train analysis of neural recordings *in vivo*, the network connectivity differs from the Richter model in several essential ways. The model has been shown to mimic the normal and abnormal respiratory neural waveforms including the inspiratory ramp, inspiratory and expiratory off-switches, as well as apnea and apneusis. Rybak and colleagues [1997a, b] proposed a similar RCPG model that is modulated by both the membrane properties of the unit neuron and afferent feedback of the respiratory system.

11.3.3 Pacemaker and Hybrid Models

Respiratory rhythm may also originate from endogenous pacemaker cells. In neonatal rats, certain conditional bursting pacemaker neurons have recently been identified in a region of the ventrolateral medulla referred to as the pre-Botzinger complex [Smith et al., 1991]. Network oscillation by mutual inhibition is difficult in neonates because of immaturity of the GABAergic inhibitory system. During the postnatal developmental stage there may be progressive transformation from pacemaker to network oscillation with possibly some form of hybrid operation in the transition period [Smith, 1994]. A hybrid RCPG model composed of a neural network oscillator driven by a pacemaker cell (Figure 11.3) has been proposed [Matsugu et al., 1998].

11.3.3.1 Nonlinear Dynamics

An empirical (black-box) approach to studying rhythmic behavior is to model the oscillation as limit cycles of a nonlinear oscillator. A classic example of limit-cycle oscillation is the Van der Pol oscillator:

$$\ddot{V} = \epsilon \left\{ 1 - \left(\frac{V}{a} \right)^2 \right\} V - V \tag{11.15}$$

where ϵ and a are shape and amplitude parameters, respectively. This model has been shown to mimic the phase resetting and phase singularity properties of the RCPG [Eldridge et al., 1989] which are typical

of any oscillator with isolated limit cycles. Similar properties are exhibited by a network oscillator model of RCPG [Ogilvie et al., 1992] which produces similar limit cycles.

Another property of nonlinear oscillators is that they may be entrained by (or phase-locked to) other oscillators that are coupled to them. The respiratory rhythm has been shown to be entrained by a variety of oscillatory inputs including locomotion, mechanical ventilation, blood gas oscillation, and musical rhythm.

A third property of nonlinear oscillators is that the limit-cycle trajectory may bifurcate and become quasiperiodic or chaotic when the system is perturbed by nonlinear feedback or other oscillatory sources. The resting respiratory rhythm is highly rhythmic in vagotomized animals but may become chaotic in normal humans [Donaldson, 1992] and vagi-intact animals [Sammon and Bruce, 1991] especially when lung volume is reduced [Sammon et al., 1993]. Both entrainment quasiperiodic and chaotic regimes have been demonstrated in a network oscillator model of the RCPG that is driven by periodic inputs [Matsugu et al., 1998]. The significance of nonlinear variations in respiratory pattern is discussed in a recent review [Bruce, 1996].

11.4   Optimization Models

All control systems are meant to accomplish certain (implicit or explicit) control objectives, it is perhaps too simplistic to assume that the sole objective of respiration is to meet the metabolic demand; a complex physiologic system may subserve multiple objectives that are vital to animal survival. One approach to understanding respiratory control is therefore to discover the innate control objective that fits the observed behavior of the controller.

11.4.1   Optimization of Breathing Pattern

Any given level of ventilation may be produced by a variety of breathing patterns ranging from deep-and-slow to shallow-and-rapid breathing. How is the breathing pattern set for each ventilatory level? Rohrer [1925] was among the first to recognize that respiratory frequency at rest may be chosen by the controller to minimize the work rate of breathing, a notion that was subsequently advanced by Otis and colleagues [1950]. Mead [1960] showed that the resting frequency may be determined more closely on the basis of optimal inspiratory pressure–time integral, a measure of the energy cost of breathing. Neither the work nor energy measure, however, correctly predicts the inspiratory flow pattern [Bretschger, 1925; Ruttimann and Yamamoto, 1972]; such discrepancy has led to the suggestion that the optimization criterion may consist of a weighted sum of work and energy expenditures [Bates, 1986] or some higher-order terms [Yamashiro and Grodins, 1971; Hämäläinen and Sipilä, 1984].

Similarly, the optimization principle has also been applied to the prediction of airway caliber and dead space volume [Widdicombe and Nadel, 1963] as well as end-expiratory lung volume and respiratory duty cycle [Yamashiro et al., 1975]. In most cases, the cost functions are generally found to be relatively flat in the resting state but may become much steeper during CO_2 or exercise stimulations [Yamashiro et al., 1975]. This may explain the observed variability of breathing pattern which is generally more pronounced at rest than during hyperpnea or ventilatory loading.

11.4.2   Optimization of Ventilation

The classical optimization hypothesis of Rohrer [1925] and Bretschger [1925] suggests that conservation of energy may be an important factor in the genesis of breathing pattern. It thus appears that the controller is charged with two opposing objectives: to meet the metabolic demand by performing the work of breathing, and to conserve energy by minimizing the work. How does the controller reconcile such conflict? One possible solution is to establish priority. In a hierarchical model of respiratory control, metabolic needs take priority over energetic needs. At the higher hierarchy (outer/chemical feedback loop) ventilatory output is set by feedforward/feedback proportional control of the chemical plant to meet the metabolic

demand, whereas at the lower hierarchy (inner/vagal feedback loop) breathing pattern is optimized by the RCPG for efficient energy utilization by the mechanical plant at a ventilation set by the higher hierarchy.

A potential drawback of such a hierarchical system is that it is nonrobust to perturbations. Changes in ventilatory load, for example, would disrupt the ventilatory command from the feedforward signal. This is at variance with the experimental observation of a load compensation response of the controller which protects ventilation against perturbations of the mechanical plant at rest and during exercise [Poon et al., 1987a, b; Poon, 1989a, b]. Furthermore, if the prime objective of the controller were indeed to meet the metabolic demand (i.e., to maintain chemical homeostasis), then the hierarchical control system seems to perform quite poorly; it is well known that arterial chemical homeostasis is readily disrupted environmental changes.

Another form of conflict resolution is compromise. Poon [1983a, 1987] proposed that an optimal controller might counterbalance the metabolic needs versus energetic needs of the body, and the resulting compromise would determine the ventilatory response. The tug-of-war between the two conflicting control objectives may be represented by a compound optimization criterion which reflects the balance between the chemical and mechanical costs of breathing:

$$J = \begin{cases} J_c + J_m \\ \{\alpha(P_e CO_2 - \beta)\}^2 + \ln \dot{W} \end{cases} \tag{11.16}$$

The power (quadratic) form and logarithmic form for J_c and J_m correspond, respectively, to the classical Steven's law and Fechner–Weber law of sensory perception [Milsum, 1966]. Assuming that the work rate of breathing $\dot{W} \sim \dot{V}_f^2$, Equation 11.16 yields an optimal ventilatory response that conforms with the normal hypercapnic ventilatory response during CO_2 inhalation and the isocapnic ventilatory response during exercise [Poon, 1983a, 1987]. Furthermore, by generalizing Equation 11.16 to include other chemical and work rate components, it is possible to predict the normal ventilatory responses to hypoxia and acidosis [Poon, 1983a], mechanical loading [Poon, 1987b], as well as breathing pattern responses to chemical and exercise stimulation [Poon, 1983b].

The ventilatory optimization model [Poon, 1983a, b, 1987b] has several interesting implications. First, it provides a unified and coherent framework for describing the control of ventilation and control of breathing pattern with a common optimization criterion. Second, it offers a parsimonious explanation of exercise hyperpnea and ventilatory load compensation responses, without the need to invoke any putative exercise stimulus and load compensation stimulus. Third, it suggests that disruption of chemical homeostasis (e.g., during CO_2 inhalation) may represent an optimal response as much as maintenance of homeostasis during exercise.

Energetics of breathing is only one of many constraints that conflict with the metabolic cause of respiration. Another is the sensation of dyspnea which may be a limiting factor at high ventilatory levels [Oku et al., 1993]. A general optimization criterion may therefore include both energetic and dyspneic penalties as follows:

$$J = \{\alpha(P_a CO_2 - \beta)\}^2 + 2\ln \dot{V}_E + k\dot{V}_E^2 \tag{11.17}$$

where k is a weighting factor. At low to moderate ventilatory levels the energetic component (logarithmic term) dominates, and at high ventilatory levels the dyspneic component ($k \cdot \dot{V}_E^2$) dominates in counterbalancing the chemical component. In addition, the ventilatory apparatus may also be constrained by other factors such as behavioral and postural interference, which may further tip the balance of the optimization equation. It has been suggested that the periodic breathing pattern at extremely high altitudes may represent an optimal response for the conservation of chemical and mechanical costs of hypoxic ventilation [Ghazanshahi and Khoo, 1993].

11.4.3 Optimization of Neural Waveform

The neural output of the controller has been traditionally described in terms of measurable quantities such as breathing pattern and ventilation. A more accurate representation of the control signal is $P_{mus}(t)$ which drives the respiratory pump. The resulting continuous inspiratory and expiratory airflow, Equation 11.9, then determine V_E and all other ventilatory patterns. The control problem the RCPG must solve is how to optimize $P_{mus}(t)$ in order to deliver adequate ventilation without incurring excessive energy (or other) losses. It has been shown by Poon and colleagues [1992] that many interesting characteristics of the RCPG conform to a general optimal control law that calls for dynamic optimization of $P_{mus}(t)$.

The model of Poon and coworkers [1992] assumes a compound optimization criterion, Equation 11.16, with a mechanical penalty given by a weighted sum of the work rate of inspiration and expiration

$$\dot{W} = \dot{W}_t + \lambda \dot{W}_E \tag{11.18}$$

where

$$
\begin{aligned}
\dot{W} &= \frac{1}{T_T} \int_0^{T_1} \frac{P_{mus}(t)\dot{V}(t)}{[1 - P_{mus}(t)/P_{\max}]^n [1 - P_{mus}(t)/p_{\max}]^n} \, dt \\
\dot{W}_E &= \frac{1}{T_T} \int_{T_l}^{T_T} P_{mus}(t)\dot{V}(t) \, dt
\end{aligned}
\tag{11.19}
$$

The terms $P_{\max}$ and $\dot{P}_{\max}$ denote the limiting capacities of the inspiratory muscles, and n is an efficiency index. The optimal $P_{mus}(t)$ output is found by minimization of J subjects to the constraints set by the chemical and mechanical plants, Equation 11.1 and Equation 11.9. Because $P_{mus}(t)$ is generally a continuous time function with sharp phase transitions, this amounts to solving a difficult dynamic nonlinear optimal control problem with piecewise smooth trajectories. An alternative approach adopted by Poon and coworkers [1992] is to model $P_{mus}(t)$ as a biphasic function

$$
P_{mus}(t) = \begin{cases}
a_0 + a_1 t + a_2 t & 0 \le t \le T_1 \\
P_{mus}(T_1) \exp\left[-\dfrac{(t - T_1)}{\tau} \right] & T_1 \le t \le T_T
\end{cases}
\tag{11.20}
$$

where a_0, a_1, a_2, and t are shape parameters; T_1 is the duration of the inspiratory phase of neural activity. The optimal P_{mus} waveform is given by the set of optimal parameters $a_0^\star$, $a_1^\star$, $a_2^\star$, $t^\star$, $T_1^\star$, $T_T^\star$ that minimize Equation 11.16.

Poon and colleagues [1992] have shown that the dynamic optimization model predicts closely the $P_{mus}(t)$ trajectories under various conditions of ventilatory loading as well as respiratory muscle fatigue and weakness (Figure 11.4). In addition, the model also accurately predicts the ventilatory and breathing pattern responses to combinations of chemical and exercise stimulation and ventilatory loading [Poon et al., 1992], all without invocation of any putative exercise stimulus or load compensation stimulus. The generality of model predictions strongly supports the hypothesis that neural processing in the RCPG is governed by an optimization law.

11.5 Self-Tuning Regulator Models

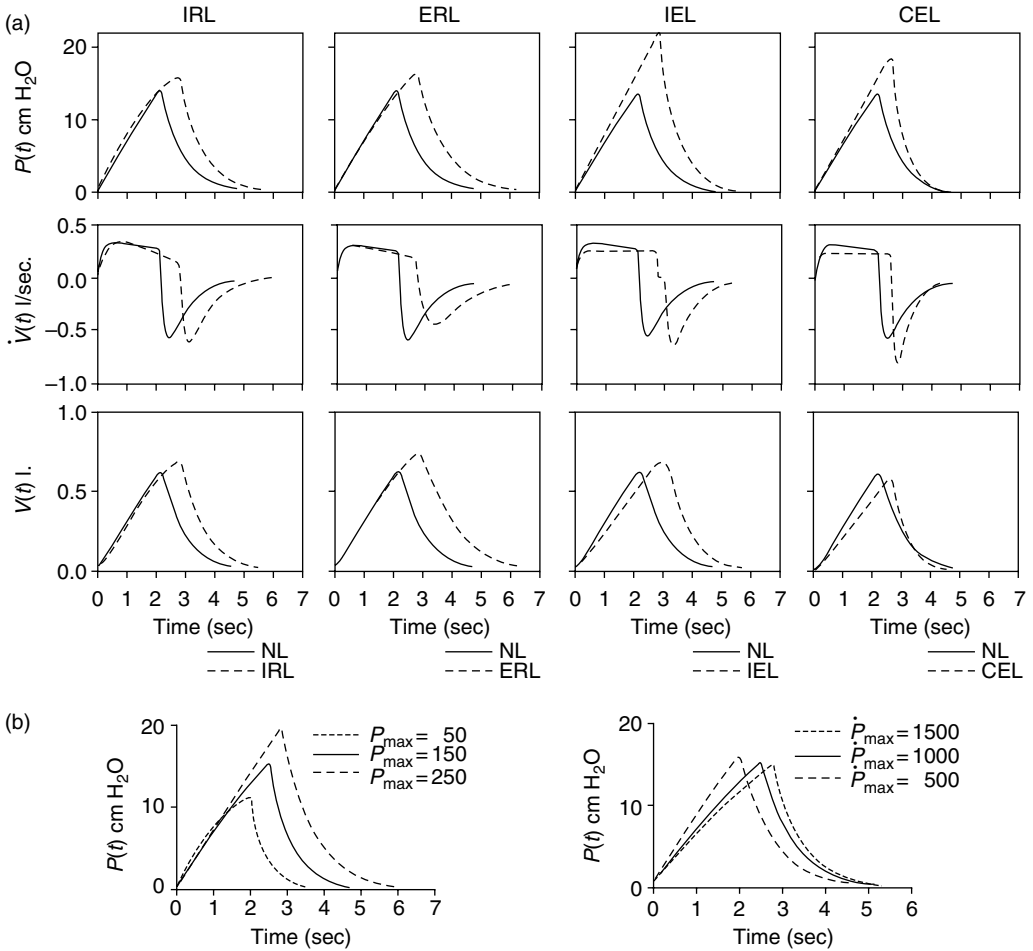
Optimization models suggest an empirical objective function that might be obeyed by the controller. They do not, however, reveal the mechanism of such neural optimization. Priban and Fincham [1965] suggested that an optimal operating for arterial pH, PCO_2, and PO_2 might be achieved by a self-adaptive controller which seeks the optimal solution by a process of hill climbing. There is increasing evidence that the respiratory system is an adaptive control system [Poon, 1992a].


FIGURE 11.4 (a) Optimal waveforms for respiratory muscle driving pressure, $P(t)$; respiratory airflow, $\dot{V}$; and respired volume, V, during normal breathing (NL) or under various types of ventilatory loads; IRL and ERL, inspiratory and expiratory resistive load; IEL and CEL, inspiratory and continuous elastic load. (b) Optimal waveforms for $P(t)$ under increasing respiratory muscle fatigue (amplitude limited; *upper* panel) and muscle weakness (rate limited; *lower* panel). (From Poon and coworkers [1992]. With permission.)

There are two basic requirements in any adaptive system. The first is that in order to adapt to changes, the system signals must be constantly fluctuating or persistently exciting. This should be readily satisfied by the respiratory system which is inherently oscillatory [Yamamoto, 1962] and chaotic [Donaldson, 1992; Sammon and Bruce, 1992]. Another requirement is that the system must be able to learn and then memorize the changes in the environment. Learning and memory in neuronal circuits are generally believed to result from synaptic modifications in the form of long-term or short-term potentiation which are mediated by NMDA receptors [Bliss and Collingridge, 1993]. Evidence for learning and memory in the RCPG is provided by the recent discoveries of both short-term potentiation [Fregosi, 1991; Wagner and Eldridge, 1991] and long-term potentiation [Martin and Mitchell, 1993] *in vivo*. Similar short and long-term memories have been identified recently in brain stem cardiorespiratory-related region *in vitro* [Zhou et al., 1997]. Also, neonatal mice which lack functional NMDA receptors have been found to suffer severe respiratory depression [Poon et al., 1994]. It has been shown that learning and memory in the brain are sufficient to achieve an optimal behavior characterized by the chemoreflex response and isocapnic exercise response [Poon, 1991].

One form of synaptic modification — correlation Hebbian learning [Sejnowski and Tesauro, 1989] — has been suggested to be compatible with the ventilatory optimization model [Poon, 1993, 1996; Young and Poon, 1998]. According to this neuronal model, variations in the chemical feedback and mechanical feedback signals converging at a Hebbian synapse in the RCPG may induce short-term potentiation if they are negatively correlated, or short-term depression if they are positively correlated. In other words, the controller gain may be adaptively increased or decreased depending on the coupling between the cause and effect of respiration. During exercise, ventilatory neural output and chemical feedback are strongly negatively correlated (since S_{pco_2} has a large negative value) so that the controller learns to increase its gain, G_0, in proportion to metabolic load. During CO_2 inhalation, $\dot{V}_E$ and P_aCO_2 are only weakly correlated (i.e., S_{pco_2} is small), and the controller gain remains unchanged. Such a neural controller is analogous to a self-tuning regulator [Åstrom and Wittenmark, 1975] which regulates the output by adaptive adjustment of system parameters.

Implicit in such a self-tuning regulator model is the assumption that afferent inputs may up- or down-regulate the RCPG by inducing synaptic potentiation or depression of neural transmission. Respiratory short- and long-term potentiation have been variously reported as indicated above. The possibility of synaptic depression was recently demonstrated in the nucleus tractus solitarius of the medulla [Zhou et al., 1997].

Similarly, it is possible that some form of synaptic learning might be at work in the RCPG to modulate pattern generation, thereby resulting in an optimal $P_{mus}(t)$. However, experimental and simulation data are presently lacking for verification of this conjecture.

11.6 Conclusion

Many empirical and functional models have been proposed to describe various aspects of the respiratory control system. The classical chemostat model is useful in describing chemoreflex responses but may be too simplistic to explain the variety of system responses to exercise input and mechanical disturbances. The recent discovery of various complex behaviors of the controller such as nonlinear dynamics, optimization, and learning suggest that the RCPG may be endowed with highly sophisticated computational characteristics. Such computational capability of the RCPG may be important for the maintenance of optimal physiologic conditions under changing environments. The computational problem — which amounts to dynamic optimal control of a nonlinear plant — is a very difficult one even by the standard of modern digital computers but seems to be solved by the RCPG from instant to instant with relative ease. This remarkable ability of the respiratory neural network is interesting from both biologic and engineering standpoints. Understanding how it works may shed light on not only the wisdom of the body [Cannon, 1932] but also on the design of novel intelligent control systems with improved speed, accuracy and economy.

Nomenclature

A_c, A_p	Activity of central, peripheral chemoreceptor
a, b	Slope and intercept of CO_2 response curve; l/min/mmHg, mmHg
J_c, J_m, J	Chemical, mechanical, and total costs of breathing
KCO_2	Solubility constant of CO_2 in blood; $mmHg^{-1}$
$MbCO_2$	Metabolic CO_2 production in brain tissues; l/min STPD
P_ACO_2, P_AO_2	Alveolar partial pressure of CO_2, O_2; mmHg
P_aCO_2, P_aO_2	Arterial partial pressure of CO_2, O_2; mmHg
P_bCO_2	Brain tissue PCO_2; mmHg
P_jCO_2, P_fO_2	Inspired partial pressure of CO_2, O_2; mmHg
P_{aw}	Airway pressure; cmH_2O
P_{mus}	Respiratory muscle driving pressure; cmH_2O

Q_b	Cerebral blood flow; l/min
RCPG	Respiratory central pattern generator
R_{rs}, E_{rs}	Total respiratory resistance, elastance; $cmH_0/l/sec$, cmH_2O/l
S_{pco_2}	Input–output sensitivity of chemical plant, $SP_ACO_2/S\dot{V}_F$ mmHg/l/min
T_j, T_F, T_T	Inspiratory, expiratory, and total respiration duration; sec
V	Lung volume above relaxation volume; l
V_bCO_2	Brain tissue store of CO_2; l
$\dot{V}CO_2, \dot{V}O_2$	Whole-body metabolic CO_2 production, O_2 consumption; l/min STPD
V_D/V_T	Ratio of respiratory dead space to tidal volume
$V_lCO_2; V_lO_2$	Lung tissue store of CO_2, O2; l
$\dot{V}_b$	Total ventilation of the lung; l/min BTPS
W	Work rate of breathing

Neural Networks for Physiological Control

James J. Abbas
Arizona State University

12.1 Introduction

This chapter is intended to provide a description of **neural network** control systems and of their potential for use in biomedical engineering control systems. Neural network techniques have been used by the engineering community in a variety of applications, with particular emphasis on solving pattern recognition and pattern classification problems [Grossberg, 1988a, b; Pao, 1988; Carpenter, 1989; Hecht-Nielsen, 1989; Sanchez-Sinencio and Lau, 1992; Zurada, 1992; Nerrand etal., 1993; Hagan et al., 1996]. More recently, there has been much research into the use of these techniques in control systems [Antsaklis, 1990; Miller et al., 1990b; White and Sofge, 1992]. Much of this research has been directed at utilizing neural network techniques to solve problems that have been inadequately solved by other control systems techniques. For example, neural networks have been used in adaptive control of nonlinear systems for which good models do not exist. The success of neural network techniques on this class of problems suggest that they may be particularly well suited for use in a wide variety of biomedical engineering applications. It should be emphasized that the field of neural network control is a relatively new area of research and that it is not intended to replace traditional engineering control. Rather, the focus has been on the integration of neural network techniques into control systems for use when traditional control systems alone are insufficient.

There are several textbooks available on neural networks that provide good presentations of the implementation and applications of neural network techniques [Simpson, 1990; Sanchez-Sinencio and Lau, 1992; Zurada, 1992; Hagan et al., 1996]. Recently, a few books have been published that review the application of neural network techniques to control systems problems [Miller et al., 1990b; White, 1992].

This chapter is intended to provide an introduction to neural network techniques and a guide to their application to biomedical control systems problems. The reader is referred to recently published textbooks and numerous journal articles for the specific information required to implement a given neural network control system.

12.2 Neural Network Basics

The term neural networks is used to refer to a class of computational algorithms that are loosely based upon the computational structure of the nervous system. There is a wide variety among various neural network algorithms, but the key features are that they have a set of inputs and a set of outputs, they utilize distributed processing, and they are adaptive. The basic idea is that computation is collectively performed by a group of distinct units, or neurons (sometimes referred to as processing elements), each of which receives inputs and performs its own local calculation. These units interact by providing inputs to each other via synapses and some units interact with the environment via input/output signals. The connectivity of various units determines the structure, or architecture, of the network. Adjustments to the strengths of the synapses (i.e., adjustments to the **synaptic weights**) modify the overall input–output properties of the network and are adjusted via a **learning algorithm**. The design of a neural network includes the specification of the neuron, the architecture, and the learning algorithm.

Most neural networks are based on a model of a neuron that captures the most basic features of real neurons: a neuron receives inputs from other neurons via synapses and the output from a neuron is a nonlinear function of a weighted summation of its inputs. There are many different sets of equations that capture these basic features; the following set of equations is commonly used:

$$y_i = \sum_{i=1}^{n} w_{ij} x_i$$

$$z_j = \frac{1}{(1 + e^{-my_j})}$$

(12.1)

where y_j is the weighted summation of inputs to neuron j, x_i is the input from neuron i, n is the number of neurons providing synaptic input to neuron j, w_{ij} is the synaptic weight from neuron i to neuron j, z_j is the output from neuron j, and m is the slope of the sigmoidal output function. Note that in this set of equations, the output of a neuron is a static nonlinear function of the weighted summation of its inputs. Some commonly used variations on this model include: the use of different nonlinear output functions [Lippman, 1987], the use of recurrent inputs (i.e., past values of a neurons output would be included in the input summation) [Pineda, 1989; Williams and Zipser, 1989], and the use of dynamic neurons (i.e., Equation 12.1 would be a differential equation rather than an algebraic one) [Hopfield, 1982; Grossberg, 1988a; Carpenter, 1989]. The use of recurrent inputs and/or dynamic neuron models may be particularly important for applications in the control of dynamic systems because they provide the individual neurons with memory and temporal dynamics [Pineda, 1989].

Most applications use networks of neurons that are arranged in layers. The most commonly used architecture is a three layer network which has an input layer, a hidden layer and an output layer. A feedforward neural network architecture is one in which each neuron receives input from neurons in the previous layer. The number of neurons in each layer must be specified by the designer. There are some heuristic rules, but no solid theory, to guide the designer in specifying the number of neurons [Zurada, 1992]. Some commonly used variations on this architecture include: the use of only a single layer of neurons [Widrow, 1962; Kohonen, 1989], the use of bidirectional connections between layers [Carpenter, 1989], the use of intra-layer connections [Kohonen, 1989], the use of pruning techniques which cut some of the connections for greater efficiency [Zurada, 1992], and the use of heterogeneous networks in which more than one neuron model is used to describe the various neurons in the network [Hecht-Nielson, 1989].

A general form of a neural network learning algorithm is given by:

$$\Delta w_{ij} = f(\eta, z_i, z_j, e_{ij})$$

This equation states that the change in synaptic weight is a function of the learning rate (η), the activation of the presynaptic neuron (z_i), the activation of the postsynaptic neuron (z_j), and a training signal (e_{ij}). Several different learning algorithms have been developed [Grossberg, 1988a; Rumelhart and McClelland, 1988; Hinton, 1989; Fogel and sebald, 1990; Hecht-Nielsen, 1990], most of which fit into this general form, but may not use all of the terms. An example is Hebbian learning [Hebb, 1949; Brown et al., 1990] in which the change in weight is proportional to the product of the presynaptic activation and the postsynaptic activation. Often, gradient descent techniques are used to adjust the synaptic weights. The most commonly used learning algorithm, error backpropagation, uses an error gradient descent technique and passes the output error backwards through the network to determine the training signal for a given neuron [Rumelhart and McClleland, 1988; Vogl et al., 1988; Pineda, 1989]. Most of the commonly used learning algorithms are classified as supervised learning techniques because they use a specification of the desired output of the network to determine the output error of the network. Other learning algorithms, such as reinforcement learning (discussed below) can be used in situations when it is not possible to directly specify the desired output of the network.

In most engineering applications, the neural network is used to perform a nonlinear mapping from the space of network inputs to the space of network outputs. In addition to the internal specifications of the network discussed above, the engineer using a neural network must select the signals to be used as input to the network and the signals to be used as output from the network. Although this decision appears to be trivial, in many applications it is not. For applications in control systems, the selection of input and output signals is dependent upon how the neural network fits into the overall structure of the system. Several different options are described below.

12.3 Neural Network Control Systems

Neural networks have often been applied in control systems where, at a block diagram level, the neural network replaces one component of the control system. Typically, the motivation for utilizing the neural network lies in the ability to perform nonlinear mappings, in the ability to handle a wide range of model structures, and/or in the ability of the network to adapt. While there has been activity in the development of a theoretical framework for neural network control systems, most applications to-date have been heuristically-based to one degree or another [Miller et al., 1990b; Nguyen and Widrow, 1990; Farotimi et al., 1991; Wang et al., 1992; White and Sofge, 1992; Quinn and Espano Chied, 1993]. The field of neural network control has been described as bridging the gap between mathematically-based control systems engineering and heuristically-based artificial intelligence [Barto, 1990].

In designing a neural network control system, one must select the overall structure of the system and decide which components will utilize neural network algorithms. Several examples of control system structures are provided below, each of which utilizes one or more neural networks as described above. This section of the chapter provides a brief overview of some neural control systems that have potential for application in biomedical control systems. For excellent, thorough reviews of recent developments in neural network control systems, the reader is referred to Miller [1990b] and White and Sofge [1992].

12.3.1 Supervised Control

In this structure (Figure 12.1), the neural network is used to mimic, and eventually replace, an existing control system. Here, the neural network is used in a traditional feedback arrangement where it performs a mapping from the system outputs to the system inputs. The network would be trained using data collected from the actual system or a computer simulated model with the original controller active. The training signal for the network would be the difference between the output of the original controller and the
FIGURE 12.1   Supervised control system structure.

output of the network. After the network learns to adequately mimic the original controller, the training is completed. Thus, the synaptic weights would no longer be adapted, and the original control system would be replaced by the neural network. This type of an arrangement could be useful in situations where the neural network could perform the task less expensively or more efficiently than the original one. One situation would be when the original control system requires such heavy computation that it is impractical for real-time use on an affordable computer system. In this case, the neural network might be able to learn to perform the same (or functionally equivalent) operation more efficiently such that implementation on an affordable general purpose computer or on specialized neural network hardware would be practical. A second situation would be when the original control system is a human operator that might be either expensive or prone to error. In this case the neural network is acting as an adaptive expert system that learns to mimic the human expert [Werbos, 1990]. A third situation would be when the neural network could learn to perform the control using a different, and more easily measured, set of output variables [Barto, 1990]. This type of application would be particularly well-suited for biomedical applications in which an invasive measurement could be replaced by a non-invasive one.

12.3.2 Direct Inverse Control

In direct inverse control, (Figure 12.2), the neural network is used to compute an inverse model of the system to be controlled [Levin et al., 1991; Nordgren and Meckl, 1993]. In classical linear control techniques, one would find a linear model of the system then analytically compute the inverse model. Using neural networks, the network is trained to perform the inverse model calculations, that is, to map system outputs to system inputs. Biomedical applications of this type of approach include the control of arm movements using electrical stimulation [Lan et al., 1994] and the adaptive control of arterial blood pressure [Chen et al., 1997].

A variety of neural network architectures can be used in this direct inverse control system structure. A multi-layer neural network architecture with error **backpropagation** learning could be used off-line to learn an inverse model using a set of system input/output data. If on-line learning is desired, a feedforward model of the system can be trained while a feedback controller is active [Miyamoto et al., 1988; Miller, 1990a]. This technique, referred to as feedback error learning [Miyamoto et al., 1988], uses the control signal coming from the feedback controller as the training signal for the feedforward controller update. The idea used here is that if the feedforward control is inadequate, the feedback controller would be active and it would lead to updates in the feedforward controller. To achieve the rapid learning rates that would be desirable in on-line feedback error learning, typically single-layer networks have been used or the learning has been constrained to occur at one layer. This type of an approach is particularly useful in applications where on-line fine tuning of feedforward controller parameters is desired.

12.3.3 Model-Based Approaches to Control

Neural network approaches have been used as an alternative to other nonlinear techniques for modeling physiological systems [Chon et al., 1998]. Several neural network control systems have utilized model-based approaches in which the neural network is used to identify a forward nonlinear system

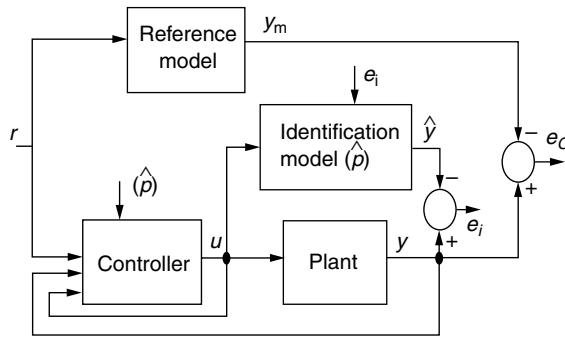
FIGURE 12.2   Direct inverse control system structure.
FIGURE 12.3   Backpropagating system output error through the system model.


FIGURE 12.4   Indirect adaptive control system structure.

model. Often, these systems utilize neural network components in control system architectures that have been developed using linear or nonlinear components.

For many control applications, system output error can be readily measured but in order to adapt the controller parameters one needs to relate system output error to controller output (system input) error. One strategy would be to use the derivative of the system's output error with respect to its input to perform gradient descent adaptation of the controller parameters. However, there is no direct way of calculating the derivative of the system's output error with respect to its input and therefore it must be approximated. To implement such an approximation, a pair of multi-layer neural networks (Figure 12.3) have been used: one for identification of a forward model of the plant, and one for implementation of the controller [Barto, 1990]. The forward model is used to provide a means of computing the derivative of the model's output with respect to its input by backpropagating the error signal (the actual plant output tracking error) through the model of the plant to estimate the error in the control signal. The error in the control signal can then be backpropagated through the controller neural network. As described here, the backpropagation algorithm is used to minimize the output error of the system, which is a special case of maximization of utility. Although this is a very powerful technique with potential applications in a wide variety of nonlinear control problems, its primary limitation for many biomedical applications is the relatively slow training rate achieved by the backpropagation algorithm.

Neural networks have also been used in model reference adaptive control (MRAC) structures (Figure 12.4) [Naranedra and Parthasarathy, 1990; Narendra, 1992]. This approach builds upon established techniques for adaptive linear control and incorporates neural networks to address the problem of controlling nonlinear systems. The MRAC approach is directed at adapting the controlled system such

that it behaves like a reference model, which is specified by the control system designer. In the structure shown in Figure 12.4, the identification model is a model of plant dynamics, the parameters of which are identified online using the identification error (the difference between the actual and the estimated plant outputs) as the training signal. The controller uses the estimates of the plant parameters, reference inputs, and system outputs to determine inputs to the system. In the neural network version of the control system structure, neural networks can be used for the identification of the system model, for the controller, or for both. Multi-layer neural networks using error backpropagation or a modified version of error back-propagation, termed dynamic backpropagation, have been used for adaptive control of nonlinear systems [Narendra and Parthasarathy, 1990; Narendra, 1992].

A third model-based approach is neural predictive control, which is a neural network version of nonlinear model predictive control [Trajanoski and Wach, 1998]. In this approach, the neural network is used for off-line identification of a system model, which is then used to design a nonlinear model predictive controller. This design may provide suitable control of nonlinear systems with time-delays and thus may be particularly useful in biomedical applications. Recent computer simulation studies have demonstrated positive results for control of insulin delivery [Trajanoski and Wach, 1998].

12.3.4 Adaptive Critics

All of the approaches to control discussed thus far have utilized supervised learning techniques. The training signal used for adaptation in these techniques is an error vector that gives the magnitude of the error in the system output signal and the direction in which it should change. For many complex, multi-variable control problems this type of system output error information is not readily available. The only measure available might be a scalar measure of system performance that is not directly related to the system outputs in a way that is understood by the control system designer. In such cases, a directed search of the control system parameter space could be performed in order to maximize (optimize) the scalar performance measure. Dynamic programming is a control systems engineering technique that has been used for optimal control of linear systems but these techniques are not well suited for large-scale systems or nonlinear systems. Neural networks have been used in an approach that is similar to dynamic programming in order to optimize system performance of large-scale nonlinear systems. These techniques, termed "adaptive critic methods," utilize a structure (Figure 12.5) in which a critic module provides an evaluation signal to the controller module. The controller module utilizes a **reinforcement learning algorithm** in order to optimize performance. The details of this class of neural network controllers are beyond the scope of this chapter, but descriptions and example applications are given in [Barto, 1990, 1992; Werbos, 1992].

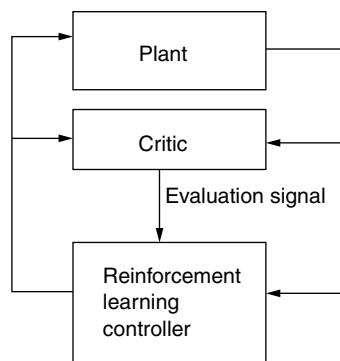
Adaptive critic algorithms may be particularly useful in several biomedical engineering control systems where the relationship between system performance and measurable system outputs are ill-defined. While


FIGURE 12.5   Adaptive critic control system structure.

these methods that use reinforcement learning may be attractive because they are general and do not require detailed information about the system, this increased generality comes at a cost of increased training times [Barto, 1990]. Supervised learning methods, when they can be used, can be more efficient than reinforcement learning methods.

12.3.5 Neurophysiologically Based Approaches

All neural network systems are based upon neurophysiological models to some degree, but in most cases this biological basis is very superficial, as is evident in the description given above. Computational neuroscience is a term used to describe the development of computational models of the nervous system [Koch and Segev, 1989; Schwartz, 1990; Bower, 1998]. Such models are intended to be used by neuroscientists in their basic science efforts to understand the functioning of the nervous system. There are several examples of neural network control system designs that have utilized models developed in the field of computational neuroscience [Bullock and Grossberg, 1988; Houk etal., 1990; Taga et al., 1991; Beer et al., 1993; Abbas, 1995]. These designs have extended the notion of "mimicking the nervous system" beyond what is used in most neural networks. The reasoning behind this approach is based upon a view that biological systems solve many problems that are similar to, or exactly the same as, those faced in many engineering applications and that by mimicking the biological system we may be able to design better engineering systems. This reasoning is similar to the motivation for much of the work in the neural network field and for the recent emphasis in biomimetic techniques in other engineering disciplines.

One approach to incorporating a stronger neurophysiological foundation has been to utilize an architecture for the overall control system that is based upon neurophysiological models, that is, mimicking the neurophysiological system at a block diagram level. This type of approach has led to the development of hierarchical control systems that are based upon the hierarchical structure of the human motor control system [Kawato et al., 1987; Srinivasan et al., 1992].

A second approach to incorporating a stronger neurophysiological foundation has been to utilize more realistic models of neurons and of their interconnections in the design of the neural network [Beer, 1990; Houk et al., 1990; Missler and Kamangar, 1995]. An example of this approach is the design of a coupled oscillator neural network circuit that is based upon the locomotor control system of the cockroach [Beer et al., 1992; Quinn and Espenschied, 1993]. In this neural network, some of the neurons are capable of endogenously oscillating due to intrinsic membrane currents and the network is heterogeneous, meaning that each neuron is not described by the same model. Most of the parameters of the models are fixed. This network has been shown to robustly generate patterns for statically-stable gaits at various speeds.

A biomedical control system that utilizes a neurophysiologically-based approach has been developed for use in Functional Neuromuscular Stimulation (FNS) systems [Abbas, 1995; Abbas and Chizeck, 1995]. FNS is a rehabilitation engineering technique that uses computer-controlled electrical stimuli to activate paralyzed muscle. The task of a control system is to determine appropriate stimulation levels to generate a given movement or posture. The neural network control system utilizes a block diagram structure that is based on hierarchical models of the locomotor control system. It also utilizes a heterogenous network of neurons, some of which are capable of endogenous oscillation. This network has been shown to provide rapid adaptation of the control system parameters [Abbas and Chizeck, 1995; Abbas and Triolo, 1997] and has been shown to exhibit modulation of reflex responses [Abbas, 1995].

12.4 Summary

This chapter presents an overview of the relatively new field of neural network control systems. A variety of techniques are described and some of the advantages and disadvantages of the various techniques are discussed. The techniques described here show great promise for use in biomedical engineering applications in which other control systems techniques are inadequate. Currently, neural network control systems lack the type of theoretical foundation upon which linear control systems are based, but recently

there have been some promising theoretical developments. In addition, there are numerous examples of successful engineering applications of neural networks to attest to the utility of these techniques.

Defining Terms

Backpropagation: A technique used to determine the training signal used for adjusting the weights of a given neuron in a neural network.

Learning algorithm: An algorithm used to update the synaptic weights in a neural network.

Neural network: A term used to refer to a broad class of computational algorithms that are loosely based on models of the nervous system.

Reinforcement learning algorithms: Learning algorithms that utilize a system performance measure (that may or may not have a direct, known relationship to output error of the neural network) as a training signal for the neural network.

Supervised learning algorithms: Learning algorithms often used in neural networks that use the output error of the neural network as a training signal.

Synaptic weight: A scaling factor on the signal from one neuron in a network to another.

Methods and Tools for Identification of Physiologic Systems

Vasilis Z. Marmarelis
University of Southern California

The problem of system identification in physiology derives its importance from the need to acquire quantitative models of physiologic function (from the subcellular to the organ system level) by use of experimental observations (data). Quantitative models can be viewed as summaries of experimental observations that allow scientific inference and organize our knowledge regarding the functional properties of physiologic systems. Selection of the proper (mathematical or computational) form of the model is based on existing knowledge of the system's functional organization. System identification is the process by which the system model is determined from data. This modeling and identification problem is rather challenging in the general use of a physiologic system, where insufficient knowledge about the internal workings of the system or its usually confounding complexity prevents the development of an explicit model. The models may assume diverse forms (requiring equally diverse approaches) depending on the specific characteristics of the physiologic system (e.g., static/dynamic, linear/nonlinear) and the prevailing experimental conditions (e.g., noise contamination of data, limitations on experimental duration). This chapter will not address the general modeling issue, but rather it will concentrate on specific methods and tools that can be employed in order to accomplish the system identification task in most cases encountered in practice. Because of space limitations, the treatment of these system identification methods will be consistent with the style of a review article providing overall perspective and guidance while deferring details to cited references.

Since the complexity of the physiologic system identification problem rivals its importance, we begin by demarcating those areas where effective methods and tools currently exist. The selection among candidate models is made on the basis of the following key functional characteristics (1) static or dynamic; (2) linear or nonlinear; (3) stationary or nonstationary; (4) deterministic or stochastic; (5) single or multiple inputs and/or outputs; (6) lumped or distributed. These classification criteria do not constitute an exhaustive list but cover most cases of current interest. Furthermore, it is critical to remember that contaminating noise (be it systemic or measurement-related) is always present in an actual study, and

experimental constraints often limit experimentation time and the type of data obtainable from the system. Finally, the computational requirements for a practicable identification method must not be extraordinary, and the obtained results (models) must be amenable to physiologic interpretation, in addition to their demonstrated predictive ability.

A critical factor in determining our approach to the system modeling and identification task is the availability and quality of prior knowledge about the system under study with respect to the mechanisms that subserve its function. It can be said in general that, if sufficient knowledge about the internal mechanisms subserving the function of a system is available, then the development of an explicit model from first (physical or chemical) principles is possible, and the system modeling and identification task is immensely simplified by reducing to an estimation problem of the unknown parameters contained in the explicit model. Although the ease of this latter task depends on the manner in which the unknown parameters enter in the aforementioned explicit model, as well as on the quality of the available data, it is typically feasible. Furthermore, the obtained model is amenable to direct and meaningful physiologic interpretation. Unfortunately, it is rare that such prior knowledge (of adequate quality and quantity) is available in systems physiology. It is far more common that only limited prior knowledge is available, relative to the customary complexity of physiologic systems, that prevents the development of an explicit model from first principles and necessitates the search for a model that is compatible with the available input–output data.

Thus, the system identification problem is typically comprised of two tasks:

1. *Model specification*: the selection or postulation of a model form suitable for the system at hand
2. *Model estimation*: the estimation of the unknown parameters or functions contained within the specified model, using experimental data

All prior knowledge about the system under study is utilized in the model specification task. This includes results from specially designed preliminary experiments, which can be used to establish, for instance, whether the system is static or dynamic, linear or nonlinear, and so on. The model estimation task, however, relies on the quality of the available data (e.g., spectral characteristics, noise conditions, data length) and may set specific data-collection requirements.

This chapter will focus on practicable methods to perform both the model specification and model estimation tasks for systems/models that are static or dynamic and linear or nonlinear. Only the stationary case will be detailed here, although the potential use of nonstationary methods will be also discussed briefly when appropriate. In all cases, the models will take deterministic form, except for the presence of additive error terms (model residuals). Note that stochastic experimental inputs (and, consequently, outputs) may still be used in connection with deterministic models. The cases of multiple inputs and/or outputs (including multidimensional inputs/outputs, e.g., spatio-temporal) as well as lumped or distributed systems, will not be addressed in the interest of brevity. It will also be assumed that the data (single input and single output) are in the form of evenly sampled time-series, and the employed models are in discrete-time form (e.g., difference equations instead of differential equations, discrete summations instead of integrals).

In pursuing the model specification task, two general approaches have developed: parametric and nonparametric. In the parametric approach, algebraic or difference equation models are typically used to represent the input–output relation for static or dynamic systems, respectively. These models are accordingly linear or nonlinear, and contain a (typically small) number of unknown parameters. The latter may be constant or time-varying depending on whether the system or model is stationary or nonstationary. The precise form of these parametric models (e.g., degree/order of equation) must be determined in order to complete the model specification task. This precise form is either postulated a priori or guided by the data (in which case it is intertwined with the model parameter estimation task) as outlined in the following section.

In the nonparametric approach, the input–output relation is represented either analytically (in convolutional form through Volterra–Wiener expansions where the unknown quantities are kernel functions),

computationally (i.e., by compiling all input–output mapping combinations to look-up tables) or graphically (in the form of operational surfaces/subspaces in phase-space). The graphical representation, of course, is subject to the three-dimensional limitation for the purpose of visual inspection. The model specification requirements for the Volterra–Wiener formulation consist of the order of system nonlinearity and system memory, and, for the computational or graphical approach, they consist of defining the appropriate phase-space mapping dimensions, as discussed below. Of the nonparametric approaches, the Volterra–Wiener (kernel) formulation has been used more extensively in a nonlinear context and will be the focus of this review, since nonlinearities are ubiquitous in physiology. Note that the nonparametric model estimation task places certain requirements on the experimental input (i.e., sufficient coverage of the frequency bandwidth and amplitude range of interest in each application) in order to secure adequate probing of the system functional characteristics.

An important hybrid approach has also developed in recent years that makes use of block-structured or modular models. These models are composed of parametric and/or nonparametric components properly connected to represent reliably the input–output relation. The model specification task for this class of models is more demanding and may utilize previous parametric and/or nonparametric modeling results. A promising variant of this approach, which derives from the general Volterra–Wiener formulation, employs principal dynamic modes as a canonical set of filters to represent a broad class of nonlinear dynamic systems. Another variant of the modular approach that has recently acquired considerable popularity but will not be covered in this review is the use of artificial neural networks to represent input–output nonlinear mappings in the form of connectionist models. These connectionist models are often fully parametrized, making this approach affine to parametric modeling, as well.

The relations among these approaches (parametric, nonparametric, and modular) are of critical practical importance and the subject of several recent studies [Marmarelis, 1994, 1997]. Considerable benefits may accrue from the combined use of these approaches in a cooperative manner that aims at securing the full gamut of distinct advantages specific to each approach.

In the following sections, an overview of these methodologies will be presented and the relative advantages and disadvantages in practical applications will be briefly outlined. The ultimate selection of a particular methodology hinges upon the specific characteristics of the application at hand and the prioritization of objectives by the individual investigator. Two general comments are in order:

1. No single methodology is globally superior to all others, that is, excelling with regard to all criteria and under all possible circumstances. Judgment must be exercised in each individual case
2. The general system identification problem is not solvable in all cases at present, and challenging problems remain for future research

13.1 Parametric Approach

Consider the input and output time-series data, $x(n)$, respectively. If the system is static and linear, then we can employ the simplest (and most widely used) model of linear regression

$$y(n) = ax(n) + b + \varepsilon(n) \tag{13.1}$$

to represent the input–output relation for every n, where $\varepsilon(n)$ represents the noise or error term (or model residual) at each n. The unknown parameters (a, b) can be easily estimated through least-squares fitting, using a well-developed set of linear regression methods (e.g., ordinary least-squares or generalized least-squares depending on whether $\varepsilon(n)$ is a white sequence).

This model can be extended to multiple inputs $\{x_1, x_2, \ldots, x_k\}$ and outputs $\{y_i\}$ as

$$y_i(n) = a_1 x_1(n) + a_2 x_2(n) + \cdots + a_k x_k(n) + b + \varepsilon(n) \tag{13.2}$$

and well-developed multiple linear regression techniques exist that can be used for estimation of the unknown parameters $(a_1, a_2, \ldots, a_k, b)$ for each output y_i. Although these estimation methods are widely known and readily available in the literature — see, for instance, Eykhoff [1974] and Soderstrom and Stoica [1989] — they will be briefly reviewed at the end of this section.

In the event of nonstationarities, the regression coefficients (model parameters) will vary through time and can be estimated either in a piecewise stationary fashion over a sliding time window (batch processing) or in a recursive fashion using an adaptive estimation formula (recursive processing). The latter has been favored and extensively studied in recent years [Ljung and Soderstrom, 1983; Goodwin and Sin, 1984; Ljung, 1987], and it is briefly outlined at the end of this section.

If the system is static and nonlinear, then a nonlinear input–output relation

$$y(n) = \sum_{j=1}^{J} c_j P_j[x(n)] + \varepsilon(n) \tag{13.3}$$

can be used as a parametric model, where the $\{P_j\}$ functions represent a set of selected nonlinear functions (e.g., powers, polynomials, sinusoids, sigmoids, exponentials or any other suitable of functions over the range of x), and $\{c_j\}$ are the unknown parameters that can be easily estimated through linear regression — provided that the $\{P_j\}$ functions do not contain other unknown parameters in a nonlinear fashion. In the latter case, nonlinear regression methods must be used (e.g., the gradient steepest-descent method) that are well developed and readily available [Eykhoff, 1974; Ljung, 1987; Soderstrom and Stoica, 1989], although their use is far from problem-free or devoid of risk of misleading results (e.g., local minima or noise effects). Naturally, the choice of the $\{P_j\}$ functions is critical in this regard and may depend on the characteristics of the system or the type of available data.

These cases of static systems have been extensively studied to date but have only limited interest or applicability to actual physiologic systems, since the latter are typically dynamic — that is, the output value at time n depends also on input and/or output values at other previous times (lags). Note that the possible dependence of the present output value on previous output values can be also expressed as a dependence on previous input values. Thus, we now turn to the all-important case of dynamic systems.

For linear (stationary) dynamic systems, the discrete-time parametric model takes the form of an *a*uto-*r*egressive *m*oving *a*verage with e*x*ogenous variable (ARMAX) equation:

$$
\begin{aligned}
y(n) = &\alpha_1 y(n-1) + \cdots + \alpha_k y(n-k) + \beta_0 x(n) + \beta_1 x(n-1) \\
&+ \cdots + \beta_1 x(n-1) + w(n) + \gamma_1 w(n-1) + \cdots + \gamma_m w(n-m)
\end{aligned}
\tag{13.4}
$$

where $w(n)$ represents a white noise sequence. This ARMAX model is a difference equation that expresses the present value of the output, $y(n)$, as a linear combination of k previous values of the output (AR part), l previous (and the present) values of the input (X part), and m previous (and the present) values of the white noise disturbance sequence (MA part) that compose the model residual (error). When $\gamma_i = 0$ for all $i = 1, \ldots, m$, the residuals form a white sequence, and the coefficients $(\alpha_1, \ldots, \alpha_k, \beta_0, \beta_1, \ldots, \beta_l)$ can be estimated through the ordinary least-squares procedure. However, if any γ_i is nonzero, then unbiased and consistent estimation requires generalized or extended least-squares procedures, similar to the one required for the multiple regression model of Equation 13.2 when $\varepsilon(n)$ is a nonwhite error sequence (reviewed at the end of the section).

Although the estimation of the ARMAX model parameters can be straightforward through multiple linear regression, the model specification task remains a challenge. The latter consists of determining the maximum lag values (k, l, m) in the difference Equation 13.4 from given input–output data, $x(n)$ and $y(n)$. A number of statistical procedures have been devised for this purpose (e.g., weighted residual variance, Akaike information criterion), all of them based on the prediction error for given model order (k, l, m) compensated properly for the remaining degrees of freedom (i.e., the total number of data minus the number of parameters). It is critical that the prediction error (typically, in mean-square sense) be

evaluated on a segment of input–output data distinct from the one used for the estimation of the model parameters. Application of these criteria is repeated successively for ascending values of the model order (k, l, m), and the model specification process is completed when an extremum (minimum or maximum, depending on the criterion) is achieved [Soderstrom and Stoica, 1989].

For nonlinear (stationary) systems, the ARMAX model can be extended to the NARMAX model (nonlinear ARMAX) that includes nonlinear expressions of the variables on the right side of Equation 13.4 [Billings and Voon, 1984]. For instances, a second-degree multinomial NARMAX model of order $(k = 2, l = 1, m = 0)$ with additive white-noise residuals takes the form

$$
\begin{aligned}
y(n) = {} & \alpha_1 y(n-1) + \alpha_2 y(n-2) + \alpha_{1,1} y^2(n-1) + \alpha_{1,2} y(n-1)y(n-2) \\
& + \alpha_{2,2} y^2(n-2) + \beta_0 x(n) + \beta_1 x(n-1) + \beta_{0,0} x^2(n) \\
& + \beta_{0,1} x(n)x(n-1) + \beta_{1,1} x^2(n-1) + \gamma_{1,0} y(n-1)x(n) \\
& + \gamma_{2,0} y(n-2)x(n) + \gamma_{1,1} y(n-1)x(n-1) \\
& + \gamma_{2,1} y(n-2)x(n-1) + w(n)
\end{aligned}
\tag{13.5}
$$

Clearly, the form of a NARMAX model may become rather unwieldy, and the model specification task (i.e., the form and degree of nonlinear terms, as well as the number of input, output, and noise lags involved in the model) is very challenging. Several approaches have been proposed for this purpose [Billings and Voon, 1984, 1986; Korenberg, 1988; Haber and Unbenhauen, 1990; Zhao and Marmarelis, 1994], and they are all rather involved computationally. However, if the structure of the NARMAX model is established, then the parameter estimation task is straightforward in a manner akin to multiple linear regression — since the unknown parameters enter linearly in the NARMAX model.

It is evident that all these multiple linear regression problems defined by Equation 13.2 to Equation 13.5 can be written in a vector form:

$$
y(n) = \phi^{\mathrm{T}}(n)\theta + \varepsilon(n)
\tag{13.6}
$$

where $\phi(n)$ represents the vector of all regression variables in each case, and θ denotes the unknown parameter vector. For a set of data points $(n = 1, \ldots, N)$, Equation 13.6 yields the matrix formulation

$$
y = \Phi\theta + \varepsilon
\tag{13.7}
$$

The ordinary least-squares (OLS) estimate of θ

$$
\hat{\theta}^{\mathrm{OLS}} = [\Phi^{\mathrm{T}}\Phi]^{-1}\Phi^{\mathrm{T}}y
\tag{13.8}
$$

yields unbiased and consistent estimates of minimum variance, if $\varepsilon(n)$ is a white sequence; otherwise, the generalized least-squares (GLS) estimator

$$
\hat{\theta}^{\mathrm{GLS}} = [\Phi^{\mathrm{T}}\Sigma^{-1}\Phi]^{-1}\Phi^{\mathrm{T}}\Sigma^{-1}y
\tag{13.9}
$$

ought to be used to achieve minimum estimation variance, where Σ denotes the covariance matrix of ε. Practical complications arise from the fact that Σ is not a priori known and, therefore, must be either postulated or estimated from the data. The latter case, which is more realistic in actual applications, leads to an iterative procedure that may not be convergent or yield satisfactory results (i.e., start with an OLS estimate of θ; obtain a first estimate of ε and Σ; evaluate a first GLS estimate of θ; obtain a second estimate of ε and Σ; and iterate until the process converges to a final GLS estimate of θ). As an alternative to this

iterative procedure, an estimate of the moving-average model of the residual term:

$$\varepsilon(n) = w(n) + \gamma_1 w(n-1) + \cdots + \gamma_m w(n-m) \tag{13.10}$$

may be obtained from initial OLS estimation, and the covariance matrix Σ may be estimated from Equation 13.10. Although this alternative approach avoids problems of convergence, it does not necessarily yield satisfactory results due to the dependence on the noise model estimation of Equation 13.10. Equivalent to this latter procedure is the residual whitening method, which amounts to prefiltering the data with the inverse of the transfer function corresponding to Equation 13.10 (prewhitening filter), prior to OLS estimation. Finally, the parameter vector may be augmented to include the coefficient $\{\gamma_i\}$ of the moving-average model of the residuals in Equation 13.10, leading to a pseudo-linear regression problem (since the estimates of $w(n)$ depend on $\hat{\theta}$) that is operationally implemented as an iterative extended least-squares (ELS) procedure [Ljung and Soderstrom, 1983; Billings and Voon, 1984, 1986; Ljung, 1987; Soderstrom and Stoica, 1989].

In the presence of nonstationarities, the parameter vector θ may vary through time, and its estimation may be performed either in a piecewise stationary manner (with segment-to-segment updates that may be obtained either recursively or through batch processing) or by introducing a specific parametrized time-varying structure for the parameters and augmenting the unknown parameter vector to include the additional parameters of the time-varying structure (e.g., a pth degree polynomial structure of time-varying model parameters will introduce p additional parameters for each time-varying term into the vector θ, that need be estimated from the data via batch processing).

Any batch processing approach folds back to the previously discussed least-squares estimation methods. However, the recursive approach requires a new methodological framework that updates continuously the parameter estimates on the basis of new data. This adaptive or recursive approach has gained increasing popularity in recent years, although certain important practical issues (e.g., speed of algorithmic convergence, effect of correlated noise) remain causes for concern in certain cases [Ljung and Soderstrom, 1983; Goodwin and Sin, 1984; Ljung, 1987]. The basic formulae for the recursive least-squares (RLS) algorithm are

$$\hat{\theta}(n) = \hat{\theta}(n-1) + \Psi(n)[y(n) - \phi^{\mathrm{T}}(n)\hat{\theta}(n-1)] \tag{13.11}$$

$$\Psi(n) = \gamma(n)P(n-1)\phi(n) \tag{13.12}$$

$$P(n) = P(n-1) - \gamma(n)P(n-1)\phi(n)\phi^{\mathrm{T}}(n)P(n-1) \tag{13.13}$$

$$\gamma(n) = [\phi^{\mathrm{T}}(n)P(n-1)\phi(n) + \alpha(n)]^{-1} \tag{13.14}$$

where the matrix $P(n)$, the vector $\Psi(n)$, and the scalar $\gamma(n)$ are updating instruments of the algorithm computed at each step n. Note that $\{\alpha(n)\}$ denotes a selected sequence of weights for the squared prediction errors in the cost function and is often taken to be unity. This recursive algorithm can be used for on-line identification of stationary or nonstationary systems. A critical issue in the nonstationary case is the speed of algorithmic convergence relative to the time-variation of the system/model parameters. Its initialization is commonly made as: $\hat{\theta}(0) = 0$ and $P(0) = c_0 I$, where c_0 is a large positive constant (to suppress the effect of initial conditions) and I is the identity matrix.

It is important to note that when output autoregressive terms exist in the model, the regression vector $\phi(n)$ is correlated with the residual $\varepsilon(n)$, and, thus, none of the aforementioned least-squares estimates of the parameter vector will converge to the actual value. This undesirable correlation weakens when the predicted output values are used at each step for the autoregressive lagged terms (closed-loop mode or one-step predictive model) instead of the observed output values (open-loop mode or global predictive model). To remedy this problem, the instrumental variable (IV) method has been introduced that makes use of a selected IV that is uncorrelated with the residuals but strongly correlated with the regression vector

$\phi(n)$ in order to evaluate the least-squares estimate [Soderstrom and Stoica, 1989]. The IV estimates can be computed in batch or recursive fashion.

In closing this section, we should note that a host of other estimation methods has been developed through the years and that these methods are operationally affine to the foregoing ones (e.g., prediction-error methods, stochastic approximation, gradient-based methods) or represent different statistical approaches to parameter estimation (e.g., maximum likelihood, bayesian approach) including the state-space formulation of the problem, that cannot be detailed here in the interest of space [for review, see Eykhoff, 1974; Goodwin and Payne, 1977; Ljung and Soderstrom, 1983; Goodwin and Sin, 1984; Ljung, 1987; Soderstrom and Stoica, 1989].

13.2 Nonparametric Approach

In the linear stationary case, the discrete-time nonparametric model takes the convolutional form:

$$y(n) = \sum_{m=0}^{M} h(m)x(n-m) + \varepsilon(n) \tag{13.15}$$

where $\varepsilon(n)$ is an output-additive error/noise term and $h(m)$ is the discrete impulse response of the linear time-invariant (stationary) system with memory extent M. For finite-memory systems (i.e., when $h(m)$ becomes negligible for $m > M$ and M is finite), the estimation of $h(m)$ from input–output data can be accomplished by multiple regression, since the model of Equation 13.15 retains the form of a parametric model with no autoregressive terms. Note that any stable ARMAX model can be put in the form of Equation 13.15, where $M \to \infty$ and $h(m)$ is absolute-summable. The estimation of $h(m)$ can be also accomplished in the frequency domain via discrete Fourier transforms (DFTs, implemented as FFTs), observing the fact that convolution turns into multiplication in the frequency domain. Particular attention must be paid to cases where the input DFT attains very small values to avoid numerical or estimation problems during the necessary division. In actual physiologic practice, many investigators have chosen to perform experiments with specific input waveforms to facilitate this identification task, that is, the use of an impulsive input of unit strength directly yields $h(m)$, or the use of sinusoidal inputs of various frequencies yields directly the values of the DFT of $h(m)$ at the corresponding frequencies (covering the entire frequency range of interest).

In the nonlinear stationary case, the most widely used methodology for nonparametric modeling is based on the Volterra functional expansions and Wiener's theory that employs a gaussian white noise (GWN) test input in conjunction with a modified (orthogonalized) Volterra functional expansion. Wiener's critical contribution is in suggesting that GWN is an effective test input for identifying non-linear systems of a very broad class and in proposing specific mathematical procedures for the estimation of the unknown system descriptors (kernels) from input–output data, as outlined below [for more details, see Schetzen, 1980; Rugh, 1981; Marmarelis and Marmarelis, 1987; Marmarelis, 2004].

The input–output relation of a causal nonlinear stationary system in discrete time is seen as a mapping of a vector comprised of the input past (and present) values onto the (scalar) present value of the output:

$$y(n) = F[x(n'), n - M \le n' \le n] \tag{13.16}$$

where M is the system memory and F is a fixed multivariate function representing this mapping — note that, in continuous time, F is a functional. If the system is nonstationary, the function F varies through time. If the function F is analytic and the system is stable, then a discrete-time Volterra series expansion

exists of the form:

$$y(n) = \sum_{i=0}^{\infty} \sum_{m_1=0}^{M} \cdots \sum_{m_i=0}^{M} k_i(m_1, \ldots, m_i) x(n - m_1) \cdots x(n - m_i) \tag{13.17}$$

This series converges for any stable system within the radius of convergence defined by the input ensemble. If the multivariate function F is not analytic but is continuous, then a finite-order Volterra model can be found that achieves any desirable degree of approximation (based on the Stone–Weierstrass theorem).

The multiple convolutions of the Volterra model involve kernel functions $\{k_i(m_1, \ldots, m_i)\}$ which constitute the descriptors of the system nonlinear dynamics. Consequently, the system identification task is to obtain estimates of these kernels from input–output data. These kernel functions are symmetric with respect to their arguments.

When a sinusoidal input is used, then the ith order Volterra functional (i.e., the i-tuple convolution in the Volterra model) gives rise to output harmonics of order $i, (i - 2), \ldots, (i - 2j)$ where j is the integer part $i/2$. When an impulse $A\delta(n)$ is used as input, then the ith order Volterra functional is contributing the term $A_i k_i(n, \ldots, n)$ to the output. This suggests that the Volterra kernels of a general system cannot be separated from each other and directly determined from input–output data, unless the Volterra expansion is of finite order. For a finite-order Volterra expansion, kernel estimation can be achieved through least-squares fitting procedures [Stark, 1968; Watanabe and Stark, 1975; Korenberg, 1988] or by use of specialized test inputs such as multiple impulses or step function [Schetzen, 1965; Stark, 1968; Shi and Sun, 1990] and sums of sinusoids of incommensurate frequencies [Victor et al., 1977], although the testing and analysis procedures can be rather laborious in those cases. The latter method yields estimates of the system kernels in the frequency domain at the selected input frequencies (and their harmonic/intermodulation frequencies) with increased accuracy but with limited frequency resolution.

The inability to estimate the Volterra kernels in the general case of an infinite series prompted Wiener to suggest the orthogonalization of the Volterra series when a GWN test input is used. The functional terms of the Wiener series are constructed on the basis of a Gram–Schmidt orthogonalization procedure requiring that the covariance between any two Wiener functionals be zero. The resulting Wiener series expansion takes the form:

$$y(n) = \sum_{i=0}^{\infty} G_i[h_i; x(n'), n' \leq n]$$

$$= \sum_{i=0}^{\infty} \sum_{j=0}^{i/2} \frac{(-1)^j i! P^j}{(i - 2j)! j! 2^j} \sum_{m_1} \cdots \sum_{m_i} h_i(m_1, \ldots, m_{i-2j}, l_1, l_1, \ldots, l_j, l_j)$$

$$x(n - m_1) \cdots x(n - m_{i-2j}) \tag{13.18}$$

where $[i/2]$ is the integer part of $i/2$ and P is the power level of the GWN input. The set of Wiener kernels $\{h_i\}$ is, in general, different from the set of Volterra kernels $\{k_i\}$, but specific relations exist between the two sets [Marmarelis and Marmarelis, 1978; Marmarelis, 2004].

The Wiener kernels depend on the GWN input power level P (because they correspond to an orthogonal expansion), whereas the Volterra kernels are independent of any input characteristics. This situation can be likened to the coefficients of an orthogonal expansion of an analytic function being dependent on the interval of expansion. It is therefore imperative that Wiener kernel estimates be reported in the literature with reference to the GWN input power level that they were estimated with. When a complete set of Wiener kernels is obtained, then the complete set of Volterra kernels can be evaluated. Approximations of Volterra kernels can be obtained from Wiener kernels of the same order estimated with various input power levels. Complete Wiener or Volterra models can predict the system output to any given input.

When the Wiener or Volterra model is incomplete, the accuracy of the predicted output will be, in general, different for the two models and will depend on each specific input.

The orthogonality of the Wiener series allows decoupling of the various Wiener functionals and the estimation of the respective Wiener kernels from input–output data through cross-correlation [Lee and Schetzen, 1965]

$$h_i(m_1, \ldots, m_i) = \frac{1}{i! P^i} E[y_i(n) x(n - m_1) \cdots x(n - m_i)] \tag{13.19}$$

where $y_i(n)$ is the ith response residual

$$y_i(n) = y(n) - \sum_{j=0}^{i-1} G_j(n) \tag{13.20}$$

The simplicity and elegance of the cross-correlation technique led to its adoption by many investigators in modeling studies of nonlinear physiologic systems [Stark, 1968; McCann and Marmarelis, 1975; Marmarelis and Marmarelis, 1978; Marmarelis, 1987, 1989, 1994].

Since the ensemble average of Equation 13.19 is implemented in practice by time-averaging over a finite data-record, and since GWN is not physically realizable, many importance practical issues had to be explored in actual applications of the cross-correlation technique. To name but a few: the generation of appropriate quasi-white test signals (that adequately approximate the ideal and not physically realizable GWN); the choice of input bandwidth relative to the system bandwidth; the accuracy of the obtained kernel estimates as a function of input bandwidth and record length; the effect of extraneous noise and experimental imperfections. An extensive study of some of these practical considerations can be found in Marmarelis and Marmarelis [1978] and in Marmarelis [1979].

A broad class of effective quasi-white test signals (CSRS) has been introduced that can be easily generated on the computer and may follow any zero-mean symmetric (discrete or continuous) amplitude probability density function [Marmarelis, 1977]. The use of this type of test signal allows through analysis of kernel estimation errors via cross-correlation and the optimization of the input bandwidth B (for given record length N) on the basis of a total mean-square error (TMSE) criterion for the ith-order kernel estimate given by:

$$(\text{TMSE})_i = \frac{a_i}{B^4} + \frac{b_i B^{i-1}}{N} \tag{13.21}$$

where a_i and b_i are positive constants characteristic of the ith-order kernel [Marmarelis, 1979].

The cross-correlation technique results in considerable variance in the kernel estimates, unless very long data-records are available, because of the stochastic nature of the input. This has prompted the use of pseudo-random m-sequences [Ream, 1970; Billings and Fakhouri, 1981; Moller, 1983; Sutter, 1992] — which can reduce considerably the data-record requirements and yield improved estimation accuracy, provided that proper attention is given to certain problems in their high-order autocorrelation functions. To the same end, frequency-domain methods have been proposed for kernel estimation [Brillinger, 1970; French, 1976; Victor et al., 1977] yielding computational savings in some cases and offering a different perspective for the interpretation of results.

To reduce the requirements of long experimental data records and improve the kernel estimation accuracy, least-squares methods also can be used to solve the classical linear inverse problem described earlier in Equation 13.6, where the parameter vector θ includes all discrete kernel values of the finite Volterra model of Equation 13.17, which is linear in these unknown parameters (i.e., kernel values). Least-squares methods also can be used in connection with orthogonal expansions of the kernels to reduce the number of unknown parameters, as outlined below. Note that solution of this inverse problem via OLS requires inversion of a large square matrix with dimensions $[(M + I + 1)!/((M + 1)!I!)]$, where M is

the kernel memory and I is the (maximum) nonlinear order of the Volterra model. Since direct inversion of this matrix may require considerable computing effort and be subject to conditioning problems, it is often expedient to solve this inverse problem by use of QR decomposition that offers certain computational and numerical advantages. One such implementation is Korenberg's exact orthogonalization method [Korenberg, 1988], which estimates the discrete kernel values through least-squares fitting of a sequence of orthogonal vectors built from input values in accordance with the Volterra expansion (effectively forming the Q orthogonal matrix of the QR decomposition). Other numerical methods also can be used for matrix inversion, depending on the requirements of each application. Likewise, a variety of orthogonal bases can be used for kernel expansion in order to obtain a more concise representation of the kernels in each particular application. The use of the Laguerre orthogonal basis typically results in reduction of the number of unknown parameters for most physiologic system kernels (due to their built-in exponential structure), with consequent improvement in estimation accuracy [Watanabe and Stark, 1975; Marmarelis, 1993, 2004]. Thus, if $\{b_j(m)\}$ is a complete orthonormal basis defined over the system memory $[O, M]$, then the ith-order Volterra kernel can be expanded as

$$k_i(m_1, \ldots, m_i) = \sum_{j_1} \cdots \sum_{j_i} c_i(j_1, \ldots, j_i) b_{j_1}(m_1) \cdots b_{j_i}(m_i) \tag{13.22}$$

Then the Volterra model of Equation 13.17 takes the form:

$$y(n) = \sum_i \left\{ \sum_{j_1} \cdots \sum_{j_i} c_i(j_1, \ldots, j_i) v_{j_1}(n) \cdots v_{j_i}(n) \right\} \tag{13.23}$$

where,

$$v_j(n) \sum_{m=0}^{M} b_j(m) x(n - m) \tag{13.24}$$

and the expansion coefficients $\{c_i(j_1, \ldots, j_i)\}$ of the unknown kernels can be estimated through multiple regression of $y(n)$ on the multinomial terms composed of the known functions $\{v_j(n)\}$. The kernel estimates are then reconstructed on the basis of Equation 13.22. This kernel estimation method has been shown to be far superior to the conventional cross-correlation technique in terms of estimation accuracy and robustness to noise or experimental imperfections [Marmarelis, 1993, 2004].

Based on this observation, a general model for the Volterra class of systems can be proposed that is comprised of a set of parallel linear filters with impulse response functions $\{b_j(m)\}$ whose outputs are fed into a multi-input static nonlinearity, $y = f(v_1, v_2, \ldots)$, to produce the system output. If was Wiener who first proposed the use of Laguerre functions (albeit in continuous-time form) for the set $\{b_j(m)\}$, since they are defined over the interval $[0, \infty)$ compatible with causal systems and can be generated in analog form — a fashionable model at the time — by a simple RC ladder network. He also suggested that the multi-input static nonlinearity be expanded in terms of orthogonal hermite functions to yield a system characterization in terms of the resulting Hermite expansion coefficients that are estimated through covariance computations. For a review of this approach, see Schetzen [1980]. This approach has been viewed as rather unwieldy and has not found many applications to date. However, the use of Laguerre expansions of kernels (in discrete time) in conjunction with least-squares fitting has been shown to be rather promising for practical kernel estimation from short and noisy data records [Marmarelis, 1993, 2004] and consequently suitable for experimental studies of physiologic systems.

The greatest obstacle to the broader use of the Volterra–Wiener approach has been the practical limitations in estimating high-order kernels due to two reasons (1) The amount of required computations increases geometrically with the order of estimated kernel; (2) kernel functions of more than three

dimensions are difficult to inspect or interpret meaningfully. As a result, application of this approach has been limited to weakly nonlinear systems (second or third order).

A practical way of overcoming this limitation in the order of estimated kernels has been recently presented as a spin-off of studies on the relation between Volterra models and feedforward artificial neural networks [Marmarelis and Zhao, 1994; Marmarelis, 2004]. According to this approach, a perceptronlike network with polynomial activation functions is trained with the experimental data using a modified version of the back-propagation algorithm. The parameters of the resulting network can be subsequently converted to kernel estimates of arbitrary high order (although the network itself is a nonlinear model of the system on its own right). This alternative to current kernel estimation algorithms seems to hold significant promise, since it relaxes many of the requirements of existing methods (e.g., input whiteness and low-order models) at the only apparent cost of greater computing effort.

In the event of nonstationarities, the kernel become dependent on time, and their estimation can be accomplished either in a piecewise stationary manner (when the nonstationary is slow relative to the system dynamic bandwidth) or through truly nonstationary estimation methods. In the former case, the piecewise stationary estimates can be obtained over adjacent segments or using sliding (overlapping) windows along the time record. They can be subsequently displayed in a time-ordered sequence (revealing the time-varying pattern), under the assumption of system quasi-stationarity over the data segment or sliding window. Kernel estimation through truly nonstationary methods may be accomplished by (1) adaptive methods, employing the recursive least-squares formulae previously reviewed, which track changes in least-squares kernel estimates by continuous updating based on the output prediction error at each discrete step [Goodwin and Sin, 1984]; (2) ensemble-averaging methods, employing direct averaging of results obtained from many repetitions of identical experiments, which are rarely used because the latter is seldom feasible or practical in a physiologic experimental setting; (3) temporal expansion methods, employing explicit kernel expansions over time to avoid the experimental burden of the ensemble-averaging approach and the methodological constraints of adaptive methods, which utilize a single input–output data record to obtain complete nonstationary model representations under mild constraints [Marmarelis, 1981].

We note that the Volterra–Wiener approach has been extended to the case of nonlinear systems with multiple inputs and multiple outputs [Marmarelis and McCann, 1973; Marmarelis and Naka, 1974; Westwick and Kearney, 1992; Marmarelis, 2004] where functional terms are introduced, involving cross-kernels which measure the nonlinear interactions of the inputs as reflected on the output. This extension has led to a generalization for nonlinear systems with spatio-temporal inputs that has found applications to the visual system [Yasui et al., 1979; Citron et al., 1981]. Extension of the Volterra–Wiener approach to systems with spike (action potential) inputs encountered in neurophysiology also has been made, where the GWN test input is replaced by a Poisson process of impulses [Krausz, 1975]; this approach has found many applications including the study of the hippocampal formation in the brain [Sclabassi et al., 1988]. Likewise, the case of neural systems with spike outputs has been explored in the context of the Volterra–Wiener approach, leading to efficient modeling and identification methods [Marmarelis et al., 1986; Marmarelis and Orme, 1993; Marmarelis, 2004].

The mathematical relations between parametric (NARMAX) and nonparametric (Volterra) models have been explored, and significant benefits are shown to accrue from combined use [Zhao and Marmarelis, 1998]. These studies follow on previous efforts to relate certain classes of nonlinear differential equations with Volterra functional expansions in continuous time [Rugh, 1981; Marmarelis, 1989; Marmarelis, 2004].

Only brief mention will be made of the computational and graphical nonparametric methods of phase-space mappings. The computational method requires prior specification of the number of input and output lags that are needed to express the present output value as

$$y(n) = G[y(n-1), \ldots, y(n-k), x(n), x(n-1), \ldots, x(n-l)] \tag{13.25}$$

where $G[\bullet]$ is an unknown function which maps the appropriate input–output vector $z(n) = [y(n-1), \ldots, y(n-k), x(n), \ldots, x(n-l)]$ onto the present value of the output $y(n)$. Then, using experimental

data, we compile on the computer a list of correspondences between $z(n)$ and $y(n)$ in the form of an empirical model that can predict the output for a given z by finding the closest correspondence within the compiled list (look-up table) or using a properly defined interpolation scheme.

The graphical method is based on the notion that the mathematical model of a discrete-time finite-order (stationary) dynamic system is, in general, a multivariate function $f(\bullet)$ of the appropriate lagged values of the input–output variables

$$f[y(n), y(n-1), \ldots, y(n-k), x(n-1), \ldots, x(n-l)] = 0 \qquad (13.26)$$

This function (model) is a "constraint" among these input–output lagged (and present) values at each time instant n. The number of variables that partake in this relation and the particular form of $f(\bullet)$ are characteristic of the system under study. Therefore, in a geometric sense, the system (and its model) are represented by a subspace in a multidimensional space defined by the coordinate system of these variables. If one can define the appropriate space by choosing the relevant variables, then a model can be easily obtained by following the vector point corresponding to the data through time — provided that the input is such that the data cover the model subspace densely. If the input is ergodic, then sufficiently long observations will allow reliable estimation of the system model.

Although this is an old and conceptually straightforward idea, it has not been widely used (except in some recent studies of chaotic dynamics of autonomous systems, where no input variable exists) because several important practical issues must be addressed in its actual implementation, for example, the selection of the appropriate coordinate variables (embedding space) and the impracticality of representation in high-dimensional spaces. If a low-dimensional embedding space can be found for the system under study, this approach can be very powerful in yielding models of strongly nonlinear systems. Secondary practical issues are the choice of an effective test input and the accuracy of the obtained results in the presence of extraneous noise.

13.3 Modular Approach

The practical limitations in the use of Volterra–Wiener models for strongly nonlinear systems have led some investigators to explore the use of block-structured or modular models in the form of cascaded or parallel configurations of linear subsystems (L) and static nonlinearities (N). This model representation often provides greater insight into the functional organization of the system under study and facilitates that identification task by allowing separate estimation of the various component subsystems (L and N), thereby avoiding the computational burden associated with the dimensionality of high-order kernel functions. The advantages afforded by this approach can be had only when prior specification of the structure of the modular model is possible.

Simple cascade models (e.g., L–N, N–L, L–N–L) have been studied extensively, yielding estimates of the component subsystems with moderate computational effort [Marmarelis and Marmarelis, 1978; Billings and Fakhouri, 1982; Korenberg and Hunter, 1986; Shi and Sun, 1990]. Distinctive kernel relationships (e.g., between first-order and second-order kernels) exist for each type of cascade model, which can be used for validation of the chosen modular model on the basis of the kernel estimates obtained from the data — a task that is often referred to as structural identification. Thus, the combined use of the modular and nonparametric approaches may yield considerable benefits. This idea can be extended to more complicated modular structures entailing multiple parallel and cascaded branches [Chen et al., 1990; Korenberg, 1991]. The case of nonlinear feedback in modular models attracts considerable interest, because of its frequent and critical role in physiologic control and autoregulation. A case of weak nonlinear feedback in sensory systems has received thorough treatment [Marmarelis, 1991, 2004]. Naturally, the analysis becomes more complicated as the complexity of the modular model increases. Particular mention should be made of a rather complex model of parallel L–N–L cascades (usually called the S_m model) that covers a broad class of nonlinear systems [Billings and Fakhouri, 1981; Rugh, 1981].

A method for the development of a general model for the Volterra–Wiener class of systems, which assumes a modular form, was originally proposed by Wiener and his associates and is reviewed in Schetzen [1980]. A general modular model, comprised of parallel L–N cascades, also has been proposed by Korenberg [1991], and another, employing principal dynamic modes as a filterbank whose outputs feed into a multi-input static nonlinearity, has been recently proposed by Marmarelis [1997].

This latter general model evolved from the original Wiener modular model. It was first adapted to studies of neural systems that generate spikes (action potentials), whereby a threshold-trigger is placed at the output of the general modular model that obviates the use of high-order kernels and yields a parsimonious complete model [Marmarelis and Orme, 1993]. The importance of this development is found in that, ever since the Volterra–Wiener approach was applied to the study of spike-output neural systems, it had been assumed that a large number of kernels would be necessary to produce a satisfactory model prediction of the timing of output spikes, based on the rationale that the presence of a spike-generating mechanism constitutes a hard nonlinearity. Although this rationale is correct if we seek to reproduce the numerical binary values of the system output using a conventional Volterra–Wiener model, the inclusion of a threshold trigger in our modular model yields a compact and complete model (of possibly low order) that predicts precisely the timing of the output spikes [Marmarelis et al., 1986]. This also led to a search for the principal pathways of dynamic transformations of neural signals using eigen-decomposition of a matrix composed of the Laguerre expansion coefficients of the first- and second-order kernels [Marmarelis and Orme, 1993]. The estimation of these principal dynamic modes is accomplished via the aforementioned eigen-decomposition [Marmarelis, 1994] or through the training of a specific artificial neural network (a modified perceptron with polynomial activation functions) using a modified back-propagation algorithm [Marmarelis and Zhao, 1997]. The latter method holds great promise in providing a practical solution to the ultimate problem of nonlinear system identification, because it is not limited to low-order nonlinearities and does not place stringent requirements on the necessary input–output data, but it does retain a remarkable degree of robustness in the presence of noise.

The methodology employing Principal Dynamic Modes (PDM) holds great promise in addressing the long-standing problem of dimensionality in high-order nonlinear systems, as well as in the most challenging case of multiinput/multioutput systems, because of the compactness of representation that it achieves. Several recent applications of the PDM approach to a variety of physiological systems (neural, cardiovascular, renal, metabolic) have demonstrated this promise [for a comprehensive review, see Marmarelis, 2004].

Autoregulating Windkessel Dynamics May Cause Low Frequency Oscillations

Gary M. Drzewiecki

14.1 Introduction

The control of blood flow is a process involving neural and metabolic mechanisms. It is widely accepted that neural processes accomplish short term control of blood precapillary flow resistance such that blood pressure and flow are regulated. While metabolic processes dominate in the long term [Guyton, 1963] they ultimately determine the regulated blood flow levels in the various tissues in accordance with metabolic demands. This is achieved locally by the precapillary sphincters that adjust the duration and number of capillaries open and which, in turn, determine the value of the peripheral resistance, R_s. Another theory suggests that it is the mechanical effect of pressure and flow that stimulates vascular smooth muscle to react. However experiments have shown that tissue blood flow and systemic circulation is directly related to its metabolic demand [Berne and Levy, 1977]. Experimental observations of low frequency flow oscillations can be found in studies of a single vascular bed as well as the entire systemic circulation. This differs from mechanical stimulation where researchers have employed a drug response. For example,

Kenner and Ono [1972] have observed what they termed flow autooscillations in the carotid and femoral arteries of the dog, following intravenous administration of acetylcholine. Similar oscillations in flow have been observed following the infusion of adenosine into the coronary circulation [Wong and Klassen, 1991]. These researchers attributed this response to opposing vasodilator and vasoconstrictor processes.

Other experimental evidence of low frequency resonance can be found in measurements of heart rate variability and blood pressure variability spectra [Chess et al., 1975; Akselrod et al., 1981; Pagani et al., 1986]. Experiments in animals have shown that low frequency oscillations persist following denervation [Rimoldi et al., 1990], during external constant cardiac pacing [Wang et al., 1995], and in animals and humans with an artificial heart [Yambe et al., 1993; Cooley et al., 1998]. To our knowledge, the origin of the low frequency resonance in the variability spectrum, the so-called Mayer waves [Mayer, 1876] is currently unexplained, although vasoregulatory dynamics has been proposed. The study by Yambe et al. [1993] revealed that the long waves were nearly 100% correlated with the periodicity of peripheral resistance.

Further autoregulatory instability has been observed in the pathological situation. For example, prominent low frequency oscillations have been observed during heart failure [Goldberger et al., 1984]. While it has been proposed that these oscillations follow the respiratory rate, they have been observed to occur at even lower frequencies.

With innervation intact, the circulation at rest maintains constant ventricular stroke volume and blood pressure, on average. In addition, the regulation of cardiac output is accomplished primarily through the control of peripheral resistance. Then, the slow changes in heart rate (f_h) are directly related to cardiac output (CO) and inversely to peripheral resistance (R_s), so that, $f_h \propto \text{CO} \propto 1/R_s$ [Berne and Levy, 1977]. This relationship is fundamental to the vascular theory of heart rate variation [Hering, 1924] and underscores the role of a time varying peripheral resistance. In this chapter, the dynamics of peripheral resistance control is examined analytically as an explanation of the very low frequency variation in heart rate.

14.2 Background

The control of blood flow resistance has been analyzed theoretically at both the organ and the microcirculatory level. Since metabolic demand of the tissue is related to oxygen uptake under aerobic conditions, Huntsman et al. [1978] developed a model for control of blood flow resistance for skeletal muscle based on this concept. In this study, it was found that the metabolic control considerably outweighed that of neural and myogenic. The time frame of observation was also important, where longer time periods emphasized the metabolic control factors. The model controlled flow by means of regulating the oxygen stored in the extra-vascular spaces. The control of peripheral resistance was affected by invoking the relationship between arterial diameter and oxygen tension. This model successfully predicted the large blood flow response following a brief occlusion.

The autoregulation response should ultimately arise from the action of multiple precapillary sphincters and resistance arterioles in the microcirculation. The control of flow in a microvascular model was analyzed by Mayrovitz et al. [1978]. This model included muscular arterial and venous vasomotion, capillary filtration and reabsorption, and lymph flow. Tissue pressure was assumed to be regulated and was used to provide the control pathway for the activation of the precapillary sphincter. Local flow was found to vary considerably with periodic sphincter activity. This model demonstrated that autoregulation of flow is likely to find its genesis at the microcirculatory level.

Although our knowledge of pulse propagation in the arterial system is extensive, it has been useful to approximate the relationship between pressure and flow in a single artery or vascular bed. Such approximations have been referred to as reduced arterial system models of which the three element Windkessel is the most widely employed [Westerhof et al., 1971; Noordergraaf, 1978]. This Windkessel model is modified here to study the effects of peripheral resistance.

The three element Windkessel model approximates the pulse propagation quality of the arterial system as a combination of an infinitely long tube, which is represented by its characteristic impedance, Z_o,

in series with a parallel arrangement of a peripheral flow resistance, R_s, and a total arterial compliance, C_s. Within a single cardiac cycle, these three parameters are generally assumed to be constants [Toorop et al., 1987]. Recent studies have scrutinized this assumption. For example, the compliance has been shown to depend on the level of arterial pressure [Bergel, 1961]. Other studies have called into question the accuracy of the various methods employed to experimentally determine their values [Stergiopulos et al., 1995a]. This difficulty has been addressed by Quick et al. [1998] who showed that wave reflection imparts frequency dependence on the values of R_s and C_s.

The Windkessel model is often employed as a simplified load for the left ventricle. Under steady conditions and a fixed heart rate, this model is appropriate. But, given the case of varying ventricular function, the model responds inaccurately. The difficulty lies in the regulation of cardiac output, that is, autoregulation is not provided. To correct this problem, our group has employed an iterative procedure that permits R_s to change such that cardiac output is maintained [Drzewiecki et al., 1992]. This procedure, although providing autoregulation, does not account for the dynamics associated with this physiological mechanism.

In this chapter, the dynamics of autoregulation are incorporated into the modified Windkessel model. The frequency response of this autoregulating Windkessel is then predicted and compared with that of the standard three element model. The time response is also determined and discussed relative to the experimental observations in the literature. The stability of the model is also examined with respect to very low frequency oscillation in peripheral resistance.

The physical relationships that govern the Windkessel model are now reviewed. Time dependency is provided by the blood volume storage property of arterial compliance, C_s. The time derivative of peripheral arterial pressure, P_s, is proportional to the difference in blood flow into and out of the compliance, according to,

$$\frac{dP_s}{dt} = \left(Q - \frac{P_s - P_o}{R_s} \right) \frac{1}{C_s P_s} \tag{14.1}$$

where Q is the inflow. P_o accounts for the critical closing pressure [Alexander, 1977]. The input pressure, P, is then determined from the sum of pressure due to flow through the characteristic impedance and the pressure, P_s,

$$P = Q Z_o + P_s \tag{14.2}$$

The arterial compliance may be treated as a function of pressure also, accounting for large changes in blood pressure. The pressure dependence of compliance is then modeled by an exponential function [Liu et al., 1989; Li et al., 1990], as,

$$C_s = a\, e^{-b P_s} \tag{14.3}$$

where a and b are empirical constants evaluated from experimental data.

14.3 Modeling Methods

14.3.1 Steady Regulation

In this study, it will be assumed that the local tissue bed or whole animal is in a steady metabolic state. For this regulated condition, the level of blood flow is denoted Q_0, the peripheral resistance, R_{so}, and the pressure across it, P_{so}. The relation between these quantities reads,

$$P_{so} = R_{so} Q_0 \tag{14.4}$$

When the flow is disturbed, the value of the peripheral resistance is adjusted in an attempt to restore flow to Q_0. Since the control of flow is not ideal, the new steady flow condition is described by

$$P_s = R_{reg} Q \tag{14.5}$$

where R_{reg} is the new value of peripheral resistance. Applying the simplest form of control, which is also imperfect, it is assumed that the change in peripheral resistance is proportional to the change in flow, that is, linear proportional control. The change in peripheral resistance is then determined from the control equation,

$$\Delta R_s = R_{reg} - R_{so} = \frac{G(Q - Q_0)}{Q_0} \tag{14.6}$$

where G is defined as the autoregulatory gain.

14.3.2 Autoregulation Dynamics

There are two dynamic effects that must be accounted for to accurately model the physiological control mechanism. First, the change in peripheral resistance is delayed. This represents a delay from the time that the flow changes to when the vascular smooth muscle activity actually initiates the process of correcting the flow. This time delay in the change of peripheral resistance is denoted τ_Q. To account for this effect, the change in peripheral resistance determined from the steady value was written as $\Delta R_s(t - \tau_Q)$.

Physiologically, even when peripheral resistance adjusts, it cannot be changed instantaneously. To account for the slow change in resistance, a first-order rate equation was used to represent the slow action of vascular smooth muscle. Thus, the time dependent value of peripheral resistance was determined from the following,

$$\frac{dR_s}{dt} = \frac{1}{\tau_{sm}} \Delta R_s(t - \tau_Q) \tag{14.7}$$

where the time constant for smooth muscle action is τ_{sm}. This equation simply states that the rate of change of peripheral resistance with respect to time is proportional to desired change in resistance, ΔR_s.

The net effect of delay in autoregulation and smooth muscle response is to cause R_s to slowly approach its new control value, as defined by Equation 14.6.

14.3.3 Regulatory Limitations

If the actual blood flow differs significantly from Q_0, the regulatory error can be large. Since a linear model is being employed here, the value of R_s predicted by Equation 14.4 to Equation 14.7 may fall outside of the physiological range. Thus, the time dependent value of R_s was limited to maximum and minimum values of $1.6R_{so}$ and $0.4R_{so}$, respectively. These values correspond with maximal vasoconstriction and vasodilation. When the computations reveal that the limit has been reached, the limited value of resistance was then inserted into Equation 14.1 of the Windkessel model. Otherwise, the time dependent value obtained from Equation 14.7 was employed.

The two differential equations (Equation 14.1 and Equation 14.7) govern the time dependent characteristics of the autoregulating Windkessel model. They were integrated numerically by a computer. All parameters were evaluated for the canine systemic arterial system (Table 14.1).

TABLE 14.1 Parameters

Parameter	Value	Description
Z_o	0.25 mmHg/ml/sec	Characteristic impedance
C_s	0.50 ml/mmHg	Arterial compliance
R_{so}	3.10 mmHg/ml/sec	Basal peripheral resistance
a	3.0 ml/mmHg	Nonlinear compliance constant
b	0.02 mmHg^{-1}	Nonlinear compliance constant
G	5.0	Autoregulation gain
Q_0	27.0 ml/sec	Regulated flow level
τ_Q	5.0 sec	Flow delay time
τ_{sm}	3.0 sec	Smooth muscle time constant

14.4 Results

14.4.1 Autoregulation Curve

The standard experimental approach to measuring the autoregulation curve of a vascular bed has been to slowly vary input flow while recording pressure. Alternatively, one may alter pressure while measuring flow. In either case, the dependent variable stabilizes after several minutes. The set of final values results in the steady state autoregulation curve. This procedure was followed using the autoregulating Windkessel model (Figure 14.1). To reduce computation time, the time constants of the model were shortened. This does not affect the result, but simply shortens the time to reach steady state.

The model generated autoregulation curve shows three distinct segments. The low flow segment was found to be a line of slope $0.4R_{so}$, and corresponds with maximal vasodilation. There was no control of flow in this region either. The middle flow segment represents the autoregulatory range. The peripheral resistance was found to alter continuously in accordance with the feedback control relationship of Equation 14.6 in this region. The slope of this segment was also proportionate to the autoregulatory gain factor, G, of the model. A greater slope reflects tighter control of flow, but, as will be shown later, can lead to autoregulatory instability.

14.4.2 Input Impedance

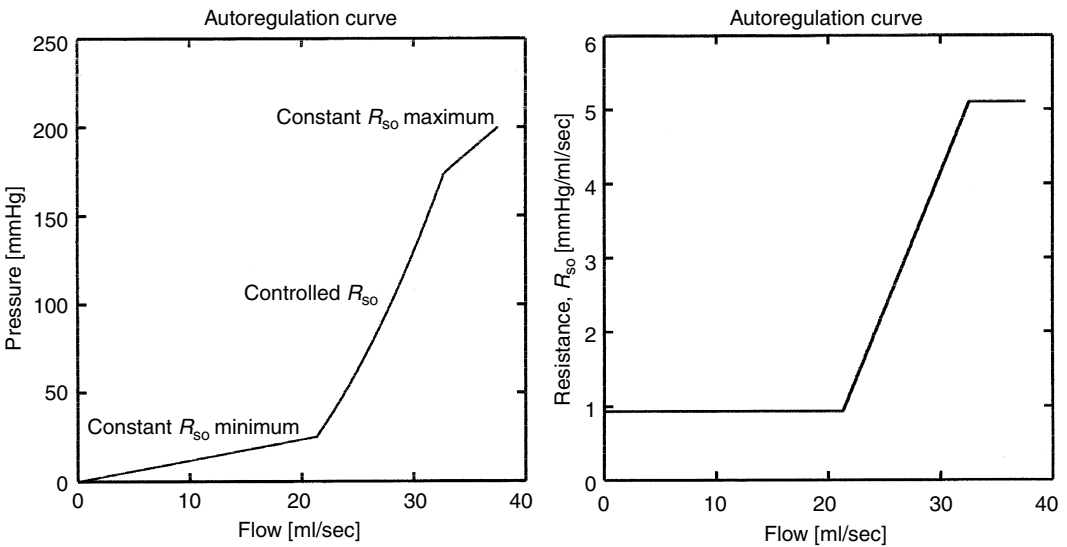
The frequency response of the autoregulating Windkessel was determined by applying a small constant amplitude flow sinusoid as input while the mean flow is held fixed. The resulting sinusoidal pressure response was computed from the model. The response was evaluated for as many cycles as were needed to obtain a sinusoidal steady state. For frequencies much below the heart rate, this required up to 30 sec. The input impedance magnitude was then obtained by finding the ratio of the sinusoidal pressure and flow amplitudes over the range of frequencies. Phase was determined by finding the phase difference between the pressure and flow waves (Figure 14.2a,b). In order to compare these results with the conventional modified Windkessel, the input impedance was reevaluated when the autoregulatory gain is zero ($G = 0$) and is shown on the same graphs.


FIGURE 14.1   Pressure and flow relationship of the canine aorta obtained from the autoregulating Windkessel in the steady state. Flow regulation occurs in the range where the slope is steepest.
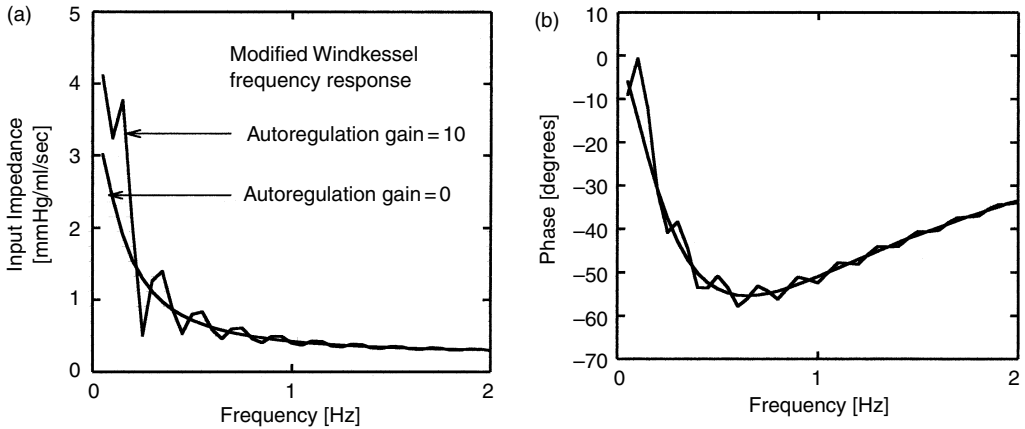

FIGURE 14.2 Input impedance magnitude (a) and phase (b) frequency spectrum obtained from the model. The oscillating curve represents active autoregulation. The smooth curve is the standard three-element Windkessel with constant peripheral resistance.

The high frequency impedance was found to be identical for both models. This might be expected, since autoregulation is slow compared with the heart rate. An unexpected result was that the impedance and phase were found to oscillate at about that of the modified Windkessel for frequencies near the heart rate. This oscillation was traced to the autoregulation delay time, τ_Q. The magnitude of these oscillations was found to increase further if the autoregulatory gain is increased. If the gain or the delay time was reduced to zero, the oscillations are eliminated. These oscillations in the frequency domain could have been predicted by referring to the Fourier transform of a delayed time function.

The very low frequency portion of the autoregulating impedance magnitude was higher in comparison with that of the unregulated Windkessel, where impedance approaches R_s at zero frequency. This can be explained by referring again to Figure 14.1. Instead of converging to R_s, the autoregulating imped-ance approaches the slope of the pressure–flow curve. That is because the sinusoidal response measures the dynamic variation about the flow control point, Q_0. This is not contradictory, since the mean pressure divided by the mean flow is simultaneously $R_s = R_{so}$, at this point. And, the derivative of pressure, $\mathrm{d}P/\mathrm{d}Q$, for a given flow, must be the slope of the autoregulation curve in the steady state.

14.4.3 Flow Step Response

The pressure was computed from the model given a step increase in flow above the control level. A flow step was initiated 2.0 sec from the beginning of the calculations (Figure 14.3). An immediate increase in pressure occurs. This coincided with the time dependent increase in blood volume that shifts into the compliance, C_s. The peripheral resistance did not change during this time due to flow delay. It remains at the control value of R_{so}. Five seconds later, the resistance begins to increase toward the new value required by Equation 14.4 and for autoregulation. Pressure increased nearly in proportion with resistance. The rate of change was determined by the time constant of smooth muscle response, τ_{sm}, and Equation 14.5. An equilibrium value was reached about 20 sec after the flow step occurred.

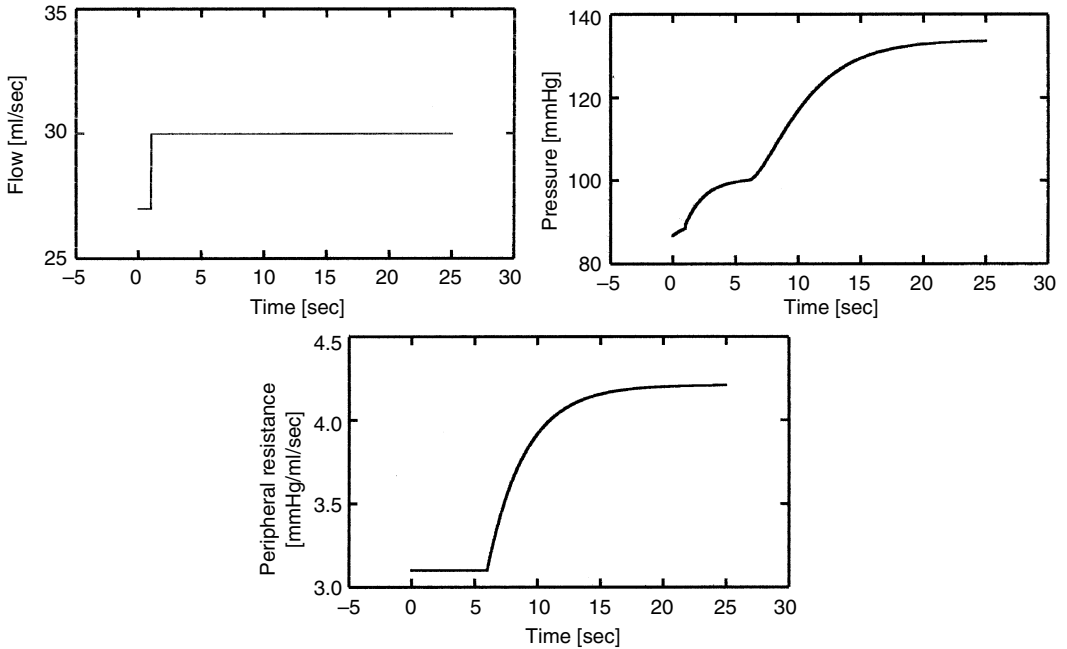
The above flow step response was repeated with a constant amplitude flow pulse added to the mean flow (Figure 14.4). A flow step was initiated 10 sec from the beginning of computations. The envelope of the pressure response follows that shown in Figure 14.3, but additionally permits the observation of systolic and diastolic pressures. It was found that the pulse pressure amplitude increases following the step. This was associated with the decrease in pressure dependent compliance due to elevated pressure (Equation 14.3).


FIGURE 14.3 Flow step response of the model for steady levels of flow. The time responses of pressure and peripheral resistance are shown.
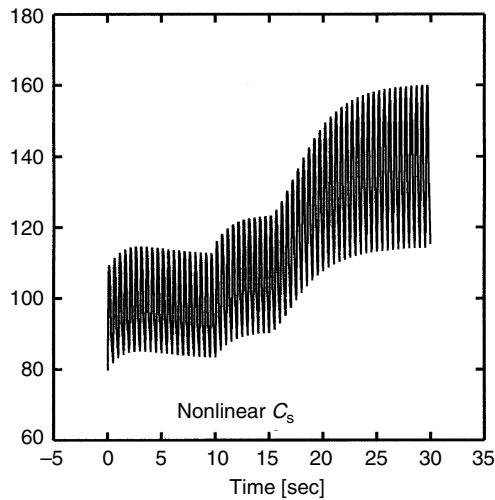

FIGURE 14.4 Flow step response as in Figure 14.3, but with the addition of constant pulsatile flow. The effect of nonlinear compliance is evident as the pulse pressure increases following the increase in mean flow.

14.4.4 Pressure Step Response

The flow was computed from the model following a step change in input pressure. The step change was initiated immediately by altering the initial condition for pressure from the steady state value of 83 to 90 mmHg (Figure 14.5).

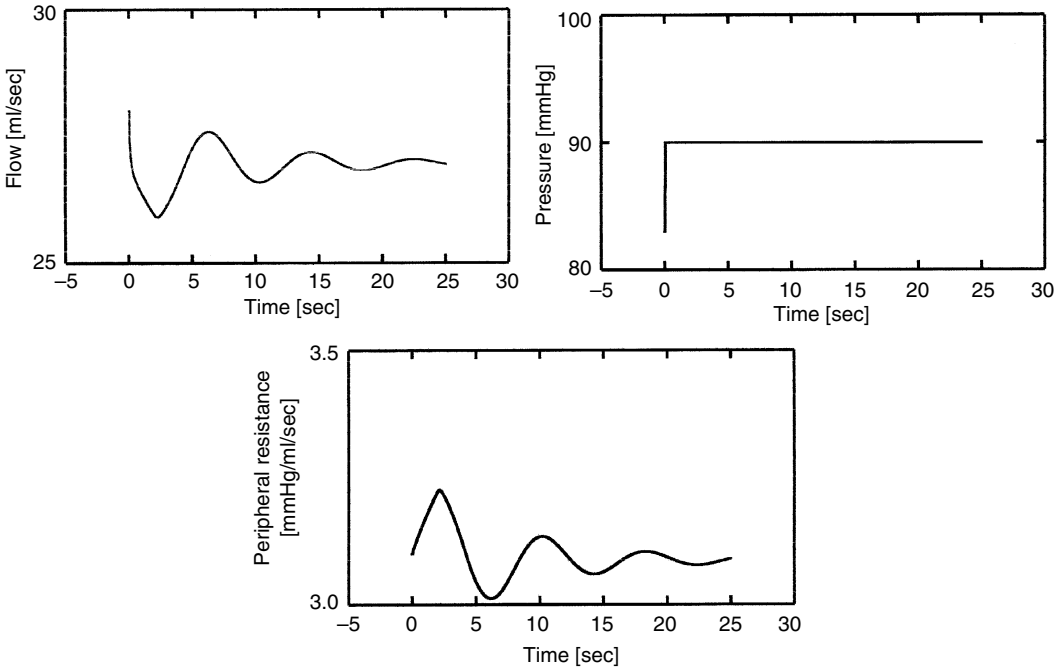
The graphs for flow and resistance were found to be 180° out of phase. This was expected, since they are inversely proportional for constant pressure. Part of the initial increase in flow was due to transient


FIGURE 14.5 Pressure step response computed from the model ($\tau_Q = 2$, $\tau_{sm} = 5$, and $G = 10$). The step was produced by altering the initial condition for pressure at $t = 0$. Note that pressure and resistance are 180° out of phase. A damped resonant response is evident with a resonant frequency of ∼0.1 Hz.

filling of the compliance, C_s. Flow was found to oscillate about its control value. This was reasonable since the control system consists of feedback with two time lags. Thus, the stability of control becomes a consideration. It was found that increasing τ_Q or the gain factor, G, led to unstable low frequency pressure oscillations. The smooth muscle time constant, τ_{sm}, was found to possess a damping effect and could be increased to eliminate oscillations. Thus, too rapid smooth muscle activation and accurate autoregulation were predicted to be a destabilizing influence on the circulation. Since the flow resistance was always limited to either maximal vasoconstriction or vasodilation, the amplitude of the oscillations was also constrained.

As another type of pressure step, an arterial occlusion was computed from the model. A 2 sec occlusion was applied by rapidly reducing the input pressure to zero and then restoring it to the preocclusion level. The initial effect was to cause a rapid negative flow (Figure 14.6). This represents blood volume decrease of the arterial compliance. The effect was brief since the outflow time constant is less than one second. Peripheral resistance was unchanged until the end of the occlusion due to autoregulation delay. Afterwards, it rapidly dropped to the minimal resistance level of complete vasodilation. When the occlusion was released, the flow rapidly increased. Initially, the flow was briefly high at positive values as the blood volume of the compliance was restored. Flow remained elevated to relieve the ischemia. Following a delay time, flow was then restored to its initial value prior to occlusion. This was done in an oscillatory manner.

14.4.5 Minimal Circuit Model

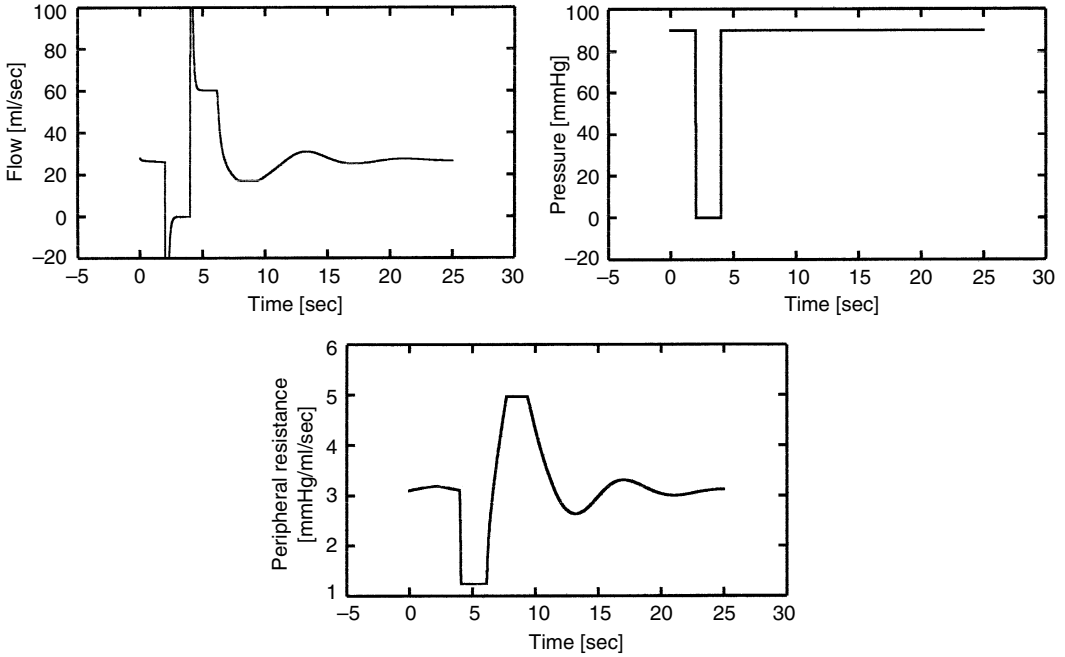
As in much of hemodynamic research, the Windkessel model, as well as others, have been portrayed in electrical circuit form. The autoregulating Windkessel described here cannot be simplified completely in circuit form. But, a useful approximation was designed. It was assumed that the time constants of autoregulation


FIGURE 14.6 A vascular occlusion produced by reducing the input pressure to zero for 2 sec. The flow response transients are due to compliance effects. Flow increases to maximum value corresponding with complete vasodilation. A damped oscillatory response returns the flow and resistance to control levels.
FIGURE 14.7 Simplified autoregulating Windkessel in electrical circuit form.

and smooth muscle activation are minimal. Then, autoregulation is immediate. Additionally, it was assumed that vasoconstriction and vasodilation are not limited. Under these conditions, the circuit model of Figure 14.7 can be used to approximate the autoregulating Windkessel. The constant current source represents the control value of autoregulated flow, Q_0. The resistance, R_{auto}, is the slope of the autoregulation line (Figure 14.1). When the actual flow, $Q = Q_0$, the average blood pressure is equal to the pressure source, MAP. Also, under this condition, $R_s = R_{so} = \text{MAP}/Q_0$. Note, that these expressions assume that the pressure drop across the characteristic impedance, Z_o, is negligible.

The impedance frequency spectrum was evaluated for the autoregulating circuit model. It was found to follow the result previously shown in Figure 14.2, with the exception of impedance oscillations. The predicted impedance was in error by the amount of the oscillation amplitude. On average, over a range of frequencies, the error was negligible. Hence, for steady state conditions, the minimal circuit model offers a simple solution to the autoregulating Windkessel. The transient step responses, as predicted by the complete model, cannot be reproduced by this simplified circuit model.

14.5 Discussion

The autoregulation curve described in the current model differs from physiological data only in the sense that it is a segmented linear description. This was due to the fact that the model assumed linear feedback regulation. The actual flow regulation system possesses nonlinearities not accounted for in the current model. Most researchers have found that the steady state pressure flow curve is sigmoidal [Folkow, 1953; Granger and Guyton, 1969]. Other researchers have expressed these nonlinearities as feedback gain that is flow dependent [Van Huis et al., 1985]. Still others have found that a linear pressure–flow relationship is a good approximation within the normal physiological range of blood pressure [Sagawa and Eisner, 1975]. In this case, the current model would be most accurate when flow is near Q_0 and blood pressure is near MAP.

The autoregulation curve has been shown to be affected by the carotid baroreflex function [Shoukas et al., 1984]. Increased carotid pressure leads to a decrease in peripheral resistance so that blood pressure can be maintained at a given cardiac output. In spite of the baroreceptor effect, these same researchers have shown that the steady state pressure-flow curve remains sigmoidal in shape. Thus, the concept of a steady state autoregulation curve applies just as well as when the baroreceptors are functional. The net effect of the baroreceptor response is to decrease the autoregulatory gain, as observed by a decrease in the slope of the steady state pressure-flow curve. This might be expected since pressure has the opposite effect on peripheral resistance to that of flow [Burattini et al., 1991]. This would have the added benefit of stabilizing the autoregulation system by preventing its gain from becoming too high (see stability below). Thus, since the autoregulating Windkessel does not incorporate this response, its primary value is in the analysis of peripheral vascular beds. And, provided that the autoregulatory gain is reduced to account for the baroreceptor effect, it can be applied to the systemic circulation.

The autoregulating Windkessel incorporates the critical closing pressure phenomenon [Alexander, 1977]. Critical closing causes the flow to cease at a slightly positive pressure, P_o. Debate over the mechanism that leads to P_o continues. Since its value is typically small compared with systemic blood pressure, its value was set to zero here.

The low frequency impedance of the autoregulating Windkessel was found to be greater than that predicted by the modified Windkessel (Figure 14.2). The sinusoidal input impedance of a vascular bed has not been explored extensively below the frequency of the heart rate. Sipkema and Westerhof [1980] examined the low frequency range experimentally using an external sinusoidal pump. Under these conditions, it was found that the low frequency impedance approaches the slope of the autoregulation curve, as predicted by the autoregulating Windkessel. These researchers distinguish the low frequency impedance from peripheral resistance by defining it as a dynamic resistance.

Input impedance measurements have identified a variation in the frequency spectrum. While experimental studies have not provided an explanation for the origin of these variations, the current model ties them to autoregulation delay (τ_Q). The model predicts that the spectrum should follow an oscillatory pattern, particularly for frequencies at and below the heart rate. Moreover, the sinusoidal steady state may not be easily achieved experimentally. The model required over one minute duration to obtain the steady state response. The model further predicts an erratic or random variation in the impedance spectrum if the steady state was not obtained. Another explanation could be that the different vascular beds may possess slightly different delay times. When measured at the aorta, this may appear as impedance scatter. Other researchers have attributed the source of impedance variations to nonlinear vascular properties [Stergiopulos et al., 1995b].

The flow step response of the model follows experimental studies quite precisely [Braakman et al., 1983; Shoukas et al., 1984; Van Huis et al., 1985]. Others have observed experimentally an initial autoregulation delay and a slow adjustment of the vascular smooth muscle in response to a step in flow. The time constants of the model were determined in accordance with previous observations. The time course of the flow step response was similar for a single vascular bed and for the entire systemic circulation. Experimental measurements found no oscillations in response to a flow step for the systemic circulation [Shoukas et al., 1984]. Hence, employing a higher order model than was used here would be of little value.

But, *in vivo* measurements in organs have detected the presence of oscillations in the step flow response [Westerhof et al., 1983]. The amplitude of these oscillations were small. Modifying the model to include these higher order dynamics may be at the sacrifice of simplicity and was not considered in this study.

The flow step response examines the autoregulation control under open loop conditions. This procedure essentially forces the flow to a specific level independent of the tissue's metabolic demands. The results of this experiment provide information about the dynamics of the regulatory process. Alternatively, the pressure step response permits autoregulation to function under *in vivo* conditions and provides the closed loop response. Under these conditions, the autoregulating Windkessel shows a damped resonant flow response. This resonant behavior was linked to the time lag of flow regulation. Damping was provided by the slow smooth muscle function. Others have modeled the resonant behavior of autoregulation as a second-order control system that attempts to regulate blood pressure by adjusting the peripheral resistance [Burattini et al., 1987]. While this approach may achieve a similar response, the physiological mechanism differs from that employed in our model. Moreover, data obtained from the open loop flow response, supports the use of a time lag theory. In general, oscillations have been modeled and observed in other biological systems that possess time lags in their feedback pathways [An der Heiden, 1979]. It may be reasonable to expect that biology accomplishes flow autoregulation in a way similar to other types of homeostasis.

While the response to a vasoactive drug was not computed from the autoregulation model, it can be obtained by applying a step change in the time dependent value of R_s [Kenner and Ono, 1972]. In this case, the model also predicts that oscillatory flow will result. Hence, the model suggests, alternatively, that the origin of oscillations may be due to regulatory delays. This interpretation, though, does not rely on conventional control system analysis and does not involve the parasympathetic and sympathetic reflex pathways [Wong and Klassen, 1991].

The model predicted that autoregulation can be unstable for some parameter values. When the parameters were calibrated to match flow step experiments, the model produced a stable result. But, the pressure step can best be characterized as a damped low frequency resonance. Experimental evidence of very low frequency resonance can be found in measurements of the heart rate variability and blood pressure variability spectra [Chess et al., 1975; Akselrod et al., 1981; Pagani et al., 1986], following denervation [Rimoldi et al., 1990], during external constant cardiac pacing [Wang et al., 1995], and in animals with total artificial heart [Yambe et al., 1993]. This experimental observation that a nervous system is not necessary to produce such low frequencies in the cardiovascular system has been perplexing. So much so, that these oscillations have been referred to as the Mayer waves [Mayer, 1876], an observed but currently unexplained phenomenon. The autoregulation model provided here supports the theory that these low frequency oscillations find their origin in the intrinsic delay of flow regulation.

Model parameter values that lie outside the normal physiological range can further enhance autoregulatory instability. Abnormal values may occur in the pathological situation. Oscillations in pressure and flow were predicted by the model to lie well below heart rate, in the range below 0.1 Hz for the dog. For example, prominent low frequency oscillations have been observed during heart failure [Goldberger et al., 1984]. While it has been proposed that these oscillations follow the respiratory rate, they have been observed to occur at even lower frequencies. The autoregulating Windkessel model offers a possible explanation of the source of these oscillations given pathological conditions. It also suggests the possibility that they may be used to noninvasively monitor the condition of the autoregulatory system.

14.6 Conclusions

The autoregulating Windkessel was found to accurately reproduce the experimental flow step response of both vascular beds and the systemic circulation. The model further provided the steady-state pressure-flow autoregulation curve, in linearized form. The impedance spectrum was predicted to differ from that of the three element Windkessel for frequencies below the heart rate. For frequencies near zero, the impedance approached the slope of the pressure–flow autoregulation curve, as opposed to peripheral

resistance. But, simultaneously, the average pressure divided by the average flow of the model yielded the usual value of peripheral resistance. The low frequency impedance spectrum was also predicted to contain oscillations that were traced to autoregulatory delay. This result provides an explanation of the variability obtained experimentally during multi-beat examination of the impedance spectrum. The pressure step response of the autoregulating Windkessel revealed a damped low frequency resonant behavior. The model parameters that cause increased autoregulatory gain and decreased damping were found to lead to sustained flow oscillations at frequencies well below the heart rate. This resonance explains the origin of very low frequencies observed in the heart rate variability spectrum referred to as the Mayer waves.

15.1 Introduction

The mechanical system being controlled is referred to as the **plant**. The configuration of the system at any instant in time comprises the plant **states**. The devices that power the system are called **actuators**. The signals driving the actuators are called **controls**. The **controller** encompasses processes by which the controls are generated. The time histories of the plant states in response to the control signals are referred to the system **trajectory**.

Controllers can be designed to function without sensors and therefore without knowledge of the actual plant trajectory (**open-loop control**, Figure 15.1a). **Reference-based open-loop controllers** precompute and store control signals, and execute the desired motor task in real time. To correct for disturbances and modeling errors a feedback controller with ongoing knowledge of the effects of the disturbances can be used. **Closed-loop system** (Figure 15.1b), or so-called *error-driven controllers* use feedback information from sensors measuring the states. Both controllers described require the full knowledge on the system parameters, desired trajectories of the system components, and allowed tracking errors. Operation of an open-loop or closed-loop controller can be simulated using analytic tools derived from mechanics and mathematics.

Nonanalytic control is a technique that attempts to mimic the organization found in biological systems. Nonanalytic control considers the system operation as a block box. Heuristics or machine intelligence or both are used to determine the mappings between inputs and outputs of the specific system operation that are adequate for the implementation of nonanalytic external control (Figure 15.1c).

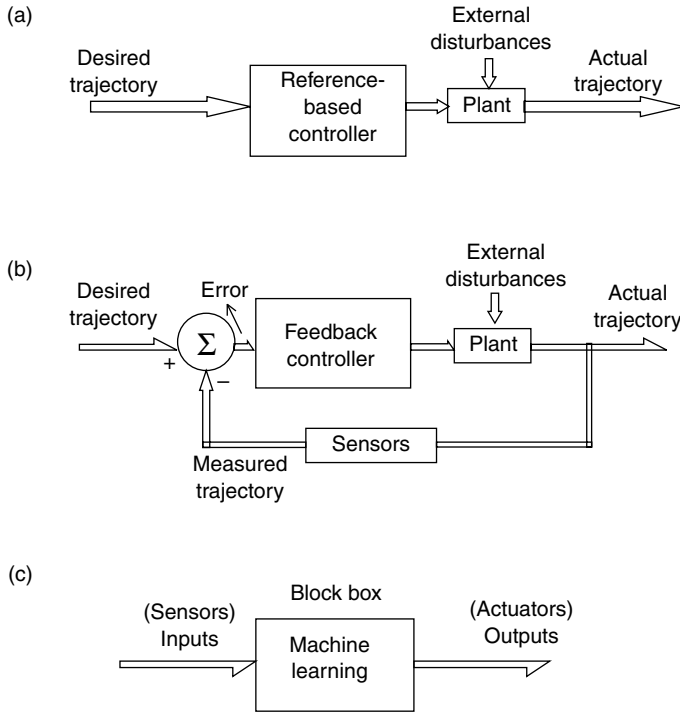
15-1


FIGURE 15.1   Open (a) and closed-loop (b) control systems. Nonanalytic model (c) for control of movements.

Control of movements in humans is a very complex task dealing with large-scale, nonlinear, time-variable, dynamically nondetermined, redundant system [1]. A dynamical system may change its states in a continuous way. Without an optimization criterion, all trajectories of a system are equivalent. The term trajectory has a broad meaning; it does refer to the way the system coordinates vary in the course of transition from the current to the next **state**. An optimization criterion assigns to each transition trajectory or a subset of trajectories, a value so that they can be arranged in the order of preference. In some cases, the trajectories of the dynamical system may be well-ordered so that a single solution stands in front. Such a trajectory is given the name the optimal solution. Instances when optimal solutions of control tasks exist, or can be analytically determined, are relatively rare although this term is used rather loosely in everyday life.

15.2 Biological Control of Movements

The skeletomotor system provides the structure and drives to move the body and limbs relative to the surroundings and to maintain the posture in space. The motor systems act on the environment by transforming neural information and metabolic energy into movement. Changes in external events or in the internal environment, signaled by the sensory systems, set up commands that are transmitted to the skeletal muscles by nerve impulses. The muscles convert the neural information into a command that transforms chemical into mechanical energy by generating a contractile force.

The control of movement and posture is achieved solely by adjusting the degree of contraction of skeletal muscles; however, this control requires that the motor systems be provided with a continuous flow of information about events from the periphery. Exteroceptors provide the motor systems with information about the spatial coordinates of the objects. Proprioceptors relay information about the position of the body vs. the vertical, the angles of the joints, the length and tension of muscles, and so on. Through

proprioceptors, the motor systems gain access to information about the condition of the peripheral motor plant, the muscles and joints that have to be moved. The motor systems need information about the consequences of their actions. Both exteroceptors and proprioceptors provide this information, which can then be used to calibrate the next series of motor commands. Thus, motor mechanisms are intimately related to and functionally dependent upon sensory information.

The following three properties are especially important for the control (1) Muscles contract and relax slowly. Changes in muscle tension do not represent a simple one-to-one transformation of the firing patterns of motor neurons. The muscle filters the information contained in the temporal pattern of the spike train produced by motorneurons. Because of this filtering action, muscles faithfully reproduce only those signals that vary slowly. The ability of the muscular force to follow fluctuations is greatly diminished if the signals fluctuate rapidly. This indicates that it is necessary to alternate contraction in opposing muscle in order to produce fast change of the force; (2) Muscles have spring-like properties; thus, within limits, the tension exerted by muscles varies in proportion to length. Neural input is changing the muscles' resting length and stiffness. The actual change of muscle length depends on the neural drive and also on both initial lengths of the muscle and external loads; and (3) The motor systems need to control many muscles acting at the same joint simultaneously with muscles acting at different joints. Reaching while standing is an example of using many muscles to achieve a task. Bringing a segment of the hand to a desired position requires contraction of a group of muscles acting as prime movers (agonist muscles), yet antagonist muscles, which oppose the actions, must be controlled.

Mechanisms for control of posture: There are multiple definitions of posture [2–5]. When dealing with posture two functions emerge [6] (1) the antigravity operation. This function includes first the building up of the body segment configuration against gravity. A related function is the static and dynamic support provided by skeletal segments in contact with the support base to the moving segments; and (2) the interface for perception and action between the environment and the body. The orientation with respect to space of given segments such as head or trunk serves as a reference frame for the perception of the body movements with respect to space and for balance control. They also serve as a reference frame for the calculation of the target position in space and for the calculation of the trajectories for reaching the targets.

Quiet standing comprises some swaying of the body. During quiet standing, the gravity, ground reaction forces, and inertial forces produced by swaying are in equilibrium. The center of mass (CoM) is the point at the body where the resultant gravity force acts. The projection of the CoM to the base of support is called the center of gravity (CoG). The point of origin of the ground reaction force, the point through which the resultant ground reaction forces passes, is named the center of pressure (CoP). Maintaining posture is a process of continuous swaying of the body around the position of labile stability. Since the human body contains many segments that move relative to each other, CoM constantly changes its position; therefore, CoG constantly moves in the ground-contact plane. The central nervous system has to adjust the relative position of segments to prevent falling, that is, to control many muscles according to ensure dynamic equilibrium.

Mechanisms for control of walking: Walking is among the most highly automated movements of humans. The bipedal locomotion of humans is an unusually stable structure, although the mechanical structure is far from the favorable. All basic details of normal walking may be found in each and every able-bodied subject. Individual differences between subjects neither depend on the differences in the structure of walking, nor on the assembly of elements encountered, but only in the rhythms and amplitudes of the ratios between these elements.

As described, the posture is the state of equilibrium in which the net torque and force generated by gravity and muscles are zero, and only minimal sway exists around the quasi-stable inverted pendulum position. Walking occurs once the equilibrium ceases to exist because of the change of internal forces caused by muscle activity. The change of internal forces will cause the center of gravity to move out of the stability zone, and the body will start falling. Human walking starts, therefore, after the redistribution of internal forces allowing gravity to take over. The falling is prevented by bringing the contralateral leg

in front of the body, hence, providing new support position. Once the contralateral leg supports the body weight and the ipsilateral leg pushes the body up and forward due to the momentum, the body will move in the direction of progression, and ultimately come directly above the supporting leg. This new inverted pendulum position is transitional; momentum and gravity will again bring the body into the falling pattern. Cyclic repetition of the described events is defined as bipedal locomotion or walking.

The major requirements for successful locomotion are (1) production of a locomotor rhythm to ensure support to the body against gravity; (2) production of muscle forces that will result with the friction force required for propelling it to the intended direction; (3) dynamic equilibrium of the moving body; and (4) adaptation of these movements to meet the environmental demands and the tasks selected by the individual.

Control of goal-directed movement: Goal-directed movement is a planned change of arm and hand segments positions, ultimately leading to a task. This movement depends on a balance of initial programming and subsequent correction. Initial programming is based partly on visual perception of objects, and partly on propriception (e.g., a visual cue is used to decide whether to pick up the object with one or two hands, and what type of grasp to use). The accuracy of visual perception determines the initial programming.

The visual information is used to identify a target and its location in space, and also for corrections of ongoing movement. Goal-directed movement for a seen object usually benefits from visual feedback. This observation raises the question of how visual guidance is used in the control of reaches and grasps. There are at least three aspects of this problem (1) visual localization of the target in extra-personal space and suitable coding of that information for use by the arm motor system; (2) visual monitoring of the hand before and during its movement through space; and (3) visual adjustment of the final position of the hand to touch, grasp, or retrieve successfully the object of interest [7].

It has been shown unequivocally that reaching is more accurate in the presence than in the absence of vision of the arm just before [8] and during the movement [8–10]. Since this improvement was observed even for movements that were completed within 200 msec, it was proposed [11] that visual cues from arm motion are being processed at higher speeds than the timing assumed necessary (190 to 260 msec) to utilize external visual feedback [12].

The nervous system can learn to achieve desired levels of accuracy by adjusting control signals to accommodate factors such as changing musculoskeletal geometry, and dynamics. For example, when an object is grasped and lifted with fingers, the grip force varies directly in an anticipation of the load force as determined by mass and acceleration of the object [13–16].

Although the results of Morasso [17] are usually taken as strong evidence for spatial planning, several investigators have pointed out that end-point trajectories are not completely straight but instead gently curved in many parts of workspace, particularly in the sagittal plane [18]. This might be evidence for joint space trajectory planning, but the curvature seen in this movement is insufficient to support simple joint space interpolation, which would lead to much larger curvature. To account for this Hollerbach et al. [18] proposed a modification to joint space interpolation, which they termed "staggered joint interpolation," in which different joints begin moving at different times in order to produce straighter trajectories. However, this model cannot account for the reversals seen in the study of Morasso [17]. Hollerbach and Atkeson [19] proposed a way to directly control joint, which also yields straight-line hand paths. The method is to vary the onset times for the motions of the joints. Another experiment, which tried to prove that movement is joint space planned [20], was a simple act of pointing to a target.

Redundancy and motor equivalence: Bernstein [21] postulated the main problem of control of voluntary movement as the elimination of redundant degrees of freedom. The method used by nature to resolve the problem of redundancy and increase the efficiency of movement comes from the dependencies between components of the motor system. These dependencies could be understood as constraints and they ultimately decrease the number of variables to be controlled.

Motor equivalent behavior can be understood as the ability to use redundant degrees of freedom to compensate for temporary constraints on the effectors while producing movement trajectories to targets. There are some advantages of having the ability to perform a task in many ways (e.g., such as avoiding obstacles). The essence of motor equivalence is the ability to transform one type of sensory information

into another. This is not present at birth. Transformations must be adapted (calibrated) in different circumstances like growth or handicap.

An important element to understand is the role and organization of the highly redundant muscles. The best way to do so is to analyze electrical activity of muscles, that is, the electromyography (EMG). The first detailed EMG analysis [22] of agonist and antagonist muscle activity in humans during flexion-extension movements of the arm showed a so-called triphasic pattern. The triphasic pattern is a strict alteration between agonist and antagonist EMG activity: the initiation of a distinct burst of activity in the agonist is followed by a distinct burst of activity in the antagonist. After a brief silent period in the agonist, activity returns in the form of a second burst. The existence of a consistent relationship between muscle activation patterns and the kinematic (or kinetic) variables of movement indicates which of these variables are important in planning appropriate motor output [23].

Grasping: Grasping is a part of the prehension, a process of orienting the hand, opening it so that the object fits comfortably, contacting the object, and forming a firm grip.

The selection of the grasp depends on both the function that has to be achieved and the physical constraints of the object and the hand. A fundamental functional constraint is that once the object is grasped it is not to be dropped. The posture used by the hand during the task must be capable of overcoming perturbations and include anticipated forces that may act at the object. There are different prehensile classifications, methods to classify hand postures, developed by researchers from different prospectives (e.g., medical, robotics) [24]. Schlesinger [25] suggested a taxotomy that was developed to capture the versatility of human hands for designing functionally effective prosthetic hands. The simplest taxotomy includes set of five grasp postures. For practical reasons this classification can be further reduced to only three grasps: lateral, palmar, and pinch grasps. Analyzing grasping in typical daily activities shows that these three grasps are responsible for almost 95% of all functions.

The task for the motor system of the hand is to build an "opposition space," which would take into account both the shape of the object and the biomechanics of the hand [26,27]. Experimental data suggest that there are preferred orientations for the hand opposition space. The hand posture selected during the preshape defines the optimal opposition space for applying the required forces to the object [28]. Using the term opposition authors described three basic directions along which the human hand can apply forces (1) pad opposition occurring between hand surfaces along a direction parallel to the palm. The surfaces are typically the volar surface of the fingers and thumb near or on the pads (pinch grasp); (2) palm opposition occurring between hand surfaces along a direction perpendicular to the palm (palmar grasp); and (3) side opposition occurring in the direction generally transverse to the palm (lateral grasp). Paulignan et al. [29] showed that the same orientation of the hand was retained during prehension of the same object placed at different positions in the working space, which implies different degrees of rotation of the wrist or the elbow.

15.3   Modeling of Human Extremities

Modeling of a human body with the emphasis to the extremities is the prerequisite for the synthesis of analytic control [30–33]. Human extremities are unlike any other plant encountered in control engineering especially in terms of joints, actuators, and sensors. This fact must be kept in mind when applying the general equations of mechanics to model the dynamics of functional motions. A simple extension of analytical tools used for the modeling of mechanical plants to the modeling of biomechanical systems may easily produce results in sharp discrepancy to reality.

A basic problem in motor control of human extremities is in *planning* of motions to solve a previously specified task, and, then, *controlling* the extremity as it implements the commands. In terms of mechanics, extremities could be adopted as the rigid mechanical segments connected by joints and surrounded by muscles, tendons, ligaments, and soft tissue that can set the joint angle, joint angular velocity, and acceleration to any value within its range. Muscles and tendons can also control the joint stiffness. The motions of extremities are called *trajectories* and consist of a sequence of positions, velocities, and

accelerations of any part of the system (e.g., hand, fingertip, foot, etc.). It is anticipated that by using laws of mechanics one can determine necessary muscle forces to follow the given trajectory.

A body segment, when exposed to physiological loading, can be modeled as a **rigid body**, even though it contains somewhat flexible bones and soft tissue (e.g., muscles, tendons, ligaments, skin, etc). Inertial properties of a rigid body are its mass and the inertia tensor. The inertia tensor for a rigid body provides information on inertial properties of the body when rotating. The mass for a rigid body describes its inertia for translation type of movements. In reality the inertial properties change: the center of mass is shifting because the masses relatively move during contractions and passive stretching of muscles, relative movements of bones and other soft tissue modify the geometry, and polycentric joints virtually change the length of a body segment.

The second issue in the modeling relates to joint structures. A joint is modeled as a **kinematic pair**. The theory of mechanisms defines connection of neighboring segments as kinematic pairs having up to five degrees of freedom (DOF). Most common human joints are rotational kinematic pairs having three DOF (ball joint), or only one DOF (pin joint). However, many movements cannot be simplified to a pin or a ball joint. Some human joints must be represented with double mechanical joints (e.g., ankle joint consists of one joint for internal–external rotation, and inversion–eversion, and the other joint for movements in sagittal plane [flexion–extension]). Sometime the body segment rotation results from more complex structures such as two parallel bones connected between two neighboring joints (e.g., supination–pronation). Human joints are spatial and polycentric, and the displacement of the center of rotation results in the virtual change of the geometric and inertial properties of the body segment.

Speaking of mechanics one needs to distinguish the *forward kinematics* from the *inverse kinematics*. The direct kinematics is concerned with the determination of the position of body parts in the absolute reference frame given joint angles, whereas the inverse kinematics computes joint angles for a given position of the body part. Of these two, the direct **kinematic analysis** is the simplest by far, with a straightforward solution for the unique end point of the body part corresponding to the given joint angles. On the other hand, the feasibility of an inverse kinematics solution depends on the redundancy of the structure, as well as the offsets and constraints.

The redundancy is an important feature in biological systems. The concept of *redundancy* requires a distinction between a **degree of freedom** and a permissible motion (e.g., rotation). The term DOF pertains exclusively to that permissible motion which is independent from other motions. A free rigid body has a maximum of six DOF, and a rigid body connected to another rigid body by a ball joint can have a maximum of three DOF; thus, any body segment has less or maximum three DOF. Speaking of a structure as a whole, the total number of permissible rotations is termed system DOF. Some permissible rotations are not independent and they should not be called DOF (e.g., two parallel hinge joints). It is difficult to determine which permissible rotations should be controlled, and which will be constrained by themselves due to anatomical and physiological limitations.

Decomposing the linked structure into a set of single links is essential for numerical simulation. Internal forces within the body generated by muscle activities become external forces and torques when the dynamics of a single link is considered. The muscle is a linear actuator, with a very complex behavior depending on its length, velocity of shortening, firing rate, recruitment, and type. *Muscle models* [34] can be grouped to three classes (1) Crossbridge models including sarcomere — microscopic, conventional crossbridge, and unconventional crossbridge models; (2) Fiber models; and (3) Whole muscle — macroscopic models (viscoelastic and black box models). The distinctions between these classes are not absolute (e.g., micro–macro).

The modeling and control of movements in this chapter relates to external control of muscles via so-called functional electrical stimulation. Macroscopic viscoelastic models started from the observation that the process of electrical stimulation transforms the viscoelastic material from a compliant, fluent state into the stiff, viscous state. Levin and Wyman [35] proposed a three-element model — damped and undamped elastic element in series. Hill's work [36] demonstrated that the heat transfer depends upon the type of contraction (isometric, slow contracting, etc). The model includes the force generator, damping and elastic elements. Winters [37] generalized Hill's model in a simple enhancement of the original, which

makes no claim to be based on the microstructure. Winters's model deals with joint moments:

$$M = M_0 - B\dot{\Theta}, \quad M_0 = AM_{0m}f(\Theta)$$

M is the muscle moment exerted about the joint, M_0 is the isometric moment (active state) with a maximum possible value M_{0m}, Θ is the joint angle corresponding to the current contractile element length, A is a normalized activation variable ($A = 0$ for relaxed muscle, $A = 1$ for a tetanized muscle), $f(\Theta)$ is the normalized tetanic length–tension relation, and B is a variable damping coefficient. For shortening muscle

$$B = M_0(1 + \alpha)/(\dot{\Theta} + \gamma\dot{\Theta}_0), \quad \dot{\Theta} < 0$$

whereas for lengthening muscle

$$B = M_0(1 - \beta)/(\dot{\Theta} + \gamma\dot{\Theta}_0), \quad \dot{\Theta} > 0$$

where α, β, and γ are constants.

Zajac [38] proposed an appealing new version of the Hill model designed primarily for use in studies of mechanical interactions in multiple muscle systems. Muscles are connected to a skeleton with tendons, and they have spring-like behavior when stretched. A variety of different nonrigid structures are included in the musculoskeletal system (e.g., ligaments) adding different elastic and damping effects. Nonlinear models of electrically stimulated muscle have been reviewed by Durfee [68]. Block models are only one of several possible structures, which can be used in biological system identification. Where there are only two blocks, one of that is nonlinear, may be placed before or after the dynamic block, in so-called Hammerstein or Wiener forms. Techniques for identifying the parameters for these models were investigated in details by Kearney and Hunter [40].

Dynamic analysis deals with two problems: determination of forces and torques when desired laws of motion are known (*forward dynamics*), and determination of trajectories and laws of motion when torques and forces are prescribed (*inverse dynamics*). Forward dynamics is a simple problem, and the only difficulty comes from error generated through numerical derivation on noisy input data. Using laws of mechanics (D'Alembert principle [41,42], Newton–Euler method [38,43–47], Lagrange equations [48–51], Basic theorems of mechanics [52], etc.) in inverse dynamics works only for open-chain structures such as an arm when reaching, or a leg during the swinging, but it is neither applicable for closed-chain structures such as legs during the double-support phase in walking, or the arm when contacting an immobile object, nor in redundant systems. Every closed, chained structure is dynamically undetermined and the only possibility to determine forces and torques is to use the theory of elasticity. The theory of elasticity assumes that the elements of the structure are solid (not rigid), and it is inappropriate for control design because of its extreme complexity. Approximate solution of the dynamics of a closed-chain mechanism assumes how forces and torques are distributed in the structure. In the case of locomotion, it is necessary to introduce at least three equations in order to be able to determine the dynamics of the process. In most cases the chain is limited to a small number of admissible rotations. The reason for simplification is twofold: the problem can be solved and the simulation results can be interpreted.

The complexity of a body segment dynamical model depends on the number and types of body segments, the joints connecting the segments, and the interaction among the segments and the environment. How complex is a model required for dynamic analysis of externally controlled walking, standing, manipulation, and grasping? Some decisions on how complex the model should be are simple, others are not. For instance, lower limb can be assumed rigid during standing and walking. More controversial is the decision on how many segments should be assumed, and how many DOFs should be assumed for each joint.

Several studies deal with strategies for prolonged standing [53–58] and functional electrical stimulation-aided gait [59–64].
FIGURE 15.2 A sketch of a human body used for modeling of locomotion. Rigid body segments (left) are driven with two pairs of muscles (right). See the text for details.

Recent studies are concerned with estimating parameters required for modeling and simulation [65–74]. Many of the results are very useful; however, the presentations are incomplete and difficult to reproduce.

15.4 Analytic Models for Control of Movements

Attempts to analyze multijoint structures are often characterized by reducing the number of DOF to a manageable level. Locomotion is often decomposed into a component in the sagittal plane, and smaller components in the frontal and horizontal planes. Using smaller number of links is essential for simulation of gait.

A double, planar, pendulum with a moving hanging point, representing a human leg, is included here to illustrate the modeling. The remaining part of the body is represented as a single force acting to the moving hanging point (hip joint), hip joint torque (Figure 15.2). Two pairs of muscles acting around the hip and knee joints actuate the leg. Both monoarticular and biarticular muscles add to the joint torques. Estimating the relative contribution of monoarticular and biarticular muscles is very difficult but possible [75].

The model does not include ankle and phalangeal joints. The following system of differential equations describes the dynamics:

$$A_1\ddot{\phi}_S + A_2\ddot{\phi}_T \cos(\phi_T - \phi_S) + A_3\dot{\phi}_T^2 \sin(\phi_T - \phi_S) - A_4\ddot{x}_H \sin\phi_S$$
$$- A_5(\ddot{y}_H + g)\cos\phi_S - X_G L_S \sin\phi_S + Y_G L_S \cos\phi_S = M_S \tag{15.1}$$

$$B_1\ddot{\phi}_T + B_2\ddot{\phi}_S \cos(\phi_T - \phi_S) + B_3\dot{\phi}_S^2 \sin(\phi_T - \phi_S)$$
$$- B_4\ddot{x}_H \sin\phi_T - B_5(\ddot{y}_H + g)\cos\phi_T - X_G L_T \sin\phi_T + Y_G L_T \cos\phi_T = M_T \tag{15.2}$$

$$A_1 = J_{CS} + m_S d_S^2, \qquad B_1 = J_{CT} + m_S L_T^2 + m_T d_T^2$$
$$A_2 = m_S d_S L_T, \qquad B_2 = A_2, \qquad A_3 = -A_2, \qquad B_3 = B_2$$
$$A_4 = m_S d_S, \qquad B_4 = m_S L_T + m_T d_T, \qquad A_5 = -A_4, \qquad B_5 = -B_4$$

There are several torques contributing to the total torques acting at the links

$$M_S = -M_K, \qquad M_T = M_K + M_H$$
$$M_K = M_K^f - M_K^e - M_K^r, \qquad M_H = M_H^f - M_H^e - M_H^r \tag{15.3}$$

The following notations are used: S — the shank segment (including the foot); T — the thigh segment; C_S, C_T — the center of the mass of the shank and thigh segments; H — the hip joint; K — the knee joint; G — the point of ground contact; d_S, d_T — distances of the proximal joint to the centers of the masses; L_S, L_T — lengths of the shank and thigh; m_S, m_T — masses of the shank and thigh; J_{CS}, J_{CT} — moments of inertia of the shank and thigh about the central axes perpendicular to xOy plane; g — gravitational acceleration; F_H — force acting at the hip joint; X_G, Y_G — horizontal and vertical components of the ground reaction force; M_S, M_T — total torques acting at the shank and thigh segments; M_K, M_H — joint torques at the knee and hip joints; $\ddot{x}_H$, $\ddot{y}_H$ — horizontal and vertical components of the hip acceleration; ϕ_S, ϕ_T — angles of the shank and thigh vs. the horizontal axis (Ox); ϕ_K, ϕ_H — angles of the knee and hip joint; ϕ_{TR} — angle of the trunk vs. the horizontal axis (Ox).

Flexion of a joint is defined to be the positive direction for angular changes; hence, the flexor torque is assumed to be positive. Index f is for the equivalent flexor muscle, and index e for the equivalent extensor muscle. The contribution of passive tissue crossing the joints is included by a "resistive" torque (index r), which will be described below.

A three-multiplicative-factor model used is a modified version of the Hill model (Figure 15.3). Active muscle force depends on the neural activation, muscle length, and velocity of shortening or lengthening [41,42]. The model is formulated as a function of joint angle and angular velocity, rather than muscle length and velocity. The three-factor model is given by:

$$M_a = A(u)f(\phi)g(\dot{\phi}) \tag{15.4}$$

where M_a is the active torque generated by a muscle contraction; $A(u)$ is the dependence of a torque on the level of muscle activity u depending on the stimulus amplitude, pulse width, and stimulus frequency; $f(\phi)$ is the dependence on the angle ϕ; and $g(\dot{\phi})$ is the dependence on the angular velocity $\dot{\phi}$. The parameter u is normalized to the range $0 \le u \le 1$. According to the literature [76], the muscle model described by Equation 15.1 can predict the muscle torque with 85 to 90% accuracy during simultaneous, independent, pseudorandom variations of recruitment, angle, and angular velocity.

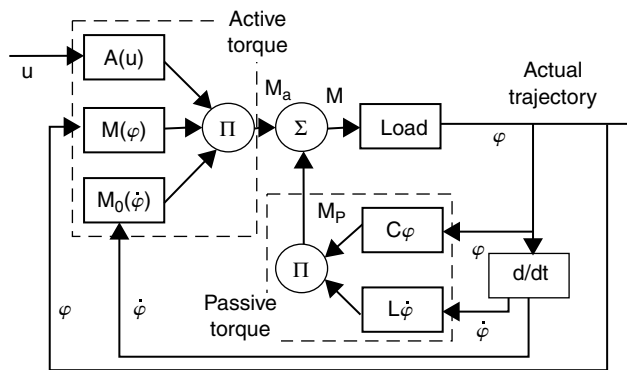
Activation $A(u)$: In accordance with the literature [76–79] the muscle response to electrical stimulation was approximated by a second-order, critically damped [76,77], low-pass filter with a delay. Thus, the


FIGURE 15.3   A three factor multiplicative model of a muscle (active torque). The model includes antagonist muscle (passive torque).

activation dynamics were assumed to be expressed by the following equation:

$$\frac{A(j\omega)}{U(j\omega)} = \frac{\omega_p^2}{\omega^2 + 2j\omega\omega_p + \omega_p^2} e^{-j\omega t_d} \tag{15.5}$$

where $A(j\omega)$ is the Fourier transform of the muscles' contractile activity, $U(j\omega)$ is the Fourier transform of the muscle's electrical activity, ω_p is muscle's natural frequency (typically in the range of 1 to 3 Hz), t_d is the excitation-contraction and other delays in the muscle.

Joint torque $(f(\phi))$ dependence on a joint angle: The nonlinear function relating torque and joint angle is simulated by a quadratic curve, $F = a_0 + a_1\phi + a_2\phi^2$. The torque generated can not be negative for any angle, so

$$f(\phi) = \begin{cases} F & \text{if } F \geq 0 \\ 0 & \text{if } F < 0 \end{cases} \tag{15.6}$$

Coefficients a_i define the shape of the torque-angle curve and they are determined as the best fit through the experimental data recorded. The quadratic polynomial was selected as the simplest adequate fitting curve as described elsewhere [73,80]. Note that each of the quantities is nonnegative.

Normalized joint torque $(g(\dot{\phi}))$ dependence on the angular velocity: The normalized joint torques vs. joint angular velocities can be modelled piecewise linear:

$$g(\dot{\phi}) = \begin{cases} c_{ij}, & \dot{\phi} < (1 - c_{ij})/c_{ij} \\ 1 - c_{ij}\dot{\phi}, & (1 - c_{ij})/c_{ij} \leq \dot{\phi} < 1/c_{ij} \\ 0, & 1/c_{ij} \leq \dot{\phi} \end{cases} \tag{15.7}$$

The coefficients c_{ij} determine the slope and saturation level of the linearized torque vs. velocity of the muscle shortening. These coefficients can be determined using the method described in Reference 81.

Resistive joint torque: Soft tissue, passive stretching of antagonistic muscles, and ligaments introduce nonlinearities, which can be modeled as:

$$M^r = d_{11}(\phi - \phi_0) + d_{12}\dot{\phi} + d_{13}\,e^{d_{14}\phi} - d_{15}\,e^{d_{16}\phi} \tag{15.8}$$

The presented form was developed heuristically, and it shows that the resistive torques depend on both the joint angle and its angular velocity. The two first terms are the contributions of passive tissues crossing the joints (dissipative properties of joints) reduced to first-order functions. The other terms are the nonlinear components of the resistive torques around the terminal positions, and are modeled as double exponential curve [73].

15.5 Nonanalytic Modeling of Movements

As said, the control of movements in humans is a highly complex task, the model of the body and extremities is complicated and not observable per se, the trajectories are not known in advance, the driving resources are user specific and time variable; thus, real-time control using analytical tools is probably not feasible.

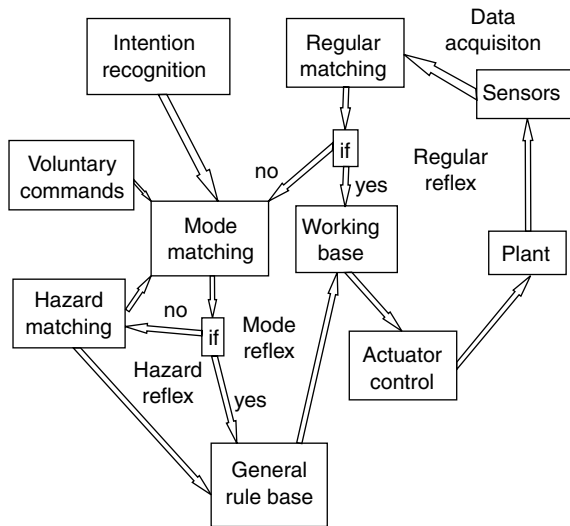
An alternative is to model the process of locomotion as a black box with multiple inputs and outputs. Tomović [82] proposed a nonnumerical control method, called **artificial reflex control** (ARC). ARC (Figure 15.4) refers to a skill-based expert using rules that have an *If–Then* structure [83]. The locomotion is presented as a sequence of discrete events. Each of these discrete events can be described in terms of a sensory pattern and a motor activity. A sensory pattern occurring during particular motor activity can be recognized with the use of human-made (artificial or natural) sensors. The specific discrete event is called


FIGURE 15.4 A scheme of the organization of a skill-based multilevel control for locomotion. Regular reflexes are sequences of system states connected with conditional If–Then expressions within a single mode of the gait, mode reflexes relate to the change of the mode of the gait (level, slope, stairs, etc.), and hazard reflexes are for situations where software or hardware cannot drive the system upon the preferred sequence of system states.

the state of the system by analogy to the state of finite-state automata [82,84]. This skill-based expert system is of the *On–Off* type and does not consider explicitly the system dynamics.

A rule-based control system has a hierarchical structure. The highest level is under volitional control of the user. Automatic adaptation to environmental changes and modes of gait is realized using artificial reflex control. The execution of the artificial reflex has to be tuned for smooth functional movements. Advantages of this **hierarchical control** method are the following (1) adaptivity, (2) modularity, (3) ease of application, and (4) possibility of integration into a man–machine system. Rule-based control was tested in hybrid assistive systems [85,86] and artificial legs [83].

Nonanalytic control can be described as cloning the biological control [87,88]. The basic mechanisms for implementation of such algorithms are rule-based controllers (RBCs) [89]. RBC were applied for assistive systems to restore locomotion with handcrafted [82,85,90,91], and lately automatically determined knowledge base [92–97] with limited success. An RBC is a system implementing "If–Then" **production rules**, where "If" part describes the sensory and motor state of the system, while "Then" part of a rule defines the corresponding motor activity to follow.

It was hypothesized that machine learning (ML) can acquire the needed knowledge for RBC (see Chapter 14 of Abbas, this book). Learning in general can be described as capturing and memorizing of connectivisms between facts (Figure 15.5). ML is a computerized capturing and memorizing process. The study [93] used simulation results of a fully customized biomechanical model as inputs and outputs required for an ML. The following MLs were compared (1) a multilayer perceptron (MLP) with the Levenberg–Marquardt improvement of backpropagation (BP) algorithm [98]; (2) an adaptive-network-based fuzzy inference system (ANFIS) [99]; and (3) combination of an entropy minimization type of inductive learning (IL) technique [92,97,100] and a radial basis function (RBF) type of artificial neural network (ANN) [101,102] with orthogonal least squares (OLS) learning algorithm [101].

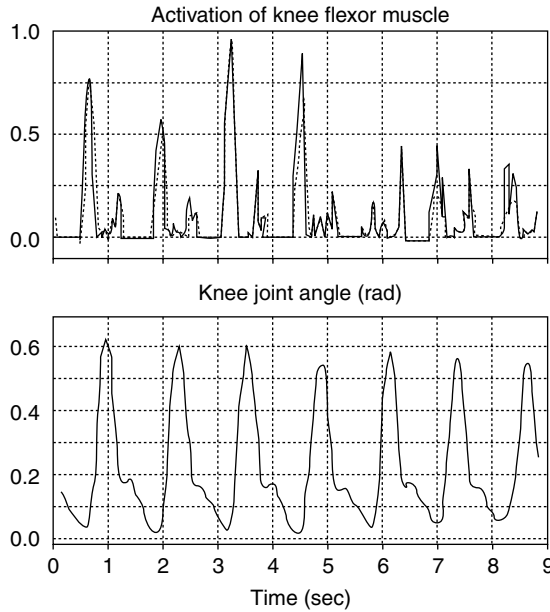
A comparison of IL with adaptive logic networks (ALNs) using restriction rules [95,96] shows that ALNs have some advantages over IL. Heller et al. [92] compared an IL method based on an algorithm called "hierarchical mutual information classifier" [103] with an MLP with BP algorithm in reconstructing muscle activation from kinematic data during normal walking. The conclusion was that both techniques show comparable performance, although each technique has some advantages over the other. A comparison of IL method based on minimization of entropy and the RBF network in predicting muscle


FIGURE 15.5 A mapping obtained as a result of radial basis function and artificial neural network (RBF ANN) learning algorithm. The knee joint angle sensory information for first four consecutive strides (full line, bottom panel), the ground reactions, and the hip accelerations were used as inputs for training. The activation of knee flexor muscles for the same four strides (full line, upper panel) was used for output during the training. The upper panel presents superimposed desired activation of muscles (full line) and a predicted activity of the muscle by a RBF ANN (dashed line) obtained from a trained network for seven consecutive steps. See text for details.

activation and sensory data from the history of sensory data for a human with spinal cord injury (SCI) [93] shows that the best generalization comes from combining both. The benefits of merging fuzzy logic and an ANN were explored extensively in the literature [99–104].

Investigations of MLPs have been intensified since the formulation of the BP learning algorithm [98]. An MLP is a feed-forward network, typically consisting of several layers of nonlinear processing nodes called hidden layers with a linear output layer. Processing nodes take as input only the outputs of the previous layer, which are combined as a weighted sum and then passed through a nonlinear processing function known as the "activation function." This activation function is typically sigmoidal in shape. An MLP with three hidden layers can form arbitrarily complex decision regions and can separate classes that are meshed together. It can form regions as complex as those formed using mixture distributions and nearest neighbor classifiers [105].

The BP learning algorithm is a generalization of a gradient descent algorithm. The BP algorithm may lead to a local, rather than a global error minimum. If the local minimum found is not satisfactory, use of several different sets of initial conditions or a network with more neurons can be tried. A simple BP algorithm is very slow because it must use low learning rates for stable learning. There are ways to improve the speed and general performance of a BP algorithm. It can be improved in two different ways: by heuristics and by using more powerful methods of optimization. Speed and reliability of BP can be increased by techniques called momentum and adaptive learning rates (e.g., Levenberg–Marquardt modification of BP algorithm).

Fuzzy sets are a generalization of conventional set theory. They were introduced by Zadeh [106] as a mathematical way to represent vagueness in everyday life. A formal definition of fuzzy sets that has been presented by many researchers is following: a fuzzy set A is a subset of the universe of discourse X that admits partial membership. The fuzzy set A is defined as the ordered pair $A = \{x, m_A(x)\}$, where $x \in X$ and $0 \leq m_A(x) \leq 1$. The membership function $m_A(x)$ describes the degree to which the object

x belongs to the set A, where $m_A(x) = 0$ represents no membership, and $m_A(x) = 1$ represents full membership.

One of the biggest differences between conventional (crisp) and fuzzy sets is that every crisp set always has a unique membership function, whereas every fuzzy set has an infinite number of membership functions that may represent it. This is at once both a drawback and advantage; uniqueness is sacrificed, but this gives a concomitant gain in terms of flexibility, enabling fuzzy models to be "adjusted" for maximum utility in a given situation.

The typical steps of a "fuzzy reasoning" consist of (1) Fuzzification, that is, comparing the input variables with the membership functions of the premise (IF) parts in order to obtain the membership values between 0 and 1; (2) Weighing, that is, applying specific fuzzy logic operators (e.g., AND operator, OR operator, etc.) on the premise parts membership values to get a single number between 0 and 1; (3) Generation, that is, creating the consequent (THEN) part of the rule; and (4) Defuzzification, that is, aggregating the consequent to produce the output.

There are several kinds of fuzzy rules used to construct fuzzy models. These fuzzy rules can be classified into the following three types according to their consequent form [107]:

1. Crisply defined constant in the consequent:

$$R_i : \text{IF } x_1 \text{ is } A_{i1} \text{ and } \cdots \text{ and } x_m \text{ is } A_{im} \text{ THEN } y \text{ is } c_i$$

2. A linear combination of the system's input variables in the consequent:

$$R_i: \text{IF } x_1 \text{ is } A_{i1} \text{ and } \cdots \text{ and } x_m \text{ is } A_{im} \text{ THEN } y \text{ is } g_i(x_1, \ldots, x_m) = b_0 + b_1 x_1 + \cdots + b_m x_m$$

3. Fuzzy set in the consequent:

$$R_i: \text{IF } x_1 \text{ is } A_{i1} \text{ and } \cdots \text{ and } x_m \text{ is } A_{im} \text{ THEN } y \text{ is } B_i$$

where R_i is the ith rule of the fuzzy system, x_j $(j = 1, 2, \ldots, m)$ are the inputs to the fuzzy system, and y is the output from the fuzzy system. The linguistic terms A_{ij} and B_i are fuzzy sets, c_i and b_j denote crisp constants.

The so-called zero-order Sugeno, or Takagi–Sugeno–Kang fuzzy model [108] has rules of the first type, whereas the first-order Sugeno fuzzy model has rules of the second type. The easiest way to visualize the first-order Sugeno fuzzy model is to think of each rule as defining the location of a "moving singleton" (a single spike from the consequent) depending on what the input is. Sugeno models are similar to the Mamdani model [109] which has rules of the third type, and which is more intuitive, but computationally less efficient. Fuzzification and weighing are exactly the same, but generation and defuzzification are different [107].

For the type of fuzzy rules used in Mamdani model various methods are available for defuzzification: the centroid of area, bisector of area, middle of maximum, largest of maximum, and so forth [110], but all of these methods are based on the calculation of the two-dimensional-shape surface, that is on the integration. The Sugeno style enhances the efficiency of the defuzzification process because it greatly simplifies the computation; that is, it has to find just the weighted average of a few data points. The implication method (generation) is simply multiplication and the aggregation operator just includes all of the singletons.

Membership functions are subjective and context-dependent, so there is no general method to determine them. Currently, when fuzzy set theory is applied in control systems, the system designers are given enough freedom to choose membership functions and operators, usually in a trial and error way. After a hand-tuning process, the system can function effectively. However, the same methodology is hardly applicable when the system is a general purpose one, or when the context changes dynamically. This suggests an explanation why the most successful applications of fuzzy logic happen in control systems, rather than in natural language processing, knowledge base management, and general purposes reasoning.

The IL is a symbolic technique, which uses supervised learning and generates a set of "if-then-else" decision rules. A method [97] is based on an algorithm called "hierarchical mutual information classifier" [92,103]. This algorithm produces a decision tree by maximizing the average mutual information at each partitioning step. It uses Shannon's entropy as a measure of information. Mutual information is a measure of the amount of information that one random variable contains about another random variable. It is a reduction of the uncertainty of one random variable due to the knowledge of the other. An effective method of integrating results of a mutual information algorithm into a production rule formalism, following the original work of Watanabe [100] and Pitas [111], was done by Nikolić [112]. While generating the decision tree, the algorithm performs a hierarchical partitioning of the domain multidimensional space. Each new node of the decision tree contains a rule based on a threshold of one of the input signals. Each new rule further subdivides the example set. The training is finished when each terminal node contains members of only one class. An excellent feature of this algorithm is that it determines threshold automatically based on the minimum entropy. This minimum entropy method is equivalent to determination of the maximum probability of recognizing a desired event (output) based on the information from input.

Radial basis function (RBF) network is a feed-forward network. The RBF has a single output node and a single hidden layer which contains as many neurons as are required to fit the function within the specifications of error goal. The transformation from the input space to the hidden-unit space is nonlinear, whereas the transformation from the hidden-unit space to the output space is linear. A common learning algorithm for RBF networks is based on first choosing randomly some data points as radial basis function centers and then using singular value decomposition to solve for the weights of the network. An arbitrary selection of centers may not satisfy the requirement that centers should suitably sample the input domain. Furthermore, in order to achieve a given performance, an unnecessarily large RBF network may be required. Since a performance of an RBF network critically depends upon the chosen centers, we used an alternative learning procedure based on the OLS learning algorithm [101]. By providing a set of inputs and corresponding outputs, the values of weights and bias, and RBF centers (parameters for RBF network) can be determined using the OLS algorithm in one pass of the learning data so that a network of an adequate size can be constructed.

When an input vector is presented to such a network, each neuron in the hidden layer will output a value according to how close the input vector is to the centers vector of each neuron. The result is that neurons with centers vector are very different from the input vector will have outputs near zero. These small outputs will have a negligible effect on the linear output neurons. In contrast, any neuron whose centers vector is very close to the input vector will output a value near 1. If a neuron has an output of 1, its output weights in the second layer pass their values to the neuron in the second layer. The width of an area in the input space to which each radial basis neuron responds can be set by defining a spread constant for each neuron. This constant should be big enough to enable neurons to respond strongly to overlapping regions of the input space. The same spread constant is usually selected for each neuron.

15.6   Hybrid Modeling of Controllers

Feedback error learning (FEL) is a hybrid technique [113] using the mapping to replace the estimation of parameters within the feedback loop in a closed-loop control scheme. FEL is a feed-forward neural network structure, under training, learning the inverse dynamics of the controlled object. This method is based on contemporary physiological studies of the human cortex [114], and is shown in Figure 15.6.

The total control effort *u* applied to the plant is the sum of the feedback control output and network control output. The ideal configuration of the neural network would correspond to the inverse mathematical model of the system's plant. The network is given information of the desired position and its derivatives, and it will calculate the control effort necessary to make the output of the system follow the desired trajectory. If there are no disturbances the system error will be zero.

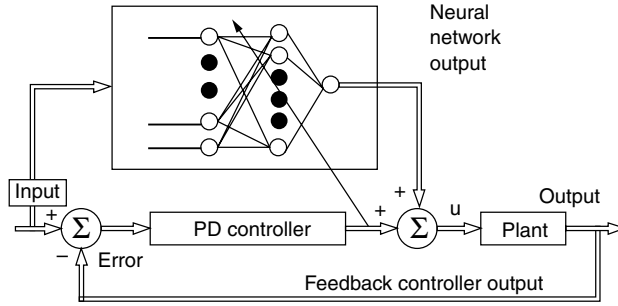
The configuration of the neural network should represent the inverse dynamics of the system when training is completed. It was prudent to use a total energy approach as basis for the neural network, because


FIGURE 15.6 Model for the hybrid modeling of controllers using feedback error learning algorithm. The inclined arrow represents the learning.
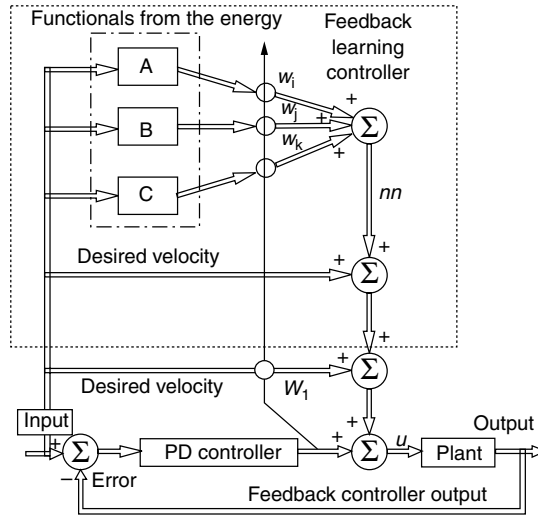

FIGURE 15.7 Scheme of the feedback error learning controller used for the one degree of freedom system. See text for details.

only the commanded input and its first derivative is required for the FEL controller. By comparison, if the FEL were based on the mathematical model, the second derivative would be needed for the neural network to operate [115].

Figure 15.7 depicts a more in-depth explanation of the FEL strategy. The system input and output are labeled θ_d and θ. The proportional-plus-derivative (PD) feedback controller is included to provide stability during training of the neural network [114,116–118]. Enclosed in the dashed rectangle is an FEL controller, which outputs the necessary control signal, based on the desired inputs. The total energy of the system (nn) is calculated through parallel processing within the neural network, consisting of the functionals (A,B,C, . . .) obtained from the total energy expression, the synaptic weights w_i, w_j, and w_k. In addition to the above-mentioned synaptic weights, w_l is associated with damping losses. The training of the FEL controller is facilitated by changing the synaptic weights based on the output from a PD controller. The learning rule used, was proposed by Kawato et al. [119] and it is given as follows:

$$w_{i\text{new}} = w_{i\text{old}} + u_{\text{PD}} A \eta \Delta t$$

where $w_{i\text{new}}$ is the new value of the synaptic weight, $w_{i\text{old}}$ is the old value, u_{PD} is the output from the PD controller, A is the network functional associated with weight w_i, η is the learning rate, and Δt is

the integration step used in the computer simulation. A learning rate is included to control the rate of growth of the synaptic weights. The learning rule, as proposed by Kawato et al. [113], is based on the assumption of slow growth of the synaptic weights. The weights are initialized at zero, and the learning rates adjusted so the growths of the weights are uniform. This causes the weights to reach their final value at the same point in time, causing the error to approach zero. Subsequently, the learning as a function of error will level off, and the training of the neural network will be completed. However, if the growth of the weights is not homogeneous, it will result in an unbounded growth of the weights. The vertical line in Figure 15.7 pointing upward through w_i, w_j, w_k, and w_l symbolizes the learning. After the total energy is calculated, the time derivative is taken and divided by the desired velocity. The losses are calculated by multiplying the desired velocity by the weight w_l, and are then added to the control signal. Finally, the control effort from the FEL controller is added to the PD control effort.

In essence, the output of the feedback controller is an indication of the mismatch between the dynamics of the plant and the inverse-dynamics model obtained by the neural network. If the true inverse-dynamic model has been learned, the neural network alone will provide the necessary control signal to achieve the desired trajectory [118,120].

Defining Terms

Actuator: Device that power a system.

Artificial reflex control: Expert system using rule-based control.

Closed-loop system: Control system which uses information about the output to correct the control parameters to minimize the error between the desired and actual trajectory.

Controls: The signals driving the actuators.

Controller: Process by which the controls are generated.

Degree of freedom: Independent variable defining the position. A free rigid body has six degrees of freedom, a ball joint three, and a hinge joint one.

Dynamic analysis: Analytic simulation of movements of the system considering forces, torques, and kinematics. Forward dynamics uses the geometry and kinematics as input, and provides forces and torques as outputs; inverse dynamics starts from forces and torques and determines kinematics and geometry of the system.

Hierarchical control: Multilevel control allowing the vertical decomposition of the system.

Kinematic analysis: Analytic simulation of movements of the system considering positions, velocities, and accelerations.

Kinematic pair: Connection of two neighboring segments.

Nonanalytic control: Mappings between inputs and outputs to be used for control.

Open-loop control: Control method that uses a prestored trajectory and the model of the system to control the plant.

Plant: The mechanical system being controlled.

Production rule: "If–Then" conditional expression used in experts systems.

Reference-based open-loop control: Control which precomputes and stores control signals, and execute the desired motor task in real-time.

Rigid body: Set of material points with the distances between points being fixed.

State: The configuration of the system at any instant in time.

Trajectory: The time histories of the plant states in response to the control signals.

The Fast Eye Movement Control System

John D. Enderle
University of Connecticut

16.1 Introduction

In this section, a broad overview of the fast eye movement control system is presented. A fast eye movement is usually referred to as a **saccade**, and involves quickly moving the eye from one image to another image. This type of eye movement is very common and is observed most easily while reading — when the end of a line is reached the eyes are moved quickly to the beginning of the next line. A qualitative description of the fast eye movement system is given first in the introduction and then followed by a brief description of saccade characteristics. Next, the earliest quantitative saccade model is presented and then followed by more complex and physiologically accurate models. Finally, the saccade generator, or saccade controller is then discussed on the basis of anatomical pathways and control theory. The purpose of this review is focused on mathematical models of the fast eye movement system and its control strategy, rather than on how visual information is processed. The literature on the fast eye movement system is vast, and thus this review is not exhaustive, but rather a representative sample from the field.

The **oculomotor system** responds to visual, auditory, and vestibular stimuli, which results in one of five types of eye movements: fast eye movements, smooth pursuit eye movements, vestibular ocular movements, vergence eye movements, and optokinetic eye movements. Each of these movements is

16-1

controlled by a different neuronal system and all of these controllers share the same final common pathway to the muscles of the eye. In addition to the five types of eye movements, these stimuli also cause head and body movements. Thus, the visual system is part of a multiple input–multiple output system.

Regardless of the input, the oculomotor system is responsible for movement of the eyes so that images are focused on the central $\frac{1}{2}^{\circ}$ region of the retina known as the fovea. Lining the retina are photoreceptive cells that translate images into neural impulses. These impulses are then transmitted along the optic nerve to the central nervous system (CNS) via parallel pathways to the superior colliculus (SC) and the cerebral cortex. The fovea is more densely packed with photoreceptive cells than the retinal periphery; thus a higher resolution image (or higher visual acuity) is generated in the fovea than the retinal periphery. The purpose of the fovea is to allow us to *clearly* see an object and the purpose of the retinal periphery is to allow us to *detect* a new object of interest. Once a new object of interest is detected in the periphery, the saccade system redirects the eyes, as fast as possible, to the new object. This type of saccade is typically called a goal-directed saccade.

During a saccade, the oculomotor system operates in an open-loop mode. After the saccade, the system operates in a closed-loop mode to ensure that the eyes reached the correct destination. The reason that the saccade system operates without feedback during a fast eye movement is simple; information from the retina and muscle proprioceptors is not transmitted quickly enough during the eye movement for use in altering the control signal.

The oculomotor plant and saccade generator are the basic elements of the saccadic system. The oculomotor plant consists of three muscle pairs and the eyeball. These three muscle pairs contract and lengthen to move the eye in horizontal, vertical, and torsional directions. Each pair of muscles acts in an antagonistic fashion due to reciprocal innervation by the saccade generator. For simplicity, the models described here involve only horizontal eye movements and one pair of muscles, the lateral and medial rectus muscle.

16.2 Saccade Characteristics

Saccadic eye movements, among the fastest voluntary muscle movements the human is capable of producing, are characterized by a rapid shift of gaze from one point of fixation to another. The usual experiment for recording saccades is for a subject to be made to sit before a horizontal target display of small light emitting diodes (LEDs), and instructed to maintain their eyes on the lit LED by moving their eyes as fast as possible to avoid errors. A saccade is made by the subject when the active LED is switched off, and another LED is switched on. Saccadic eye movements are conjugate and ballistic, with a typical duration of 20–100 msec and a latency of 150–300 msec. The **latent period** is thought to be the time interval during which the CNS determines whether to make a saccade, and if so, calculates the distance the eyeball is to be moved, transforming retinal error into transient muscle activity.

Generally, saccades are extremely variable, with wide variations in the latent period, time to peak velocity, peak velocity, and saccade duration. Furthermore, variability is well coordinated for saccades of the same size; saccades with lower peak velocity are matched with longer saccade durations, and saccades with higher peak velocity are matched with shorter saccade durations. Thus, saccades driven to the same destination usually have different trajectories.

To appreciate differences in saccade dynamics, it is often helpful to describe them with saccade **main sequence diagrams** [Bahill, 1975]. The main sequence diagrams plot saccade peak velocity–saccade magnitude, saccade duration–saccade magnitude, and saccade latent period–saccade magnitude. Shown in Figure 16.1 are the main sequence characteristics for a subject executing 54 saccades. Notice that the peak velocity–saccade magnitude is basically a linear function until approximately 15° after which it levels off to a constant for larger saccades. Many researchers have fit this relationship to an exponential function. The solid lines in Figure 16.1a include an exponential fit to the data for positive and negative eye movements. The lines in the first graph are fitted to the equation

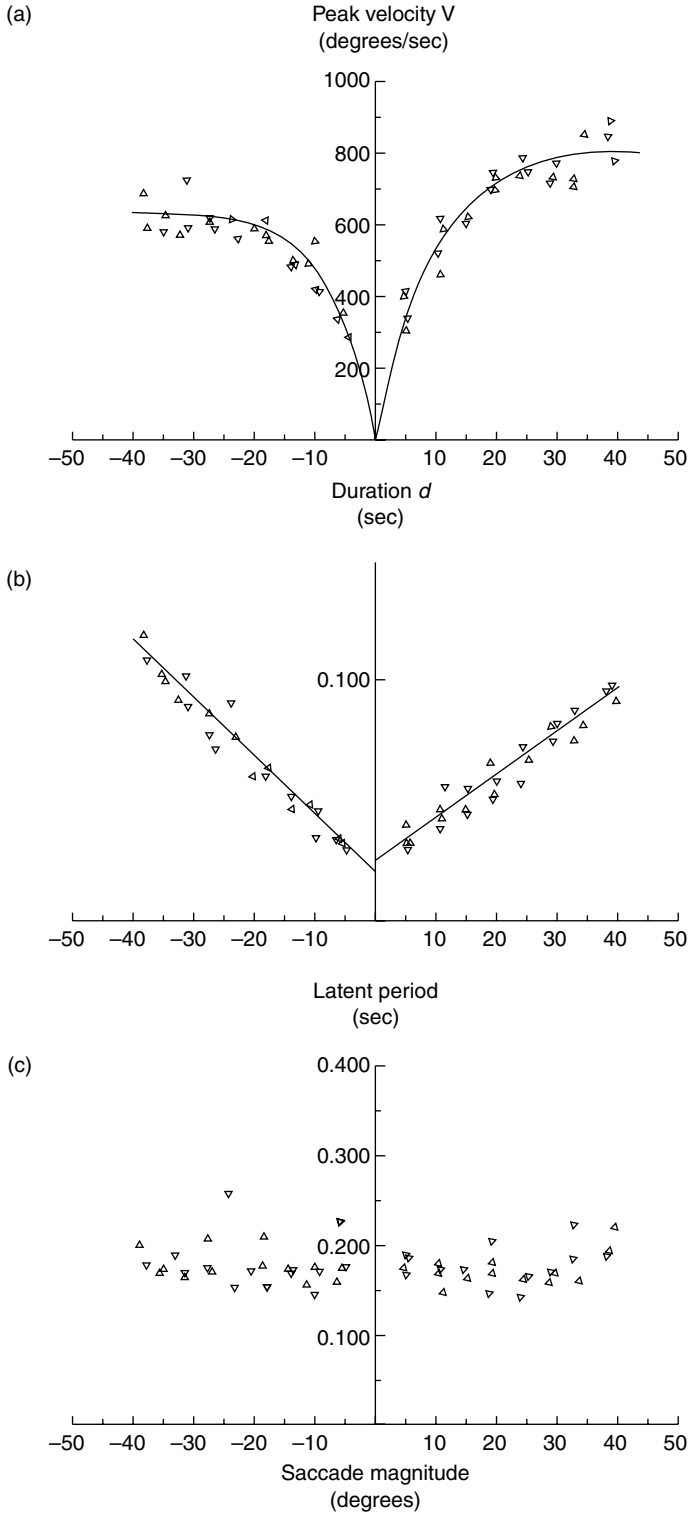
$$V = \alpha_i(1 - e^{-x/\beta_i}) \tag{16.1}$$


FIGURE 16.1 Main sequence diagrams. (a) peak velocity–saccade magnitude, (b) saccade duration–saccade magnitude, and (c) latent period–saccade magnitude for 54 saccadic eye movement by a single subject. (From Enderle, J.D. 1988. *Aviation, Space, Environ. Med.* 59:309–313. With permission.)

where V is the maximum velocity, x the saccade size, and the constants α_i and β_i evaluated to minimize the summed error squared between the model and the data. Note that α_i is to represent the steady state of the peak velocity–saccade magnitude curve and β_i is to represent the "time constant" for the peak velocity–saccade magnitude curve. For this data set, α_i equals 825 and 637, and β_i equals 9.3 and 6.9, for positive and negative movements, respectively. The exponential shape of the peak velocity–saccade amplitude relationship might suggest that the system is nonlinear, if one assumes a step input to the system. A step input would provide a linear peak velocity–saccade amplitude relationship. In fact, the saccade system is not driven by a step input, but rather a more complex pulse-step waveform. Thus, one cannot conclude that the saccade system is nonlinear solely based on the peak velocity–saccade amplitude relationship.

Shown in Figure 16.1b is data depicting a linear relationship between saccade duration–saccade magnitude. The dependence between saccade duration and saccade magnitude also might suggest that the system is nonlinear, if one assumes a step input. Since the input is not characterized by a step waveform, one cannot conclude that the saccade system is nonlinear solely based on the saccade duration–saccade magnitude relationship.

Shown in Figure 16.1c is the latent period–saccade magnitude data. It is quite clear that the latent period does not show any linear relationship with saccade size, that is, the latent period's value is independent of saccade size. In the development of the oculomotor plant models, the latent period will be implicitly assumed within the model.

16.3 Westheimer Saccadic Eye Movement Model

The first quantitative saccadic eye movement model, illustrated in Figure 16.2, was published by Westheimer [1954]. Based on visual inspection of a recorded 20° saccade, and the assumption of a step controller, Westheimer proposed the following second order model:

$$J\ddot{\theta} + B\dot{\theta} + K\theta = \tau(t) \tag{16.2}$$

To analyze the characteristics of this model and compare it to data, it is convenient to solve Equation 16.2 for peak velocity and duration through Laplace analysis. The transfer function of Equation 16.2, written
FIGURE 16.2 A diagram illustrating Westheimer's [1954] second-order model of the saccade system. The parameters J, B, and K are rotational elements for moment of inertia, friction, and stiffness, respectively, and represent the eyeball and its associated viscoelasticity. The torque applied to the eyeball by the lateral and medial rectus muscles is given by $\tau(t)$, and θ is the angular eye position. (Reprinted from Enderle, J.D., Blanchard, S., and Bronzino, J. 2005, *Introduction to Biomedical Engineering, Second Edition*, p. 729, Figure 12.12. With permission from Elsevier.)

in standard form, is given by:

$$H(s) = \frac{\theta(s)}{\tau(s)} = \frac{\omega_n^2/K}{s^2 + 2\zeta\omega_n s + \omega_n^2} \tag{16.3}$$

where $\omega_n = \sqrt{(K/J)}$ and $\zeta = B/(2\sqrt{KJ})$. Based on the saccade trajectory for a 20° saccade, Westheimer estimated $\omega_n = 120$ rad/sec, and $\zeta = 0.7$. With the input $\tau(s) = \gamma/s$, $\theta(t)$ is determined as:

$$\theta(t) = \frac{\gamma}{K} \left[1 + \frac{e^{-\zeta\omega_n t}}{\sqrt{1-\zeta^2}} \cos(\omega_d t + \phi) \right] \tag{16.4}$$

where

$$\omega_d = \omega_n \sqrt{1-\zeta^2} \quad \text{and} \quad \phi = \pi + \tan^{-1} \frac{-\zeta}{\sqrt{1-\zeta^2}}$$

Duration, T_p, is found by first calculating

$$\frac{\partial\theta}{\partial t} = \frac{\gamma e^{-\zeta\omega_n t}}{K\sqrt{1-\zeta^2}} [-\zeta\omega_n \cos(\omega_d t + \phi) - \omega_d \sin(\omega_d t + \phi)] \tag{16.5}$$

then determining T_p from $(\partial\theta/\partial t)|_{t=T_p} = 0$, yielding

$$T_p = \frac{\pi}{\omega_n \sqrt{1-\zeta^2}} \tag{16.6}$$

With Westheimer's parameter values, $T_p = 37$ msec for saccades of all sizes, which is independent of saccade magnitude and not in agreement with the experimental data that has a duration which increases as a function of saccade magnitude.

Predicted saccade peak velocity, $\dot\theta(t_{mv})$, is found by first calculating

$$\frac{\partial^2\theta}{\partial t^2} = \frac{-\gamma e^{-\zeta\omega_n t}}{K\sqrt{1-\zeta^2}} (-\zeta\omega_n(\zeta\omega_n \cos(\omega_d t + \phi) + \omega_d \sin(\omega_d t + \phi))$$

$$+ (-\zeta\omega_n\omega_d \sin(\omega_d t + \phi) + \omega_d^2 \cos(\omega_d t + \phi))) \tag{16.7}$$

and then determining time at peak velocity, t_{mv}, from $(\partial^2\theta/\partial t^2)|_{t=t_{mv}} = 0$, yielding

$$t_{mv} = \frac{1}{\omega_d} \tan^{-1} \left(\frac{\sqrt{1-\zeta^2}}{\zeta} \right) \tag{16.8}$$

Substituting t_{mv} into Equation 16.7 gives the peak velocity $\dot\theta(t_{mv})$. Using Westheimer's parameter values and with the saccade magnitude given by $\Delta\theta = \gamma/K$ based on the steady state value from Equation 16.3, we have from Equation 16.5

$$\dot\theta(t_{mv}) = 55.02\Delta\theta \tag{16.9}$$

that is, peak velocity is directly proportional to saccade magnitude. As illustrated in the main sequence diagram shown in Figure 16.1a, experimental peak velocity data has an exponential form, and not a linear function as predicted by the Westheimer model.

Westheimer noted the differences between saccade duration–saccade magnitude and peak velocity–saccade magnitude in the model and the experimental data and inferred that the saccade system was not linear because the peak velocity–saccade magnitude plot was nonlinear, and the input was not an abrupt step function. Overall, this model provided a satisfactory fit to the eye position data for a saccade of 20°, but not for saccades of other magnitudes. Interestingly, Westheimer's second-order model proves to be an

adequate model for saccades of all sizes, if one assumes a different input function as described in the next section. Due to its simplicity, the Westheimer model of the oculomotor plant is still popular today.

16.4   Robinson's Model of the Saccade Controller

In 1964, Robinson performed an experiment to measure the input to the eyeballs during a saccade. To record the input, one eye was held fixed using a suction contact lens, while the other eye performed a saccade from target to target. Since the same innervation signal is sent to both eyes during a saccade, Robinson inferred that the input, recorded through the transducer attached to the fixed eyeball, was the same input driving the other eyeball. He estimated that the neural commands controlling the eyeballs during a saccade are a pulse plus a step, or simply, a pulse-step input.

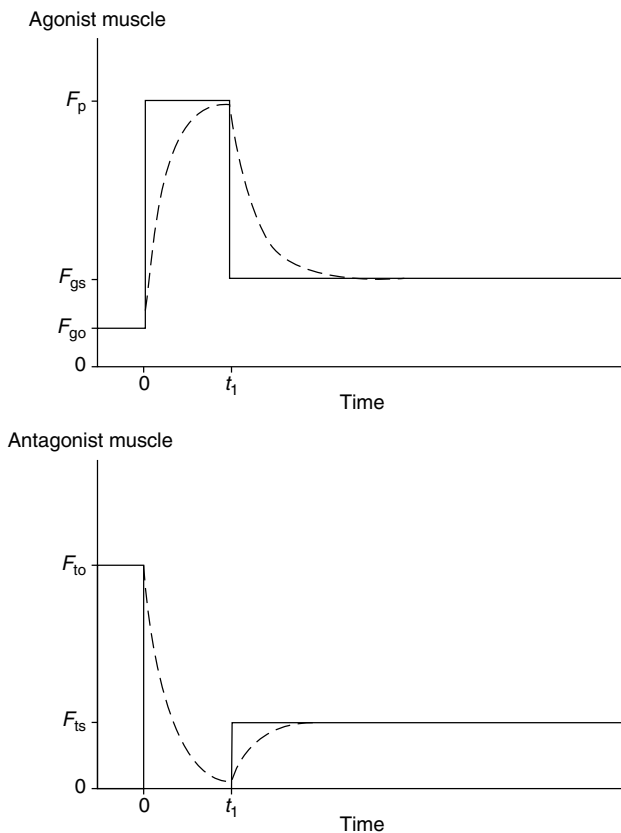
It is important to distinguish between the tension or force generated by a muscle, called muscle tension, and the force generator within the muscle, called the **active state tension generator**. The active state tension generator creates a force within the muscle that is transformed through the internal elements of the muscle into the muscle tension. Muscle tension is external and measurable, and the active state tension is internal and unmeasurable. Moreover, Robinson [1981] reports that the active state tensions are not identical to the neural controllers, but described by low-pass filtered pulse-step waveforms. The neural control and the active state tension signals are illustrated in Figure 16.3. The agonist pulse input is required to get the eye to the target as soon as possible, and the step is required to keep the eye at that location.


FIGURE 16.3   Agonist and antagonist neurological control signals (solid lines) and the agonist and antagonist active state tensions (dashed lines). Note that the time constant for activation is different than the time constant for deactivation. (From Enderle, J.D. and Wolfe, J.W. 1987. *IEEE Trans. Biomed. Eng.* 34:43–55. With permission.)

Robinson [1964] also described a model for fast eye movements (constructed from empirical considerations), which simulated saccades over a range of 5 to 40° by changing the amplitude of the pulse-step input. Simulation results were adequate for the position–time relationship, but the velocity–time relationship was inconsistent with physiological evidence. To correct this deficiency of the model, physiological studies of the oculomotor plant were carried out during the 1960s through the 1970s that allowed the development of a more **homeomorphic** oculomotor plant. Essential to this work was the construction of oculomotor muscle models.

16.5 A Linear Homeomorphic Saccadic Eye Movement Model

In 1980, Bahill and coworkers presented a linear fourth order model of the oculomotor plant, based on physiological evidence, that provides an excellent match between model predictions and eye movement data. This model eliminates the differences seen between velocity predictions of the model and the data, and also the acceleration predictions of the model and the data. For ease in presentation, the modification of this model by Enderle and coworkers [1984] will be used.

Figure 16.4 illustrates the mechanical components of the oculomotor plant for horizontal eye movements, the lateral and medial rectus muscle, and the eyeball. The agonist muscle is modeled as a parallel combination of an active state tension generator F_{AG}, viscosity element B_{AG}, and elastic element K_{LT}, connected to a series elastic element K_{SE}. The antagonist muscle is similarly modeled as a parallel combination of an active state tension generator F_{ANT}, viscosity element B_{ANT}, and elastic element K_{LT}, connected to a series elastic element K_{SE}. The eyeball is modeled as a sphere with moment of inertia J_P, connected to viscosity element B_P and elastic element K_P. The passive elasticity of each muscle is included in spring K_P for ease in analysis. Each of the elements defined in the oculomotor plant is ideal and linear.
FIGURE 16.4 This diagram illustrates the mechanical components of the oculomotor plant. The muscles are shown to be extended from equilibrium, a position of rest, at the primary position (looking straight ahead), consistent with physiological evidence. The average length of the rectus muscle at the primary position is approximately 40 mm, and at the equilibrium position is approximately 37 mm. θ is the angle the eyeball is deviated from the primary position, and variable x is the length of arc traversed. When the eye is at the primary position, both θ and x are equal to zero. Variables x_1 through x_4 are the displacements from equilibrium for the stiffness elements in each muscle. Values x_{p1} through x_{p4} are the displacements from equilibrium for each of the variables x_1 through x_4 at the primary position. The total extension of the muscle from equilibrium at the primary position is x_{p1} plus x_{p2} or x_{p3} plus x_{p4}, which equals approximately 3 mm. It is assumed that the lateral and medial rectus muscles are identical, such that x_{p1} equals x_{p4} and x_{p3} equals x_{p2}. The radius of the eyeball is r. (From Enderle, J.D., Wolfe, J.W., and Yates, J.T. 1984. *IEEE Trans. Biomed. Eng.* 31:717–720. With permission.)

Physiological support for this model is based on the muscle model by Wilkie [1968], and estimates for the **extraocular muscle** elasticities and the passive tissues of the eyeball are based on experiments by Robinson et al. [1969, 1981] and Collins [1975] and studies of extraocular muscle viscosity by Bahill et al. [1980].

By summing the forces at junctions 2 and 3 (the equilibrium positions for x_2 and x_3) and the torques acting on the eyeball, using Laplace variable analysis about the operating point, the linear homeomorphic model, as shown in Figure 16.4, is derived as

$$\delta(K_{SE}(K_{ST}(F_{AG} - F_{ANT}) + B_{ANT}\dot{F}_{AG} - B_{AG}\dot{F}_{ANT})) = \dddot{\theta} + P_3\ddot{\theta} + P_2\ddot{\theta}P_1\dot{\theta} + P_0\theta \quad (16.10)$$

where

$$K_{ST} = K_{SE} + K_{LT}, \quad J = \frac{57.296 J_P}{r^2}, \quad B = \frac{57.296 B_P}{r^2}, \quad K = \frac{57.296 K_P}{r^2}, \quad \delta = \frac{57.296}{rJB_{ANT}B_{AG}}$$

$$C_3 = \frac{JK_{ST}(B_{AG} + B_{ANT}) + BB_{ANT}B_{AG}}{JB_{ANT}B_{AG}}$$

$$C_2 = \frac{JK_{ST}^2 + BK_{ST}(B_{AG} + B_{ANT}) + B_{ANT}B_{AG}(K + 2K_{SE})}{JB_{ANT}B_{AG}}$$

$$C_1 = \frac{BK_{ST}^2 + (B_{AG} + B_{ANT})(KK_{ST} + 2K_{SE}K_{ST} - K_{SE}^2)}{JB_{ANT}B_{AG}}$$

$$C_0 = \frac{KK_{ST}^2 + 2K_{SE}K_{ST}K_{LT}}{JB_{ANT}B_{AG}}$$

The agonist and antagonist active state tensions, are given by the following low-pass filtered waveforms:

$$\dot{F}_{AG} = \frac{N_{AG} - F_{AG}}{\tau_{AG}} \quad \text{and} \quad \dot{F}_{ANT} = \frac{N_{ANT} - F_{ANT}}{\tau_{ANT}} \quad (16.11)$$

where N_{AG} and N_{ANT} are the pulse-step waveforms shown in Figure 16.3, and $\tau_{ag} = \tau_{ac}(u(t) - u(t - t_1)) + \tau_{de}u(t - t_1)$ and $\tau_{ant} = \tau_{de}(u(t) - u(t - t_1)) + \tau_{ac}u(t - t_1)$ are the time-varying time constants [Bahill et al., 1980].

Based on an analysis of experimental evidence, Enderle and Wolfe [1988] determined parameter estimates for the oculomotor plant as: $K_{SE} = 125 \text{ Nm}^{-1}$, $K_{LT} = 32 \text{ Nm}^{-1}$, $K = 66.4 \text{ Nm}^{-1}$, $B = 3.1 \text{ Nsec m}^{-1}$, $J = 2.2 \times 10^{-3} \text{ Nsec}^2 \text{ m}^{-1}$, $B_{AG} = 3.4 \text{ Nsec m}^{-1}$, $B_{ANT} = 1.2 \text{ Nsec m}^{-1}$ and $\delta = 72.536 \times 10^6$, and the steady state active state tensions as:

$$F_{AG} = \begin{cases} 0.14 + 0.0185\theta \ N & \text{for } \theta < 14.23° \\ 0.0283\theta \ N & \text{for } \theta \geq 14.23° \end{cases} \quad (16.12)$$

$$F_{ANT} = \begin{cases} 0.14 - 0.00980\theta \ N & \text{for } \theta < 14.23° \\ 0 \ N & \text{for } \theta \geq 14.23° \end{cases} \quad (16.13)$$

Since saccades are highly variable, estimates of the dynamic active state tensions are carried out on a saccade-by-saccade basis. One method to estimate the active state tensions is using the system identification technique, a conjugate gradient search program carried out in the frequency domain [Enderle and Wolfe, 1988]. Figure 16.5 to Figure 16.7 show the system identification technique results for an eye movement response to a 15° target movement. A close fit between the data and model prediction is seen in Figure 16.5. Figure 16.6 and Figure 16.7 further illustrate the accuracy of the final parameter estimates for velocity and acceleration. Estimates for agonist pulse magnitude are highly variable for saccade to saccade, even for the same size (see Figure 9 of Enderle and Wolfe [1988]). Agonist pulse duration is closely coupled with pulse amplitude; as the pulse amplitude increases, the pulse duration decreases for saccades of the same
FIGURE 16.5 Saccadic eye movement in response to a 15° target movement. magnitude. Reasonable values for the pulse amplitude for this model range from about 0.6 to 1.4 N. The larger the magnitude of the pulse the larger the peak velocity of the eye movement.

16.6 Another Linear Homeomorphic Saccadic Eye Movement Model

The previous linear model of the oculomotor plant is derived from a nonlinear oculomotor plant model by Hsu et al. [1976], and based on a linearization of the force–velocity curve [Bahill et al., 1980]. Muscle viscosity traditionally has been modeled with a hyperbolic force–velocity relationship. Using the linear model of muscle reported by Enderle and coworkers [1991], it is possible to avoid the linearization, and derive an updated linear homeomorphic saccadic eye movement model.

The linear muscle model has the static and dynamic properties of rectus eye muscle, a model without any nonlinear elements. The model has a nonlinear force–velocity relationship that matches muscle data using linear viscous elements; and the length tension characteristics are also in good agreement with muscle data within the operating range of the muscle. Some additional advantages of the linear muscle model are that a passive elasticity is not necessary if the equilibrium point $x_e = -19.3°$, rather than $15°$, and muscle viscosity is constant that does not depend on the innervation stimulus level.

Figure 16.8 illustrates the mechanical components of the updated oculomotor plant for horizontal eye movements, the lateral and medial rectus muscle, and the eyeball. The agonist muscle is modeled as a parallel combination of viscosity B_2 and series elasticity K_{SE}, connected to the parallel combination of active state tension generator F_{AG}, viscosity element B_1, and length tension elastic element K_{LT}. Since viscosity does not change with innervation level, agonist viscosity is set equal to antagonist viscosity. The
FIGURE 16.8 This diagram illustrates the mechanical components of the updated oculomotor plant. The muscles are shown to be extended from equilibrium, a position of rest, at the primary position (looking straight ahead), consistent with physiological evidence. The average length of the rectus muscle at the primary position is approximately 40 mm, and at the equilibrium position is approximately 37 mm. θ is the angle the eyeball is deviated from the primary position, and variable x is the length of arc traversed. When the eye is at the primary position, both θ and x are equal to zero. Variables x_1 through x_4 are the displacements from equilibrium for the stiffness elements in each muscle, and θ_5 is the rotational displacement for passive orbital tissues. Values x_{p1} through x_{p4} are the displacements from equilibrium for each of the variables x_1 through x_4 at the primary position. The total extension of the muscle from equilibrium at the primary position is x_{p1} plus x_{p2} or x_{p3} plus x_{p4}, which equals approximately 3 mm. It is assumed that the lateral and medial rectus muscles are identical, such that x_{p1} equals x_{p4} and x_{p3} equals x_{p2}. The radius of the eyeball is r. (Reprinted from Enderle, J.D., Blanchard, S., and Bronzino, J. 2005, *Introduction to Biomedical Engineering, Second Edition*, p. 764, Figure 12.33. With permission from Elsevier.)

antagonist muscle is similarly modeled with a suitable change in active state tension to F_{ANT}. The eyeball is modeled as a sphere with moment of inertia J_P, connected to a pair of viscoelastic elements connected in series; the update of the eyeball model is based on observations by Robinson [1981]. Each of the elements defined in the oculomotor plant is ideal and linear.

The differential equation describing oculomotor plant model shown in Figure 16.8 is derived by summing the forces acting at junctions 2 and 3, and the torques acting on the eyeball and junction 5, and using Laplace variable analysis about the operating point, is given by

$$\delta(K_{SE}K_{12}(F_{AG} - F_{ANT}) + (K_{SE}B_{34} + B_2K_{12})(\dot{F}_{AG} - \dot{F}_{ANT}) + B_2B_{34}(\ddot{F}_{AG} - \ddot{F}_{ANT}))$$
$$= \dddot{\theta} + P_3\dddot{\theta} + P_2\ddot{\theta} + P_1\dot{\theta} + P_0\theta \qquad (16.14)$$

where

$$J = \frac{57.296 J_p}{r^2}, \quad B_3 = \frac{57.296 B_{p1}}{r^2}, \quad B_4 = \frac{57.296 B_{p2}}{r^2}, \quad K_1 = \frac{57.296 K_{p1}}{r^2}, \quad K_2 = \frac{57.296 K_{p2}}{r^2},$$

$$B_{12} = B_1 + B_2, \quad B_{34} = B_3 + B_4, \quad K_{12} = K_1 + K_2, \quad \delta = \frac{57.296}{rJ B_{12} B_{34}}$$

$$C_3 = \frac{B_{12}(J K_2 + B_3 B_4) + JB_4 K_{ST} + 2B_1 B_2 B_{34}}{JB_{12} B_4}$$

$$C_2 = \frac{JK_{ST} K_2 + B_3 B_4 K_{ST} + B_{12} B_3 K_2 + 2K_{SE} B_{34} B_1 + K_1 B_{12} B_4 + 2B_2 K_{LT} B_{34} + 2B_1 K_{12} B_2}{JB_{12} B_4}$$

$$C_1 = \frac{K_{ST}(B_3 K_2 + K_1 B_4) + K_1 K_2 B_{12} + 2K_{LT} K_{SE} B_{34} + 2B_1 K_{12} K_{SE} + 2B_2 K_{LT} K_{12}}{JB_{12} B_4}$$

$$C_0 = \frac{2K_{LT} K_{SE} K_{12} + K_1 K_{ST} K_2}{JB_{12} B_4}$$

Based on an analysis of experimental data, suitable parameter estimates for the oculomotor plant are: $K_{SE} = 125$ Nm^{-1}, $K_{LT} = 60.7$ Nm^{-1}, $B_1 = 2.0$ Nsec m^{-1}, $B_2 = 0.5$ Nsec m^{-1}, $J = 2.2 \times 10^{-3}$ Nsec^2 m^{-1}, $B_3 = 0.538$ Nsec m^{-1}, $B_4 = 41.54$ Nsec m^{-1}, $K_1 = 26.9$ Nm^{-1}, and $K_2 = 41.54$ Nm^{-1}. Based on the updated model of muscle and length tension data [Collins, 1975], steady state active state tensions are determined (as described in Enderle et al. [1991]) as:

$$F = \begin{cases} 0.4 + 0.0175\theta \ N & \text{for } \theta \geq 0° \\ 0.4 + 0.0125\theta \ N & \text{for } \theta < 0° \end{cases} \tag{16.15}$$

Saccadic eye movements simulated with this model have characteristics which are in good agreement with the data, including position, velocity and acceleration, and the main sequence diagrams.

16.7 Saccade Pathways

Clinical evidence, lesion, and stimulation studies all point toward the participation of vitally important neural sites in the control of saccades, including the cerebellum, superior colliculus (SC), thalamus, cortex, and other nuclei in the brain stem, and that saccades are driven by two parallel neural networks [Enderle, 1994, 2002]. From each eye, the axons of retinal ganglion cells exit and join other neurons to form the optic nerve. The optic nerves from each eye then join at the optic chiasm, where fibers from the nasal half of each retina cross to the opposite side. Axons in the optic tract synapse in the lateral geniculate nucleus (a thalamic relay), and continue to the visual cortex. This portion of the saccade neural network is concerned with the recognition of visual stimuli. Axons in the optic tract also synapse in the SC. This second portion of the saccade neural network is concerned with the location of visual targets and is primarily responsible for goal-directed saccades.

Saccadic neural activities of the SC and cerebellum, in particular, have been identified as the saccade initiator and terminator, respectively, for a goal-directed saccade. The impact of the frontal eye field and the thalamus, while very important, has less important roles in the generation of goal-directed saccades to visual stimuli. The frontal eye fields are primarily concerned with voluntary saccades, and the thalamus appears to be involved with corrective saccades. Shown in Figure 16.9 is a diagram illustrating important sites for the generation of a conjugate goal-directed horizontal saccade in both eyes [Enderle, 1994, 2002]. Each of the sites and connections detailed in Figure 16.9 are fully supported by physiological evidence. Some of these neural sites are briefly described herein.

The SC contains two major functional divisions: a superficial division and an intermediate or deep. Inputs to the superficial division are almost exclusively visual and originate from the retina and the visual cortex. The deep layers provide a site of convergence for sensory signals from several modalities and a source of efferent commands for initiating saccades. The SC is the initiator of the saccade and thought to translate visual information into motor commands.

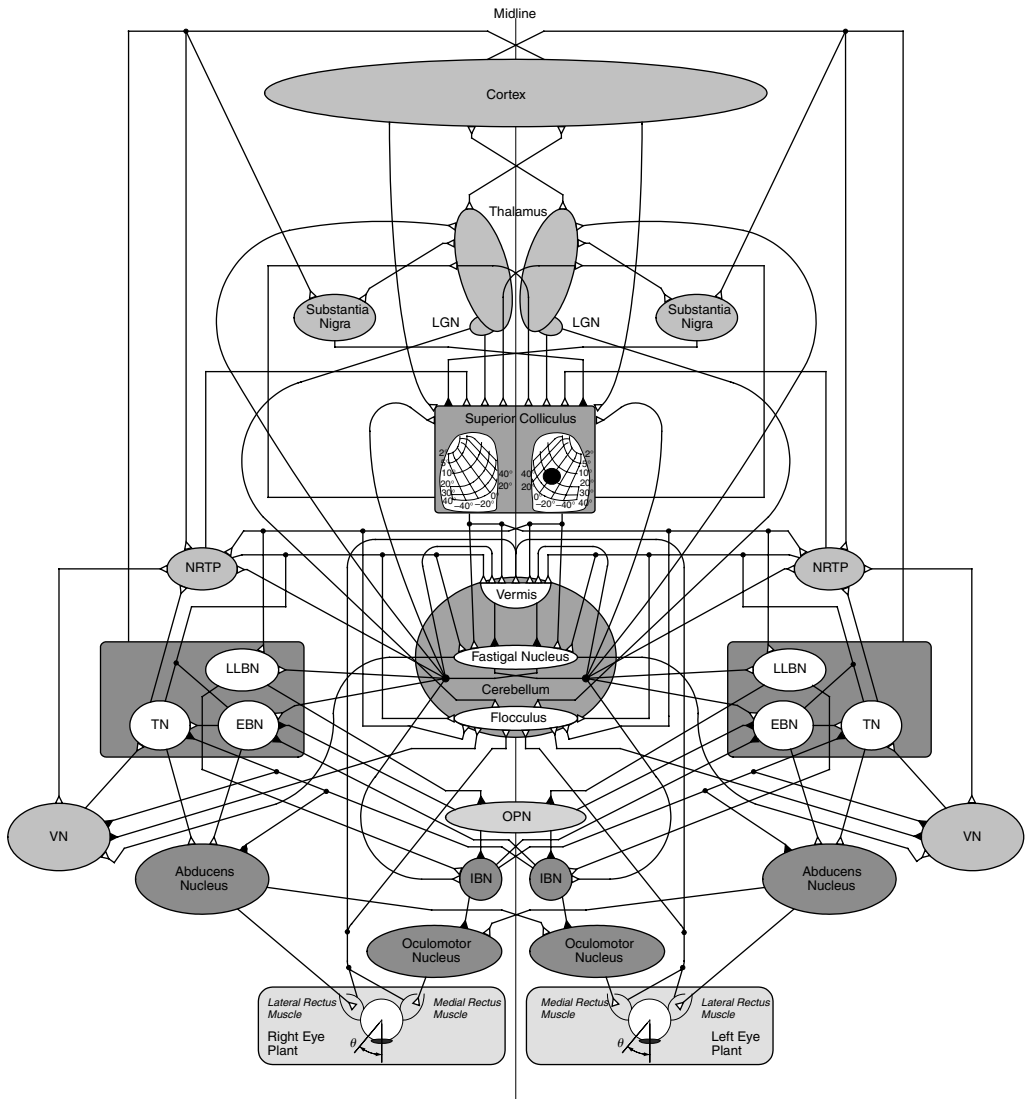
The deep layers of the SC initiate a saccade based on the distance between the current position of the eye and the desired target. The neural activity in the SC is organized into movement fields that are associated with the direction and saccade amplitude, and does not involve the initial position of


FIGURE 16.9 Shown is a diagram illustrating important sites for the generation of a conjugate horizontal saccade in both eyes. It consists of the familiar premotor excitatory burst neurons (EBN), inhibitory burst neurons (IBN), long-lead burst neurons (LLBN), omnipause neurons (OPN), tonic neurons (TN), and the vestibular nucleus, abducens nucleus, oculomotor nucleus, cerebellum, substantia nigra, nucleus reticularis tegmenti pontis (NRTP), the thalamus, the deep layers of the superior colliculus (SC), and the oculomotor plant for each eye. Excitatory inputs are shown with ⊿, inhibitory inputs are shown with a ⊿. Consistent with current knowledge, the left and right structures of the neural circuit model are maintained. This circuit diagram was constructed after a careful review of the current literature. Each of the sites and connections is supported by firm physiological evidence. Since interest is in goal-directed visual saccades, the cortex has not been partitioned into the frontal eye field and posterior eye field (striate, prestriate, and inferior parietal cortices).

the eyeball whatsoever. The movement field is shown in Figure 16.10 for a 20° saccade. Neurons active during a particular saccade are shown as the dark circle, representing a desired 20° eye movement. Active neurons in the deep layers of the SC generate a high frequency burst of activity beginning 18–20 msec before a saccade and end sometime toward the end of the saccade; the exact timing for the end of the burst firing is quite random and can occur slightly before or slightly after the saccade ends. Each active bursting
FIGURE 16.10   Movement fields of the superior colliculus.

neuron discharges maximally, regardless of the initial position of the eye. Neurons discharging for small saccades have smaller movement fields, and those for larger saccades have larger movement fields. All of the movement fields are connected to the same set of long-lead burst neurons (LLBN).

The cerebellum is responsible for the coordination of movement, and is composed of a cortex of gray matter, internal white matter, and three pairs of deep nuclei: fastigial nucleus (FN), the interposed and globose nucleus, and dentate nucleus. The deep cerebellar nuclei and the vestibular nuclei transmit the entire output of the cerebellum. Output of the cerebellar cortex is carried through Purkinje cells. Purkinje cells send their axons to the deep cerebellar nuclei and have an inhibitory effect on these nuclei. The cerebellum is involved with both eye and head movements, and both tonic and phasic activities are reported in the cerebellum. The cerebellum is not directly responsible for the initiation or execution of a saccade, but contributes to saccade precision. Sites within the cerebellum important for the control of eye movements include the oculomotor vermis, FN and the flocculus. Consistent with the operation of the cerebellum for other movement activities, the cerebellum is postulated here to act as the coordinator for a saccade, and act as a precise gating mechanism.

The cerebellum is included in the saccade generator as a time-optimal gating element using three active sites during a saccade: the vermis, FN and flocculus. The vermis is concerned with the absolute starting position of a saccade in the movement field and corrects control signals for initial eye position. Using proprioceptors in the oculomotor muscles and an internal eye position reference, the vermis is aware of the current position of the eye. The vermis is also aware of the signals (dynamic motor error) used to generate the saccade via the connection with the nucleus reticularis tegmenti pontis (NRTP) and the SC.

With regard to the oculomotor system, the cerebellum has inputs from SC, lateral geniculate nucleus (LGN), oculomotor muscle proprioceptors, and striate cortex via NRTP. The cerebellum sends inputs to the NRTP, LLBN, excitatory burst neurons (EBN), VN, thalamus, and SC. The oculomotor vermis and FN are important in the control of saccade amplitude, and the flocculus, perihypoglossal nuclei of the rostral medulla, and possibly the pontine and mesencephalic reticular formation are thought to form the integrator within the cerebellum. One important function of the flocculus may be to increase the time constant of the neural integrator for saccades starting at locations different from primary position.

The FN receives input from the SC, as well as other sites. The output of the FN is excitatory and projects ipsilaterally and contralaterally as shown in Figure 16.9. During fixation, the FN nucleus fires tonically at low rates. Twenty msec prior to a saccade, the contralateral FN bursts, and the ipsilateral FN pauses and then is discharged with a burst. The pause in ipsilateral firing is due to Purkinje cell input to the FN. The sequential organization of Purkinje cells along beams of parallel fibers suggests that the cerebellar cortex might function as a delay, producing a set of timed pulses that could be used to program the duration of the saccade. If one considers nonprimary position saccades, different temporal and spatial schemes, via cerebellar control, are necessary to produce the same size saccade. It is postulated here that the cerebellum acts as a gating device, which precisely terminates a saccade based on the initial position of the eye in the orbit.

The PPRF (paramedian pontine reticular formation) has neurons that burst at frequencies up to 1000 Hz during saccades and are silent during periods of fixation, and neurons that fire tonically during

periods of fixation. Neurons that fire at steady rates during fixation are called tonic neurons (TN) and are responsible for holding the eye steady. The TN firing rate depends on the position of the eye (presumably through a local integrator type network). The TN are thought to provide the step component to the motoneuron. There are two types of burst neurons in the PPRF called the long-lead burst neuron (LLBN) and a medium-lead burst neuron (MLBN); during periods of fixation, these neurons are silent. The LLBN burst at least 12 msec before a saccade and the MLBN burst <12 msec (typically 6 to 8 msec) before the saccade. The MLBN are connected monosynaptically with the Abducens Nucleus.

There are two types of neurons within the MLBN, the EBN and the inhibitory burst neurons (IBN). The EBN and IBN label describe the synaptic activity upon the motoneurons; the EBN excite and are responsible for the burst firing, and the IBN inhibit and are responsible for the pause. A mirror image of these neurons exists on both sides of the midline. The IBN inhibit the EBN on the contralateral side.

Also within the brain stem is another type of saccade neuron called the omnipause neuron (OPN). The OPN fires tonically at approximately 200 Hz during periods of fixation, and is silent during saccades. The OPN stops firing approximately 10 to 12 msec before a saccade and resumes tonic firing approximately 10 msec before the end of the saccade. The OPN are known to inhibit the MLBN, and are inhibited by the LLBN. The OPN activity is responsible for the precise timing between groups of neurons that causes a saccade.

To execute a saccade, a sequence of complex activities takes place within the brain, beginning from the detection of an error on the retina, to the actual movement of the eyes. A saccade is directly caused by a burst discharge (pulse) from motoneurons stimulating the agonist muscle and a pause in firing from motoneurons stimulating the antagonist muscle. During periods of fixation, the motoneurons fire at a rate necessary to keep the eye stable (step). The pulse discharge in the motoneurons is caused by the EBN and the step discharge is caused by the TN in the PPRF.

Consider the saccade network in Figure 16.9 that is programmed to move the eyes 20° [Enderle, 2002]. The contralateral SC begins firing within an appropriate locus of neurons for a 20° saccade due to a LGN retinal error. The contralateral SC then stimulates the ipsilateral LLBN and contralateral FN. The contralateral FN also stimulates the ipsilateral LLBN, and the LLBN then inhibits the tonic firing of the OPN. When the OPN cease firing, the MLBN is released from inhibition and begins firing. The ipsilateral IBN is stimulated by the ipsilateral LLBN and the contralateral FN of the cerebellum. When released from inhibition, it has been proposed that the ipsilateral EBN fire spontaneously [Enderle, 2002]. The EBN are also stimulated by the contralateral FN of the cerebellum; however, FN stimulation is not required for a saccade to be generated. The burst firing in the ipsilateral IBN inhibits the contralateral EBN, TN, and Abducens Nucleus, and the ipsilateral Oculomotor Nucleus. The burst firing in the ipsilateral EBN cause the burst in the ipsilateral Abducens Nucleus, which stimulates the ipsilateral lateral rectus muscle and the contralateral Oculomotor Nucleus. With the stimulation of the ipsilateral lateral rectus muscle by the ipsilateral Abducens Nucleus and the inhibition of the ipsilateral medial rectus muscle via the Oculomotor Nucleus, a saccade occurs in the right eye.

Simultaneously, the contralateral medial rectus muscle is stimulated by the contralateral Oculomotor Nucleus, and with the inhibition of the contralateral lateral rectus muscle via the Abducens Nucleus, a saccade occurs in the left eye. Thus the eyes move conjugately under the control of a single drive center.

The end of the saccade is normally terminated by the cerebellum. In most saccades, the SC continues to fire even though the saccade has ended. At the termination time, the cerebellar vermis, operating through the Purkinje cells, inhibits the contralateral FN and stimulates the ipsilateral FN. Some of the stimulation of the ipsilateral LLBN and IBN is lost because of the inhibition of the contralateral FN.

The ipsilateral FN stimulates the contralateral LLBN, EBN, and IBN. The contralateral EBN then stimulates the contralateral Abducens Nucleus. Further simulation of the contralateral IBN occurs from the contralateral LLBN. The contralateral IBN then inhibits the ipsilateral EBN, TN, and Abducens Nucleus, and contralateral Oculomotor Nucleus. With this inhibition, the stimulus to the agonist muscles ceases.

The ipsilateral FN stimulation of the contralateral EBN allows for modest bursting in the contralateral EBN, which stimulates the contralateral Abducens Nucleus and Ipsilateral Oculomotor Nucleus. With

the stimulation from the contralateral EBN through the contralateral Abducens Nucleus and Ipsilateral Oculomotor Nucleus, the antagonist muscles fire, causing a dynamic break. Once the SC cease firing, the stimulus to the LLBN ends allowing the resumption of OPN firing that inhibits the MLBN.

16.8 Saccade Control Mechanism

Although the purpose for a saccadic eye movement is clear, that is, to quickly redirect the eyeball to the destination, the neural control mechanism is not. Until quite recently, saccade generator models involved a ballistic or preprogrammed control to the desired eye position based on retinal error alone. Today, an increasing number of investigators are putting forth the idea that visual goal-directed saccades are controlled by a local feedback loop that continuously drives the eye to the desired eye position. This hypothesis first gained acceptance in 1975 when Robinson suggested that saccades originate from neural commands that specify the desired position of the eye rather than the preprogrammed distance the eye must be moved. The value of the actual eye position is subtracted from the desired position to create an error signal that completes the local feedback loop that drives a high-gain burst element to generate the neural pulse. This neural pulse continuously drives the eye until the error signal is zero.

Subsequently, a number of other investigators have modified the local feedback mechanism proposed by Robinson [1975] to better describe the neural connections and firing patterns of brainstem neurons in the control of horizontal saccadic eye. In addition to the Robinson model, two other models describe a saccade generator [Scudder, 1988; Scudder et al., 2002; Enderle, 1994, 2002]. All of the models involve three types of premotor neurons: burst, tonic, and pause cells, as previously described, and involve a pulse-step change in firing rate at the motoneuron during a saccadic eye movement.

While the general pattern of motoneuron activity is qualitatively accepted during a saccadic eye movement, there is little agreement on a quantitative discharge description. The saccade generator models by Robinson and Scudder are structured to provide a control signal that is proportionally weighted (or dependent) to the desired saccade size, as opposed to the saccade generator model structured to provide a control signal that is independent of saccade amplitude. Using time-optimal control theory and the system identification technique, Enderle and Wolfe [1988] investigated the control of saccades and reported that the system operates under a first-order time-optimal control. The concepts underlying this hypothesis are that each muscle's active state tension is described by a low-pass filtered pulse-step waveform in which the magnitude of the agonist pulse is a maximum regardless of the amplitude of the saccade, and that only the duration of the agonist pulse affects the size of the saccade. The antagonist muscle is completely inhibited during the period of maximum agonist stimulation. The saccade generator illustrated in Figure 16.9 operates under these principles, and provides simulations that match the data very well.

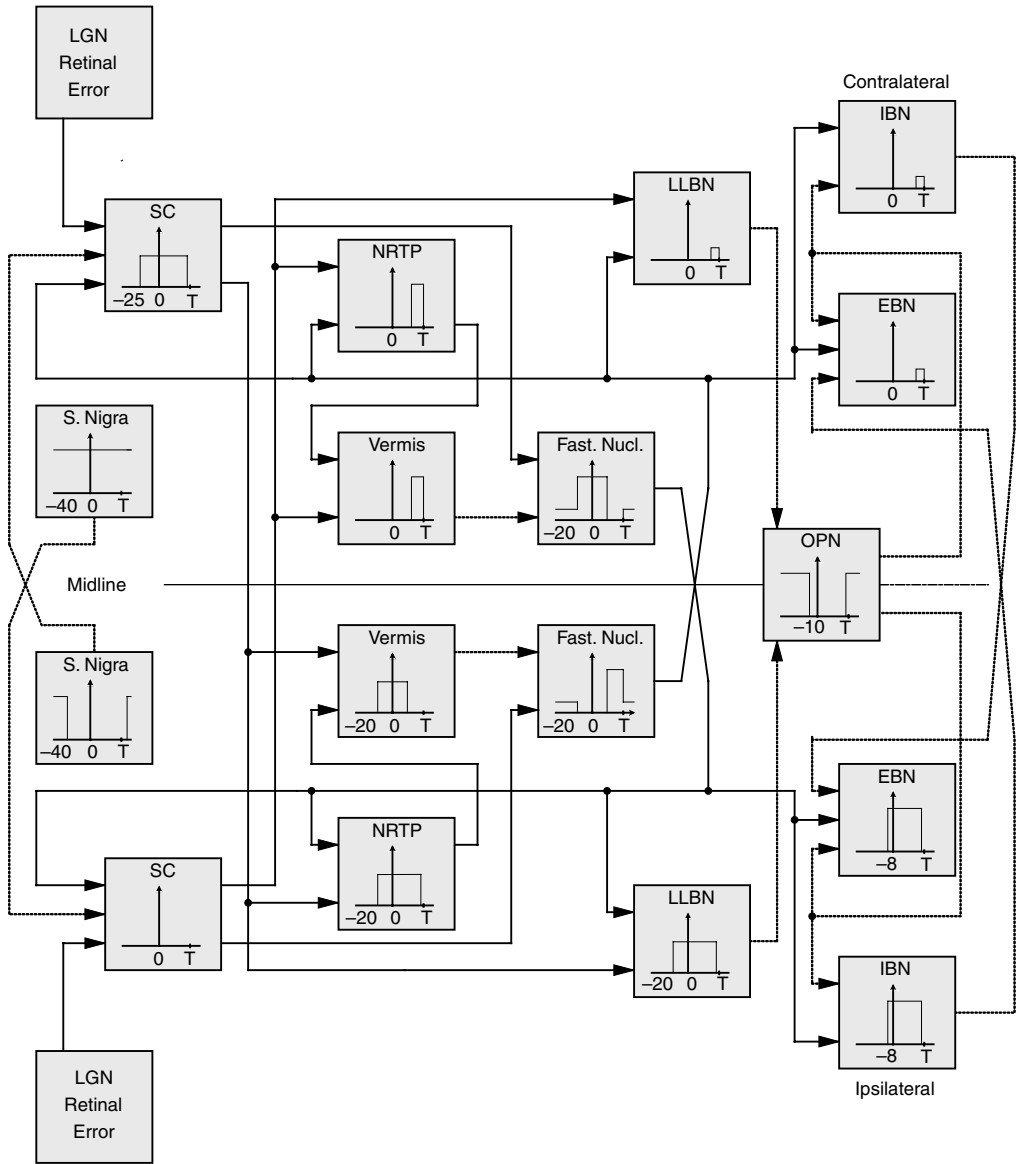
Saccadic eye movements were simulated using TUTSIM, a continuous time simulation program for the saccade generator model presented in Figure 16.9, and compared with experimental data. Neural sites (nucleus) are described via a *functional* block diagram description of the horizontal saccade generator model as shown in Figure 16.11 and Figure 16.12. Table 16.1 summarizes additional firing characteristics for the neural sites. The output of each block represents the firing pattern at each neural site observed during the saccade; time zero indicates the start of the saccade and T represent the end of the saccade. Naturally, the firing pattern observed for each block represents the firing pattern for a single neuron, as recorded in the literature, but the block represents the cumulative effect of all of the neurons within that site. Consistent with a time optimal control theory, neural activity is represented within each of the blocks as pulses and steps to reflect their operation as timing gates. The SC fires maximally, as long as the dynamic motor error is greater than zero, which is in agreement with the first-order time optimal controller and physiological evidence. Notice that the LLBN's are driven by the SC as long as there is a feedback error maintained by the cerebellar vermis. In all likelihood, the maximal firing rate by the SC is stochastic, depending on a variety of physiological factors such as the interest in tracking the target, anxiety, frustration, stress, and other factors. The actual firing patterns in the SC, the burst neurons in the PPRF (LLBN, EBN, and IBN) and abducens nucleus are simulated with filtered pulse signals, consistent


FIGURE 16.11 Part A: a functional block diagram of the saccade generator model. Solid lines are excitatory and dashed lines are inhibitory.

with the physical limitations of neurons. For the SC and the LLBN, this involves a single pulse, but for the EBN and IBN, this involves two pulses with different filters (the first pulse describes the brief rise and subsequent fall within the first 10 msec during a saccade, and the second pulse describes the steady state pulse during the saccade) and match the electrophysiological data.

Illustrated in Figure 16.13 is an extracellular single unit recording for the EBN, eye position data and a simulation for a 20° saccade. Details of the experiment are given in Enderle [1994]. A 20° saccade was simulated by using EBN data as input and the oculomotor plant in Figure 16.8. Little difference between the data and the simulation results are observed for this movement, as well as other eye movements. The saccade generator model in Figure 16.9 also provides an excellent description of the saccade system, and matches the data very well for all naturally occurring saccades, including saccades with dynamic overshoot and glissadic behavior, without parametric changes [Enderle, 1994].

TABLE 16.1 Activity of Neural Sites during a Saccade

Neural site	Onset before saccade (msec)	Peak firing rate (Hz)	End time
Abducens nucleus	5	400–800	Ends approx. 5 msec before saccade ends
Contralateral FN	20	200	Pulse ends with pause approx. 10 msec before saccade ends, resumes tonic firing approx. 10 msec after saccade ends
Contralateral SC	20–25	800–1000	Ends approx. when saccade ends
Ipsilateral cerebellar vermis	20–25	600–800	Ends approx. 25 msec before saccade ends
Ipsilateral EBN	6–8	600–800	Ends approx. 10 msec before saccade ends
Ipsilateral FN	20	Pause during saccade, and a burst of 200 Hz toward the end of the saccade	Pause ends with burst approx. 10 msec before saccade ends, resumes tonic firing approx. 10 msec after saccade ends
Ipsilateral FEF	>30	600–800	Ends approx. when saccade ends
Ipsilateral IBN	6–8	600–800	Ends approx. 10 msec before saccade ends
Ipsilateral LLBN	20	800–1000	Ends approx. when saccade ends
Ipsilateral NRTP	20–25	800–1000	Ends approx. when saccade ends
Ipsilateral substantia nigra	40	40–100	Resumes firing approx. 40–150 msec after saccade ends
OPN	6–8	150–200 (before and after)	Ends approx. when saccade ends
FIGURE 16.13 Simulated eye position in solid line shown in top graph, generated with EBN saccade data (shown in lower graph) and the oculomotor plant in Figure 16.8. Actual eye movement data recorded with the EBN data during a saccadic eye movement. (Data provided by Dr. David Sparks from his laboratory while at the University of Alabama.)

16.9 Conclusion

This section has focused on quantitative models and control of the fast eye movement system. Each of the oculomotor plant models described here are linear. Beginning with the most simple quantitative model of saccades by Westhiemer [1954], important characteristics of saccades were determined as a means of evaluating the quality of saccade models. Next, models of increasing complexity were presented with the end goal of constructing a homeomorphic saccade model of the oculomotor plant. These plant models were driven by improved models of muscle that ultimately provided an excellent match of the static and dynamic properties of rectus eye muscle. Finally, the control of saccades was considered from the basis of systems control theory and anatomical considerations. Many nonlinear models of the oculomotor plant exist and readers interested in learning about them should consult [Robinson, 1981].

Defining Terms

Active state tension generator: The active state tension generator describes the element within the muscle which creates a force. This force is different than muscle tension, which is the force due to the active state tension generator and all of the other elements within the muscle.

Extraocular muscles: The six muscles attached directly to the outside of the eyeball, and consists of the medial, lateral, superior, inferior recti, and the superior and inferior oblique muscles.

Homeomorphic: As close to reality as possible.

Latent period: The latent period is thought to be the time interval during which the CNS determines whether to make a saccade, and if so, calculates the distance the eyeball is to be moved, transforming retinal error into transient muscle activity.

Main-sequence diagrams: Summary plots of the characteristics of saccades that allows one to compare inter- and intrassubject variations. Commonly used characteristics include (1) peak velocity–saccade magnitude, (2) saccade duration–saccade magnitude, and (3) latent period–saccade magnitude.

Oculomotor system: The oculomotor system consists of the eyeball and extraocular muscles (also called the oculomotor plant), and the neural sites responsible for the eye movement.

Saccade: A saccade is a fast eye movement.

A Comparative Approach to Analysis and Modeling of Cardiovascular Function

John K-J. Li
Rutgers University

Adow Innovation

Abraham Noordergraaf
University of Pennsylvania

17.1 Introduction

Although the cardiovascular system and its parts do not always work as simple linear systems, they frequently work, similarly, and in some cases, optimally. One can only marvel at the amazing similarities that exist, structurally and dynamically, across a large number of mammalian species. These similarities occur in spite of grossly different body weights and social–ecological environments of the many different species. The constant biological transformations that occurred did not seem to alter these similarities significantly.

Using physical principles and applying engineering techniques, we can model the cardiovascular systems of different mammals. However, the complexity of the beat-to-beat dynamic performance of the heart and its interaction with the vascular systems makes this a major challenge. This complexity can be substantially reduced when we first impose appropriate biological scaling laws and identify relevant invariant features that appear across species in the mammalian class.

In terms of structure and function, there are a number of characteristics that must vary with size, and they are consequently scaled with respect to body weight. Examples include: size of the heart, volume of

blood, length of the aorta, and cardiac output. Other characteristics however, are invariant. Examples are: blood pressure, ejection fraction, heart beats per life time, capillary, and red blood cell sizes.

It was not until the 17th century that Harvey [1628], in his now famous "De Motu Cordis," rejected Gaelenus' theory, and proposed the closed circulation. This allowed him to explain the intermittent pumping function of the heart as a consequence of systolic ejection and diastolic filling. He also made comparisons of circulatory function from his many "Anatomical Exercises Concerning the Motion of the Heart and Blood in Living Creatures," performed on several mammalian species, avians, and amphibians. The quantification of blood pressure amplitudes and cardiac output in mammalian species, however, was first introduced by Hales [1733] a century later. Until this day, blood pressure and cardiac output are still regarded as the most pertinent clinical variables that govern the function of the cardiovascular system.

D'Arcy Thompson's [1917] "On Growth and Form" paved yet another path to modern comparative biological studies. This is followed by Huxley's [1932] work on the "Problems of Relative Growth" in which he based many of his biological interpretations on allometric relations.

Allometry is defined as the change of proportions with increase of size both within a single species and between adults of related groups. The allometric formula relates any measured physical quantity Y to body mass M, with a and b as derived or measured empirical constants. This resulted in the now familiar power law,

$$Y = aM^b \tag{17.1}$$

This formula expresses simple allometry. In the special case when the exponent is 0, Y is independent of body mass M: the physical variable is said to be invariant with body mass. When b is 1/3, the variable is said to be dependent on body length; when b is 2/3, Y is dependent on body surface area, and when $b = 1$, Y is simply proportional to body mass. This provided what is known as the basis of the "one-third power law" or geometric scaling [Lambert and Teissier, 1927]. It has recently been challenged by the "one-fourth power law" as the basis of biological allometric formulation [West et al., 1997].

The allometric equation has proven to be powerful for characterization of similarities among species. It is effective in relating a physiological phenomenon, either structural or functional, among mammals of grossly different body mass. A similarity criterion is established when Y, formulated in terms of either product(s) or ratio(s) of physically measurable variables, remains constant despite changes in body mass, and is dimensionless. Thus, the exponent b must necessarily be zero. In other words, similarity is present whenever any two, dimensionally identical, measurements occur in a constant ratio to each other. If such a ratio exists among different species, then a similarity criterion is established as the scaling law. This approach of establishing biological similarity criteria has been very useful [Stahl, 1963a, b, 1965; Gunther and DeLa Barra, 1966a, b; Gunther, 1975; Li, 1987, 1996, 2000].

17.2 Dimensional Analysis of Physiological Function

The theorem of dimensional analysis was introduced by Buckingham in 1915. It states that if a physical system can be properly described by a certain set of dimensional variables, it may also be described by a lesser number of dimensionless parameters which incorporate all the variables.

We shall now illustrate the use of dimensional analysis with the application of Laplace's law to mammalian hearts. The beat-to-beat pumping ability of the mammalian heart is determined by its force-generating capability and the lengths of its constituent muscle fibers, as governed by the Starling's experimental observations on the heart. The formula for calculating force or tension, however, has been based on the law of Laplace

$$T = pr \tag{17.2}$$

which states that the pressure difference, p, across a curved membrane in a state of tension is equal to the tension in the membrane, T, divided by its radius of curvature, r [Woods, 1892]. This law has been applied

to both blood vessels [Burton, 1954] and the heart [Li, 1986a]. To apply this formula, a certain geometric shape of the heart has to be assumed in order to arrive at the radius or radii of curvature. The ventricle has therefore been described geometrically as either a thin-walled or thick-walled sphere or ellipsoid. The myocardium, which encloses the ventricular chamber, actually, has finite wall thickness. Also, the long-axis diameter that is, the base-to-apex distance is greater than the short-axis diameter. When the left ventricle is considered as thin-walled ellipsoid, there are two principle radii of curvature, r_1 and r_2. Laplace's law dictates:

$$p = T(1/r_1 + 1/r_2) \tag{17.3}$$

For the ventricle as a sphere, $r_1 = r_2$ so that

$$p = 2T/r \tag{17.4}$$

In a cylinder such as the blood vessel, one radius is infinite, so that

$$p = T/r \tag{17.5}$$

which indicates that a greater tension in the wall is needed to balance the same distending pressure. Both arterial pressure and ventricular pressure have been found to be similar in many mammalian species.

The larger the size of the mammalian heart, the greater the tension exerted on the myocardium. To sustain this greater amount of tension, the wall of the larger mammal must thicken proportionally with increasing radius of curvature. This results in a larger heart weight. The Lame relation that accounts for wall thickness, h, therefore substitutes Laplace's law:

$$T = pr/h \tag{17.6}$$

A dimensional matrix can be readily formed by first expressing T, r, p, and h in the mass (M), length (L), and time (T) system, that is, $4T = M^1 T^{-2}$, $r = L^1$, $p = M^1 L^{-1} T^{-2}$, and $h = L^1$:

$$
\begin{array}{c|cccc}
 & T & r & p & h \\
\hline
M & 1 & 0 & 1 & 0 \\
L & 0 & 1 & -1 & 1 \\
T & -2 & 0 & -2 & 0 \\
\end{array}
\tag{17.7}
$$

To derive dimensionless parameters (π_i), Buckingham's pi-theorem needs to be utilized. To reiterate, the number of pi-numbers (j) is equal to the number of physical quantity considered ($n = 4$) minus the rank ($r = 2$) of the matrix (Li, 1983, 1986a). Thus, there will be two pi-numbers, denoted π_1 and π_2.

$$\pi_1 = T/ph \quad \text{and} \quad \pi_2 = h/r \tag{17.8}$$

They provide a description of the geometric and mechanical relations of the mammalian hearts and Laplace's Law is implicit in the ratio of the two,

$$I = \pi_1/\pi_2 = T/pr \tag{17.9}$$

17.3   Invariant Numbers and Their Physiological Applications

In general, both π_1 and π_2 and their ratio, I, are not only dimensionless, they are also independent of mammalian body mass. That is, π_2 indicates that ratio of ventricular wall thickness to its radius, h/r, is invariant among mammals. This also establishes a scaling factor. They are thus considered invariant numbers, that is, of the form $[M]^0[L]^0[T]^0 =$ a dimensionless constant. This invariance implies that Laplace's law applies to all mammalian hearts [Martin and Haines, 1970; Li, 1986a].

Clinical implications of some of this finding can be easily appreciated. For instance, in the case of pathological cardiac hypertrophy, the h/r ratio is significantly altered as a consequence of increased wall thickness [Li et al., 1997]. This latter increase has been suggested as the result of an adaptation process by which the wall tension is normalized Equation 17.6. While in an enlarged and failing heart, the greater tension due to a larger radius of curvature results in excess myocardial oxygen demand.

Another example of scaling invariance can be found in blood flow in arteries. A dimensional matrix is first formed by incorporating parameters that are thought of as pertinent. These are the density (ρ) and viscosity (η) of the fluid, diameter (D) of the blood vessel, and velocities of the flowing blood (v) and of the pulse wave (c).

	ρ (g/cm^3)	c (cm/sec)	D (cm)	η (poise)	v (cm/sec)
M	1	0	0	1	0
L	-3	1	1	-1	1
T	0	-1	0	-1	-1
	k_1	k_2	k_3	k_4	k_5

$$(17.10)$$

where k_ns are Rayleigh indices referring to the exponents of the parameters. The pi-numbers can readily be obtained. Two of these are the well-known Reynold's number (Re), essential for identifying viscous similitude and laminar to turbulent flow transitions [Li, 1988], Re $= \rho v D/\eta$, and the Mach number, Ma $= v/c$, or the ratio of blood velocity to pulse wave velocity. Allometric relation gives

$$\text{Ma} = 0.04\, M^{0.0} \tag{17.11}$$

which is nondimensional and invariant with respect to mammalian body mass. Although the Reynold's number is also dimensionless, it is not an invariant function of mammalian body mass,

$$\text{Re} = 260.76\, M^{0.42} \tag{17.12}$$

Thus, dimensionless pi-numbers do not necessarily expose similarity principles, that is, scaling factors are not necessarily invariant numbers.

17.4   Comparative Analysis of the Mammalian Circulatory System

Allometric relations of anatomic structures and physiological functions are useful for identifying similarities of the circulatory function of different mammalian species [Li, 1996, 1998]. Obvious factors that are important in determining function are heart rate and size, cardiac efficiency and contractility, stroke volume, and blood pressure. Some examples of circulatory allometry are given in Table 17.1, and can be found in other sources [Stahl, 1963a, b, 1965; Juznic and Klensch, 1964; Holt et al., 1968, 1981; Calder III, 1981, 1996; Dawson, 1991; Li, 1987, 1996, 1998].

TABLE 17.1 Allometric Relations of Some Hemodynamic Parameters, $Y = aM^b$ (M in kg)

Parameter	Y	a	b	Reference
Heart rate (sec^{-1})	f_h	3.60	-0.27	Adolph [1949]
Stroke volume (ml)	V_s	0.66	1.05	Holt et al. [1968]
Pulse velocity (cm/sec)	c	446.0	0.0	Li [1987, 1996]
Arterial pressure (dyn/cm^2)	p	1.17×10^5	0.033	Gunther and Guerra [1955]
Radius of aorta (cm)	r	0.205	0.36	Holt et al. [1981]
Length of aorta (cm)	L	17.5	0.31	Li [1987, 1996]
Metabolic rate (ergs/sec)	MR	3.41×10^7	0.734	Kleiber [1947]
Heart weight (kg)	M_h	0.0066	0.98	Adolph [1949]

In mammals, the ratio of heart weight to body mass is an invariant with the heart accounting for about 0.6% of body mass. In allometric form [Adolph, 1949; Gunther and DeLa Barra, 1966a], this is

$$M_h = 6.6 \times 10^{-3} \, M^{0.98} \tag{17.13}$$

where the heart weight M_h and body weight M are both in grams. With M_h in g and M in kg, this has been given [Holt et al., 1968] as

$$M_h = 2.61 \, M^{1.10} \tag{17.14}$$

It should be readily apparent that experimental conditions and ecological factors can influence the empirical constants a and b. The above exponents for the heart weight (M_h), however, do not differ significantly from the theoretical exponent of 1.0 ($M^{1.0}$). The deviations arise from statistical fits of regressions to experimental data. It is also readily apparent that if a variable scales as $M^{1.0}$, then the allometric equation can be made invariant by taking a ratio with M in denominator, that is, normalizing with body mass.

The stroke volume (V_s) is also an invariant when normalized to heart weight or to body mass,

$$V_s = 0.66 \, M^{1.05} \text{ ml} \quad \text{or} \quad 0.74 \, M^{1.03} \text{ ml} \tag{17.15}$$

Stroke volume has long been considered a critical hemodynamic quantity in assessing ventricular function. Its product with mean blood pressure, bears a direct relation to the energy expenditure of the heart, or the external work, EW,

$$\text{EW} = pV_s \tag{17.16}$$

This is the work performed by the heart in order to perfuse the vasculature during each contraction, or in other words, the work necessary to overcome the arterial load during each ejection. Blood pressures are generally invariant with respect to body mass in mammals. Of course, there are exceptions due to unusual body size and shape [McMahon, 1973, 1983], such as the giraffe [Goetz et al., 1960] for identifiable reasons. This also indicates that the heart is basically a pressure source; maintaining an average constant blood pressure is of utmost importance. The process of blood pressure control is complex, and important roles are played by baroreceptors, the renin–angiotensin system and the autonomic nervous system, just to name a few subsystems. Allometrically, the mean arterial pressure is expressed as

$$p = 1.17 \times 10^5 \, M^{0.033} \text{ dynes/cm}^2 = 87.8 \, M^{0.033} \text{ mm Hg} \tag{17.17}$$

The exponent is slightly, though statistically it is not significantly different from 0 ($p = aM^0$). Thus, the external work is given by

$$\text{EW} = 0.87 \times 10^5 M^{0.063} \text{ ergs} = 0.0087 M^{1.06} \text{ J} \tag{17.18}$$

A larger ventricle generates a greater amount of external work. The quantity of blood that is ejected per beat (stroke volume), however, is a constant fraction of the amount contained in the heart as end-diastolic volume. Thus, ejection fraction, as it is termed, is thus an invariant among mammals,

$$F_{ej} = V_s/V_{ed} = 0.6\text{–}0.7 \tag{17.19}$$

In a failing heart, the ejection fraction can decrease substantially (to 0.2 say), as a result of a reduced stroke volume and an enlarged heart size.

The smaller the mammal, the smaller is its heart weight, but the faster its heart rate (f_h;7):

$$tf_h = 4.02 \, M^{-0.25} \, \sec^{-1} \tag{17.20}$$

Smaller mammals have shorter life spans, since the total number of heart beats in a mammal's lifetime is invariant. Within an individual mammal, rapid (and random) heart rhythms beyond normal often result in cardiac arrhythmias, such as ventricular tachycardia. On the other hand, it is interesting to note here that "cardiac slowing," which reduces heart rate, can actually have the beneficial consequence of increasing longitivity.

Cardiac output, deemed by Hales [1733] as a valuable quantity describing ventricular function is given as the product of stroke volume and heart rate, or the amount of blood pumped out of the ventricle per minute,

$$CO = V_s f_h = (0.74 \, M^{1.03})(4.02 \, M^{-0.25})60/1000 = 0.178 \, M^{0.78} \text{ l/min} \tag{17.21}$$

Cardiac output is closely related to metabolic rate, since the heart supplies oxygen and nutrients for metabolism. Table 17.2 gives a comparison of cardiac output in several species. Deviations from this equation have been found in very small mammals [White et al., 1968]. Since blood pressure is invariant, cardiac output is limited by the total peripheral resistance to blood flow of the mammalian systemic arterial tree, which is obtained as

$$R_s = p/CO = 2.8 \times 10^6 M^{-0.747} \text{ dyn sec cm}^{-5} \tag{17.22}$$

Thus, the peripheral resistance follows the $-3/4$ power of mass [West et al., 1997], and is inversely proportional to the metabolic rate ($+3/4$). This relation can be strongly altered under local conditions, such as vasoconstriction or vasodilation. This derived allometric equation can be compared to that reported by Gunther and Guerra [1955] who gave an equation conforming more closely to the 2/3 power:

$$R_s = 3.35 \times 10^6 \, M^{-0.68} \text{ dyn sec cm}^{-5} \tag{17.23}$$

TABLE 17.2 Cardiac Output of Some Mammalian Hearts Based on the Allometric Equation CO = $0.178 \, M^{0.78}$ l/min

Species	Body weight (kg)	Cardiac output (l/min)
Elephant	2000	67
Horse	400	19
Man	70	5
Dog	20	1.8
Rabbit	3.5	0.5
Mouse	0.25	0.06
Tree Shrew	0.005	0.003

17.5   Metabolic Turn-Over Rate and Cardiac Work

The energy requirement of cardiac muscle fibers and the useful work they can generate are of considerable interest [Starling and Visscher, 1926; Robard et al., 1959; Li, 1983; Liao et al., 2003]. They define the mechanical efficiency of the cardiac pump. In hemodynamic terms, the efficiency of the heart is defined as the ratio of external mechanical work (EW) to myocardial oxygen consumption (MVO$_2$):

$$e = \text{EW}/\text{MVO}_2 \tag{17.24}$$

The efficiency of the heart is an invariant among mammalian species [Li, 1983a, b].

EW is also termed stroke work and is represented as the area encircled by the left ventricular pressure–volume (P–V) diagram during each heart beat. The external mechanical work generated by the heart per unit body or heart weight is constant for mammalian species [Li, 1983a, b], that is,

$$\text{EW}/M = \text{constant} = (pV_\text{s})/M \tag{17.25}$$

This result is also of considerable physiological importance, since it states that the cardiac external work intensity, is invariant among mammals. Species differences in cardiac energetics, however, have been reported [Loiselle and Gibbs, 1979]. For man, taking $V = 75$ ml, $p = 100$ mm Hg, $M = 70$ kg, and $M_\text{h} = 370$ g, the external work is about 1 J and the coefficient is about 2.7 J/kg. In terms of heart weight, this is

$$\text{EW} = 2.7 \text{ J/kg} \quad \text{or} \quad \text{EW} = 1/70 \text{ J/kg} \tag{17.26}$$

in terms of body mass. For a 2100-kg elephant, its left ventricle is estimated to generate about 30 J for each heart beat. Examination of the dimensions gives:

$$\text{EW}/M = [M]^0[L]^2[T]^{-2} \tag{17.27}$$

Although this ratio is constant among mammalian species, it is not dimensionless. Therefore, it is not an invariant number.

17.6   Comparative Pulse Transmission Characteristics

Mammalian arterial system exhibits geometric and elastic nonuniformities. Geometric taper of the aorta alone is associated with an increased elastic modulus away from the heart. Vascular branching occurs where target organ perfusion is necessary, increasing the total vascular cross-sectional area. Arterial wall-thickness-to-lumen-radius ratios are invariant at corresponding anatomic sites in mammalian species. The ratio of aortic length to its diameter is also an invariant [Holt et al., 1981; Li, 1987]. In addition, the sizes of terminal arterioles and capillaries, as well as of red blood cells are also virtually invariant among mammalian species regardless of their body size. These represent structural invariants, giving rise to global vascular perfusion characteristics that are amazingly similar.

Similar pressure and flow waveforms are recorded in aortas of different mammalian species [Kenner, 1972; Noordergraaf et al., 1979; Li, 1987, 2000; Figure 17.1]. This suggests that corresponding pulse transmission characteristics may also be similar. Nonuniformities in geometry and elasticity, as well as viscous damping, could give rise to varying impedances to blood flow along the arterial tree. Pressure and flow pulses could therefore be modified as they travel away from the heart as they encounter mismatches of these impedances. Impedance to pulsatile flow is like resistance to steady flow and can be viewed as complex resistances that vary with frequency. Impedance is calculated as the complex ratio of pressure to flow for each harmonic, or multiples of heart rate. When the impedance is determined at the ascending aorta, or the entrance to the arterial tree, it is termed input impedance. Vascular input impedance (Z_in) can be used to characterize the global properties of the arterial system.
FIGURE 17.1   Simultaneously measured ascending aortic pressure and flow waveforms in three mammalian species, namely the horse, man, and dog, with grossly different body weights. Similarities in waveforms are obvious. Blood pressure magnitudes are similar.

TABLE 17.3   Data for Different Mammals for Analysis of Arterial Pulse Transmission Characteristics

	Body mass M (kg)	Heart rate f_h (beats/min)	Phase velocity c (cm/sec)	System length l (cm)	Reflection coefficient Γ (experimental)	Reflection coefficient Γ (non-dimensional)	Propagation constant $\times l$ γl
Horse	400	36	400	110	0.36	0.42	1.13
Man	70	70	500	65	0.38	0.45	1.06
Dog	20	90	400	45	0.39	0.42	1.01
Rabbit	3	210	450	25	0.41	0.48	0.93

$Z_o/R_s = 0.1$ is used in the calculation of Γ and γ.

When the characteristic impedance of the proximal aorta (Z_o) is matched to the input impedance of the arterial tree, that is, $Z_{in} = Z_o$, maximum transmission is present and reflection of the propagating pulse does not occur. Under this "matched impedances" condition, the pulsatile energy is totally transmitted to organ vascular beds. In normal physiological conditions, however, there is some mismatching of the impedances close to the peripheral organs. This causes the reflection of the propagating pressure and flow pulses. The fraction of the propagating pulse that is reflected is given by the reflection coefficient [Li, 1986, 2004], related to the impedances as

$$\Gamma = (Z_{in} - Z_o)/(Z_{in} + Z_o) \qquad (17.28)$$

The magnitude of the reflection coefficient at normal resting heart rate is about 0.4, similar for many mammalian species (Table 17.3). The resolution of pressure and flow waveforms into their respective forward and reflected components [Li, 2000, 2004] are shown in Figure 17.2.

Pulse propagation characteristics [Li et al., 1981] can be quantified with a propagation constant,

$$\gamma = \alpha + j\beta \qquad (17.29)$$

where α is the attenuation coefficient, describing pulse damping due to viscous losses and β, the phase constant, denoting the relative amount of phase shift or pulse transmission time delay due to finite pulse propagation velocity, c. In the mammalian aorta, the pulse wave velocity is invariant, as seen from the allometric relation

$$c = \omega/\beta = 446\, M^0 \text{ cm sec}^{-1} \qquad (17.30)$$

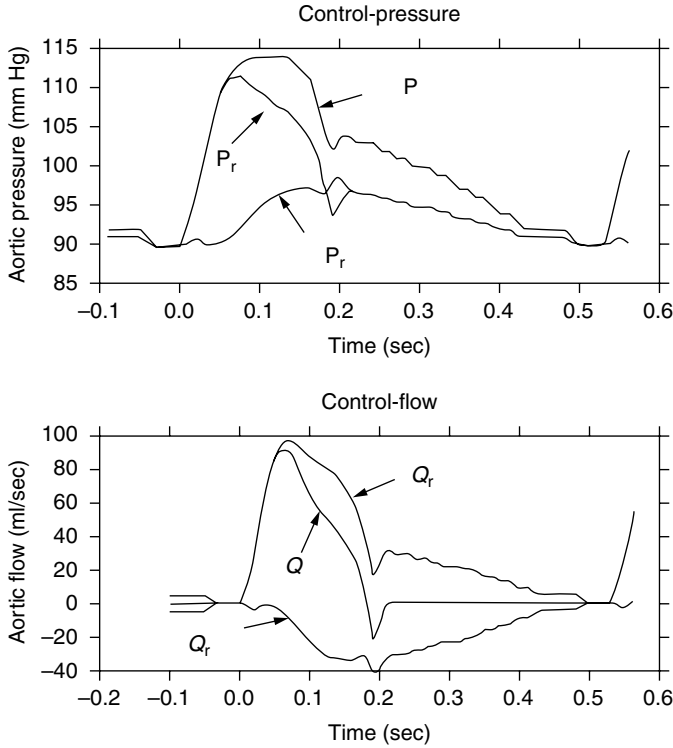
where $\omega = 2\pi f_h$, $f_h =$ heart rate (sec^{-1}).


FIGURE 17.2 Simultaneously measured canine aortic pressure and flow in the aorta when resolved into its forward (P_f, Q_f) and reflected (P_r, Q_r) components.
FIGURE 17.3 The coupled model of the left ventricle (LV) and the arterial system (AS). The LV is represented here by a time-varying compliance and a resistance. The AS is represented by the modified windkessel model with characteristic impedance, Z_o, peripheral resistance, R_s, and compliance of the arterial system, C. $C(P)$ denotes the case when compliance is allowed to change with blood pressure levels.

To compare gross features of the arterial trees of different mammals, modeling approach can be particularly useful. The modified windkessel model of the systemic arterial system that is coupled to the heart (Figure 17.3) has been shown to represent well the features of the input impedance of the systemic arterial tree. For this representation, the input impedance is

$$Z_{in} = Z_o + R_s/(1 + j\omega CR_s) \tag{17.31}$$

dominated by Z_o, R_s, the systemic peripheral resistance as shown before, and C, the total systemic arterial compliance, representing the elastic storage properties of the arteries:

$$C = 0.18 \times 10^{-4} \, M^{0.95} \, \text{g cm}^4 \, \text{sec}^2 \qquad (17.32)$$

It is clear that the peripheral resistance decreases, while compliance increases with mammalian body size. Thus, the dynamic features of blood pressure and flow pulse transmission can be scaled through this kind of modeling. The ratio of Z_o/R_s corresponds to the ratio of pulsatile energy loss due to oscillatory flow to the energy dissipated due to steady flow (to overcome R_s) and has been reported to be between 5 and 10% and is an invariant for the mammalian arterial circulation [Li, 1996, 2004].

Some of the pulse transmission characteristics for horse, man, dog and rabbit are summarized in Table 17.3. The ratio of pulse propagation wavelength, λ, for the fundamental harmonic, to the length of the aorta, l, equals about 6, independent of the body mass of the mammal. The product of γl is about 1, again independent of the mammalian body mass and confirming that the propagation characteristics along mammalian aortas are similar. The global reflection coefficient is also practically invariant. This occurs in spite of vast differences in heart rate, systemic peripheral resistance, total systemic arterial compliance, and aortic characteristic impedance that are associated with different body sizes.

17.7 Optimal Design Features

These observed phenomena concerning pulse transmission, pulse wave velocity, and input impedance as discussed above must all be attributed to a common mechanism [Li and Noordergraaf, 1991]. The architecture of the branching arterial junctions is such that only a portion of the pulse wave generated by the ventricle reaches the capillaries. Another part is reflected in the periphery, principally in the arteriolar beds. Reflected waves encounter mismatched branching sites on their return trip to the ventricle. As a result, a negligible fraction of the reflected pulse wave actually reaches the heart, with the exception of the lowest frequency component for which the wavelength is comparable to the effective length of the vascular system.

Another important feature of the optimal design of the mammalian arterial tree network is that there is minimal loss of pulsatile energy due to vascular branching [Li et al., 1984]. The vascular junctions are practically impedance matched. In other words, the characteristic impedance of the mother vessel is closely matched to the branching daughter vessels. This implies that the geometric and elastic properties of the daughter vessels match that of the mother vessel. As such, pulse transmission at a vascular branching junction is met with minimal local reflection. This results in the facilitation of vascular perfusion with minimal energy loss en route to organ vascular beds.

18.1 Introduction

The evolution of the human in caring for others is reflected in the development of cardiopulmonary resuscitation (CPR). Superstition, divine intervention, and, finally, science have contributed to the development of a technique which may allow any person to save another's life. Fully 50% of the first presentation of coronary artery disease is sudden death, typically in (western) men [1]. However, achieving a clear understanding of why CPR saves some lives remains shrouded in mist; mist made even thicker by contradictory reports, different schools of thought, and persistently low-survival rates.

Despite the suggestion that much remains unclear, CPR is not new. Initially known as closed-chest cardiac resuscitation (CCCR), an early report of CPR as performed today, in an 18-year-old woman, dates from 1858 [2]. Following airway obstruction and hypoxia, cardiac arrest occurred. Artificial respiration and compressions on the anterior chest wall for 6 min resolved the incident successfully. Surprisingly little seems to have changed in CCCR since that early report.

Even though CPR has been researched extensively, the number of survivors remains disappointingly small. Survival rates as low as a few percent and extending upward to 30% (most frequently around 10%) survival for "out-of-hospital" resuscitation have been reported, without a clear understanding of why some patients do and others do not survive when given the same care. CPR is a technique taught to tens of thousands each year.

This chapter addresses functional aspects of CPR required for a working understanding of the biomedical aspects of CPR. It does not purport to be a CPR course, although practical aspects relevant to understanding will be addressed, though not exhaustively. The development in CPR and the contributions of science to this development is presented, with emphasis on the cardiovascular system and only on the artificial respiratory aspects when needed. Schools of thought, chronologically organized, with the effects of physical and experimental models on their development and validity will allow the reader to analyze strengths and weaknesses.

18.2   Basic Models and Methods in CPR: Fundamental Characteristics

Cardiopulmonary resuscitation, as a generally known and accepted technique, typically addresses the combination of some form of artificial respiration and artificial mechanical support for the circulation. The most clear-cut case for application of CPR is that of a heart attack: electromechanical dysfunction of the heart, leading to uncoordinated movement of the ventricles and loss of cardiac output. As the brain is starved for oxygen, loss of consciousness follows within seconds and breathing ceases shortly thereafter. If no support is given, death will follow in minutes.

Initially, resuscitation focused on what is now known as opening the airway and artificial respiration and was performed when breathing had stopped (a clearly visible aspect), or after drowning. Recognition of the separate entity of the circulation and of the appearance of arrhythmias did not occur until the 1900s.

18.2.1   Open-Chest Cardiac Resuscitation

Early CPR was associated with specific illnesses and often a perioperative occurrence. Interest surged with the advent of large-scale use of inhalation anesthesia during the late 1840s [3]. The first report of an unsuccessful human attempt is attributed to Niehaus in 1880, and the first successful case is attributed to Igelsrud in 1904 [4,5].

The technique for open-chest cardiac resuscitation (OCCR) was simple and based on experimental work done in the 1870s by Schiff on laboratory animals [6]. Ventilation was provided by opening the airway and blowing in air. The chest could be opened between two ribs (fourth and fifth) on the left side so that the heart could be stimulated and compressed by enveloping the ventricles with one hand and squeezing rhythmically and pressing against an inside wall of the chest. Care was taken to compress the heart below the annulus (the border between ventricles and the atria) in order to avoid interference with coronary arterial or venous flow. During abdominal surgery the heart could be approached sub- or transdiaphragmatically, in which the subdiaphragmatical approach was most common. In 1953, Stephenson et al. [7] published a manuscript describing an international accumulation of 1200 cases, reporting a 28% long-term survival rate. It should be noted that 21% of these patients was less than 10 years old and that while ventricular fibrillation was recognized, electric defibrillation may have been utilized. This contrasted

with a retrospective report with by Briggs et al. [8] of 58% survival, using data from the Massachusetts General Hospital.

Using open-chest cardiac compression a cardiac output approaching 90% of normal could be achieved and maintained for long periods of time. Mortality due to infection was low (ca. 4.7%) even by modern standards, undermining suggestions that a "second killer" exists in the use of OCCR [9]. In this series of 43 patients a definitive survival rate of 74% was described.

Pike et al. [3] compared OCCR with CCCR and reported, "where we have been sure that the heart has stopped entirely, although for the briefest period, extra-thoracic massage alone has proved useless."

Open-chest cardiac resuscitation, mainly an in-hospital procedure, remained the method of choice until the beginning of the 1960s, when it was quickly replaced by the CCCR technique. The change from OCCR to CCCR occurred rapidly, despite scientific evidence strongly holding that this transition was controversial. Regular, resurgent efforts to reintroduce OCCR have found only a minor toehold in medicine, despite recent insights and many contemporary reports [10]. (See Section 18.3.1.13 on minimally invasive direct cardiac massage.)

18.2.2 The Transition to Closed-Chest Cardiac Resuscitation

Creating movement of blood without opening the chest and enclosing the heart by the hand and directly compressing it, was first described in a series of human case reports by Koenig in 1885 [11]. In 1960, Kouwenhoven et al. [12] published what later became known as a landmark article, describing CCCR in general terms and claiming a 70% permanent success rate. The mechanism underlying their technique mimicked that of OCCR, based on the assumption that artificial CPR or compression systole caused direct compression of the heart between the sternum and the thoracic vertebral column at about Th_7–Th_8. During CPR systole the pressure in the (left) ventricle was assumed to be higher than the pressure in the atria, closing the atrioventricular valves, allowing for (right) atrial inflow, and creating a systemic and pulmonary arterial to venous pressure gradient [13]. This was thought to cause forward flow of sufficient magnitude to support life for up to several hours.

A clinical follow-up paper was published by Jude et al. [14]. While return of spontaneous circulation (ROSC) was achieved in 78%, only 24% survived to leave the hospital. If further subdivision is made for the patients with recognizable sudden cardiac death (24 patients), then the intervention length was 2 to 120 min, with 20% reaching ROSC and only 13% of this group to leave the hospital alive.

Further studies, in humans, comparing OCCR and CCCR were not performed [15], and OCCR gradually was reduced to a specialized technique, performed by a few physicians under a limited number of conditions.

18.2.3 Application of Closed-Chest Cardiac Resuscitation

Closed-chest cardiac resuscitation quickly gained popularity as a procedure that lay people could perform, and a number of psychomotor aspects became important. The term CCCR gradually transformed to CPR, in order to emphasize the cardiac and pulmonary aspects in resuscitation, while de-emphasizing the suggestion that the heart was being pumped. The psychomotor skills, often synonymous with basic life support (BLS), became central issues on how CPR is performed, and it has been suggested that they are core issues in survival.

The key psychomotor aspects include compression depth, compression frequency, duty cycle, and interruption of chest compression (for ventilation), and were defined in the early papers, although in some cases the motivation for the specific choice was unclear.

Compression depth is reported as the distance that the sternum is moved from its neutral position in the direction of the vertebral column. It is performed by applying significant external force on the lower half of the sternum, typically with one hand overlying the other. Compression frequency refers to the number of compression–relaxation cycles per minute, and is typically reported as the frequency without subtraction of noncompression time (i.e., for ventilation). The duty cycle refers to the fractions of time,

TABLE 18.1   Summary of the Values Given for Essential Aspects of CCCR (External Cardiac Massage), with Emphasis on the Circulatory Aspects

Year	Hand placement on the sternum	Impression depth	C:R ratio	Frequency (frequency during compressions)	Other aspects
1960	Lower half	1.5–2 in.	n.a.	60 min^{-1}	5:1 compression:ventilation
1974	Lower half (1.5 in. above xyphoid)	1.5–2 in.	1:1	60 min^{-1} (2 caregivers) 80 min^{-1} (1 caregiver)	No pause for ventilation (5:1) 5 sec pause allowed
1980	Lower half	1.5–2 in.	1:1	60 min^{-1} (2 caregivers) 80 min^{-1} (1 caregiver)	No pause for ventilation 5 sec pause allowed
1992	Lower half	1.5–2 in.	1:1	80–100 min^{-1} (both)	6 sec ventilation pause
2000	Lower half	1.5–2 in.	1:1	100 min^{-1}	2 sec per ventilation (15:2)

Note that the table is adapted from the American Heart Association "Standards and Guidelines." For explanation of abbreviations, see text. Abbreviations: C:R = compression to relaxation ratio. See Section 18.2.2 for a detailed explanation. (5:1) = 5 compressions followed by 1 ventilation. No pause implies that the chest compression will continue, that is, the time available for ventilation is 0.5 sec.

expressed as percentages, for compression as opposed to relaxation, and may also incorporate maintenance of compression or relaxation state. For example: a 40% duty cycle refers to (a) 40% compression, (b) 40% relaxation, and (c) 20% maintenance of relaxation. During one-rescuer CCCR, interruption of the compressions is required to clear the airway, ventilate the patient, and reposition the hands on the sternum. It may also include time needed to evaluate the electrocardiogram, check for respiration or pulsations, defibrillation, etc.

Other aspects such as hand position, use of a noncompressible underlying surface, opening the airway, and ventilation volumes have been discussed and adapted over time but have remained less central to the survival question. In Table 18.1 a summary is presented showing the consistency of the values over time.

Clinical realism requires that several additional concepts be understood. These are:

- *Oxygen delivery*: The purpose of CPR is to create sufficient circulation of oxygenated blood to maintain cellular metabolism and integrity.
- *Pressure*: Not arterial systolic or diastolic, but mean pressure is related to perfusion. Flow may be extrapolated by (mean) pressure differences at two different points in the vasculature. Direct measurement of flow in CPR conditions remains difficult.
- *Flow*: This is extrapolated from pressure differences. Coronary perfusion pressure (CPP) or myocardial perfusion pressure (MPP) is mean diastolic arterial pressure minus mean diastolic right atrial pressure. CPP is also used to denote cerebral perfusion pressure, equal to mean arterial minus mean intracranial pressures. In the former at least 15 mmHg [16] and in the latter 60 mmHg have been suggested as being required to sustain oxygenation of the myocardium and neuronal integrity [17]. Coronary perfusion occurs during diastole and remains dependant on myocardial wall tension, intrapericardial pressure.
- *Critical coronary perfusion pressure*: As stated above, flow is related to the pressure gradient. However, in stenotic vessels, flow will remain disproportionally low, as autoregulation cannot cause the maximal vasodilation in the healthier vessels. This may exacerbate regional hypoxia, the build up of low energy phosphates and acidosis.

18.2.4 The "Cardiac" and the "Thoracic" Pump Theories

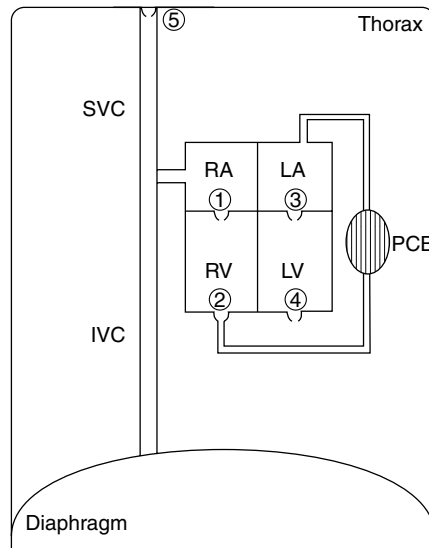
Gradually, divergent opinions appeared as to the mechanism by which blood was actually pumped. Two schools of thought developed. The "cardiac" pump theory [12] suggested that pumping was achieved by direct compression of the heart, despite doubts expressed about the ability of the heart to function as a unidirectional pump under CCCR conditions as early as 1961 [18]. Weale, in his "letter to the


FIGURE 18.1 Schematics of the heart and the relevant structures for CPR. Valves listed as numbers. (1) Right atrioventricular valve or tricuspid valve; (2) right ventricular valve or pulmonary valve; (3) left atrioventricular valve or mitral valve (4–6 cm^2); (4) left ventricular valve or aortic valve (2.6–3.5 cm^2); (5) Niemann's valve, a nonanatomical valve in the cerebral-to-thoracic venous circulation. SVC = superior vena cava; IVC = inferior vena cava; RA = right atrium (pressure −1 to +7 mmHg); LA = left atrium; RV = right ventricle (pressure 15–25/0–8 mmHg), ejection fraction 40–60% with end-diastolic volume of 100–160 ml; LV = left ventricle (ejection fraction 40–75%). PA = pulmonary artery (15–25/8–15 mmHg); PCB = pulmonary capillary bed.

editor," proposed an alternative theory. It became popularized as the "thoracic" pump theory, but was not functionally reported until 1976 [19].

Central to the theoretical models of cardiac or thoracic pumping are two biomedical aspects. These are the actions of valves and the source of the blood volume that is being displaced. In Figure 18.1, a much-simplified representation of the relevant structures in CPR is given, to support and lend clarity to the modeling strategies described later.

The cardiac pump theory advocates that there is (direct) pressure on the ventricles. This is supported by indications that compression depth is related to output, that cardiac (or more specifically ventricular) deformation is related to stroke volume, that the duration of compression has no effect, and that an increased compression rate will increase flow [17]. In the original manuscripts, as well as over time, 1.5 to 2 in. (4 to 5 cm) has been maintained as standard. Forward flow of blood is assumed to be caused by competent atrioventricular valves and sufficient competence of the aortic and pulmonary valves to avoid regurgitation during CPR diastole. Implicitly, ventricular filling is essential and artificial systole must be sufficiently frequent to generate acceptable flow, as stroke volumes may be relatively small compared to the normal 60 to 100 ml per beat at ejection fractions of 40 to 75%. Mitral valve closure during CPR systole is deemed essential for the "cardiac" pump theory to work.

The "thoracic" pump theory [19] was suggested when patients with proven ventricular fibrillation on the EKG remained conscious for up to 90 sec, if they coughed forcefully, and kept coughing. Both fibrillation and cough had been triggered by the coronary catheterization procedure which prompted this clinical observation. The thoracic pump theory suggests that it is not the heart which is forced to pump by compression during CCCR or which supplies the volume to be displaced, but the blood volume in the thoracic cavity (i.e., the pulmonary circulation), with forward flow being generated by the arteriovenous pressure gradient, and (functional) valves at the thoracic outlet. The pressure chamber has been suggested to be the right ventricle, the pulmonary vasculature, and the complete left heart all connected in series. Transmitral flow during compression systole is considered characteristic of "thoracic" pump thinking.

This controversy remains active, although there is increasing evidence that in any one clinical case both theories may pertain. In both cases optimal performance of the technique seems to produce no more than 30% of normal cardiac output. It is recognized that many factors may be involved, for example, chest diameter, which confuse study outcomes [20]. Duration of circulatory failure, pH in tissue and in blood, underlying disease, and other causes, may also be factors.

18.2.5 Animal Models

When looking at the literature, the reader will note that animal models have long been used in the absence of the opportunity to study CPR in humans carefully and in an organized fashion. The choice of animal model may influence the outcome. Aspects to consider are:

- The anterior to posterior dimensions of the chest in relationship to the heart. This may be reported as anterior–posterior to lateral sizing. Increasingly small animals have been seen as models for humans with highly compliant, relatively oblong chests, as in children.
- The support/position of the animal. Many animals are unstable in a pure dorsal decubitus (lying on their back). A lateral decubitus, or a dorsal position, but supported by a "V" shaped cradle may be used to overcome this, but the former influences the distances between compression surfaces and the latter may limit lateral movement of the chest wall.
- The force, velocity, or distance used during CPR. Moving the sternum 2 in. in a small animal (chest diameter of 5 in.) may not translate to movement of 2 in. in a human (chest diameter upward of 10 in. or 24 cm).
- The method of inducing anesthesia, inducing ventricular fibrillation for CPR [21].
- The length of time between steps/series/controls. In series of experiments animals may be used as their own controls, with a few minutes between one technique followed by another. Return to baseline conditions is often impossible.
- The type of monitoring used for data acquisition.

The current standard (animal) model for CPR is the pig. However, care should be taken in extrapolating this data to humans for the same reasons [22].

18.2.6 Summary of This Section

Two distinct conceptual theories have been purported to explain why blood moves during CPR. Animal models may provide increased insights, but may also give rise to confusion. Although the "cardiac" pump theory (Kouwenhoven) and the "thoracic" pump theory (Criley) have been promoted as one-or-the-other mechanism, it has gradually become accepted over time that depending on the physiology of the patient the blood flow may be caused by either or both, perhaps alternating or time sensitive.

18.3 Variations in CPR Technique Based on Physiological Expectations and Modeling

The poor results, in terms of cardiac output, as well as in terms of survivors, found when larger-scale studies were published, initiated the development of what has become known as "adjuvants" to standard CPR or alternative CPR techniques. These techniques, all based on the application of CPR as CCCR, described by Kouwenhoven et al. [12] in 1960, attempt to improve survival using a variation of the baseline technique. The main line of adjuvants is presented in the order of their initial publication. Their underlying conceptual models are explained. Where possible, human data is referenced.

Standard CPR (S CPR), or basic life support (BLS) anno 2000 consists of a device-free, one- or two-caregiver technique, involving external chest compression on the lower half of the sternum, with a compression depth of 4 to 5 cm, at a frequency of 100 compression per minute with a duty cycle of 50%.

Compressions are supplemented by ventilations in a ratio of 15 compression to 2 ventilations of about 800 ml (one caregiver), and this respiratory pause should be shorter than 6 sec.

18.3.1 Adjuvant Techniques in CPR

18.3.1.1 Simultaneous Ventilation and Chest Compression (SVC) CPR

As an early variation of CCCR [23], this adjuvant, functionally a model supportive of the "thoracic" pump theory, suggests that insufflating the lungs, with simultaneous compression on the chest, should create optimal flow of blood out of the thoracic cavity by the (high) intrathoracic pressures generated. The technique, known as SVC-CPR, requires a formal airway to avoid excessive gastric insufflation, as high airway pressures are used to add to intrathoracic pressure change caused by the external compression. This mechanism was not supported by Harris et al. [24], due to other considerations and remained a dormant technique until the 1980s when Chandra et al. [25] revitalized it. This group, noting airway pressures of 60 to 110 cm H_2O, found more than a 100% improvement over baseline values for carotid flow, while working in humans. However, a large study (994 enrolled) in humans found a significantly detrimental effect in outcome [26], and it is currently not advocated for general use by the ILCOR 2000 guidelines [1]. The cause of the detrimental effect may be that open alveoli become severely overdistended, and that the pulmonary capillary bed becomes underperfused.

18.3.1.2 Static (Manual) Abdominal Binding

Having noted the limited cardiac output under CCCR conditions, experiments were performed with the use of epinephrine, volume loading, and static abdominal binding over the whole abdomen [27]. While demonstrating improvement in cerebral blood flow, at unspecified pressures, by improving the arterial to venous pressure gradient, as well as improving cardiac filling, the technique was not deemed useful due to extensive abdominal trauma. Not until the 1980s did further human data support static binding. The improvements were suggested to (a) increase intrathoracic pressure (decrease in pressure loss due to movement of the flaccid diaphragm and abdominal wall), (b) increase functional arterial resistance, and (c) redistribute blood volume to compartments above the diaphragm out of the abdominal compartment due to the flaccid nature of the diaphragm [28]. In a laboratory study in dogs, Niemann et al. [29] could not support the premises, finding that venous return is dependent on venous capacitance more than on the peripheral-to-central venous pressure gradient. Static abdominal binding is not in clinical use. No original research papers have appeared on this specific topic in more than 10 years. While listed separately, MAST-CPR is a specific form of static abdominal binding (see Section 18.3.1.6).

18.3.1.3 Cough CPR

Cough CPR [19,30], and its external variant, vest CPR, have been mentioned as the prototype for CPR without (direct) cardiac compression and is a "pure" application of the "thoracic" pump theory. The mechanism for coughing is clear: the diaphragm contracts strongly after a deep breath. With the upper airway partially obstructed forceful contraction will compress the air in the lungs and create equal pressure change on all intrathoracic structures. The intrathoracic pressure can reach 100 to 140 mmHg during the 0.2 to 0.5 sec of glottic closure and exhalation. Blood, not compressible, will move out of the high-pressure area to low-pressure areas. To achieve effective forward flow some (at least one) anatomical or functional valves and resistance differences are required. Reflux into the cerebral venous system is avoided by Niemann's valves, a functional set of valves at the thoracic outlets [31]. A similar functional valvular obstruction at the level of the diaphragm is unproven, with retrograde flow being limited by the peripheral capillary beds and arteriolar resistance. Cough CPR is considered a proven and useful clinical entity within specific settings, such as the coronary catheterization laboratory. Some hospitals routinely describe it in patient information folders and have the nursing staff issue instructions on the technique prior to procedures.

18.3.1.4   Altered Compression Duration

Birch et al. [33,35] suggested that the duration of compression might be an important factor in effective CCCR. In a prospective human study, increasing the duration of standard CPR systole to 60% of cycle time, in the range of 40 to 80 compressions per minute, improved the arterial flow index to 185% of control value. A 50% compression duration (compression : relaxation ratio of 1), was introduced as standard and still is advocated. Caregiver skills evaluation has demonstrated that at higher frequencies, that is, compression rates greater than 120 cpm, the compression : relaxation ratios almost always approach 1.

Later, other studies, typically in conjunction with much higher compression rates or increased force of compression (see Section 18.3.1.9), suggested that the rate in which compressions are performed may be more important than the duty cycle (duration of the compression as little as 20%). In addition, it became clear that only CPR performed mechanically (i.e., the Thumper®) is able to effectively perform short duty cycles at higher compression rates. Duty cycle alteration might be expected to effect output during CPR only from a "thoracic" pump approach [17].

18.3.1.5   Negative Airway Pressure

The use of negative airway pressure [34] in a noncardiac pump and nonthoracic pump model promised potential improvement in CPR. The concept rests on basic physiological principles directly relating to intrathoracic pressure changes influencing venous return. Cardiac output is dependent on venous return. With intermittent positive-pressure ventilation (mouth-to-mouth or using a respirator), intrathoracic pressure is predominantly positive, reducing venous return by interfering with the pressure gradient. The negative airway pressure creates an artificially normal negative segment in the pressure curve, in theory recreating a pressure cycle similar to that seen under spontaneous breathing. The technique has fallen into disuse due to extensive ventilation to perfusion mismatch (shunting) in the lung and severe atelectasis. However, a variation on this concept, in the form of a transient occlusion of the airway during decompression of the chest is currently under clinical investigation (see Section 18.3.1.15).

18.3.1.6   MAST-Augmented CPR

This technique uses pneumatically inflated "military antishock trousers" with an abdominal compartment and two-leg compartments [35]. Conceptually, it will decrease the arterial inflow into the lower extremities by increasing the peripheral resistance and decrease the venous pool in the legs by compression of the superficial and deep veins. This should generate a small, one-time, fluid challenge to the central circulation, known as autotransfusion and decrease the systemic vascular bed size. The autotransfusion has been suggested to be in the order of 8 to 12 ml/kg body weight. Since low peripheral vascular resistance during CPR is a major concern, with the MAP generally lower than 40 mmHg, improvements are theoretically possible. Studies in humans have not been able to demonstrate improved outcome, perhaps due to the involved nature of application. As opposed to static abdominal binding (Section 18.3.1.2), the MAST does not explicitly cause diaphragmatic splinting.

18.3.1.7   Synchronized Ventilation and Abdominal Compression

As a byproduct of work on cough CPR (Section 18.3.1.3 and Section 18.3.1.10), Rosborough found that using ventilation to increase intrathoracic pressure with simultaneous compression of the abdominal compartment maintained carotid artery flows similar to flows from standard CPR in dog experiments [36]. This model, based on a pure "thoracic" pump concept, has not been demonstrated to improve outcome in humans, and has been associated with pulmonary complications attributed to high airway pressures.

18.3.1.8   Interposed Abdominal Compression (IAC) CPR

Compression of the (central) abdomen [37], with 120 to 150 mmHg, between compressions of the chest (IAC-CPR), also known as abdominal counterpulsation CPR, or phased thoracic–abdominal compression (PTAC-CPR), was shown by Ralston, in a carefully documented analysis in a small- and large-dog series, to

systematically improve systolic and diastolic arterial pressure as well as the central diastolic arteriovenous pressure gradient which is also known as CPP. The mechanism for improvement has been thought to be counterpulsation in the aorta and increased venous loading of the thoracic cavity, as demonstrated by increased antegrade flow in the vena cava inferior [38], and typically involves at least three well-trained caregivers. The Lifestick® may simplify the use of the technology, and incorporates active decompression (PTACD-CPR). Babbs [39] recently published a comprehensive review supporting IAB-CPR, which is one of the most extensively modeled and investigated concepts in CPR, presenting both the mathematical, animal, and clinical support for this technique. The safety of IAC-CPR has been investigated, without demonstrating increased aspiration or emesis, perhaps due to an increase in intra-abdominal pressure during artificial ventilation. The lifestick is in limited clinical use and has been accepted by the ILCOR guidelines for in-hospital use.

18.3.1.9 High Impact or Impulse CPR

This theory [16,40], uses high force/velocity for the external cardiac compressions. As a by-product, this technique uses a shorter-compression duration (i.e., as little as 20% instead of the usual 50%), without having the active intention of changing the compression depth. Rates of up to 150 compression per minute (100 compressions per minute is currently advised, see Table 18.1), have been proposed. When modeling from the cardiac pump theory, as long as the compression allows the mitral valve to close, and allows for sufficient filling time, artificial cardiac output will be determined by left ventricular end-diastolic volume. Higher compression rates will create more output. Modeled from the thoracic pump theory, the benefit may be due to the overall increase in the percentage of time actually allotted to compression.

18.3.1.10 Vest CPR

An external variant of cough CPR, vest CPR [41], has been mentioned as the prototype for CPR without (direct) cardiac compression and is conceptually pure "thoracic" pump theory. Halperin [17], working in dogs, compared standard CPR with high-frequency CPR and OCCR. Using a mechanical compression device, exact massage depths could be reproduced at any given frequency or compression duration. Vest CPR was demonstrated to displace the sternum by 0.5 ± 0.1 cm as opposed to 4.6 ± 0.1 cm in the external series. For the OCCR series the heart itself was compressed the same 4.6 ± 0.1 cm distance. Halperin notes that the rate and force (400 N) dependence as well as the outputs generated by the vest CPR, support its use and the thoracic pump model. In 1993, this was followed up by a report of 17 clinical cases [42]. This preliminary study demonstrated a small improvement in initial outcome, with better perfusion gradients. However, time needed to apply the vest, as well as its bulkiness have limited its general use. An interesting, but unsupported, anecdotal suggestion is that Vest CPR should be the principle technique used for research purposes. This is due to its independence from changes in thoracic compliance, myocardial stiffness, and ventilation parameters.

18.3.1.11 Simultaneous Chest and Abdominal Compressions (SCAC) CPR

This technique (SCAC-CPR) [43] is a variation on the model suggested by interposed abdominal compression CPR (Section 18.3.1.8). Conceptually, the simultaneous compression of chest and abdomen should create an improvement in the pressure rise, due to coupling of the thoracic and abdominal cavities (thoracic pump theory). Initial investigations seem to support improved pressure gradients, but as improved outcome has not been demonstrated, little recent work has been presented.

18.3.1.12 Active Compression–Decompression (ACD) CPR

After an anecdotal report of CPR performed successfully with a "plumbers helper," interest was stimulated in active decompression of the chest, allowing for negative intrathoracic pressure and increased venous return [44,45]. This technique became known as active compression – decompression (ACD-CPR), and has achieved routine clinical use in some countries, such as France. While discussion continues as to whether definitive survival is increased, studies have shown that flow, filling pressure, and valve movement (as "thoracic" pump) is improved with respect to standard CPR. Initial reports of significant improvement of outcome have been challenged by others who were unable to find improvements [46]. ACD-CPR

is performed as a clinical tool in many settings. Steen et al. [47], have developed a mechanical, pressure-driven device, which can combine compression with active decompression (LUCAS®) addressing the issue that ACD-CPR is caregiver unfriendly. Use of ACD-CPR, in conjunction with an inspiratory impedance valve (Section 18.3.1.15) has also been advocated recently and the preliminary results are promising.

18.3.1.13   Minimal Invasive Direct Cardiac Massage Device (MID-CM) CPR

The use of minimally invasive direct cardiac massage [48], performed by inserting a plunger-like device through a 7.5 cm incision, makes direct compression of the ventricles through the intact pericardium possible. It was introduced as part of a resurgence of OCCR in a well-defined number of situations, and is a technique similar to insertion of a chest drain. Insertion time is less than 30 sec, and as little as 10 sec may be required in trained hands. Early human work, in the prehospital setting, in patients with failed basic and advanced life support, demonstrated good clinical parameters, although one cardiac rupture was noted [49]. The conceptual model is OCCR.

18.3.1.14   pGz-CPR

A highly technical and experimental procedure, it involves horizontal head-to-foot oscillations at frequency of about 2 Hz, over small, horizontal distances. The name, pGz, refers to a periodic fractional part of the acceleration of gravity, applied along the head to foot or "Z"-axis. It has been demonstrated to produce blood flow and ventilation proportional to the amplitude and frequency of the force applied. At 2 Hz and approximately 0.6 G, 20% of baseline cardiac output, at a very low peripheral and pulmonary vascular resistance, can be achieved in a fibrillating swine model with 100% of animals achieving ROSC or initial success. Using radiolabeled microspheres injected into the circulation, preferential flow to vital organs, including the splanchic microcirculation, could be detected. Separate mechanical ventilation was not used, as pGz-CPR [50] has been shown to generate adequate ventilation and oxygenation if some positive pressure is supplied. This concept is unrelated to classic CPR models.

18.3.1.15   Inspiratory Impedance Valve (ITV or ITD) CPR

Improvement in venous return can be expected if negative intrathoracic pressure is created by "closing" the airway during the decompression phase of the external CPR cycle [51]. This induces extra priming of the pump as a mechanism to improve cardiac output, similar to the concept underlying the active compression–decompression technique. Conceptually, this model is independent of the "cardiac" or "thoracic" pump theories, although the "thoracic" (volume) aspect does play a role. This procedure involves utilizing a valvular device in combination with a facemask or attached to the endotracheal tube. It harnesses the kinetic energy stored in the compressed chest wall, creating down to $-40\ cmH_2O$ (current model: -6 to $-12\ cmH_2O$) when used in combination with active decompression (Section 18.3.1.12), and with most other CPR techniques, including standard CPR. It has been FDA-approved. Early clinical studies suggest interesting possibilities, with 40% improvement in cerebral blood flow noted. Improvement in outcome is attributed to the increased venous return, as well as improvements in CPR technique due to feedback mechanisms included in the valve. The valve must be removed when a spontaneous circulation is reinstituted or if spontaneous ventilation returns. Clinical data has been presented, showing promise, when used in conjunction with active decompression CPR [52].

18.3.1.16   Prone CPR

Alteration of the position of the whole patient (prone vs. the standard recumbent position, in both cases on a hard surface) is an anecdotal technique, which may have its roots in the classic Schafer [53] technique of artificial ventilation. This technique has the suggested advantage of no mouth-to-mouth contact and cleared airway, with ventilation caused by the chest compressions, which are bilateral on the lower ribs. By implication, prone CPR may be included in the "thoracic" pump school. Recently, the use of the prone CPR position has been reported due to dictation by positioning for a surgical procedure [54], as well as on potential psychological merits [55].

No current human or animal series, or modeling of this technique is known. Suggestions that the technique might be "thoracic" pump dependent are based solely on the noncentral hand placements [55]. It is interesting to note that one of the figures supplied earlier by Jude et al. [14] depicts the prone position.

Despite all the above mentioned CPR techniques and variations, a recent meta-analysis demonstrated that the survival of prehospital arrest is no greater than 6.4%, even when the best of the U.S. situations (Cook County, Seattle Washington) is factored in [30]. This rate has not only not improved but has decreased over earlier reports.

18.3.2 Summary of This Section

A plethora of functional and conceptual models for external support of the collapsed circulation are available. It remains disturbing that definitive survival in the majority of these applications continues to be poor. Devices, used in ACD-CPR (Section 18.3.1.12) and the ITD-CPR (Section 18.3.1.15) offer windows of opportunity, but have — as yet — not lived up to expectations, although the sum of knowledge is increasing. Additions to the basis laid down in the 1960s, plus the polarization offered by the "cardiac" or "thoracic" pump conceptual models, clearly fail to fully explain the behavior of the circulation in arrest. The commitment to simplicity in CPR teaching is a refreshing balm in the face of all the theoretical, modeling, and device options. However, it should not become its own goal.

18.4 From Clinical Experiments to Biomedical and Biophysical Understanding

Animal, and even more so human, experiments are handicapped by restrictions that nature and moral attitude impose. For example, it is difficult to direct changes in intrathoracic pressure, generated by compression of the thorax, to particular organs while excluding others. Similar difficulties apply to alterations in air pressure caused by the respiratory system. These examples may be supplemented by any number of other experiments, which should be performed using current technology in view of their presumed instructive value. Some of the confusing results from both animal and clinical research may be caused by limitations in experimental techniques. An example of this was the use of labeled microspheres to document myocardial perfusion.

Progress in understanding of the complex phenomena related to CPR suffered seriously during the entire period in which experiments were performed without the benefit of analytical studies.

18.4.1 Earlier Mathematical, Mechanical, and Animal Models in CPR

In Section 18.3, a wide variety of variations on the principle of external cardiac massage, as suggested by Kouwenhoven et al. [12] were summarized. Mathematical models with distributed properties have found extensive application for the purpose of supporting the experimental observations related to these variations, especially by Babbs et al. and by Beyar et al., both teams starting in 1984, later joined by other teams (see Reference 56, for an extensive review). Mathematical modeling addressing fundamental aspects in this area is of recent vintage [57].

18.4.1.1 Mechanical and Animal Models

Central to CPR is displacement of the sternum in order to either compress the heart directly or to achieve an increase in intrathoracic pressure. In most cases, the thoracic rib cage, responsible for most of the viscoelastic stiffness, will be relatively rigid (i.e., most patients requiring resuscitation are elderly), and a careful balance is required between applying enough force to depress the sternum, without causing undue damage. A consensus exists about the complexity of the psychomotor skills needed to sustain life, and the need to train and retrain these skills in order to achieve adequate life support. The most frequently used mechanical model in CPR remains the training manikin, of which a wide scale of models is available.

An analysis of force deemed adequate for chest compressions demonstrates a surprising range in human experiments, when standardized to Newtons based on area of compression. The range is 245–769 N, with compliances of 0.1 to 2.9×10^{-2} cm N^{-1}. In a review of forces used in mathematical modeling experiments, the range is 59–400 N [56].

Investigation directed at modeling the compliance of the human thoracic cavity in the elderly, has been performed. As early as 1976 the Emergency Care Research Institute suggested that 30 kg should produce a sternal depression of 3.8 to 5 cm [58]. Little work has been done to validate mechanical models in use [59], while work by Gruben et al. [60] on dogs, and Bankman et al. [61] on humans is not reflected in the mechanics modeled in CPR manikins. Force needed to compress the sternum in different manikins varied up to 140% at compression depth of 4 to 5 cm. Within one type of commonly used manikin, differing only in length of time in use, differences in pressure needed to reach 5 cm were found to vary from 37 to 46.5 kPs.

Recently, devices have been introduced to improve compression pressure. These devices, placed between the hands and the anterior chest wall, offer a visual reference to the force being applied. One such device, the CPREzy is being subjected to extensive clinical and bench testing, and seems to improve the consistency of the compression pressure. However, the "correct" depth of an individual patient remains a matter of individual caregiver interpretation.

For many years, small animal models have been utilized for modeling CPR in humans. Small animals, such as cats, pigs, and dogs, weighing from 5 to 20 kg have been used. Regrettably, small-animal experiments are dissimilar to the (elderly) human, but may be carefully applied for neonatal or small pediatric models. More recently, swine, weighing at least 20 kg have become the standard for experiments. This is not only due to improved similarity between the position of the heart and availability of the model, but is mostly due to improved estimation of the cardiac to thoracic cavity size ratio, and the similar ventrodorsal and lateral ratios to humans.

18.4.2   Recent Biomedical Insights: Compression Depth

Much of the research and development in CPR has followed the line of thinking set out by Kouwenhoven in 1960. In the following section the emphasis is shifted to evaluation of a widely accepted aspect, which was not properly scrutinized before, namely the sternum depression depth, discussed in Section 18.2.3, earlier. Additional information is needed to verify whether depression depth may or may not be a factor in the poor outcome after sudden cardiac death. This threshold, conceptually, applies to the "cardiac" pump theory.

There have been suggestions that a threshold depression depth must be observed before cardiac compression becomes effective [62]. Of principal interest would be whether the current recommendations could, in fact, directly cause cardiac compression in the general population (i.e., when the Kouwenhoven et al. recommendations are actually followed with 1.5 to 2 in. depression depth). Noordergraaf et al. [56] measured the transverse distances from the internal border of the sternum to the most ventral aspect of the curved, underlying, vertebral body using CT-scans in 50 cases. Each structure (cardiac, vascular, and esophagus) in these planes was listed, with the diameters of cardiac and vascular cavities described at T_1 and T_2. The cranial transverse slice, T_1, was taken to be the lowest visible border of the pulmonary valve, effectively the upper edge of the hand position on a standard sternum as well as the upper edge of the heart. The T_2 position was taken to be the lowest border of the tricuspid valve, that is, the mid position of the hand.

In this study, representative data was sought, with regard to age, gender, and weight. The distance, at the upper measuring plane, from the inside border of the sternum to the ventral aspect of the underlying vertebral body was 12.6 ± 2.4 cm. In this transverse plane the following structures were identified: the outflow tracts in all patients, which were in 80% of cases central veins, in 35% of cases the descending thoracic aorta, and incidentally the esophagus.

The internal distance T_2 was 13.4 ± 2.3 cm, with a difference of 11.1 ± 1.2 cm between outside and inside diameters. The structures found in the plane between the sternum and the vertebral body were

predominantly the right atrium, the esophagus, which was in a majority of cases part of the right ventricle, and in some cases the left atrium with only an edge of the left ventricle. The descending thoracic aorta lay, in most cases, lateral of the vertebral column. The cardiac structures in this line being 8.6 ± 1.6 cm. The "noncardiac" distance available was 4.6 ± 1.6 cm (with a range of 1.8 to 7.3 cm).

These results do not contradict Kouwenhoven et al. [12] in suggesting that part of the heart may not be directly compressed between bony structures when moving the sternum dorsally for up to 5.1 cm to cover the mean value of 4.2 cm between bony and cardiac structures. Initially noted in clinical instructions adjusting the compression depth to the individual characteristics of the patient has recently resurfaced as a brief aside [1]. With part of the cardiac structure subject to direct compression, notably the right atrium and to a lesser degree the right ventricle, it remains difficult to explain significant size reduction of the left ventricle reported in clinical and animal echocardiographic studies, even when supposed restrictive aspects of the pericardium are incorporated [63,64].

These experimental observations lead to the conclusion that CCCR is not, in general, imitation of OCCR, because the heart, as a whole, and in particular the left ventricle, is not in the line of compression and the space to be bridged is too large.

18.4.3 Description of a Model to Assist Analysis

Careful formulation and development of mathematical expressions offer a way to resolve some of the difficulties mentioned above between the differing conceptual models in CPR. Figure 18.2 shows a schematic of the cardiovascular closed loop, consisting of eight blocks, anatomically identified in the figure. Cardiovascular events within each block are specified by algebraic and differential equations, as needed. The equations contain the unknown blood pressure and blood flow variables as they relate to parameters covering effects of the viscous and inertial properties of blood, elastic properties of heart and vessels, controls, such as ventricular stimulation and relaxation, and valves. The blocks are interconnected as dictated by anatomical and physiological requirements. These equations permit inclusion of local, regional, or global respiratory influences at the discretion of the user. By defining terms with the circulation, that is, the peripheral resistance, and keeping this constant without the use of drugs, the effect of compression force on the heart can be measured as a single variable.

The results of a long-ranging effort to restrict the size of models to their dominant features by elimination of small effects or details no longer popular were incorporated throughout [65]. This action had a significant effect on the number of equations, currently standing at around 50, replacing several hundreds originally [66]. Such reduction must be carried out judiciously; arbitrary reduction of the size may have ruinous effects on the behavior of the model, pointed out as early as 1943 by Landes [67]. In addition

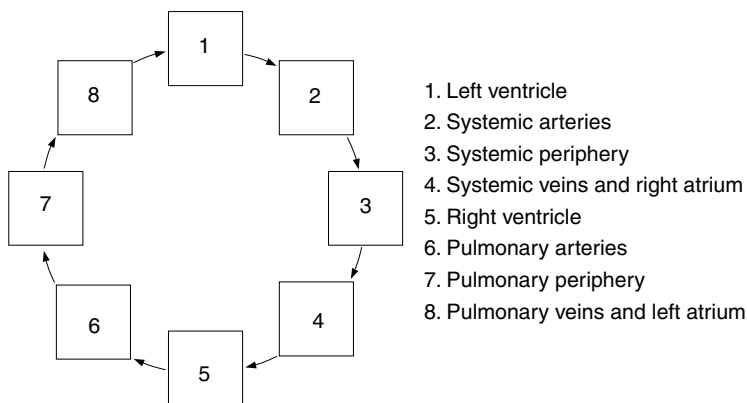
1. Left ventricle
2. Systemic arteries
3. Systemic periphery
4. Systemic veins and right atrium
5. Right ventricle
6. Pulmonary arteries
7. Pulmonary periphery
8. Pulmonary veins and left atrium


FIGURE 18.2 Schematic of the circulatory model. Each of the eight blocks represents one section in the model. The two ventricles (blocks 1 and 5) feature both inlet and outlet valves.

careful use of physiologic data for each parameter is required. Inasmuch as the heart plays a central role in this chapter, its model will be described in more detail in this section.

It will be recalled that the Frank mechanism [68] deals with isovolumetric contraction, while Patterson and Starling's observations [69] focus on the ejecting ventricle. Both phenomena can be integrated into a single analytical expression describing ventricular pressure, p_v, as a function of ventricular volume, V_v, and time, t, formally written as $p_v(V_v, t)$. From experiments on isolated dog hearts, it was found

$$p_v(V_v, t) = \pm a(V_v - b)^2 + (cV_v - d)f(t) \tag{18.1}$$

The first term on the right, applying to the relaxed ventricle, is complemented by the second term, which covers systolic augmentation of pressure. The parameter a relates to diastolic compliance, and b denotes the diastolic volume for which the pressure equals zero. The negative sign applies only to the first term on the right and only when $V_v < b$, manifesting a suction effect at small volumes. In the second term on the right the parameters c and d determine the volume related and volume unrelated components of developed pressure. The normalized function $f(t)$ describes crossbridge formation and detachment [70,71].

Comparison between predicted (Equation 18.1) and measured pressure curves exposed the so-called ejection effect: early into ejection the predicted pressure is higher, later in ejection it is lower than the measured one (akin to Hill's 1938 force–velocity relation). To include the ejection effect quantitatively, the function $f(t)$ must be modified and Equation 18.1 becomes

$$p_v(V_v, t, Q_{ej}) = \pm a(V_v - b)^2 + (cV_v - d)F(t, Q_{ej}) \tag{18.2}$$

with

$$F(t, Q_{ej}) = f(t) - k_1 Q_{ej}(t) + k_2 Q_{ej}^2(t - k_3 t) \tag{18.3}$$

in which Q_{ej} denotes ejection flow, while k_1, k_2, and k_3 are parameters [72].

Equation 18.2 may be further generalized by inclusion of the pericardium and by taking into account the detrimental effect of ventricular overfilling [73].

Much of the criticism of the interpretation of Starling's original measured input–output relations was resolved by the introduction of a family of cardiac function curves [74], which accommodated neural and metabolic stimulation of the heart. Such influences manifest themselves in graphs of input (preload)–output (stroke volume, stroke work, etc.) as counter clockwise rotation (steeper) and stretch along the output (vertical) axis. Alteration in parameter c in Equation 18.1 and Equation 18.2 carries major responsibility for these modifications. In addition, it has recently been found that the cardiac function curve can be shifted along the horizontal (preload) axis [75]. This shift is effected by changes in air pressure, p_e, external to the cardiac chambers, such as caused by the respiratory system, or by CPR, and modifies Equation 18.2 by approximation to

$$p_v(V_v, t, Q_{ej}) - p_e = \pm a(V_v - b)^2 + (cV_v - d)F(t, Q_{ej}) \tag{18.4}$$

The new term, p_e, if negative as during inhalation, shifts the function curve to lower preloads, if positive to higher ones. For additional information about the model, Reference 76 may be consulted.

18.4.3.1 Cardiac Function in the Absence of Organized Nodal Triggers

If the heart's electrical stimulation is chaotic (fibrillation), or no longer present at all (asystole), its chambers fail to pump. The second term on the right in Equation 18.1 tends to zero, and Equation 18.1 degenerates to

$$p_v = a(V_v - b)^2 + p_e \tag{18.5}$$

Returning to CPR, the second term on the right in Equation 18.5 is now the application of external pressure, either directly as in the "cardiac" pump theory, or via general intrathoracic pressure increase as in the "thoracic" pump theory.

With positive p_e, as occurs in chest compression, ventricular blood pressure is raised by an amount p_e and ejection is promoted. There is reason to believe, however, that venous return will be impeded by the presence of this same p_e, resulting in the possibility of ejecting less blood at a higher rate of flow.

18.4.4 Impedance-Defined Flow

William Harvey [77] taught that the heart is the only pump that propels blood around the closed circulatory loop. Liebau [78], on the other hand, based on experiments with fluid mechanical models of his own design, concluded that blood could be propelled around the loop without the benefit of cardiac and venous valves. Liebau demonstrated with his simplest model, consisting of two tubes with different elastic properties, free of valves, making a closed water-filled loop, that periodic compression at an appropriate, fixed site caused steady net fluid flow around the loop, but could not explain the reason why this occurred. The explanation, developed in 1998 [57], was that Liebau worked with an asymmetric loop to which he provided energy by periodic compression at some site. This was termed impedance defined flow, in view of the nonuniform distribution of impedances around the loop. (Compression at a symmetric point, if any, generates no steady net flow, either experimentally or theoretically.)

There is, therefore no doubt whether flow can be generated in a closed loop, free of valves. Thus, it becomes of interest to determine whether the far more complex closed cardiovascular loop qualifies. Two conditions make it a candidate in principle. The first is in the human embryo, which by the end of the third week has a coordinated heart beat, that is, local compression, prior to the formation of cardiac valves about a week later [79]. The second can reportedly occur in total circulatory and respiratory collapse during the application of CPR [80].

In the postembryonic normal circulation at least two cardiac valves are always closed. This makes inapplicable the valveless closed loop, though the impedance-defined flow principle remains intact, but now at the local or regional level. This can easily be appreciated without looking in detail at the corresponding mathematical analysis. The presence of ventricular exit valves, in conjunction with high peripheral resistances results in two high-pressure reservoirs, one in the systemic, the other in the pulmonary arteries. From the peripheral resistances onward to the corresponding ventricles, impedances become smaller and pressures drop, together promoting return flow to the heart in the presence of local compression. Local compression, or contraction, occurs at many sites, including in the venules (venomotion) at the terminations of the microvasculature.

However, this set of conditions cannot remain satisfied indefinitely around a closed loop. At some point, a transformation of impedance levels must necessarily take place. Nature has solved this problem by the insertion of two sets of valves in the heart, three sets not being required [66].

If, for any reason, the heart continues to contract and relax without functional valves (open conduit), conditions revert to those visualized by Liebau, but net cardiac output reduces to a negligible level. Noordergraaf et al. [71] measured less than 60 ml/min on the model referred to earlier without valves and around 5000 ml/min with valves. This invalidates Liebau's suggestion that the cardiac valves might be superfluous.

18.4.5 Summary of This Section

Previous research in CPR appears to have focused on variations of the standard method and their validation, on the design of mechanical models, on experiments in animals in which the chest has a different shape as well as different mechanical properties, rather than on the basic features fundamental to CPR.

New research suggests that the *key function of CPR is reestablishment of cardiac valvular function* in a patient who presents with the same low blood pressure all around the cardiovascular loop.

18.5 Expectations and Current Developments

Thinking in cardiopulmonary resuscitation has, over the last decennium, seen a return to fundamentals. This restored interest in why CPR may or may not lead to survival has surpassed the tendency to expect improvements based solely on adaptation of techniques as well as simplification of techniques and is focusing more and more on understanding the circulation.

Looking forward to the "consensus in science on CPR," representing a new international standard for care in cardiopulmonary resuscitation, with both European and American (ILCOR) collaboration and expected in 2005, laboratory and clinical investigations may be focusing on a number of issues:

Modeling, using up-to-date computing and mathematical opportunities and based on valid physiological and pathophysiological data may become a leading resource in increasing understanding by allowing greater control over variables involved in CPR, while avoiding limitations created by animal and laboratory conditions. The selection and careful use of one animal substrate including correlation to human chest diameters should contribute less equivocal data [81].

Recent clinical insights may also further understanding, such as the effect of the changing compliance of the myocardium (stone heart) over time following circulatory collapse [82], and sufficient decrease in intrathoracic pressure to allow for venous return (i.e., decrease of ventilation frequency and volume), decrease in adrenergic medication, reduction in the amount of time to commencement of cardiac compressions, overfilling of the right heart, and a realistic analysis of clinical technique during CPR. These can all lay groundwork for fundamental improvements.

18.6 Summary

Open-chest cardiac resuscitation was introduced in the 19th century as a surgical procedure to force the ventricles to expel their volumes. It was replaced through Kouwenhoven's influence, by the noninvasive CCCR procedure that gained popularity after 1960. Kouwenhoven's instructions on how to apply CCCR are taught today virtually intact, though it quickly had become apparent that survival rates left much to be desired.

There has been no lack of efforts to improve outcome. In an attempt to achieve better understanding [83], literal Kouwenhoven adherents believe in what became known as the "cardiac" pump theory, while other investigators prefer the "thoracic" pump theory, since they believe that alterations in intrathoracic pressure prevail. A wide variety in "adjuvant" techniques — most but not all of them paralleling either of the two theories — was conceived and developed. Thus far, little of this effort has borne fruit convincingly.

The new century gave rise to a more basic approach. Fundamental models, using computers were introduced. As known, but not applied, it was found, with the aid of CT scans, that the ventricles are not compressed by impression of the sternum for two reasons: impression may often be too shallow and at least the left ventricle is outside the main line of compression; hence CCCR is not a straight imitation of OCCR as had been assumed.

In addition, investigators of impedance-defined flow found that when all cardiac valves are open (open conduit [80]) flow around a closed loop reduces to negligible values even when ventricular contraction is normal. Hence, CPR as a technique, should attempt to reestablish (at least part of) valvular operation in order to allow for survival of a heart too good to die.

Bioelectric Phenomena

William M. Smith
University of Alabama at Birmingham

M OST ORGANS DEPEND IN SOME WAY on electrical currents for proper function. Disruptions in normal electrophysiology can lead to serious, sometimes fatal, pathology. The currents, composed of moving ions, are the culmination of complex cellular and subcellular processes that have been and continue to be the subjects of intense investigation. In some cases, notably the brain, the currents are the immediate mediators of the ultimate role of the organ. In others, for example the heart, the currents control other processes, in this case mechanical activity, that lead to the fulfillment of the role of the organ. In either case, appropriate bioelectric activity is a necessary condition for normal physiology. Because of the centrality of bioelectricity and biomagnetics to the maintenance of health and homeostasis, many experimental and theoretical techniques have been developed to study them. This section of *The Biomedical Engineering Handbook* explores many of them and some important results that have been attained by their use.

Chapter 19 introduces the basic concepts of bioelectricity. These include the cellular level currents and voltages that initiate electrical events; the manner by which electrical currents are propagated through excitable tissue; the mechanism by which microscopic phenomena give rise to macroscopic, measurable variables; and the relationship between bioelectricity and biomagnetism. Much of what we measure in medicine and physiology are biopotentials at a distance from the source, seen through conducting but inexcitable tissue. Chapter 20 provides a mathematical basis for understanding the effects of these volume conductors. Chapter 21 provides a valuable discussion of the electrical conductivities of tissue. An understanding of basic substrate characteristics is necessary for carrying out effective experiments and formulating accurate and relevant mathematical models. For many years, investigators have sought a complete understanding of the activity of the cell membrane in excitable tissue. Chapter 22 is a description of the functional role of the membrane in a wide variety of cell types in regulation of the biochemical and electrophysiological environments of tissue. Chapter 23 provides a description of how rigorous, verified numerical techniques have been adapted and extended to accommodate models of electrophysiological phenomena. One of the first investigations into bioelectricity and its clinical and physiological importance was the development of the electrocardiogram. Chapter 24 recounts the history, physiological basis, instrumentation, and applications of the ECG. Another, less well studied, clinical application is electromyography, the study of the electrophysiological phenomena associated with skeletal muscle, described in Chapter 25. Of course, a major application of bioelectric recording and analysis is in the brain, where the electroencephalogram (EEG) reveals important information concerning physiology and pathology. Chapter 26 is a complete account of the use of the EEG. The electrical currents in tissue give rise to magnetic fields. In some applications, the acquisition and analysis of these fields using magnetocardiography and magnetoencephalography yield complementary information about the underlying processes, as described in Chapter 27. Most excitable cells require an external stimulus for activation. The stimulus can be either biochemical or electrical. Chapter 28 presents the theory and practice of stimulating tissue.

Thus, this section contains a quite broad presentation of the topic of bioelectric phenomena. At the same time, there is sufficient depth to allow an appreciation of the complexity and subtlety of the beautiful processes involved. These chapters should provide the reader with enough basic information to allow him or her to select more focused reading as necessary.

19

Basic Electrophysiology

Roger C. Barr
Duke University

19.1 Membranes

Bioelectricity has its origin in the voltage differences present between the inside and outside of cells. These potentials arise from the specialized properties of the cell membrane, which separates the intracellular from the extracellular volume. From the perspective of electrophysiology, cell membranes are not just containers separating intracellular from extracellular volumes, rather, membranes are the site of the electrically active elements — pumps, channels, and connexons joining cells — that create the voltages and currents that cause electrical events to occur. (In contrast, both intracellular and extracellular volumes serve largely as passive conductors of current, though differences in ionic concentrations between inside and outside are large and electrically significant.) Much of the membrane surface is made of a phospholipid bilayer, an

19-1

electrically inert material [Byrne and Schultz, 1988]. Because the membrane is thin (about 75 Å), it has a high capacitance, about 1 uF/cm^2. (Membrane capacitance is less in nerve, except at nodes, because most of the membrane is myelinated, which makes it much thicker.)

Electrically active membrane also includes a number of integral proteins of different kinds, with genetic origins that are increasingly well understood [Marban, 1999]. Integral proteins are compact but complex structures extending across the membrane. Each integral protein is composed of a large number of amino acids, often in a single long polypeptide chain, which folds into multiple domains. Each domain may span the membrane several times. The multiple crossings may build the functional structure, for example, a channel, through which electrically charged ions may flow. The structure of integral proteins is loosely analogous to that of a length of thread passing back and forth across a fabric to form a buttonhole. As a buttonhole allows movement of a button from one side of the fabric to the other, an integral protein may allow passage of ions from the exterior of a cell to the interior, or vice versa. In contrast to a buttonhole, an integral protein has active properties, for example, the ability to open or close. Excellent drawings of channel structure and function are given by Watson et al. [1992].

Cell membrane possesses a number of active characteristics of marked importance to its bioelectric behavior, including these (1) Some integral proteins function as pumps. These pumps use energy to transport ions across membrane, working against a concentration gradient, a voltage gradient, or both. The most important pump moves sodium ions out of the intracellular volume and potassium ions in. (2) Other integral proteins function as channels, that is, openings through the membrane that open and close over time. These channels can function selectively so that, for a particular kind of channel, only sodium ions may pass through. Another kind of channel may allow only potassium ions or calcium ions. (3) The activity of the membrane's integral proteins is modulated by signals specific to its particular function. For example, some channels open or close in response to photons or to odorants; thus they function as sensors for light or smell. Pumps respond to the concentrations of the ions they move. Rapid electrical impulse transmission in nerve and muscle is made possible by changes that respond to the **transmembrane potential** itself, forming a feedback mechanism. These active mechanisms provide ion-selective means of current crossing the membrane, both against the concentration or voltage gradients (pumps) or in response to them (channels). While the pumps build up the concentration differences (and thereby the potential energy) that allow events to occur, channels utilize this energy actively to create the fast changes in voltage and small intense current loops that constitute nerve signal transmission, initiate muscle contraction, and participate in other essential bioelectric phenomena.

19.2   Bioelectric Current Loops

Because of the electrical conductivity of tissues, voltages generated across cell membranes are associated with currents that flow across the membrane in the surrounding tissues. Bioelectricity normally flows in current loops, as illustrated in Figure 19.1. A loop includes four segments: an outward traversal of the cell membrane (current I_m^1 at position $z = z_1$), an extracellular segment (current I_e, along a path outside a cell or cells), an inward traversal of the cell membrane (current I_m^2 at $z = z_2$), and an intracellular segment (current I_i, along a segment inside the cell membrane). Each of the segments has aspects that give it a unique importance to the current loop. Intense current loops often are contained within a millimeter or less, although loops of weaker intensity may extend throughout the whole body volume. The energy that supports the current flow arises from one or both of the segments of the loop that cross the membrane. Current loops involve potential differences of about 100 mV between extremes. The charge carriers are mobile ions. Especially important are ions of sodium, potassium, calcium, and chloride because some membranes allow one or more of these ion species to move across when others cannot. Such current loops not only exist within tissue but in electrically active tissue often modify the electrical state of surrounding tissue in such a way that the loop propagates along a nerve or muscle.
FIGURE 19.1   Bioelectric current loop, concept drawing. Current enters the membrane at $z = z_1$, flows intracellularly and emerges at z_2. Flow in the extracellular volume may be along the membrane (solid) or throughout the surrounding volume conductor (dashed).

19.2.1 Membrane Currents

Total membrane current I_m may be given mathematically as

$$I_m = I_c + I_{ion} \tag{19.1}$$

where each of these currents often is given per unit area, for example, milliamperes per square centimeter.

The first component, I_c, corresponds to the charging or discharging of the membrane capacitance. Thus

$$I_c = C_m \frac{\partial V_m}{\partial t} \tag{19.2}$$

where C_m is the membrane capacitance per unit area, V_m is the transmembrane voltage, and t is time.

The second component, I_{ion}, corresponds to the current through the membrane carried by ions such as those of sodium, potassium, or calcium. It normally is found by summing each of the individual components, for example,

$$I_{ion} = I_K + I_{Na} + I_{Ca} \tag{19.3}$$

In turn, each of the component currents is often written in a form such as

$$I_K = g_K(V_m - E_K) \tag{19.4}$$

where E_K is the equilibrium potential for K (see below), a function of K concentrations, and g_K is the conductivity of the membrane to K ions. The conductivity g_K is not constant but rather varies markedly as a function of transmembrane voltage and time. More positive transmembrane voltages normally are associated with higher conductivities, at least transiently.

When a more detailed knowledge of channel structure is included, as in the DiFrancesco–Noble model for cardiac membrane, each of the individual ionic components, for example, I_K is found in turn as a sum of the currents through each kind of channel or pump through which that ion moves.

The total transmembrane current I_m contains the summed contributions from Ic and I_{ion}, as given by Equation 19.1 This equations holds at each site on the membrane at each time, that is, all three currents are functions of both space and time. Under most circumstances, when thinking of cause and effect, it is better for one to think of I_m as a value imposed on the cell by its environment, and I_c and I_{ion} as currents

which change in response to the imposed I_m. (Often I_c is initially dominant, but subsides in magnitude as I_{ion} responds more slowly.) It is not unusual for membrane current components I_c and I_{ion} to differ both in magnitude and in direction. Thinking in terms of the current loops that exist during membrane **excitation**, one often finds that current at the site of peak outward current is dominated by I_c. At the site of peak inward current, the total current I_m usually dominated by I_{ion} (see **Propagation**, below).

19.2.2 Conduction along an Intracellular Path

Flow of electricity along a nerve or within a muscle occurs passively through the conducting medium inside the cell. The nature of the intracellular current path is closely related to the function of the current within that kind of cell. Nerve cells may have lengths of a meter or more, so intracellular currents can flow unimpeded and quickly throughout this length. Other cells, such as the muscle cells of the heart, are much smaller (about 100 mm in length). In cardiac cells, current flows intracellularly from cell to cell through specialized passages, called junctions, that occur in regions where the cell membranes fuse together. Thus intracellular regions may be connected over lengths of centimeters or more, even though each cell is much smaller. Mathematically, the intracellular current in a one-dimensional cable may be given as [Plonsey and Barr, 2000]

$$I_i = -\frac{1}{r_i} \frac{\partial \phi_i}{\partial z} \qquad (19.5)$$

where, ϕ is the intracellular potential, z is the axial coordinate, r_i is the intracellular resistance per unit length, and I_i is the longitudinal axial current per unit cross-sectional area.

19.2.3 Conduction along an Extracellular Path

When current flows outside of cells, it is not constrained to a particular path but rather flows throughout the whole surrounding conducting volume, which may be the whole body. The study of these extracellular currents, and the effects of interfaces among structures, boundaries, and changes in conductivity is called **volume conductor** theory. Current intensity is highest near the places where current enters or leaves cells through the membrane. (These sites are called sinks and sources, respectively, in view of their relation to the extracellular volume.) Current flow from bioelectric sources through the volume conductor generates small potential differences, usually with a magnitude of a millivolt or less, between different sites within the volume or on the body surface. (Current flow from artificial sources, such as stimulators or defibrillators, may generate much higher voltages.) The naturally occurring potential differences between points in the volume conductor, for example, between the arms or across the head, are those commonly measured in the study of the heart (electrocardiography), the nerves and muscles (electromyography), and the brain (electroencephalography).

Mathematically, the extracellular current is easy to specify only in the special case where the extracellular current is confined to a small space surrounding a single fiber or nerve, as shown diagramatically by the solid I_e line in Figure 19.1. In this special case, the extracellular current is equal in magnitude (but opposite in direction) to the intracellular current, that is, $I_e = -I_i$.

In most living systems, however, extracellular currents extend throughout a more extensive volume conductor, as suggested by the dashed lines for I_e in Figure 19.1. Their direction and magnitude must be found as a solution to Poisson's equation in the extracellular medium, with the sources and sinks around the active medium used as boundary conditions. In this context, Poisson's equation becomes [Plonsey and Barr, 2000]

$$\nabla^2 \phi_e = -\frac{I_v}{\sigma_e} = -\frac{\nabla \cdot \vec{J}}{\sigma_e} \qquad (19.6)$$

where I_v is the volume density of the sources (sinks being negative sources), σ_e is the conductivity of the extracellular medium, and J is the current density. The fact that, $\nabla \cdot \vec{J}$ takes on nonzero values appears at first to be physically unrealistic because it seems to violate the principle of conservation of charge. In fact, it only reflects the practice of solving for potentials and currents in the extracellular volume

separately from those in the intracellular volume. Thus the nonzero divergence represents the movement of currents from the intracellular volume across the membrane and into the extracellular volume, where they appear from sources or disappear into sinks.

19.2.4 Duality

Note the duality Equation 19.6 and the form of Poisson's equation commonly used in problems in electrostatics. There, $\nabla^2/(-\rho/\varepsilon)$, where ρ is the charge density, and ε is the permittivity. Recognition of this duality is useful not only in locating solution methods for bioelectric problems, since the mathematics is the same, but also in avoiding confusion between electrostatics and problems of extracellular current flow through a volume conductor. The problems obviously are physically quite different (e.g., permittivity ε is not conductivity σ_e).

19.3 Membrane Polarization

Ionic pumps within membranes operate, over time, to produce markedly different concentrations of ions in the intracellular and extracellular volumes around cells. In cardiac cells, the sodium–potassium pump produces concentrations (millimoles per liter) for Purkinje cells as shown in Table 19.1.

A transmembrane voltage, or polarization, develops across the membrane because of the differences in concentrations across the membrane. In the steady state, the transmembrane potential for a two-ion system is, according to Goldman's equation [Plonsey and Barr, 2000],

$$V_m = \frac{RT}{F} \ln\left(\frac{P_K[K]_e + P_{Na}[Na]_e}{P_K[K]_i + P_{Na}[Na]_i}\right) \tag{19.7}$$

where R is the gas content, T is the temperature, and F is Faraday's constant ($RT/F \approx 25$ mV). P_K and P_{Na} are the permeabilities to potassium and sodium ions, respectively. [K] and [Na] are the concentrations of these ions, and the subscripts i and e indicate intracellular and extracellular, respectively. V_m is the transmembrane voltage at steady state.

19.3.1 Polarized State

At rest, P_{Na} is much smaller than P_K. Using Equation 19.6, approximating $P_{Na} = P_K/100$, and using the concentrations in Table 19.1,

$$V_m \approx 25 \text{ mV} \times \ln\left[\frac{4 + (0.01 \times 140)}{140 + (0.01 \times 8)}\right] \approx -82 \text{ mV} \tag{19.8}$$

Cardiac Purkinje cells show a polarization at rest of about this amount. The negative sign indicates that the interior of the cell is negative with respect to the exterior.

One way to think about why this voltage exists at the steady state is as follows: In the steady state, diffusion tends to move K^+ from inside because of the much higher concentration of K^+ intracellularly. This flow is offset, however, by a flow from outside to inside due to the potential gradient, with a higher potential outside, since K^+ is a positively charged ion. With the concentrations of Table 19.1, the effects of the

TABLE 19.1 Ionic Concentrations (mmol/l)

	Na^+	K^+
Intracellular	8	140
Extracellular	140	4

diffusion gradient and potential gradient are almost equal and opposite when the potential intracellularly is about −82 mV with respect to the **extracellular potential**. The result is a steady state. Rather than a true equilibrium, this state has a small but nonzero flow of sodium ions, offset electrically by a sustained flow of potassium ions. Thus the **membrane potential** would run down over time were there no $Na^+ - K^+$ pumps maintaining the transmembrane concentrations. (In the absence of such pumps, concentration differences diminish over a period of hours.)

19.3.2 Depolarized State

Suppose the permeabilities to sodium and potassium of Equation 19.7 are changed from the values used for Equation 19.8, which approximated membrane at rest (polarized). Instead, to approximate excited membrane, suppose that P_{Na} rises in comparison with P_K so that $P_K = P_{Na}/2$. Now,

$$V_m = 25 \text{ mV} \times \ln\left[\frac{4 + (2 \times 140)}{140 + (2 \times 8)}\right] \approx 15 \text{ mV} \tag{19.9}$$

Here the positive sign for V_m indicates that the interior of the membrane is positive with respect to the exterior. Because V_m is here more nearly zero in magnitude, this excited state is called depolarized.

19.4 Action Potentials

Membranes create action potentials by actively changing their permeabilities to ions such as sodium and potassium. A comparison of the results of Equation 19.8 and Equation 19.9 shows a swing of about 100 mV between the resting and excited states (polarized to depolarized). The change of permeability from resting to excited values and then back again allows the membrane to generate an **action potential**.

Among the most important developments of the past 50 years has been the creation of a series of mathematical and numerical models of the time course and voltage dependence of the change in membrane permeabilities. These "membrane models" originally described the behavior of nerve membrane and has now been extended to many other tissues, such as skeletal muscle and cardiac muscle.

19.4.1 Cardiac Action Potentials

Action potentials that characterize actual tissue have the roughly rectangular shape that is suggested by the preceding calculation, but only as an approximation. An action potential for the cardiac conduction system simulated with the DiFrancesco–Noble model is shown in Figure 19.2. Initially, V_m has a baseline voltage (B) near −80 mV. During excitation (E), the membrane permeabilities change, and V_m rises abruptly. After the peak overshoot at about +20 mV, the potential maintains a plateau voltage (P) near −20 mV for nearly 300 msec and then recovers (R) rapidly to a baseline phase. The overall action potential duration is about 400 msec.

19.4.2 Nerve Action Potentials

For comparison, an action potential simulated with the Hodgkin–Huxley model for nerve is shown in Figure 19.3. Corresponding baseline, excitation, plateau, and recovery phases may be identified, and the voltage change between resting and excited states is again about 100 mV. The plateau phase is so short as to be virtually nonexistent, and the overall action potential duration is much shorter than that of Figure 19.2, only about 4 msec.

19.4.3 Wave Shape and Function

All excitable membranes are characterized by their ability to change membrane permeabilities and to do so selectively. Both the cardiac action potential of Figure 19.2 and the nerve action potential of Figure 19.3
FIGURE 19.2 Cardiac action potential. Computed with the DiFrancesco–Noble membrane model for the cardiac conduction system (membrane patch). *B*, baseline; *E*, excitation; *R*, recovery (repolarization).
FIGURE 19.3 Nerve action potential. Computed with the Hodgkin–Huxley model for nerve membrane (membrane patch). *B*, baseline; *E*, excitation; *P*, plateau; *R*, recovery; *A*, afterpotential.

demonstrated rapid depolarization and a subsequent slower repolarization associated with membrane permeability changes and changes of about 100 mV in V_m amplitude. Conversely, the differences also have marked importance. Cardiac action potentials have a long duration that limits the shortest interval between heartbeats. This interval must be several hundred milliseconds long to allow time for movement of blood. The extended plateau of the cardiac action potential is associated with the movement of calcium ions, which is associated with muscle contraction. In contrast, nerve action potentials perform a signaling function. This function is supported by a shorter action potential duration, which allows more variability in the number of action potentials propagated per second, an important signaling variable. Conversely, nerves had no need for contraction and no need for a plateau period for calcium ion movement.

19.5   Initiation of Action Potentials

Action potentials of tissue with a specialized sensing function (e.g., for sight or smell) have membrane channels linked to receptors for the initiating agent [Watson et al., 1992]. In contrast, a large number of membrane channels are controlled by changes in transmembrane voltage. In particular, when the potential rises from its baseline value to a threshold level, the membrane initiates the sequence of permeability changes that create an action potential. The change of transmembrane voltage initiating the action potential normally comes from currents originating in adjacent tissue (see Propagation, below). Such currents also may come from artificial sources, such as stimulators.

19.5.1   Examples

Responses of a DiFrancesco–Noble membrane to transmembrane stimuli of three magnitudes are shown in Figure 19.4. All three stimuli were 1 msec in duration. Stimulus $S1$, the largest, caused the transmembrane potential to rise from its baseline value to about -65 mV and initiated an action potential (ap1), which followed a few milliseconds after the stimulus. Stimulus $S2$ had only 80% of the intensity of $S1$, and the stimulus itself caused a transmembrane voltage change that was proportionally smaller. As did $S1$, stimulus $S2$ initiated an action potential (ap2), although there was a delay of about 200 msec before excitation occurred, and the action potential itself was somewhat diminished in amplitude. Stimulus $S3$ had 80% of the magnitude of $S2$ and caused a transmembrane voltage change that again was proportionally smaller. $S3$, however, produced no subsequent action potential.

19.5.2   Threshold

An important general result demonstrated in Figure 19.4 is that action potential initiation has a threshold behavior. That is, stimuli producing transmembrane voltages above a threshold value initiate action potentials, while those below do not. This response is called "all or none," although (as Figure 19.4 shows) there is a variation in response for near-threshold stimuli. Threshold values are not constant. The threshold value for a particular stimulus varies depending on factors such as the location of the electrodes relative to the tissue that is excited, the stimulus duration, and the amount of membrane affected.
FIGURE 19.4   Variation in stimulus magnitude. In different trials, three stimuli ($S1$, $S2$, $S3$) of decreasing magnitude were applied. Action potentials followed the first two, but not the third.

19.6 Propagation

Initiation of excitation at one end of a excitable fiber leads to an action potential there. Subsequently, action potentials may be observed at sites progressively further away. Propagating current loops are of fundamental importance to nerve or muscle function, as they allow for the transmission of information in nerves or initiation of contraction through the release of calcium, in muscle. The deterioration of propagation with disease may be in the form of a failure to propagate, or propagation with an abnormally slow velocity. In the heart, propagation along a closed path ("re-entrant propagation") is one source of cardiac disrhythmias and even death. The theory of the electric telegraph as put forward by Kelvin was perhaps the origin of the core-conductor model, which forms much of the analytical basis for the present understanding of propagation.

19.6.1 Numerical Model

Numerical models of propagation were introduced by Hodgkin and Huxley [1952] in the 1950s to demonstrate quantitatively how the events of propagation arise from the elemental flow of ionic currents in nerves. While experimentally based, such models have become increasingly precise, increasingly specialized, and much more detailed so as to reflect accurately the properties of particular tissues [e.g., Spach et al., 2004]. Such numerical models allow a consistent picture to be obtained of action potentials at different sites along a nerve or muscle structure. They are based on analyzing the interaction of spatially distributed events at one time, so as to see the consequences at a short time later.

Such a model is used here. Consider the cylindrical fiber shown in Figure 19.5, having radius $a = 75\,\mu$m and a length of 10 μm. The fiber is surrounded by an extracellular volume extending $3a$ beyond the membrane. To establish a symmetric reference potential, the outside edge of the extracellular region was connected via resistances to a junction where $\phi_e = 0$. Intracellular specific resistance R_i was 250 Ω cm, and R_e was one-third of R_i. Solutions for intracellular, extracellular, and transmembrane potentials were obtained through a process of numerical simulation. The structure of this example follows that of Spach et al. [1973], where cardiac Purkinje fibers were studied. Most of the examples below use the DiFrancesco–Noble model for Purkinje membrane [Noble et al., 1994].

19.6.2 Sequence of Action Potentials

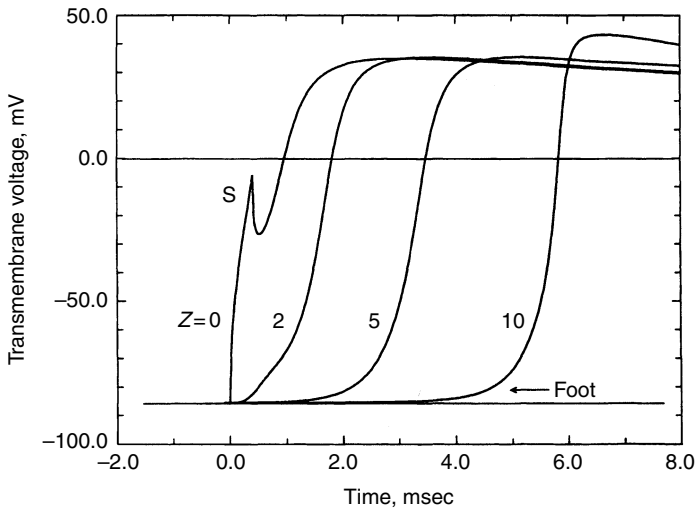
Action potentials simulated for the cylindrical fiber are shown in Figure 19.6. Waveforms are shown following a transmembrane stimulus at $z = 0$, where the first action potential originates, and also for sites
FIGURE 19.5 Geometry for numerical model. The model represented a fiber 10 mm in length. The cross section was a series of concentric bands. Nodes were spaced along the axial (z) dimension every 100 μm. These nodes are portrayed by the columns of circles drawn at four axial positions, although actually there were 101 columns. The innermost (lower) row of nodes, row 0, were sites where intracellular potentials were determined; four surrounding rows (rows 1 to 4), at increasing distances, were sites for extracellular potentials. The outermost boundary (dashed line) was assigned $\phi_c = 0$. Separation between all rows was the same as the fiber radius, $a = 75\,\mu$m. Transmembrane stimuli were applied across the membrane at $z = 0$ (nodes enclosed).


FIGURE 19.6 Action potentials for a 10-mm fiber. Transmembrane potentials $V_m(t)$ arising at z positions of 0, 2, 5, and 10 mm. The waveform at $z = 0$ shows a stimulus artefact S. $V_m(t)$ at $z = 10$ has a larger peak-to-peak rise because excitation terminates there, at the end of the fiber.

2, 5, and 10 mm away. All the action potentials have similar wave shapes, differing mainly in their timing. Although these are cardiac waveforms simulated with the DiFrancesco–Nobel model, note the markedly different impression of the wave shape seen in this figure as compared with Figure 19.2. Note also that the waveform at $z = 0$ has progressed through excitation, but not into the plateau phase, by the time of excitation at $z = 1$ cm. Secondary changes of action potential wave shape as a function of z, other than the stimulus artefact, can be discerned mainly in the baseline as it rises into the upstroke, a region called the foot. Differences in the duration of the foot reflect the time that other tissue has been excited, prior to the start of excitation at a particular site; that is, the foot is longer at sites further down the fiber.

19.6.3 Biophysical Basis

Although propagation in nerves and muscles often is compared to wave propagation of sound or light, to waves in the ocean, or to electrical waves in cables, bioelectric propagation does not have an analogous physical basis. In the former categories, energy used at the source creates a disturbance that propagates to the observer through an intervening passive medium. Propagation velocity depends on the properties of that medium. In bioelectric propagation, what is meant is that the source itself is moving down an excitable medium, the membrane, in a process more similar to setting off a chain of firecrackers. The velocities associated with bioelectric propagation relate to the magnitudes of transmembrane current passing through one site on the membrane and flowing to another and how fast the active responses of the membrane occur at the downstream sites. Although short intervals are required for passive propagation of the consequences of the active events through the surrounding tissue, these intervals are minuscule in comparison with the times required for the active changes. Consequently, most bioelectric events are analyzed as a sequence of "quasi-static" stages.

19.6.4 Velocity of Propagation

It is difficult to predict the velocity of propagation for a particular tissue structure prior to its measurement. Reported experimental velocities of propagation range from less than 0.01 m/sec to more than 10 m/sec, depending on the particular membrane and structure involved and its environment. Within a particular nerve or muscle, however, velocities vary little under normal conditions. Changes in the velocity of

propagation θ as a result of changes in fiber diameter a or specific resistivity R_i can be approximated by the equation

$$\theta = \frac{Ka}{2R_i} \tag{19.10}$$

Here K is a constant determined by the membrane properties, a is the fiber radius, and R_i is the specific resistance of the intracellular medium [Plonsey and Barr, 2000], and the equation assumes relatively low extracellular resistance.

An important relationship shown by Equation 19.10 is the proportionality of the velocity to the square root of the fiber's radius. Living systems take advantage of this relationship by having larger-diameter fibers where higher velocity is essential. For example, the giant axon of the squid carries the signal by which the squid responds to predators.

19.6.5 Transmembrane Current

The mathematical analysis of propagation is greatly aided by using the principle of conservation of charge to develop an equation for membrane current I_m that depends on the local distribution of intracellular potential rather than on currents through the membrane, as in Equation 19.1. Conservation of current requires that current through the membrane at an axial position z be the difference between current coming to that site and current leaving that site (on one side, e.g., intracellularly). Because intracellular currents follow the first derivative of ϕ_i (Equation 19.5), then for one-dimensional flow [Plonsey and Barr, 2000],

$$I_m = \frac{1}{2\pi \, a r_i} \frac{\partial^2 \phi_i}{\partial z^2} \tag{19.11}$$

Here r_i is the axial resistance per unit length, a is the fiber radius, and ϕ_i is the intracellular potential. This result is used below, as well as in many mathematical analyses of propagation, because it provides a means (sometimes the sole means) of linking the membrane current at one site to electrical events at neighboring sites.

19.6.6 Movement of the Local Current Loop

Propagation occurs when a local current loop initiates an action potential in an adjacent region. The concept of how this occurs is illustrated in Figure 19.7. At time t_1, a local current loop exists, as shown in Figure 19.7a. This local loop produces outward current at site $z = z_1$. That there must be outward current at z_1 is shown by Figure 19.7b, which plots $f(z)$ for time t_1. The gradient of ϕ_i between z_2 and z_1 is shown in Figure 19.7b. This gradient produces intracellular current into z_1 from the left but not current out on the right (because the gradient is zero to the right). Current must therefore leave through the membrane at z_1. This positive membrane current is indicated by the upward arrow at z_1 in Figure 19.7b. The positive membrane current at z_1 discharges the membrane capacitance there, so the potential at z_1 rises, producing a new voltage distribution. The change in the intracellular voltage distribution produces a shift in the site of the current loop; that is, the loop propages to the right, as shown in Figure 19.7c.

More mathematically, at z_1 at time t_1 the value of $\partial^2 \phi_i / \partial_z^2$ is markedly positive, because ϕ_i changes slope there from negative to zero. Therefore, by Equation 19.11, I_m is large and positive at $z = z_1$. Additionally, I_{ion} is relatively small at z_1 because the intracellular voltage is at its resting value, so (by Equation 19.1) I_c must be large. By Equation 19.2, if I_c is large and positive, then $\partial V_m / \partial t$ is large and positive. Thus the transmembrane potential at z_1 rises rapidly, and soon the current loop shown in Figure 19.7c is achieved.

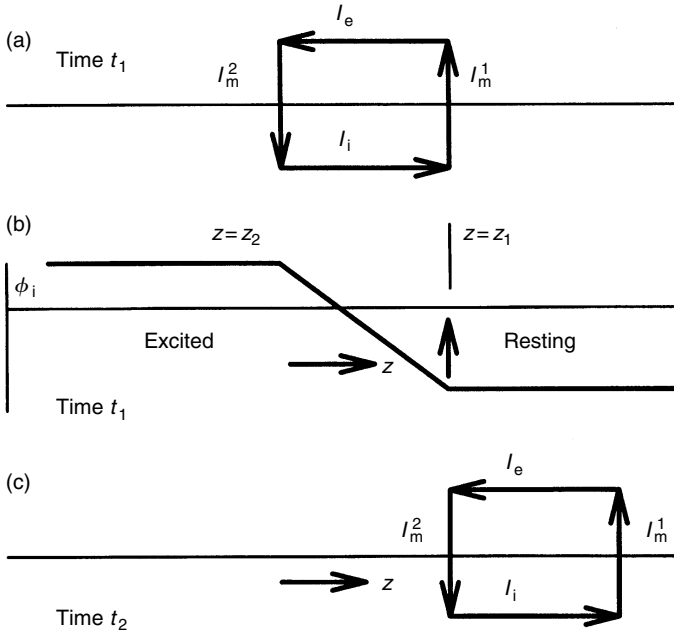
For comparison with the schematic drawings in Figure 19.7, the distribution of voltages and currents in the 1-cm simulated fiber is shown in Figure 19.8. The figure shows the transmembrane potential V_m and the total membrane current I_m. Both are shown as a function of axial distance z along the strand at time $t = 3$ msec after the stimulus. (This spatial plot came from the same simulation as the set of waveforms


FIGURE 19.7 Propagation of a current loop, concept drawing. Panels *a* and *b* draw a hypothetical current loop as it might exist at time t_1. At this time, outward current is causing the potential to rise at $z = z_1$, as indicated by the upward arrow there, in panel *b*. The result is a shift in the distribution of intracellular potential θ_i. Thus the current loop moves to the position shown in panel c.

vs. time shown in Figure 19.6.) Because $V_m = \phi_i - \phi_e$, and because in this example the extracellular potentials ϕ_e are relatively small in magnitude (see below), V_m in Figure 19.8 is a close approximation to ϕ_i in Figure 19.7.

In Figure 19.8, the total membrane current I_m is biphasic, with the outward current on the leading edge of the propagating waveform. Propagation is to the right, consistent with the direction of downward slope of V_m and consistent with the direction of movement of Figure 19.7. The inward and outward currents of the distributed pattern in Figure 19.8 are consistent with the concept of Figure 19.7, where the distribution is lumped. (One might place $z_1 \approx 4.8$ mm in Figure 19.8 and $z_2 \approx 4.0$ mm.) Figure 19.8 shows that the local current loop is more accurately described as a local current distribution, extending over a distance of a few millimeters (about 0.8 mm between the maximum and minimum of the I_m curve).

The composition of $I_m(z)$ can be evaluated by comparing I_m with its components, the ionic current I_{ion} and the membrane capacitative current I_c. At the outward current peak (the maximum of I_m), the magnitude of the capacitive component I_c is greater than the magnitude of the ionic component I_{ion}. At the inward peak (the minimum of I_m), $|I_{ion}| > |I_c|$, although both magnitudes are significant. That is, the dominant components of I_m in Figure 19.8 are consistent with the drawings in Figure 19.7. In contrast to Figure 19.7, however, the peak outward current occurs near where $V_m \approx -40$ mV rather than near the baseline value (≈ -85 mV). Consistent with Figure 19.7, Figure 19.8 shows that I_m is dominated by I_c at the peak outward I_m and increasingly more so as one moves forward on the leading edge.

19.7 Extracellular Waveforms

An understanding of the origin of extracellular waveforms is important because most electrophysiologic recordings, including those of most clinical studies, are observations of extracellular events rather than underlying transmembrane or intracellular events.
FIGURE 19.8 Potential and current distribution in a 10-mm fiber at $t = 3$ msec following a transmembrane stimulus applied at $z = 0$. The vertical scale is in millivolts for the V_m plot and in microamperes per square centimeter for the current plots. Results are from a numerical simulation using the geometry of Figure 19.6. Transmembrane potential V_m at this moment is shown by the dashed line. Note the inward and outward peaks of the transmembrane current I_m near $z = 4$ and 4.8 mm. Plots for I_c and I_{ion}, the components of I_m, also are shown. They demonstrate that on the leading edge of the waveform (higher values of z), current I_c dominates. Compare the results with the concept drawing of Figure 19.7.

Historically, extracellular waveforms were observed and their correspondence with many diseases established empirically well before their sources were known. In recent years, extracellular fields have been mapped in detail, both in time and space [Taccardi, 2002]. Though extracellular waveforms arise from membrane sources and corresponding intracellular action potentials, the extracellular–intracellular relationship is not a simple one, because it involves distance from the membrane sources, and because a given extracellular site usually is affected by currents from many different excitable fibers. Numerical models for bioelectric field problems [Gulrajani, 1998] prove extremely helpful in understanding extracellular waveforms and extracellular potential distributions ("potential maps") as they can take into account a complex pattern of current sources and the geometrical irregularities of the volume conductor, including the body surface itself.

Although extracellular waveforms $\phi_e(t)$ reflect the same current loops as the intracellular or transmembrane waveforms, their magnitude, wave shape, and timing usually are entirely different. (The greatest similarity occurs with a highly restricted extracellular volume.) With an extensive extracellular volume, the normal situation, waveforms such as those in Figure 19.9 are seen. The three waveforms come from "electrodes" just outside the fiber at $z = 0$, $z = 5$, and $z = 10$ mm, or in other words at the site of the stimulus, the middle of the strand, and the end where excitation terminates. (For reference, the intracellular potential from the middle of the fiber also is shown, reduced to 2% of its true magnitude.) All three extracellular waveforms shown are small in comparison with transmembrane waveforms, less than 1 mV peak to peak. Their wave shapes differ: Near the stimulus (0), the wave shape has a negative deflection from the stimulus and continues to be negative thereafter. In the middle, the wave shape is biphasic. A positive deflection occurs as excitation approaches, and a negative deflection occurs once it goes past (compare the timing of the extracellular and intracellular waveforms, which are from the same axial position). At the terminating end (10), the extracellular wave shape is predominantly positive, showing also a long initial rise as excitation approaches.

It is interesting that these extracellular waveforms show such large changes in wave shape as a function of position, whereas their underlying transmembrane waveforms, at the same z values, show no such
FIGURE 19.9 Extracellular waveforms from a 10-mm fiber. Extracellular potentials $\phi_e(t)$ are plotted for positions just outside the membrane at $z = 0, 5,$ and 10 mm. The transmembrane stimulus at $z = 0$ affected the waveform there, as seen by stimulus artefact S. For reference, $V_m(t)$ at $z = 5$ mm also is drawn, reduced to 2% of its true amplitude.

changes, as can be seen by comparison with the transmembrane waveforms shown in Figure 19.6. The relative timing of the extracellular as compared with the transmembrane waveforms also is noteworthy: Close to the membrane, most of the major deflections of the extracellular waveforms are confined to the short time period when the transmembrane potential is undergoing excitation. During the hundreds of milliseconds thereafter, the intracellular potential is large but changing slowly (e.g., Figure 19.2), so the transmembrane currents are small. These smaller currents are distributed and produce proportionally small deflections. As the recording site moves away from the membrane, however, the distributed recovery currents do not decline as rapidly with distance, so the potentials they produce become larger in relation to potentials produced by the currents of excitation. On the body surface, the voltages produced during recovery may have similar magnitudes and play a large role in waveform interpretation (e.g., the T wave of the electrocardiogram).

Biphasic waveforms are observed at most extracellular sites, because most sites are neither the origin or termination of excitation. Further, most real extracellular waveforms are more complicated and last longer than those shown in Figure 19.9, because they show the composite effect from many different fibers rather than a single one in isolation.

19.7.1 Spatial Relation to Intracellular

Extracellular waveforms are created by the flow of current through the volume conductor surrounding the active membrane. An expression for the extracellular potential ϕ_e, outside a cylindrical fiber with a large conducting volume was given by Spach et al. [1973] as

$$\phi_e(t_o, z) = \frac{a\sigma}{4\sigma} \int_{-\infty}^{\infty} \frac{(\partial^2 \phi_i / \partial z'^2)_{t_o}}{\left(\frac{d+a}{a}\right)^2 + \left[\frac{(z'-z)}{a}\right]^2} dz' \tag{19.12}$$

where z is the axial coordinate of the fiber, t_o is the time when the spatial distribution was obtained, ϕ_i is the intracellular potential, a is the fiber radius, and d is the perpendicular distance from the fiber membrane to the electrode. Conductivities σ_i and σ_e apply to the intracellular and extracellular conducting media, respectively. The integration limits of $\pm\infty$ recognize that the integration should be over the entire fiber.

Note that t_o must be chosen in a succession of values to generate a temporal waveform at position z and that the right-hand side of Equation 19.12 has t_o be evaluated separately for each to choice.

A number of examples of extracellular waveforms, as compared with their underlying intracellular ones, are given by Spach et al. [1973], together with an evaluation of the accuracy of Equation 19.12. A central feature of the equation is that the extracellular waveform is a weighted summation of the second spatial derivative of the intracellular potential. This relationship holds, to a good approximation, for all the extracellular waveforms shown in Figure 19.9. The different weighting for different waveforms (variation in $z' - z$ for different choices of z) produces the varying shapes of the extracellular waveforms at different sites.

19.7.2 Temporal Relation to Intracellular

If an action potential is assumed to be propagating with constant velocity θ on a long fiber, then the spatial derivative in the preceding equation can be converted to a temporal derivative using $z = \theta t$ so that

$$\phi_e(t_o, z) = \frac{a\sigma}{4\sigma} \int_{-\infty}^{\infty} \frac{(\partial^2 \phi_i / \partial z'^2)_{z_0}}{\left(\frac{d+a}{a}\right)^2 + \left[\frac{\theta(t'-t)}{a}\right]^2} \, dt' \qquad (19.13)$$

where t is time, z_o is the axial coordinate of the position where the intracellular and extracellular "electrodes" are located, and θ is the velocity with which the action potential is moving along the z-axis. The integration limits of $\pm\infty$ recognize that only in long fibers does the velocity remain approximately constant over a significant period of time.

Some of the limitations of Equation 19.13 are apparent when considering the waveforms of Figure 19.9. The equation would be suitable only for the extracellular waveform in the middle of the fiber ($z = 5$ mm). At either end, the equation would be unsuitable, because velocity is not constant through initiation or through termination of propagation.

While the general principles given above apply to virtually all extracellular waveforms, many specific features characterize the extracellular waveforms observed from individual organs. In view of their clinical importance, extensive study has thus been given to the principles of electrocardiography (heart), principles of electromyography (skeletal muscle), and principles of electroencephalography (brain).

19.8 Stimulation

Natural **stimulation** of nerves and muscle occurs in sensory sites, and artificial electrical stimulation can initiate action potentials can initiate action potentials and control propagation in much the same way.

Most stimulation for clinical purposes and most experimental studies use extracellular electrodes because positioning the electrodes outside the active tissue can be done, usually, with little or no tissue damage. Such electrical stimulation of excitable tissue has become a subject of great practical importance, particularly so now that technology allows small stimulators to be implanted and to function well over periods of many years. An analytical understanding of stimulation has been markedly advanced by the introduction by Rattay [1990] of the "activating function," a mathematical expression that identifies regions along a membrane of excitable cells where stimulation introduces currents either entering or leaving the extracellular volume. The effect of a stimulus then may be understood as a convolution of the activating function with the membrane response, e.g., the analysis by Barr and Plonsey [2003] for a tissue sheet.

As an example of some of the principles of artificial stimulation, suppose two stimulating electrodes are placed just outside the 1-cm fiber, as identified in Figure 19.10. Note that the anode is placed at $z = 10$ mm (encircled $+$), and the cathode is placed at $z = 0$ (encircled $-$). Both electrodes are extracellular. When current is injected through these electrodes, most of the current will flow along the extracellular path (thick flow line). Some current also will cross the resistive barrier formed by the membrane and flow
FIGURE 19.10 Extracellular stimulus currents, concept drawing. A stimulus is applied between and extracellular anode, at $z = 10$, and an extracellular cathode, at $z = 0$. Most current will flow in the extracellular volume (thick line). Some current will enter the intracellular volume (thin line). Current entering or leaving the membrane causes that portion of the membrane to become hyperpolarized (high z region) or depolarized (low z region).
FIGURE 19.11 Transmembrane potentials following an extracellular stimulus. The simulation used the geometry of Figure 19.5, except that the stimulus was applied to the row 2 nodes at $z = 0$ and $z = 10$ (similar to Figure 19.10). Successive plots show the transmembrane potentials as a function of z at time 0 (just before the stimulus), 0.5 msec (end of the stimulus), 3.0 msec (propagation underway), and 5.0 msec. The potential distribution at 0.5 msec is consistent in its major features with the concept drawing of Figure 19.10.

intracellularly (thin flow line). Where the intracellular current emerges from the membrane, it will tend to depolarize the membrane. (Note the effects of the stimulus on potential differences: The region depolarized is the region where the intracellular potential becomes higher as compared with the extracellular potential directly across the membrane. In contrast, the region depolarized has a lower potential near the cathode as compared with the potential at the other end of the fiber, near the anode, in both the intracellular and extracellular volumes.) If the magnitude of the depolarization is large enough in relation to the size of the depolarized region, then the stimulus will initiate action potentials and propagation.

Transmembrane potential distributions following the extracellular stimulus are shown in Figure 19.11. At time $t = 0$, the transmembrane potential (as a function of z) is flat, indicating that the membrane is uniformly in the resting state. Then a stimulus of 0.05 mA amplitude and 0.5 msec duration is applied to the stimulus electrodes, with the source–sink positioning that of Figure 19.10. Figure 19.11 shows the distribution of transmembrane potentials at $t = 0.5$ msec, the time of the end of the stimulus.

At $t = 0.5$ msec, the membrane is depolarized near the cathode (near $z = 0$) and is hyperpolarized near the anode (near $z = 10$). Interestingly, there is a small region of hyperpolarization beside the depolarized end (near $z = 2$ mm) and depolarization near the hyperpolarized end (near $z = 8$ mm), a predictable effect [Plonsey and Barr, 2000]. The transmembrane potentials along the central part of the fiber are much less affected by the stimulus than are the ends, even though the same magnitude of stimulus current flows along the entire length. This stimulus was large enough to produce action potentials, as can be seen by inspecting the transmembrane potentials for 3 msec. Figure 19.11 shows that the excitation wave that began near $z = 0$ has, by 3 msec, progressed about a third of the way down the fiber. Propagation to a further point is seen at 5.0 msec.

Many devices for medical stimulation have now come into routine use over long periods of time, for example, cardiac pacemakers. Large currents ("shocks") of artificial origin also are used to terminate action potentials in some cases, for example, cardiac defibrillators. The transmembrane potential changes induced by such shocks now have been measured in considerable detail [e.g., Zhou et al., 1996; Ideker et al., 2000].

19.9 Biomagnetism

Panofsky and Phillips [1962] show the connection between the electric field E to the magnetic field B and current j_{true} by giving two (of the four) Maxwell's equations as

$$\nabla \times H = -j_{\text{true}} + \frac{\partial D}{\partial t} \tag{19.14}$$

and

$$\nabla \times E = -\frac{\partial B}{\partial t} \tag{19.15}$$

together with the constituitive relations $H = B/\mu$ and $D = k\varepsilon_{\text{o}}E$, where μ, k, and ε_{o} are constants for a given medium.

Both currents j_{true} and changing electric fields (E and thereby D) are present naturally in and around excitable membranes, so Equation 19.14 shows that corresponding magnetic fields are to be expected. These magnetic fields are small, however, even in comparison with the earth's magnetic field. They can nonetheless be precisely measured if careful attention is paid to the design of equipment and the surroundings, as demonstrated by Wikswo and Egeraat [1991]. At present, magnetic fields are not routinely measured for clinical purposes, largely because the required equipment is more cumbersome and more expensive. Nonetheless, in principle, biomagnetic recordings offer some important advantages, including the absence of required electrode contact.

In a complementary way, rapidly changing magnetic fields induce electric fields (and thereby currents) in living tissue, as indicated by Equation 19.15. Stimulation of nerves or muscles is thereby possible, either by design (see, e.g., Roth and Basser 1990) or as a side effect of magnetic resonance imaging (MRI). Extensive consideration of biomagnetism has been presented by Malmivuo and Plonsey [1994], and Gulrajani [1998].

Defining Terms

Action potential: The cycle of changes of transmembrane potential, negative to positive to negative again, that characterizes excitable tissue. This cycle also is described as resting to excited and returning to rest.

Excitation: The change of the membrane from resting to excited states, characterized by the movement of the transmembrane potential across a threshold.

Extracellular potentials: Potentials generated between two sites outside the membrane (external to active cells), for example, between two sites on the skin, due to current flow in the volume conductor.

Intracellular (extracellular):   Inside (outside) cells.

Membrane polarization: The sustained (and approximately constant) transmembrane potential of a cell at rest that arises due to different intracellular and extracellular ionic concentrations.

Propagation: Excitation of one region of tissue as a result of an action potential in an adjacent region.

Stimulation: Change in the transmembrane potential at a site due to an influence from another site. The term is used most frequently when current is applied through wires from an artificial current source.

Transmembrane potential: The potential inside a cell membrane minus the potential just outside the membrane.

Volume conductor: The electrically conductive interior region of the body surrounding electrically active membrane.

Volume Conductor Theory

Robert Plonsey
Duke University

This chapter considers the properties of the volume conductor as it pertains to the evaluation of electric and magnetic fields arising therein. The sources of the aforementioned fields are described by $\vec{J}^i$, a function of position and time, which has the dimensions of current per unit area *or* dipole moment per unit volume. Such sources may arise from active endogenous electrophysiologic processes such as propagating action potentials, generator potentials, synaptic potentials, etc. Sources also may be established exogenously, as exemplified by electric or magnetic field stimulation. Details on how one may quantitatively evaluate a source function from an electrophysiologic process are found in other chapters. For our purposes here, we assume that such a source function $\vec{J}^i$ is known and, furthermore, that it has well-behaved mathematical properties. Given such a source, we focus attention here on a description of the volume conductor as it affects the electric and magnetic fields that are established in it. As a loose definition, we consider the *volume conductor* to be the contiguous passive conducting medium that surrounds the region occupied by the source $\vec{J}^i$. (This may include a portion of the excitable tissue itself that is sufficiently far from $\vec{J}^i$ to be described passively.)

20.1 Basic Relations in the Idealized Homogeneous Volume Conductor

Excitable tissue, when activated, will be found to generate currents both within itself and also in all surrounding conducting media. The latter passive region is characterized as a *volume conductor*. The adjective *volume* emphasizes that current flow is three-dimensional, in contrast to the confined one-dimensional flow within insulated wires. The volume conductor is usually assumed to be a monodomain (whose meaning will be amplified later), isotropic, resistive, and (frequently) homogeneous. These are simply assumptions, as will be discussed subsequently. The permeability of biologic tissues is important

20-1

when examining magnetic fields and is usually assumed to be that of free space. The permittivity is a more complicated property, but outside cell membranes (which have a high lipid content) it is also usually considered to be that of free space.

A general, mathematical description of a current source is specified by a function $\vec{J}^i\,(x, y, z, t)$, namely, a vector field of current density in say milliamperes per square centimeter that varies both in space and time. A study of sources of physiologic origin shows that their temporal behavior lies in a low-frequency range. For example, currents generated by the heart have a power density spectrum that lies mainly under 1 kHz (in fact, clinical ECG instruments have upper frequency limits of 100 Hz), while most other electrophysiologic sources of interest (i.e., those underlying the EEG, EMG, EOG, etc.) are of even lower frequency. Examination of electromagnetic fields in regions with typical physiologic conductivities, with dimensions of under 1 m and frequencies less than 1 kHz, shows that *quasi-static* conditions apply. That is, at a given instant in time, source–field relationships correspond to those found under static conditions.[1] Thus, in effect, we are examining direct current (dc) flow in physiologic volume conductors, and these can be maintained only by the presence of a supply of energy (a "battery"). In fact, we may expect that wherever a physiologic current source $\vec{J}^i$ arises, we also can identify a (normally nonelectrical) energy source that generates this current. In electrophysiologic processes, the immediate repository of energy is the potential energy associated with the varying chemical compositions encountered (extracellular ionic concentrations that differ greatly from intracellular concentrations), but the long-term energy source is the adenosine triphosphate (ATP) that drives various pumps that create and maintain the aforementioned concentration gradients.

Based on the aforementioned assumptions, we consider a uniformly conducting medium of conductivity σ and of infinite extent within which a current source $\vec{J}^i$ lies. This, in turn, establishes an electric field $\vec{E}$ and, based on Ohm's law, a conduction current density $\sigma\vec{E}$. The total current density $\vec{J}$ is the sum of the aforementioned currents, namely,

$$\vec{J} = \sigma\vec{E} + \vec{J}^i \tag{20.1}$$

Now, by virtue of the quasi-static conditions, the electric field may be derived from a scalar potential Φ [Plonsey and Heppner, 1967] so that

$$\vec{E} = -\nabla\Phi \tag{20.2}$$

Since quasi-steady-state conditions apply, $\vec{J}$ must be solenoidal, and consequently, substituting Equation 20.2 into Equation 20.1 and then setting the divergence of Equation 20.1 to zero show that Φ must satisfy Poisson's equation, namely,

$$\nabla^2\Phi = \left(\frac{1}{\sigma}\right)\nabla \cdot \vec{J}^i \tag{20.3}$$

An integral solution to Equation 20.3 is [Plonsey and Collin, 1961]

$$\Phi_p(x', y', z') = -\frac{1}{4\pi\sigma}\int_v \frac{\nabla, \vec{J}^i}{r}\,\mathrm{d}v \tag{20.4}$$

where r in Equation 20.4 is the distance from a field point $P(x', y', z')$ to an element of source at $\mathrm{d}v(x, y, z)$, that is,

$$r = \sqrt{(x - x')^2 + (y - y')^2 + (z - z')^2} \tag{20.5}$$

---

[1]Note that while, in effect, we consider relationships arising when $\partial/\partial t = 0$, all fields are actually assumed to vary in time synchronously with $\vec{J}^i$. Furthermore for the special case of magnetic field stimulation, the source of the primary electric field, $\partial\vec{A}/\partial t$, where $\vec{A}$ is the magnetic vector potential, must be retained.

Equation 20.4 may be transformed to an alternate form by employing the vector identity

$$\nabla \cdot \left[\left(\frac{1}{r} \right) \vec{J}^i \right] \equiv \left(\frac{1}{r} \right) \nabla \cdot \vec{J}^i + \nabla \left(\frac{1}{r} \right) \cdot \vec{J}^i \tag{20.6}$$

Based on Equation 20.6, we may substitute for the integrand in Equation 20.4 the sum $\nabla \cdot [(1/r)\vec{J}^i] - \nabla(1/r) \cdot \vec{J}^i$, giving the following:

$$\Phi_p(x', y', z') = -\frac{1}{4\pi\sigma} \left\{ \int_v \nabla \cdot \left[\left(\frac{1}{r} \right) \vec{J}^i \right] dv - \int_v \nabla \left(\frac{1}{r} \right) \vec{J}^i dv \right\} \tag{20.7}$$

The first term on the right-hand side may be transformed using the divergence theorem as follows:

$$\int_v \nabla \cdot \left[\left(\frac{1}{r} \right) \vec{J}^i \right] dv = \int_s \left(\frac{1}{r} \right) \vec{J}^i \cdot d\vec{S} = 0 \tag{20.8}$$

The volume integral in Equation 20.4 and Equation 20.8 is defined simply to include all sources. Consequently, in Equation 20.8, the surface S, which bounds V, necessarily lies away from $\vec{J}^i$. Since $\vec{J}^i$ thus is equal to zero on S, the expression in Equation 20.8 must likewise equal zero. The result is that Equation 20.4 also may be written as

$$\Phi_p(x', y', z') = -\frac{1}{4\pi\sigma} \int_v \frac{\nabla \cdot \vec{J}^i}{r} dv = \frac{1}{4\pi\sigma} \int_v \vec{J}^i \cdot \nabla \left(\frac{1}{r} \right) dv \tag{20.9}$$

We will derive the mathematical expressions for monopole and dipole fields in the next section, but based on those results, we can give a physical interpretation of the source terms in each of the integrals on the right-hand side of Equation 20.9. In the first, we note that $-\nabla \cdot \vec{J}^i$ is a volume source density, akin to charge density in electrostatics. In the second integral of Equation 20.9, $\vec{J}^i$ behaves with the dimensions of dipole moment per unit volume. This confirms an assertion, above, that $\vec{J}^i$ has a dual interpretation as a current density, as originally defined in Equation 20.1, or a volume dipole density, as can be inferred from Equation 20.9; in either case, its dimension are $mA/cm^2 = mA \cdot cm/cm^3$.

20.2 Monopole and Dipole Fields in the Uniform Volume of Infinite Extent

The monopole and dipole constitute the basic source elements in electrophysiology. We examine the fields produced by each in this section.

If one imagines an infinitely thin wire insulated over its extent except at its tip to be introducing a current into a uniform volume conductor of infinite extent, then we illustrate an idealized point source. Assuming the total applied current to be I_0 and located at the coordinate origin, then by symmetry the current density at a radius r must be given by the total current I_0 divided by the area of the spherical surface, or

$$\vec{J} = \frac{I_0}{4\pi r^2} \vec{a}_r \tag{20.10}$$

and $\vec{a}_r$ is a unit vector in the radial direction. This current source can be described by the nomenclature of the previous section as

$$\nabla \cdot \vec{J}^i = -I_0 \delta(r) \tag{20.11}$$

where δ denotes a volume delta function.

One can apply Ohm's law to Equation 20.10 and obtain an expression for the electric field, and if Equation 20.2 is also applied, we get

$$\vec{E} = -\nabla \Phi = \frac{I_0}{4\pi \sigma r^2} \vec{a}_r \qquad (20.12)$$

where σ is the conductivity of the volume conductor. Since the right-hand side of Equation 20.12 is a function of r only, we can integrate to find Φ, which comes out

$$\Phi = \frac{I_0}{4\pi \sigma r} \qquad (20.13)$$

In obtaining Equation 20.13, the constant of integration was set equal to zero so that the point at infinity has the usually chosen zero potential.

The dipole source consists of two monopoles of equal magnitude and opposite sign whose spacing approaches zero and whose magnitude during the limiting process increases such that the product of spacing and magnitude is constant. If we start out with both component monopoles at the origin, then the total source and field are zero. However, if we now displace the positive source in an arbitrary direction $\vec{d}$, then cancellation is no longer complete, and at a field point P we see simply the change in monopole field resulting from the displacement. For a very small displacement, this amounts to (i.e., we retain only the linear term in a Taylor series expansion)

$$\Phi_P = \frac{\partial}{\partial d} \left(\frac{I_0}{4\pi \sigma r} \right) d \qquad (20.14)$$

The partial derivative in Equation 20.14 is called the *directional derivative*, and this can be evaluated by taking the dot product of the gradient of the expression enclosed in parentheses with the direction of d (i.e., $\nabla() \cdot \vec{a}_d$, where $\vec{a}_d$ is a unit vector in the $\vec{d}$ direction). The result is

$$\Phi_p = \frac{I_0 d}{4\pi \sigma} \vec{a}_d \cdot \nabla \left(\frac{1}{r} \right) \qquad (20.15)$$

By definition, the dipole moment $\vec{m} = I_0 \vec{d}$ in the limits as $d \to 0$; as noted, m remains finite. Thus, finally, the dipole field is given by [Plonsey, 1969]

$$\Phi_p = \frac{1}{4\pi \sigma} \vec{m} \cdot \nabla \left(\frac{1}{r} \right). \qquad (20.16)$$

20.3   Volume Conductor Properties of Passive Tissue

If one were considering an active single isolated fiber lying in an extensive volume conductor (e.g., an *in vitro* preparation in a Ringer's bath), then there is a clear separation between the excitable tissue and the surrounding volume conductor. However, consider in contrast activation proceeding in the *in vivo* heart. In this case, the source currents lie in only a portion of the heart (nominally where $\nabla V_m \neq 0$). The volume conductor now includes the remaining (passive) cardiac fibers along with an inhomogeneous torso containing a number of contiguous organs (internal to the heart are blood-filled cavities, while external are pericardium, lungs, skeletal muscle, bone, fat, skin, air, etc.).

The treatment of the surrounding multicellular cardiac tissue poses certain difficulties. A recently used and reasonable approximation is that the intracellular space, in view of the many intercellular junctions, can be represented as a continuum. A similar treatment can be extended to the interstitial space. This results in two domains that can be regarded as occupying the same physical space; each domain is separated from the other by the membrane. This view underlies the *bidomain* model [Plonsey, 1989]. To reflect the

TABLE 20.1   Conductivity Values
for Cardiac Bidomain

S/mm	Clerc [1976]	Roberts [1982]
g_{ix}	1.74×10^4	3.44×10^{-4}
g_{iy}	1.93×10^{-5}	5.96×10^{-5}
g_{ax}	6.25×10^{-4}	1.17×10^{-4}
g_{ay}	2.36×10^{-4}	8.02×10^{-5}

underlying fiber geometry, each domain is necessarily anisotropic, with the high conductivity axes defined by the fiber direction and with an approximate cross-fiber isotropy. A further simplification may be possible in a uniform tissue region that is sufficiently far from the sources, since beyond a few space constants transmembrane currents may become quite small and the tissue would therefore behave as a single domain (a *monodomain*). Such a tissue also would be substantially resistive. On the other hand, if the membranes behave passively and there is some degree of transmembrane current flow, then the tissue may still be approximated as a uniform monodomain, but it may be necessary to include some of the reactive properties introduced via the highly capacitive cell membranes. A classic study by Schwan and Kay [1957] of the macroscopic (averaged) properties of many tissues showed that the displacement current was normally negligible compared with the conduction current.

It is not always clear whether a bidomain model is appropriate to a particular tissue, and experimental measurements found in the literature are not always able to resolve this question. The problem is that if the experimenter believes the tissue under consideration to be, say, an isotropic monodomain, measurements are set up and interpreted that are consistent with this idea; the inherent inconsistencies may never come to light [Plonsey and Barr, 1986]. Thus one may find impedance data tabulated in the literature for a number of organs, but if the tissue is truly, say, an anisotropic bidomain, then the impedance tensor requires six numbers, and anything less is necessarily inadequate to some degree. For cardiac tissue, it is usually assumed that the impedance in the direction transverse to the fiber axis is isotropic. Consequently, only four numbers are needed. These values are given in Table 20.1 as obtained from, essentially, the only two experiments for which bidomain values were sought.

20.4   Effects of Volume Conductor Inhomogeneities: Secondary Sources and Images

In the preceding we have assumed that the volume conductor is homogeneous, and the evaluation of fields from the current sources given in Equation 20.9 is based on this assumption. Consider what would happen if the volume conductor in which $\vec{J}^i$ lies is bounded by air, and the source is suddenly introduced. Equation 20.9 predicts an initial current flow into the boundary, but no current can escape into the nonconducting surrounding region. We must, consequently, have a transient during which charge piles up at the boundary, a process that continues until the field from the accumulating charges brings the net normal component of electric field to zero at the boundary. To characterize a steady-state condition with no further increase in charge requires satisfaction of the boundary condition that $\partial \Phi / \partial n = 0$ at the surface (within the tissue). The source that develops at the bounding surface is secondary to the initiation of the primary field; it is referred to as a *secondary source*. While the secondary source is essential for satisfaction of boundary conditions, it contributes to the total field everywhere else.

The preceding illustration is for a region bounded by air, but the same phenomena would arise if the region were simply bounded by one of different conductivity. In this case, when the source is first "turned on," since the primary electric field $\vec{E}_a$ is continuous across the interface between regions of different conductivity, the current flowing into such a boundary (e.g., $\sigma_1 \vec{E}_a$) is unequal to the current flowing away from that boundary (e.g., $\sigma_2 \vec{E}_a$). Again, this necessarily results in an accumulation of charge, and a secondary source will grow until the applied plus secondary field satisfies the required continuity of

current density, namely,

$$-\sigma_1 \partial \frac{\Phi_1}{\partial_n} = -\sigma_2 \partial \frac{\Phi_2}{\partial_n} = J_n \tag{20.17}$$

where the surface normal n is directed from region 1 to region 2. The accumulated single source density can be shown to be equal to the discontinuity of $\partial \Phi / \partial_n$ in Equation 20.17 [Plonsey, 1974], in particular,

$$K_s = J_n \left(\frac{1}{\sigma_1} - \frac{1}{\sigma_2} \right) \sigma$$

The magnitude of the steady-state secondary source also can be described as an *equivalent double layer*, the magnitude of which is [Plonsey, 1974]

$$\vec{K}_k^i = \Phi_k(\sigma_k'' - \sigma_k')\vec{n} \tag{20.18}$$

where the condition at the kth interface is described. In Equation 20.18, the two abutting regions are designated with prime and double-prime superscripts, and $\vec{n}$ is directed from the primed to the double-primed region. Actually, Equation 20.18 evaluates the double-layer source for the scalar function $\Psi = \Phi \sigma$, its strength being given by the discontinuity in Ψ at the interface [Plonsey, 1974] (the potential is necessarily continuous at the interface with the value Φ_k called for in Equation 20.18). The (secondary) potential field generated by $\vec{K}_k^i$, since it constitutes a source for Ψ with respect to which the medium is uniform and infinite in extent, can be found from Equation 20.9 as

$$\Psi_P^S = \sigma_P \Phi_P^S = \frac{1}{4\pi} \sum_k \int_k \Phi_k(\sigma_k'' - \sigma_k')\vec{n} \cdot \nabla \left(\frac{1}{r} \right) ds \tag{20.19}$$

where the superscript S denotes the secondary source/field component (alone). Solving Equation 20.19 for Φ, we get

$$\Phi_P^S = \frac{1}{4\pi \sigma_P} \sum_k \int_k \Phi_k(\sigma_k'' - \sigma_k')\vec{n} \cdot \nabla \left(\frac{1}{r} \right) ds \tag{20.20}$$

where σ_P in Equation 20.19 and Equation 20.20 takes on the conductivity at the field point. The total field is obtained from Equation 20.20 by adding the primary field. Assuming that all applied currents lie in a region with conductivity σ_a, then we have

$$\Phi_P^S = \frac{1}{4\pi \sigma_a} \int \vec{J}^i \cdot \nabla \left(\frac{1}{r} \right) dv + \frac{1}{4\pi \sigma_P} \sum_k \int_k \Phi_k(\sigma_k'' - \sigma_k')\vec{n} \cdot \nabla \left(\frac{1}{r} \right) ds \tag{20.21}$$

(If the primary currents lie in several conductivity compartments, then each will yield a term similar to the first integral in Equation 20.21.) Note that in Equation 20.20 and Equation 20.21 the secondary source field is similar in form to the field in a homogeneous medium of infinite extent, except that σ_P is piecewise constant and consequently introduces interfacial discontinuities. With regard to the potential, these just cancel the discontinuity introduced by the double layer itself so that Φ_k is appropriately continuous across each passive interface.

The primary and secondary source currents that generate the electrical potential in Equation 20.21 also set up a magnetic field. The primary source, for example, is the forcing function in the Poisson equation for the vector potential $\vec{A}$ [Plonsey, 1981], namely,

$$\nabla^2 \vec{A} = -\vec{J}^i \tag{20.22}$$

From this it is not difficult to show that, due to Equation 20.21 for Φ, we have the following expression for the magnetic field $\vec{H}$ [Plonsey, 1981]:

$$\vec{H} = \frac{1}{4\pi} \int \vec{J}^i \times \nabla\left(\frac{1}{r}\right) dv + \frac{1}{4\pi} \sum_k \int \Phi_k (\sigma_k'' - \sigma_k') \vec{n} \times \nabla\left(\frac{1}{r}\right) dS \tag{20.23}$$

A simple illustration of these ideas is found in the case of two semi-infinite regions of different conductivity, 1 and 2, with a unit point current source located in region 1 a distance h from the interface. Region 1, which we may think of as on the "left," has the conductivity σ_1, while region 2, on the "right," is at conductivity σ_2. The field in region 1 is that which arises from the actual point current source plus an image point source of magnitude $(\rho_2 - \rho_1)/(\rho_2 + \rho_1)$ located in region 2 at the mirror-image point [Schwan and Kay, 1957]. The field in region 2 arises from an equivalent point source located at the actual source point but of strength $[1 + (\rho_2 - \rho_1)/(\rho_2 + \rho_1)]$. One can confirm this by noting that all fields satisfy Poisson's equation and that at the interface Φ is continuous while the normal component of current density is also continuous (i.e., $\sigma_1 \partial \Phi_1/\partial n = \sigma_2 \partial \Phi_2/\partial n$).

The potential on the interface is constant along a circular path whose origin is the foot of the perpendicular from the point source. Calling this radius r and applying Equation 20.13, we have for the surface potential Φ_S

$$\Phi_S = \frac{\rho_1}{4\pi \sqrt{h^2 + r^2}} \left(1 + \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1}\right) \tag{20.24}$$

and consequently a secondary double-layer source $\vec{K}_S$ equals, according to Equation 20.18,

$$\vec{K}_S = \frac{\rho_1}{4\pi \sqrt{h^2 + r^2}} \left(1 + \frac{\rho_2 - \rho_1}{\rho_2 + \rho_1}\right) (\sigma_2 - \sigma_1) \vec{n} \tag{20.25}$$

where $\vec{n}$ is directed from region 1 to region 2. The field from $\vec{K}_S$ in region 1 is exactly equal to that from a point source of strength $(\rho_2 - \rho_1)/(\rho_2 + \rho_1)$ at the mirror-image point, which can be verified by evaluating and showing the equality of the following:

$$\Phi_P = \frac{1}{4\pi \sigma_1} \int \vec{K}_S \cdot \nabla\left(\frac{1}{r}\right) ds = \frac{(\rho_2 - \rho_1)/(\rho_2 - \rho_1)}{4\pi \sigma_1 R} \tag{20.26}$$

where R in Equation 20.26 is the distance from the mirror-image point to the field point P, and r in Equation 20.26 is the distance from the surface integration point to the field point.

The Electrical Conductivity of Tissues

Bradley J. Roth
Oakland University

21.1 Introduction

One of the most important problems in bioelectric theory is the calculation of the electrical potential, Φ (V), throughout a **volume conductor**. The calculation of Φ is important in impedance imaging, cardiac pacing and defibrillation, electrocardiogram and electroencephalogram analysis, and functional electrical stimulation. In bioelectric problems, Φ often changes slowly enough that we can assume it is **quasistatic** [Plonsey, 1969]; we ignore capacitive and inductive effects and the finite speed of propagation of electromagnetic radiation. (Usually for bioelectric phenomena, this assumption is valid for frequencies below about 100 kHz.) Under the quasistatic approximation, the continuity equation states that the divergence, $\nabla\cdot$, of the current density, J (A/m^2), is equal to the applied or endogenous source of electrical current, S (A/m^3):

$$\nabla \cdot J = S. \tag{21.1}$$

In regions of tissue where there are no sources, S is zero. In these cases, the divergenceless of J is equivalent to the law of **conservation of current** that is often invoked when analyzing electrical circuits. Another property of a volume conductor is that the current density and the electric field, E (V/m), are related linearly by **Ohm's Law**,

$$J = gE, \tag{21.2}$$

21-1

where g is the electrical **conductivity** (S/m). Finally, the relationship between the electric field and the gradient, ∇, of the potential is

$$\boldsymbol{E} = -\nabla\Phi. \tag{21.3}$$

The purpose of this chapter is to characterize the electrical conductivity. This task is not easy, because g is generally a macroscopic parameter (an "effective conductivity") that represents the electrical properties of the tissue averaged over many cells. The effective conductivity can vary with direction, can be complex (contain real and imaginary parts), and can depend on the temporal and spatial frequencies.

Before discussing the conductivity of tissue, consider one of the simplest and most easily understood volume conductors: saline. The electrical conductivity of saline arises from the motion of free ions in response to a steady electric field, and is on the order of 1 S/m. Besides conductivity, another property of saline is its electrical **permittivity**, ε (S sec/m). This property is related to the dielectric constant, κ (dimensionless), by $\varepsilon = \kappa\varepsilon_0$, where ε_0 is the permittivity of free space, 8.854×10^{-12} S sec/m. Dielectric properties arise from bound charge that is displaced by the electric field, creating a dipole. They can also arise if the applied electric field aligns molecular dipoles (such as the dipole moments of water molecules) that are normally oriented randomly. The DC dielectric constant of saline is similar to that of water (about $\kappa = 80$).

The movement of free charge produces conductivity, whereas stationary dipoles produce permittivity. In steady state, the distinction between the two is clear, but at higher frequencies the concepts merge. In such a case, we can combine the electrical properties into a complex conductivity, g':

$$g' = g + i\omega\varepsilon, \tag{21.4}$$

where ω (rad/sec) is the angular frequency ($\omega = 2\pi f$, where f is the frequency in Hz) and i is $\sqrt{-1}$. The real part of g' accounts for the movement of charge in phase with the electric field; the imaginary part accounts for out-of-phase motion. Both the real and the imaginary parts of the complex conductivity may depend on the frequency. For many bioelectric phenomena, the first term in Equation 21.4 is much larger than the second, so the tissue can be represented as purely conductive [Plonsey, 1969]. (The imaginary part of the complex conductivity represents a capacitive effect, and therefore technically violates our assumption of quasistationarity. This violation is the only exception we will make to our general rule of a quasistatic potential.)

21.2 Cell Suspensions

The earliest and simplest model describing the electrical conductivity of a biological tissue is a suspension of cells in a saline solution [Cole, 1968; Peters et al., 2001]. Let us consider a suspension of spherical cells, each of radius a (Figure 21.1a). The saline surrounding the cells constitutes the **interstitial space** (conductivity σ_e), while the conducting fluid inside the cells constitutes the intracellular space (conductivity σ_i). (We shall follow Henriquez [1993] in denoting macroscopic effective conductivities by g and microscopic conductivities by σ.) The cell membrane separates the two spaces; a thin layer having conductivity per unit area G_m (S/m^2) and capacitance per unit area C_m (F/m^2). One additional parameter — the intracellular volume fraction, f (dimensionless) — indicates how tightly the cells are packed together. The volume fraction can range from nearly zero (a dilute solution) to almost 1. (Spherical cells cannot approach a volume fraction of 1, but tightly packed, nonspherical cells can). For irregularly shaped cells, the "radius" is difficult to define. In these cases, it is easier to specify the surface-to-volume ratio of the tissue (the ratio of the membrane surface area to tissue volume). For spherical cells, the surface-to-volume ratio is $3f/a$.

We can define operationally the effective conductivity, g, of a cell suspension by the following process (Figure 21.1a): Place the suspension in a cylindrical tube of length L and cross-sectional area A (be sure L and A are large enough so the volume contains many cells). Apply a DC potential difference V across
FIGURE 21.1 (a) A schematic diagram of a suspension of spherical cells; the effective conductivity of this suspension is *IL/VA*. (b) An electric circuit equivalent of the effective conductivity of this suspension.

the two ends of the cylinder (so that the electric field has strength V/L) and measure the total current, I, passing through the suspension. The effective conductivity is *IL/VA*.

Deriving an expression for the effective conductivity of a suspension of spheres in terms of microscopic parameters is an old and interesting problem in electromagnetic theory [Cole, 1968]. For DC fields, the effective conductivity, g, of a suspension of insulating spheres placed in a solution of conductivity σ_e is

$$g = \frac{2(1-f)}{2+f}\sigma_e. \tag{21.5}$$

For most cells, G_m is small enough so that the membrane behaves as an insulator, and hence the assumption of insulating spheres is applicable. The net effect of the cells is to decrease the conductivity of the solution (the decrease can be substantial for tightly packed cells).

The cell membrane has a capacitance of about 0.01 F/m^2 (or, in traditional units, 1 μF/cm^2), which causes the electrical conductivity to depend on frequency. The electrical circuit in Figure 21.1b represents the suspension of cells: R_e is the effective resistance to current passing entirely through the interstitial space; R_i is the effective resistance to current passing into the intracellular space; and C is the effective membrane capacitance. (The membrane conductance is usually small enough so that it has little effect, regardless of the frequency.) At low frequencies all of the current is restricted to the interstitial space, and the electrical conductivity is given approximately by Equation 21.5 above. At high frequencies, C shunts current across the membrane, so that the effective conductivity of the tissue is:

$$g = \frac{2(1-f)\sigma_e + (1+2f)\sigma_i}{(2+f)\sigma_e + (1-f)\sigma_i}\sigma_e. \tag{21.6}$$

At intermediate frequencies, the effective conductivity has both real and imaginary parts, because the membrane capacitance contributes significantly to the effective conductivity. In these cases, Equation 21.6 still holds if σ_i is replaced by σ_i^*, where

$$\sigma_i^* = \frac{\sigma_i Y_m a}{\sigma_i + Y_m a} \quad \text{with } Y_m = G_m + i\omega C_m. \tag{21.7}$$

Figure 21.2 shows the effective conductivity (magnitude and phase) as a function of frequency for a typical tissue. The increase in the phase at about 300 kHz is sometimes called the "beta dispersion."

21.3 Fiber Suspensions

Many of the most interesting electrically active tissues, such as nerve and skeletal muscle, are better approximated as a suspension of cylinders rather than a suspension of spheres. This difference has profound
FIGURE 21.2   The magnitude and phase of the effective conductivity as a function of frequency, for a suspension of spherical cells: $f = 0.5$; $a = 20\ \mu\mathrm{m}$; $\sigma_e = 1$ S/m; $\sigma_i = 0.5$ S/m; $G_m = 0$; and $C_m = 0.01$ F/m^2.

implications because it introduces **anisotropy**. The effective electrical conductivity depends on direction. Henceforth, we must speak of the longitudinal effective conductivity parallel to the cylindrical fibers, g_L, and the transverse effective conductivity perpendicular to the fibers, g_T. (In theory, the conductivity could be different in three directions; however, often the electrical properties in the two directions perpendicular to the fibers are the same.) In general, the conductivity is no longer a scalar quantity, but is a tensor instead, and must be represented by a 3×3 symmetric matrix. If our coordinate axes lie along the principle directions of this matrix (invariably, the directions parallel to and perpendicular to the fibers), then the off-diagonal terms of the matrix are zero. If, however, we choose our coordinate axes differently, or if the fibers curve so that the direction parallel to the fibers varies over space, we have to deal with tensor properties, including off-diagonal components.

When the electric field is applied perpendicular to the fiber direction, a suspension of fibers is similar to the suspension of cells described above (in Figure 21.1a, we must now imagine that the circles represent cross sections of cylindrical fibers, rather than spherical cells). The expression for the effective transverse conductivity of a suspension of cylindrical cells, of radius a and intracellular conductivity σ_i, placed in a solution of conductivity σ_e, with intracellular volume fraction f, is [Cole, 1968]

$$g_T = \frac{(1-f)\sigma_e + (1+f)\sigma_i^*}{(1+f)\sigma_e + (1-f)\sigma_i^*}\sigma_e, \tag{21.8}$$

where Equation 21.7 defines σ_i^*. At DC, and for $G_m = 0$, Equation 21.8 reduces to

$$g_T = \frac{1-f}{1+f}\sigma_e. \tag{21.9}$$
FIGURE 21.3 An electrical circuit representing a one-dimensional nerve or muscle fiber: r_i and r_e are the intracellular and extracellular resistances per unit length (Ω/m); r_m is the membrane resistance times unit length (Ω m); and c_m is the membrane capacitance per unit length (F/m).

When an electric field is applied parallel to the fiber direction, a new behavior arises that is fundamentally different from that observed for a suspension of spherical cells. Return for a moment to our operational definition of the effective conductivity. Surprisingly, the effective longitudinal conductivity of a suspension of fibers depends on the length L of the tissue sample used for the measurement. To understand this dependence, we must consider one-dimensional **cable theory** [Plonsey, 1969]. The circuit in Figure 21.3a approximates a single nerve or muscle fiber. Adopting the traditional electrophysiology nomenclature, we denote the intracellular and extracellular resistances per unit length along the fiber by r_i and r_e (Ω/m), the membrane resistance times unit length by r_m(Ω m), and the capacitance per unit length by c_m (F/m). The cable equation governs the transmembrane potential, V_m:

$$\lambda^2 \frac{\partial^2 V_m}{\partial x^2} = \tau \frac{\partial V_m}{\partial t} + V_m, \tag{21.10}$$

where τ is the time constant, $r_m c_m$, and λ is the length constant, $\sqrt{r_m/(r_i + r_e)}$. For a truncated fiber of length L (m) with sealed ends, and with a steady-state current I (A) injected into the extracellular space at one end and removed at the other, the solution to the cable equation is

$$V_m = I r_e \lambda \frac{\sinh(x/\lambda)}{\cosh(L/2\lambda)}, \tag{21.11}$$

where the origin of the x-axis is at the midpoint between electrodes. The extracellular potential, V_e, consists of two terms: One is proportional to x, and the other is $r_e/(r_i + r_e)$ times V_m. We can evaluate V_e at the two ends of the fiber to obtain the voltage drop between the electrodes, ΔV_e

$$\Delta V_e = \frac{r_i r_e}{r_i + r_e} I \left[L + \frac{r_e}{r_i} 2\lambda \tanh\left(\frac{L}{2\lambda}\right) \right]. \tag{21.12}$$

If L is very large compared to λ, the extracellular voltage drop reduces to

$$\Delta V_e = \frac{r_i r_e}{r_i + r_e} LI \quad L >> \lambda. \tag{21.13}$$

The leading factor is the parallel combination of the intracellular and extracellular resistances. If, on the other hand, L is very small compared to λ, the extracellular voltage drop becomes

$$\Delta V_e = r_e LI \quad L << \lambda. \tag{21.14}$$

In this case, the leading factor is simply the extracellular resistance alone. Physically, there is a redistribution of current into the intracellular space that occurs over a distance on the order of a length constant. If the tissue length is much longer than a length constant, the current is redistributed completely between

the intracellular and extracellular spaces. If the tissue length is much smaller than a length constant, the current does not enter the fiber, but instead is restricted to the extracellular space. If either of these two conditions is met, then the effective conductivity ($IL/A\Delta V_e$, where A is the cross-sectional area of the tissue strand) is independent of L. However, if L is comparable to λ, the effective conductivity depends on the size of the tissue being studied.

Roth et al. [1988] recast the expression for the effective longitudinal conductivity in terms of **spatial frequency**, k (rad/m). This approach has two advantages. First, the temporal and spatial behaviors are both described using frequency analysis. Second, a parameter describing the size of a specific piece of tissue is not necessary: the spatial frequency dependence becomes a property of the tissue, not the measurement. The expression for the DC effective longitudinal conductivity is

$$g_L = \frac{(1-f)\sigma_e + f\sigma_i}{1 + \dfrac{f\sigma_i}{(1-f)\sigma_e}\dfrac{1}{1 + \left(\dfrac{1}{\lambda k}\right)^2}} \tag{21.15}$$

To relate the effective longitudinal conductivity to Equation 21.13 and Equation 21.14 above, note that $1/k$ plays the same role as L. If $k\lambda \ll 1$, g_L reduces to $(1-f)\sigma_e + f\sigma_i$, which is equivalent to the parallel combination of resistances in Equation 21.13. If $k\lambda \gg 1$, g_L becomes $(1-f)\sigma_e$, implying that the current is restricted to the interstitial space, as in Equation 21.14. Equation 21.15 can be generalized to all temporal frequencies by defining λ in terms of Y_m instead of G_m [Roth et al., 1988]. Figure 21.4 shows the magnitude and phase of the longitudinal and transverse effective conductivities as functions of the temporal and spatial frequencies.

The measurement of effective conductivities is complicated by the traditionally used electrode geometry. Typically, one uses a four-electrode technique [Steendijk et al., 1993], in which two electrodes inject current and two others measure the potential (Figure 21.5). Gielen et al. [1984] used this method to measure the electrical properties of skeletal muscle and found that the effective conductivity depended on the interelectrode distance. Roth [1989] reanalyzed Gielen et al.'s data using the spatial frequency dependent model and found agreement with some of the more unexpected features or their data (Figure 21.6). Table 21.1 contains typical values of skeletal muscle effective conductivities and microscopic tissue parameters. Table 21.2 lists nerve effective conductivities.

21.4 Syncytia

Cardiac tissue is different from the other tissues we have discussed in that it is an electrical **syncytium**: the cells are coupled through intercellular junctions. The **bidomain** model describes the electrical properties of cardiac muscle [Henriquez, 1993]. It is essentially a two- or three-dimensional cable model that takes into account the resistance of both the intracellular and the interstitial spaces (Figure 21.7). Thus, the concept of current redistribution, discussed earlier in the context of the longitudinal effective conductivity of a suspension of fibers, now applies in all directions. Furthermore, cardiac muscle is markedly anisotropic. These properties make impedance measurements of cardiac muscle difficult to interpret [Plonsey and Barr, 1986; Le Guyader et al., 2001]. The situation is complicated further because the intracellular space is more anisotropic than is the interstitial space (in the jargon of bidomain modeling, this condition is known as "unequal anisotropy ratios") [Roth, 1997]. Consequently, an expression for a single effective conductivity for cardiac muscle is difficult, if not impossible, to derive. In general, one must solve a pair of coupled partial differential equations simultaneously for the intracellular and interstitial potentials.

The bidomain model characterizes the electrical properties of the tissue by four effective conductivities: g_{iL}, g_{iT}, g_{eL}, and g_{eT}, where i and e denote the intracellular and interstitial spaces, and L and T denote the

The parameters used in this calculation are $G_m = 1$ S/m^2; $C_m = 0.01$ F/m^2; $f = 0.9$; $a = 20$ μm; $\sigma_i = 0.55$ S/m; and $\sigma_e = 2$ S/m. directions parallel to and perpendicular to the myocardial fibers. We can relate these parameters to the microscopic tissue properties by using an operational definition of an effective bidomain conductivity, similar to the operational definition given earlier. To determine the interstitial conductivity, first dissect a cylindrical tube of tissue of length L and cross-sectional area A (one must be sure that L and A are large

enough so the volume contains many cells, and that the dissection does not damage the tissue). Next, apply a drug to the tissue that makes the membrane essentially insulating (i.e., the length constant is much longer than L). Finally, apply a DC potential difference, V, across the two ends of the cylinder and measure the total current, I. The effective interstitial conductivity is IL/VA. This procedure must be performed twice, once with the fibers parallel to the axis of the cylinder, and once with the fibers perpendicular to it. To determine the effective intracellular conductivities, follow the above procedure but apply the voltage difference to the intracellular space instead of the interstitial space. Although the procedure would be

extraordinarily difficult in practice, we can imagine two arrays of microelectrodes that impale the cells at both ends of the cylinder and maintain a constant potential at each end.

Expressions have been derived for the effective bidomain conductivities in terms of the microscopic tissue parameters [Roth, 1988; Henriquez, 1993; Neu and Krassowska, 1993]. The effective conductivities in the direction parallel to the fibers are simplest. Imagine that the tissue is composed of long, straight

fibers (like skeletal muscle) and that the intracellular space of these fibers occupies a fraction f of the tissue cross-sectional area. If the conductivity of the interstitial fluid is σ_e, then the effective interstitial conductivity parallel to the fibers, g_{eL}, is simply

$$g_{eL} = (1 - f)\,\sigma_e. \tag{21.16}$$

If we neglect the resistance of the gap junctions, we obtain a similar expression for the effective intracellular conductivity parallel to the fibers in terms of the myoplasmic conductivity, σ_i: $g_{iL} = f\sigma_i$. When the gap junctional resistance is not negligible compared to the myoplasmic resistance, the expression for g_{iL} is more complicated:

$$g_{iL} = \frac{1}{1 + (\pi a^2 \sigma_i)/(bG)} f\sigma_i, \tag{21.17}$$

where G is the junctional conductance between two cells (S), b is the cell length (m), and a is the cell radius (m).

The effective interstitial conductivity perpendicular to the fibers is identical with the DC transverse effective conductivity for skeletal muscle given in Equation 21.9

$$g_{eT} = \frac{1 - f}{1 + f}\sigma_e. \tag{21.18}$$

The effective intracellular conductivity perpendicular to the fibers is the most difficult to model, but a reasonable expression for g_{iT} is

$$g_{iT} = \frac{1}{1 + (b\sigma_i)/G}\sigma_i. \tag{21.19}$$

Table 21.3 contains measured values of the bidomain conductivities (see also Roth [1997]). Typical values of the microscopic tissue parameters are also given in Table 21.3, although some are quite uncertain (particularly G).

If the intercellular junctions contribute significantly to the intracellular resistance, the bidomain model only approximates the tissue behavior [Neu and Krassowska, 1993]. For sufficiently large junctional resistance, the discrete cellular properties become important, and a continuum model no longer represents the tissue well. Interestingly, as the junctional resistance increases, cardiac tissue behaves less like a syncytium and more like a suspension of cells. Thus we have come a full circle. We started by considering a suspension of cells, then examined suspensions of fibers, and finally generalized to syncytia. Yet, when the intercellular junctions in a syncytium are disrupted, we find ourselves again thinking of the tissue as a suspension of cells.

Defining Terms

Anisotropy: Having different properties in different directions.

Bidomain: A two- or three-dimensional cable model that takes into account the resistance of both the intracellular and the extracellular spaces.

Cable theory: Representation of a cylindrical fiber as two parallel rows of resistors (one each for the intracellular and extracellular spaces) connected in a ladder network by a parallel combination of resistors and capacitors (the cell membrane).

Conservation of current: A fundamental law of electrostatics, stating that there is no net current entering or leaving at any point in a volume conductor.

Conductivity: A parameter (g) that measures how well a substance conducts electricity. The coefficient of proportionality between the electric field and the current density. The units of conductivity are siemens per meter (S/m). A siemens is an inverse ohm, sometimes called a "mho" in the older literature.

Interstitial space: The extracellular space between cells in a tissue.

Ohm's law: A linear relation between the electric field and current density vectors.

Permittivity: A parameter (ε) that measures the size of the dipole moment induced in a substance by an electric field. The units of permittivity are siemens second per meter (S sec/m), or farads per meter (F/m).

Quasistatic: A potential distribution that changes slowly enough that we can accurately describe it by the equations of electrostatics (capacitive, inductive, and propagation effects are ignored).

Spatial frequency: A parameter governing how rapidly a function changes in space; $k = 1/(2\pi/s)$, where s is the wavelength of a sinusoidally varying function.

Syncytium (pl., syncytia): A tissue in which the intracellular spaces of adjacent cells are coupled through intercellular channels, so that current can pass between any two intracellular points without crossing the cell membrane.

Volume conductor: A three-dimensional region of space containing a material that passively conducts electrical current.

Membrane Models

Anthony Varghese
University of Minnesota

The models discussed in this chapter involve the time behavior of electrochemical activity in excitable cells. These models are systems of ordinary differential equations where the independent variable is time. While a good understanding of linear circuit theory is useful in order to understand the models presented in this chapter, most of the phenomena of interest involve nonlinear circuits with time-varying components.

Electrical activity in plant and animal cells are caused by two main factors: first, there are differences in the concentrations of ions inside and outside the cell; and second, there are molecules embedded in the cell membrane that allow these ions to be transported across the membrane. The ion concentration differences and the presence of large membrane-impermeant anions inside the cell result in the existence of a polarity: the potential inside a cell is typically 30 to 100 mV lower than that in the external solution. It is important to note that almost all of this potential difference occurs across the membrane itself. The bulk solutions both inside and outside the cell are, for the most part, at a uniform potential. This **transmembrane potential difference** is in turn sensed by molecules in the membrane that control the flow of ions.

The lipid bilayer, which constitutes the majority of the cell membrane, acts as a capacitor with a specific capacitance that is typically $1 \, \mu\text{F/cm}^2$. The rest of the membrane comprises large protein molecules that act

22-1
FIGURE 22.1   Schematic representation of an action potential in an excitable cell. The abscissa represents time and the ordinate represents the transmembrane potential.

as (1) **ion channels**, (2) **ion pumps**, or (3) **ion exchangers**. The flow of ions across the membrane causes changes in the transmembrane potential, which is typically the main observable quantity in experiments.

22.1   The Action Potential

The main behavior that will be examined in this chapter is the **action potential**. This is a term used to denote a temporal phenomenon exhibited by every electrically excitable cell. A schematic representation of an action potential is shown in Figure 22.1. The transmembrane potential difference of most excitable cells usually stays at some negative potential called the *resting potential*. External current or voltage inputs can cause the potential of the cell to deviate in the positive direction and if the input is large enough the result is an action potential. An action potential is characterized by a **depolarization**, which typically results in an *overshoot*, beyond the 0 mV level (see Figure 22.1) followed by **repolarization**. Some cells may actually *hyperpolarize* before returning to the resting potential.

A key concept in the modeling of excitable cells is the idea of *ion channel selectivity*. A particular type of ion channel will only allow certain ionic species to pass through; most types of ion channels are modeled as being permeant to a single ionic species. In most excitable cells at rest, the membrane is most permeable to potassium. This is because only potassium channels (i.e., channels selective to potassium) are open at the resting potential. For a given stimulus to result in action potential the cell has to be brought to **threshold**, it, that is, the stimulus has to be larger than some critical size; smaller subthreshold stimuli will result in an exponential decay to the resting potential. The upstroke, or fast initial depolarization, of the action potential is caused by a large influx of sodium ions as sodium channels open (in some cells, entry of calcium ions through calcium channels is responsible for the upstroke) in response to a stimulus. This is followed by repolarization as potassium ions starts flowing out of the cell in reponse to the new potential gradient. While responses of most cells to subthreshold inputs are usually linear and passive, the suprathreshold response — the action potential — is a nonlinear phenomenon. Unlike linear circuits where the principle of superposition holds, the nonlinear processes in cell membranes do not allow responses of two stimuli to be added. If an initial stimulus results in an action potential a subsequent stimulus administered at the peak voltage will not produce an even larger action potential; instead it may have no effect at all. Following an action potential most cells have a **refractory period**, during which

they are unable to respond to stimuli. Nonlinear features such as these make modeling of excitable cells a nontrivial task. In addition, the molecular behavior of ion channels includes a stochastic component and is not completely understood, and therefore, it is not feasible to construct membrane models from first principles. The models in this chapter were all constructed using empirical data.

In 1952, Alan Hodgkin and Andrew Huxley published a paper showing how a nonlinear empirical model of the membrane processes could be constructed [Hodgkin and Huxley, 1952]. In the five decades since their work, the Hodgkin–Huxley (abbreviated *HH*) paradigm of modeling cell membranes has been enormously successful. While the concept of ion channels was not established when they performed their work, one of their main contributions was the idea that ion-selective processes existed in the membrane. It is now known that most of the passive transport of ions across cell membranes is accomplished by ion-selective channels. In addition to constructing a nonlinear model, they also established a method to incorporate experimental data into a nonlinear mathematical membrane model.

22.2 Patch Clamp Data

The main source of experimental data used to construct models of cell electrophysiology is the *patch clamp* method [Hamill et al., 1981]. In the *whole-cell* patch clamp configuration, a glass pipette with a very fine tip, typically 1 μm in diameter, containing a solution that is close in ionic composition to the intracellular fluid is brought to the external surface of the cell. A small amount of suction is applied to form at tight seal between the tip of the glass pipette and the membrane and by applying additional suction, the cell membrane under the tip can be ruptured and fluid in the electrode is allowed to come in physical contact with the internal fluid of the cell. With electrical contact thus established between the fluid of the glass pipette and the interior of the cell, it becomes possible to monitor as well as control cell electrical activity using electronic instruments.

The components of cellular electrophysiology can be summarized schematically in Figure 22.2a. Cell membranes may contain ion channels that allow ions to flow down their electrochemical gradient and ion pumps that move ions against their gradients. The various cell membrane channel, pump, and exchanger currents are summed in $I_{ion} = I_{ion}(V_m, \vec{y})$, which is a nonlinear function of V_m and $\vec{y}$, a vector representing the kinetics of the various channels, and so forth. The capacitance of the membrane, C_m, responds to changes in the cell transmembrane potential difference, V_m, with a capacitive current, $I_C = C_m \frac{dV_m}{dt}$. Using Kirchoff's Current Law from electrical circuit theory,

$$I_C + I_{ion} = 0 \tag{22.1}$$

which yields the basic differential equation for the cell transmembrane potential difference, V_m:

$$C_m \frac{dV_m}{dt} = -I_{ion}(V_m \cdot \vec{y}) \tag{22.2}$$

The kinetics of $\vec{y}$ is usually defined by a system of equations of the form:

$$\frac{d\vec{y}}{dt} = F(V_m, \vec{y}) \tag{22.3}$$

Cell patch-clamping allows experimenters to either inject a current while observing the response in V_m, (*current-clamp mode*, Figure 22.2b) or impose a waveform, $V_{clamp}(t)$, on the cell transmembrane potential and observe membrane current, I_m (*voltage-clamp mode*, Figure 22.2). By choosing appropriate voltage-clamp waveforms, $V_{clamp}(t)$, experimenters can make deductions about the structure of the nonlinear function $F(V_m, \vec{y})$ in Equation 22.3. The membrane current measured during voltage-clamp experiments, $I_m(t) = C_m \frac{dV_{clamp}}{dt} + I_{ion}(V_{clamp}, \vec{y})$ is then painstakingly dissected into its essential components due to the various ion channels, pumps, and exchangers by established protocols as well as by trial and error.

(a)   Cell membrane model and circuit equivalent

$$C_m \frac{dV_m}{dt} + I_{ion}(V_m, \vec{y}) = 0$$

$$\frac{d\vec{y}}{dt} = F(V_m, \vec{y})$$

(b)   Current clamp   (c)   Voltage clamp

$$C_m \frac{dV_m}{dt} + I_{ion}(V_m, \vec{y}) = I_{clamp}(t)$$

$$\frac{d\vec{y}}{dt} = F(V_m, \vec{y})$$

$$C_m \frac{dV_{clamp}}{dt} + I_{ion}(V_{clamp}, \vec{y}) = I_m$$

$$\frac{d\vec{y}}{dt} = F(V_{clamp}, \vec{y})$$
FIGURE 22.2 Schematic view of membrane currents and patch clamp techniques. Most cells have a low internal concentration of sodium (Na^+) and a high internal concentration of potassium (K^+) ions while the external concentrations are reversed. Sodium and potassium channels allow these ions to run down their electrochemical gradients while ion pumps can pump these ions against their respective electrochemical gradients. This electrical activity can be represented by an equivalent circuit shown to the left. The cell membrane capacitance is represented by the capacitor C_m and the various ionic currents are added together into a single nonlinear element through which the current I_{ion} passes. Thus the equation of circuit equivalent is: $C_m \frac{dV_m}{dt} + I_{ion}(V_m, \vec{y}) = 0$ and the time-dependent properties of the nonlinearities of I_{ion} are described by the vector equation $\frac{d\vec{y}}{dt} = F(V_m, \vec{y})$. In the *current-clamp* mode of the whole-cell patch clamp configuration, one electrode is used to inject a known current $I_{clamp}(t)$ while the other electrode is used to sense the potential inside the cell. In **voltage-clamp** mode the potential inside the cell is compared to a known voltage supplied by the experimenter and an amplifier is used to supply whatever current is required to keep the cell potential at the specified voltage $V_{clamp}(t)$. The resulting circuit equations are indicated below the circuit diagrams.

Using cloned channels overexpressed in cultured cells or *Xenopus* oocytes, a relatively pure current can be studied in isolation.

22.3 General Formulations of Membrane Currents

In this section we examine the various components common to membrane models. We start with the Nernst–Planck formulation of ion flow across a membrane. Although it is seldom used now, this equation is needed to derive other, more practical models such as the resistor-battery model or the Goldman–Hodgkin–Katz (GHK) current model. Some preliminary remarks are in order before examining these models. At dilute concentrations, ions in aqueous solutions behave like gas molecules. This is why the *gas constant*, R, is ubiquitous in models of ion flow in cells. Similarly, the phenomenon of chemisorption of gas molecules is used as an analog to study the binding of ions (and drug molecules) to receptors in the cell membrane. In chemisorption under equilibrium conditions, the fraction of gas molecules bound to fixed reaction sites is given by an expression of the form: $[C]^n/(k + [C]^n)$ where $[C]$ is the concentration of gas, k is a constant, and n is typically a small positive number. This expression is also derived from Michaelis–Menten type kinetic schemes. Similar terms arise in many membrane models cited in this chapter and they indicate that some fraction of an ionic species, C, is binding to receptor molecules on the cell surface.

22.3.1 Nernst–Planck Equations

One of the most general description of ion flow across a membrane is given by the Nernst–Planck equations. This is a partial differential equation where the independent variables represent space (x) and time (t). The main dependent variable is the concentration of the ion ($c(x, t)$). The potential ($u(x, t)$) is usually a fixed function but can be made a dependent variable in which case an additional equation is required. The Nernst–Planck equations can be written as:

$$\frac{\partial c(x,t)}{\partial t} = \frac{\partial}{\partial x} \frac{\mu(x,t)}{|z|} \left[\frac{RT}{F} \frac{\partial c(x,t)}{\partial x} + zc(x,t)\frac{\partial u}{\partial x}(x,t) \right] \tag{22.4}$$

where the symbols are defined thus:

Variable	Description	Dimensions
R	Gas constant	8314.41 mJ/(mole°K)
T	Temperature	310°K
F	Faraday's constant	96485 C/mole
u	potential	mV
c	ion concentration	$\mathrm{mol\,l^{-1}}$
z	valence of the ion	
E	electric field force	$\mathrm{mV\,m^{-1}}$
μ	ion mobility	$\mathrm{m^2 mV^{-1} sec^{-1}}$

Note that that μ can vary with both space and time depending on the type of ion channel or pump and its gating properties. Due to the complexity of this formulation, it is of limited use when examining behavior at the cellular level but it can be used to derive simpler formulations under certain assumptions as shown in the following section.

22.3.2 Hodgkin–Huxley Resistor Battery Model

This is the model that is most frequently employed to look at ions flowing through channels and is shown in terms of its circuit equivalent in Figure 22.3. This models the passive flow of ions due to a transmembrane
FIGURE 22.3 Circuit representation of membrane current. The conductance can be nonlinear as indicated by the powers p and q on the state variables m_i and h_i, respectively. These state variables are typically time-varying functions of the transmembrane potential difference, V. The battery, E_i represents the electrochemical gradient of the ionic species responsible for the current.

potential gradient, V_m, and a concentration gradient (represented in the battery, E_i) through a nonlinear membrane conductance. From the structure of the circuit, we see that the equation for the current for ionic species i has the form:

$$I_i = G_i m_i^p h_i^q (V_m - E_i) \tag{22.5}$$

where G_i represents the maximum value of the conductance of the membrane, and m_i and h_i are gating variables that vary in time and take values between 0 and 1. p and q are integers that depend on the kinetic characteristics of the membrane channel. For example, in the formulation of the sodium current in the Hodgkin and Huxley (*HH*, see below) equations, the conductance is $G_{Na} m^3 h$, that is, p is 3 and q is 1, and these values were found to result in the best fit with experimental data.

The above expression can be derived from the Nernst–Planck equations with the assumption that concentration does not vary with time. In addition the space dimension of Equation 22.4 is reduced to a two-compartment — cell interior and exterior — model. Thus the steady-state of Equation 22.4 tells us that when there is no net current flow, the transmembrane potential will equal a quantity called the "Nernst" potential: $E_i = (RT/z_i F) \ln([C]_o/[C]_i) \cdot z_i$ is the valence of the ion, $[C_i]_o$ is the concentration of the ion on the outside, and $[C_i]_i$ is the concentration on the inside. Quantities such as ion mobility are effectively lumped into a nonlinear time-varying conductance ($G_i m_i^p h_i^q$).

First order differential equations are used to model the time behavior of m_i and h_i. For example the equation for m_i will have the form:

$$\frac{dm_i}{dt} = \alpha_m (1 - m_i) - \beta_m m_i \tag{22.6}$$

where the α_m and β_m are empirically determined functions of the membrane potential. This equation is also written as: $dm_i/dt = (m_{i\infty} - m_i)/\tau_i$ where $m_{i\infty} = \alpha_m/(\alpha_m + \beta_m)$ and $\tau_i = 1/(\alpha_m + \beta_m)$. Voltage-clamp protocols are used by experiments to characterize $m_{i\infty}$ and τ_i empirically as functions of V_m for a given cell. As a result there is no unique derivation for the differential equations describing the time behavior of the gating variables. $m_{i\infty}$ and τ_i are usually nonlinear functions of voltage. This nonlinear dependence on V_m makes the coupled system of Equation 22.2 and Equation 22.3 a nonlinear system of ordinary differential equations. **Selectivity** is implicitly modeled by assuming that only one ionic species flows though a current branch. A number of current branches, one for each type of ion channel, are connected in parallel to model the interaction of the various ion currents.

Gating variables, ion channel kinetics, and Markov-state models Gating variables such as m_i and h_i earlier model the kinetic behavior of ion channels. For example, in the *HH* equations (see below), the variable "m" is used to model the process of *activation* of the sodium current. At polarized potentials, the

sodium current is turned off: m is close to 0 and therefore the sodium current conductance, $G_{Na} m^3 h$, is close to 0. As the cell depolarizes (V_m increases, see Figure 22.1), the sodium current turns on (activates) and this is modeled as an increase in the value of m until it approaches 1. Concomitant with this activation is a process that desensitizes (inactivates) the sodium current thus guaranteeing that the sodium current is transient. This is modeled using the inactivation variable h, which goes from a resting value of 1 to a value closer to 0 as V_m increases. This decrease in h causes the sodium conductance, $G_{Na} m^3 h$, to decrease even though m may be close to 1. In an excitable cell such as a nerve, skeletal, or cardiac cell, activation of the sodium current causes inward flow of sodium ions resulting in depolarization of the cell; this depolarization further activates the sodium current and a regenerative activation process continues until inactivation desensitizes the current. In the absence of other currents, the cell will stay depolarized but most excitable cells will have an outward potassium current that activates much more slowly than the fast inward sodium current. This outward potassium current causes potassium ions to leave the cell and repolarizes the cell, that is, it brings the transmembrane potential closer to the reversal potential for potassium. The sodium current is affected by repolarization in two ways: it turns off (deactivates) and it becomes resensitized (recovers from inactivation). The deactivation is modeled as a return of the m variable to values close to 0 and the recovery from inactivation is modeled as a return of h to a value closer to 1. These four processes: activation, inactivation, deactivation, and recovery from inactivation are present in many ion channels. Investigations of these processes in squid axons, native mammalian cells, and in cloned channels revealed that the *HH* formulation of these four processes were deficient in at least three ways. First, inactivation was often found to be coupled to activation rather than being independently voltage dependent as in the Hodgkin–Huxley model. Second, multiple steps were involved each of the four processes and these steps could not be adequately modeled using different values for the exponents (p and q above). Third, unlike the HH model, the speed of activation, for instance, is in some cases decoupled from the speed of deactivation. These observations resulted in the need for a more general framework for kinetics and the most commonly used one is Markov-state models [see Hille, 2001].

22.3.3 GHK Constant Field Formulation

From Equation 22.4, assuming that potential varies linearly across the membrane and that the ion flux is constant, we obtain an expression for current flow of the form [Goldman, 1943]:

$$I_i = P_i d_i^p f_i^q \frac{\frac{V_m}{RT/zF}}{1 - e^{-\frac{V_m}{RT/zF}}} \left[[C_i]_i - [C_i]_o e^{-\frac{V_m}{RT/zF}} \right] \tag{22.7}$$

where P_i is the maximum permeability of the membrane and d and f are gating variables such as m and h in Equation 22.5. This equation is frequently used when large concentration gradients are present.

22.3.4 GHK with Correction for Fixed Surface Charge

When surface charge is present on the inside or outside of the cell membrane, the effective potential gradient sensed by the channel is modified by a correction factor, $V_{surface}$, and the current then has the form [Frankenhaeuser, 1960]:

$$I_i = P_i d_i^p f_i^q \frac{\frac{V_m - V_{surface}}{RT/zF}}{1 - e^{-\frac{V_m - V_{surface}}{RT/zF}}} \left[[C_i]_i - [C_i]_o e^{-\frac{V_m - V_{surface}}{RT/zF}} \right] \tag{22.8}$$

22.3.5 Eyring Rate Theory Models of Ionic Currents

An alternative to the Nernst–Planck models of charge diffusion is the rate theory model, which views ion permeation through a channel or pump from a statistical thermodynamics perspective. In this approach, one or more energy barriers are assumed to exist at fixed points in the channel and ions permeate
FIGURE 22.4 Schematic representation of energy barrier in a rate theory model of ionic current. A single energy barrier of height G_b located at a fraction δ of the membrane thickness is assumed in this example.

the channel when the energy of the ions overcomes the energy barrier. The case of one barrier is shown schematically in Figure 22.4. The forward and backward ion flux rates can be described using Boltzmann equations as shown below.

$$k_1 = \nu e^{-(G_b - G_o) - z\delta \frac{V_m}{RT/F}} \tag{22.9}$$

$$k_{-1} = \nu e^{-(G_b - G_i) - z(1-\delta) \frac{V_m}{RT/F}} \tag{22.10}$$

where k_1 is the forward flux rate from the outside to the inside, and k_{-1} is the flux rate in the other direction; ν is some nominal flux; G_o and G_i are the the energies at the external and internal surfaces of the cell membrane; G_b is the height of the energy barrier; z is the valence of the permeating ion; δ is the location of the membrane barrier as measured from the external side of the membrane; V_m is the transmembrane potential difference and is implicitly assumed to vary linearly through the thickness of the membrane; and R, T, and F are as defined earlier. Given these flux rates, we can write the flux equations as

$$\text{influx} = [C]_o k_1 \tag{22.11}$$

$$\text{efflux} = [C]_i k_{-1} \tag{22.12}$$

If the net current is then assumed to be the difference between the efflux and the influx, it can be written as:

$$I_i = \nu \left([C]_i e^{-(G_b - G_i) + z(1-\delta) \frac{V_m}{RT/F}} - [C]_o e^{-(G_b - G_o) - z\delta \frac{V_m}{RT/F}} \right) \tag{22.13}$$

The equations for the case of multiple barriers can be derived in a similar way but are much more tedious to work through.

22.3.6 Ion Pump

Ion pumps are membrane molecules that unlike channels, require energy to function. While the workings of ion pumps can get quite complex especially if the source of energy for these pumps need to be modeled,

most models in use assume a simplied form using Michaelis–Menten terms such as:

$$I_p = I_{p\,max} \frac{[X]_i}{[X]_i + k_x} \frac{[Y]_o}{[Y]_o + k_y}$$

(22.14)

In the above equation, $I_{p\,max}$ is the maximum pump current, $[X]_i$ is the concentration of the ionic species on the inside being pumped out and $[Y]_o$ is the concentration of the ionic species on the outside being pumped in. k_x and k_y represent sensitivities of the pump to these ion concentrations.

22.3.7 Ion Exchangers

Ion exchangers are similar to ion pumps but do not require energy directly. Instead exchangers use the energy stored in a concentration gradient of ion X to transport ion Y in the opposite direction. An example of an exchanger current is the cardiac Na–Ca exhanger, which uses the concentration gradient of sodium (high outside, low inside) to pump one calcium ion out of the cell for every three sodium ions allowed into the cell. An additional difference between exchangers and pumps is that exchangers are more voltage-sensitive and are thus more readily operated in the reverse direction under physiological conditions.

22.3.8 Synapses

Yamada and Zucker [1992] have tested various kinetic mechanisms to model calcium control of presynaptic release of transmitters. The classic model of postsynaptic response to a synaptic input is the so-called *alpha* function due to Rall [1967] and has the form:

$$G(t) = \frac{t - t_0}{t_{peak}} e^{\frac{t - t_0}{t_{peak}}}$$

(22.15)

where G is usually a conductance in a resistor–battery type branch circuit. Although the alpha function is the one that is most commonly used, more detailed schemes have been constructed using kinetic models [Destexhe et al., 1994].

22.3.9 Calcium as a Second Messenger

Calcium entry into a cell frequently has a number of secondary effects such as initiation of contraction, release of neurotransmitters, and modulation of membrane ion channels. This is usually accomplished by the binding of calcium ions to calcium receptors inside the cell. Michaelis–Menten kinetic schemes with steady-state assumptions are used to model this binding and therefore expressions of the form $f = [Ca^{++}]_i^n/([Ca^{++}]_i^n + K)$ are frequently employed. Here f is the fraction of calcium that is bound to the receptor and K is the dissociation constant for the reaction, and n is the number of calcium ions that bind to each receptor molecule.

22.4 Nerve Cells

Nerve cells typically have complex geometries with axons, branching dendrites, spines, and synapses. While it was thought for a long time that dendrites could be modeled using linear resistor–capacitor circuits, it is becoming increasingly clear that nonlinear ionic currents are present in many dendritic trees. Due to technical difficulties in measuring currents in dendrites and synapses directly, most neuronal models in this chapter describe ionic currents of cell soma or axons. Since the Hodgkin–Huxley equations constitutes the basis for membrane modeling, the reader should be familiar with this model before examining the others.

Squid axon: Hodgkin and Huxley Most models of excitable cells are descendents of this model. The basic circuit equivalent of this model comprises a linear capacitance in parallel with three resistor-battery subcircuits (one each for sodium, potassium, and a nonspecific leakage channel). The *HH* equations in their original form were:

$$
\begin{aligned}
C_m \frac{dV}{dt} &= -G_{Na} m^3 h(V - E_{Na}) - G_K n^4 (V - E_K) - G_l (V - E_l) \\
\frac{dm}{dt} &= \alpha_m (1 - m) - \beta_m m \\
\frac{dh}{dt} &= \alpha_h (1 - h) - \beta_h h \\
\frac{dn}{dt} &= \alpha_n (1 - n) - \beta_n n
\end{aligned}
\tag{22.16}
$$

The rate constants were given originally as:

$$
\alpha_m = \frac{(V + 25)/10}{e^{(V+25)/10} - 1}
\tag{22.17}
$$

$$
\beta_m = 4e^{V/18}
\tag{22.18}
$$

$$
\alpha_h = 0.07 e^{V/20}
\tag{22.19}
$$

$$
\beta_h = \frac{1}{e^{(V+30)/10} + 1}
\tag{22.20}
$$

$$
\alpha_n = \frac{1}{10} \frac{(V + 10)/10}{e^{(V+10)/10} - 1}
\tag{22.21}
$$

$$
\beta_n = \frac{e(V/80)}{8}
\tag{22.22}
$$

The physical constants used in these equations are: $G_{Na} = 120$ mS/cm^2, $G_K = 36$ mS/cm^2, $G_l = 0.3$ mS/cm^2, $C_m = 1$ μF/cm^2, $E_{Na} = -115$ mV, $E_K = 12$ mV, and $E_l = -10.613$. The original equations as listed by Hodgkin and Huxley [1952] unfortunately used a sign convention that has not been followed since. Using the sign convention of today for the transmembrane potential, the rate constants can be rewritten by replacing all occurences of V with $-(V_m + 60)$.

The successes of this model include the ability to predict the velocity of action potential propagation when the spatial aspect is included, the continuous nature of the threshold of the nerve, and the repetitive firing behavior seen under the influence of a constant current. A number of remarks should be made regarding this model that hold for other models as well. First, L'Hopital's Rule allows us to compute the value of expressions of the form x/e^{x-1} as in Equation 22.17 at the point $x = 0$. Second, for temperatures other than 6.3°C an acceptable correction is the Q_{10} scaling: multiply each α and β by $\phi = 3^{(T-6.3)/10}$ where the 3 indicates that for each 10°C change in temperature, the speed of the reaction increases threefold (T is in degree Celsius). It has been found that the ratio of 3.33 for $G_{Na} : G_K$ in this model achieves a balance between a quick repolarization and continued excitability.

Toad myelinated neuron Frankenhaeuser and Huxley [1964] modified the *HH* model to describe the fast sodium and delayed rectifier potassium currents with the GHK model rather than the resistor-battery formulation used by Hodgkin and Huxley. In addition they added a small non-specific current to account for inward currents late in action potentials of myelinated neurons of the toad *Xenopus laevis*.

Gastropod neuron The model of Connor and Stevens [1971] used a *HH*-type system of differential equations to model repetitive firing in isolated gastropod neurons. This was the first model to include an inactivating potassium current (the A-type current) that has since been used in a number of other cells.

Aplysia abdominal ganglion R15 cell The bursting behavior of *Aplysia* neurons have been extensively studied. The first model was that of Plant [1976] who extended the *HH* equations to include an inactivating potassium current, a slow potassium current, and a constant hyperpolarizing current due to the Na/K pump. Bertram [1993] modeled bursting in these cells by augmenting an *HH* model with a calcium current, a second delayed rectifier type potassium current, and serotonin-activated inward-rectifying potassium current and a negative slope region calcium current. A detailed model including a fast inward sodium current, fast and slow calcium currents, a delayed rectifier and an inward rectifier potassium currents, a sodium–potassium pump, a sodium–calcium exchanger, a calcium pump, and a leakage current was described in Butera et al. [1995].

CA3 hippocampal pyramidal neurons Traub et al. [1991] have constructed a multicompartment — soma and dendrites — model of hippocampal neurons with upto six membrane currents in each compartment (i) a fast sodium current, (ii) a calcium current, (iii) a delayed rectifier potassium current, (iv) an inactivating (A-type) potassium current, (v) a long-duration calcium-activated potassium current, and (vi) a short-duration calcium-activated potassium current. Furthermore, calcium concentration changes in a restricted space beneath the membrane is modeled using a simplified linear buffering scheme. Good and Murphy [1996] modified this model to include N-, L-, and T-type calcium currents along with an AMPA-activated current and the effects of β-amyloid block of the A-type current. A branching dendritic version of the Traub et al. [1991] model with synaptic input is described in Traub and Miles [1995].

CA1 hippocampal pyramidal neurons A model that accurately predicts accomodation in CA1 neurons was constructed by Warman et al. [1994]. Using the previous work of Traub et al. [1991] and taking experimental data into consideration, they constructed a 16-compartment model with the following membrane currents (i) a fast sodium current, (ii) a calcium current, (iii) a delayed rectifier potassium current, (iv) an inactivating (A-type) potassium current, (v) a long-duration calcium-dependent potassium current, (vi) a short-duration calcium- and voltage-activated potassium current, (vii) a persistent muscarinic potassium current, and (viii) a leakage current. Unlike the Traub model separate pools of calcium were used to modulate the potassium currents. A linear buffering scheme was assumed for both internal calcium pools but the decay times were assumed to be different in each pool.

Stomatogastric ganglion neurons Epstein and Marder [1990] constructed a *HH*-type model of the lobster stomatogastric ganglion neuron with a fast sodium current, a delayed rectifier potassium current a voltage-dependent calcium current, a calcium-dependent potassium current, and a linear leakage current in order to study the mechanism of bursting oscillations in these cells.

Chopper units in the anteroventral cochlear nucleus Banks and Sachs [1991] constructed an equivalent cylinder model of chopper units in the anteroventral cochlear nucleus. The model of the soma membrane included a fast sodium current, a delayed rectifier current, a linear leakage current, and inhibitory and excitatory synaptic currents using the Rall α-wave model.

Lamprey CNS neurons The model of Brodin et al. [1991] consisted of voltage-gated sodium, potassium and calcium currents, a calcium-activated potassium current, and an NMDA receptor channel. The voltage-dependent block by magnesium of the NMDA was also modeled in this paper. Two compartments were used to model calcium concentration changes inside the cells.

Thalamocortical cells Neurons in the thalamocortical systems show various kinds of oscillatory behavior during sleep and wake cycles. It has been shown in the last decade that these neurons interact to produce a wide range of oscillatory activity. Huguenard and McCormick [1992] constructed a model of thalamic relay neurons with (i) a low-threshold transient calcium current, (ii) an inactivating (A-type) potassium current, (iii) a slowly inactivating potassium current, and (iv) a **hyperpolarization**-activated nonspecific current. McCormick and Huguenard [1992] extended the above model to simulate the behavior of thalamocortical relay neurons by adding (i) a fast sodium current, (ii) a persistent sodium current, (iii) a high-threshold calcium current, (iv) a calcium-activated potassium current, and (v) linear leakage currents. Destexhe et al. [1993a,b] have examined similar models as well.

Human node of Ranvier Schwartz et al. [1995] measured action potentials and separated membrane currents in nodes of Ranvier in human nerve trunks. Their model comprises a fast sodium current, fast and slow potassium currents, and a leakage current.

Dopaminergic neurons A minimal model of the soma with a fast sodium current and a delayed rectifier potassium current and a dendritic compartment with a sodium–potassium pump, NMDA-activated current, and leakage current was augmented with an L-type calcium current in the dendritic compartment and an A-type potassium current, T-type calcium current and a calcium-sensitive potassium current in the soma by Li et al. [1996]. An improved model with an additional N-type calcium current and another high-voltage-activated calcium current, a sodium–calcium exchanger, a calcium pump, a hyperpolarization-activated cation current, and cytosolic calcium buffering was constructed by Aminis et al. [1999] and a model focusing on the GABA- and NMDA-mediated currents was published by Komendantov et al. [2004].

Cerebellar granule cells A model of the soma with three sodium currents (a fast, a persistent, and a resurgent current), a high-threshold calcium current, and five potassium currents (fast and slow delayed rectifier currents, an A-type, an inward rectifier, and a calcium-activated potassium current) was constructed by DAngelo et al. [2001].

22.4.1 Sensory Neurons

Rabbit sciatic nerve axons A fast sodium current and a leak current was found to be sufficient to model single action potentials in the nodes of Ranvier of axons from rabbit sciatic nerve by Chiu et al. [1979]. It is likely that this model should be augmented to include potassium currents in order to model trains of action potentials accurately.

Myelinated auditory nerve neuron A detailed model of the morphology of myelination and ion channel distribution was formulated by Colombo and Parkins [1987] using the Frankenhaeuser–Huxley model as a base: it includes a fast sodium current, fast potassium current, a leakage current, and a slow sodium current.

Retinal ganglion cells Fohlmeister et al. [1990] modeled the retinal ganglion cells using a fast inactivating sodium current, a calcium current, a noninactivating (delayed-rectifier) potassium current, an inactivating potassium current, and a calcium-activated potassium current. An important feature in this model is that it models the calcium concentration inside the cell using a simplified buffering scheme and in this way they are able to model the modulation of potassium currents by calcium. A model with separate L-type and N-type calcium currents was constructed by Benison et al. [2001].

Retinal horizontal cells The model of Winslow and Knapp [1991] consisted of a fast sodium current, an inactivating (A-type) potassium current, a noninactivating potssium current, an anomalous rectifier potassium current, a calcium-inactivated calcium current, and a linear leakage current. In addition calcium concentration changes in a restricted region beneath the membrane was also modeled.

Rat Nodose neurons Schild et al. [1994] built a model comprising fast and slow sodium currents, an A-type potassium current, a delayed rectifier potassium current, T- and L-type calcium currents, a calcium-activated potassium current, a slowly inactivating potassium current, a sodium–calcium exchanger, a sodium–potassium pump, a calcium pump current, and background currents. This model was enhanced with descriptions of vesicular storage and release in Schild et al. [1995] and further tuned to fit myelinated and nonmyelinated neurons in Schild and Kunze [1997].

Muscle spindle primary endings Otten et al. [1995] extended the Frankenhaeuser–Huxley model with modifications to reproduce repetitive firing in sensory endings: in addition to the fast sodium current, fast potassium current and leakage currents of the FH model a slowly activating delayed rectifier current was required.

Vertebrate retinal cone photoreceptors A model of vertebrate photoreceptor cells that includes a light-sensitive current, an L-type calcium current, a delayed rectifier potassium current, calcium-sensitive potassium and chloride currents, a hyperpolarization-activated current, a sodium–potassium pump, and a leak current in addition to the response of the cell to a channel blocker was published by Usui et al. [1996].

Primary and secondary sensory neurons of the enteric nervous system A model of primary and secondary afferents with a fast sodium current, an N-type calcium current, a delayed rectifier potassium current,

a calcium-sensitive potassium current, and a chloride current was set up by Miftakhov and Wingate [1996].

Invertebrate photoreceptor neurons The membrane properties of nerve terminals, axons, soma, and microvilli of Type-B photoreceptors of the invertebrate *Hermissenda* were modeled using a fast sodium current, an A-type potassium current, a calcium-dependent potassium current, a delayed rectifier potassium current, a noninactivating calcium current, light-induced sodium and calcium currents, and a leakage current by Fost and Clark [1996].

Fly optic lobe tangential cells Three families of tangential cells of the blowfly were modeled by Haag et al. [1997]. The centrifugal–horizontal cell has an inward calcium current and outward potassium currents. The other cells have a fast sodium current, a delayed rectifier potassium current, and a sodium-dependent potassium current.

Rat mesencephalic trigeminal neurons Negro and Chandler [1997] have constructed a model of sensory neurons involved in brain stem control of jaw musculature. This model of the trigeminal neurons includes a fast sodium current, N- and T-type calcium currents, two A-type potassium currents, a sustained potassium current, a delayed rectifier potassium current, a calcium-dependent potassium current, a hyperpolarization-activated current, and a leakage current.

Primary afferents and related efferents A model comprising a fast sodium current, a delayed rectifier potassium current, a calcium current, and a calcium-dependent potassium current was used to model primary afferents as well as interneurons and efferent neurons connected to the afferents by Saxena et al. [1997]. A modification of the *HH* model was used in Amir et al. [2002] to model A-type dorsal root ganglion neuron cell bodies.

Myelinated Ia primary afferent neurons The intraspinal collateral of a myelinated primary afferent neuron was modeled with a myelination morphology by D'Incamps et al. [1998] and included a fast sodium current, a delayed rectifier potassium current, and a Rall synaptic current at a particular node of Ranvier in the network.

22.4.2 Efferent Neurons

Sympathetic neurons of the superior cervical ganglia Superior cervical ganglion neurons were modeled by Belluzzi and Sacchi [1991] using the following membrane currents (i) sodium currents with fast and slow components, (ii) a GHK-type calcium current, (iii) a delayed rectifier potassium current, (iv) an inactivating (A-type) potassium current, and (v) a calcium-activated potassium current. One drawback of this model is that the calcium activation of the potassium channels was modeled using a fixed time delay rather than by allowing the internal calcium concentration to change.

Small intestine cholinergic and adrenergic neurons Miftakhov and Wingate [1994a] used the *HH* equations (fast sodium current, delayed rectifier potassium current, and a leakage current attributed to chloride channels) and added a system of equations to model the release of the neurotransmitter acetylcholine by the presynaptic terminal. Similarly release of noradrenaline was modeled in Miftakhov and Wingate [1994b].

Pyloric constrictor neurons of the lobster Models of the crab lateral pyloric neuron were modified to include a fast sodium current, an A-type potassium current, a delayed rectifier potassium current, a calcium current, a calcium-dependent potassium current, and a leak current by Harris-Warrick et al. [1995] to examine the effect of the neurotransmitter dopamine on the A-type current. This model was augmented by Harris-Warrick et al. [1995] to include a hyperpolarization-activated current.

Mammalian Spinal Motoneuron Halter et al. [1995] set up a detailed model of myelinated motoneurons with myelination morphology and ionic currents including: a fast sodium current, fast and slow delayed rectifier potassium currents, and a leak current.

Leech heartbeat oscillator Interneuron Interneurons controlling the leech heartbeat were modeled using: a fast sodium current, an A-type potassium current, an inward rectifier current, fast and slowly inactivating calcium currents, a persistent sodium current, a hyperpolarization-activated current, slowly inactivating and persistent potassium currents, and synaptic chloride currents [Nadim et al., 1995].

Snail RPa1 bursting neuron A model including a fast sodium current, a delayed rectifier potassium current, a voltage-dependent calcium current, a voltage- and calcium-dependent calcium current, and a leak current was constructed by Berezetskaya et al. [1996] to investigate the bursting behavior of pacemaker cells of the *Helix pomatia*.

Vertebrate motoneuron Data from motoneurons from various species were put together to construct a generic model of vertebrate motoneurons by Booth et al. [1997]. This model contains a fast sodium current, a delayed rectifier potassium current, L- and N-type calcium currents, and a calcium-dependent potassium current.

Xenopus central pattern generator neuron A model of *Xenopus* embryo swimming central pattern generator neurons with *HH* currents was modified by Tabak and Moore [1998] to include a voltage- and magnesium-sensitive NMDA channel current and a Rall alpha-wave mechanism for non-NMDA postsynaptic currents.

22.5 Skeletal Muscle Cells

Frog Sartorius muscle cell Skeletal muscle cells have a significant amount of current flowing through the cell membrane in the T-tubules of the cells. For this reason, it becomes imperative to model the currents in the T-tubules along with the rest of the cell membrane. The Adrian and Peachey [1973] equations are a system of coupled *HH*-type circuits and thus have a significant spatial component. The equations describing the velocity field have the same structure as the Hodgkin–Huxley equations. Two models were suggested in the paper: if sodium and potassium channels are assumed to exist in the T-tubules, the usual *HH* formulation of the corresponding currents are used; otherwise, only a linear leakage current appears in the voltage equation.

Barnacle muscle Morris and Lecar [1981] sought to model the oscillatory activity in current-clamped barnacle muscle fibers using just two noninactivating currents: a fast calcium current and a potassium current. It should be kept in mind that their model does not take into account the presence of a calcium chelator (EGTA) inside the cells used to obtain experimental results. Their equations have the same general structure as the *HH* equations:

$$C_m \frac{dV}{dt} = -G_L(V - E_L) - G_{Ca}\, m(V - E_{Ca}) - G_K n(V - E_K) \tag{22.23}$$

$$\frac{dm}{dt} = \lambda_m(m_\infty - m) \tag{22.24}$$

$$\frac{dn}{dt} = \lambda_n(m_\infty - n) \tag{22.25}$$

where:

$$m_\infty = \frac{1}{2}\left(1 + \tan h \frac{V - v_1}{v_2}\right) \tag{22.26}$$

$$\lambda_m = \overline{\lambda_m} \cos h \frac{V - v_1}{2v_2} \tag{22.27}$$

$$n_\infty = \frac{1}{2}\left(1 + \tan h \frac{V - v_3}{v_4}\right) \tag{22.28}$$

$$\lambda_n = \overline{\lambda_n} \cos h \frac{V - v_3}{2v_4} \tag{22.29}$$

Typical values of the parameters are: $C_m = 20\ \mu\text{F/cm}^2$, $G_L = 2\ \text{mS/cm}^2$, $G_K = 8\ \text{mS/cm}^2$, $G_{Ca} = 4\ \text{mS/cm}^2$, $E_L = -50\ \text{mV}$, $E_K = -70\ \text{mV}$, $E_{Ca} = 100\ \text{mV}$, $v_1 = 10\ \text{mV}$, $v_2 = 15\ \text{mV}$, $v_3 = 10\ \text{mV}$, $v_4 = 14.5\ \text{mV}$, $\overline{\lambda_m} = 0.1$, and $\overline{\lambda_n} = 0.06667$. An alternative model of the calcium current was also

proposed. Instead of the *HH* resistor-battery type formulation, a GHK formulation was suggested:

$$I_{Ca} = G_{Ca} m \frac{V/12.5}{1 - e^{V/12.5}} \left[1 - \frac{[Ca^{++}]_i}{[Ca^{++}]_o} e^{V/1.25} \right] \tag{22.30}$$

where typical values of $[Ca^{++}]_i$ and $[Ca^{++}]_o$ were 0.001 and 100 mM, respectively.

22.6 Endocrine Cells

Pancreatic β-cells An interesting electrophysiological phenomena occurs in the Islet of Langerhans of the pancreas: the release of insulin is controlled in these islets by trains of action potentials occuring in rapid bursts followed by periods of quiescence. This "bursting" behavior occurs only in intact islets: single cells do not display such bursting activity. Chay and Keizer [1983] was the first attempt to model this phenomenon quantitatively. Sherman et al. [1988] sought to explain the absence of bursting β-cells using the idea of "channel-sharing." Keizer [1988] modified this model by substituting an ATP- and ADP-dependent K channel instead of the Ca-dependent K channel. This model was then further improved by Keizer and Magnus [1989]. Sherman et al. [1990] constructed a domain model to examine the effect of Ca on Ca channel inactivation. Further refinements have been made by Keizer and Young [1993]. A new slowly activating calcium-dependent potassium current and a calcium subspace model was added in Goforth et al. [2002] and Zhang et al. [2003]. A recent model [Fridlyand et al., 2003] incorporates a detailed model of calcium uptake and release and sodium, IP3, and ATP signaling.

Pituitary Gonadotrophs and Corticotrophs Li et al. [1995] have constructed a model of membrane fluxes and calcium release from the endoplasmic reticulum of rat pituitary gonadotrophs. The membrane currents modeled include an L- and T-type calcium currents, delayed rectifier and calcium-sensitive potassium currents and a leak current. A modification of this model was used by LeBeau et al. [1997] to model pituitary corticotroph cells.

22.7 Cardiac Cells

Purkinje fiber Older models of the Purkinje fiber [Noble, 1960, 1962; Noble and Tsien, 1969; McAllister et al., 1975] failed to model the pacemaking currents correctly. Also, external and internal concentration changes were not modeled until the work of DiFrancesco and Noble [1985]. (The original paper contained a number of errors and a corrected listing of the model equations can be found in Varghese and Winslow [1993]). Despite the fact that the magnitude of the changes in calcium concentrations is at odds with recent experimental observations, this model has been very influential in directing modeling efforts. Most cardiac models being constructed now use the DiFrancesco–Noble structure.

Sinoatrial node As was the case with Purkinje fibers, the pacemaking mechanism was not modeled correctly in older models [Yanagihara et al., 1980; Bristow and Clark, 1982] and it was only after the Purkinje fiber model of DiFrancesco and Noble [1985] that accurate models of the sinoatrial node models could be constructed. An excellent summary of these modeling efforts can be found in Wilders et al. [1991] complete with listings of the equations. The most detailed model of sinoatrial node cells to-date is that of Demir et al. [1994]; this model includes a biophysically accurate description of internal calcium buffering and varying extracellular concentrations. A model similar to ones in Wilders et al. [1991] was augmented to model the effects of acetylcholine changes outside sinoatrial node cells by Dokos et al. [1996].

Atrial muscle The first detailed model of the excitation–contraction coupling mechanism in heart cells was constructed by Hilgemann and Noble [1987] and a single cell model was completed by Earm and Noble [1990]. A similarly detailed model of rabbit atrial cells was constructed by Lindblad et al. [1996] and modified to fit data from human atrial cells by Nygren et al. [1998]. Another model of human atrial cells based on the ventricular cell model of Luo and Rudy [1994] but with improved calcium handling equations was formulated by Courtemanche et al. [1998]. The main differences between the Nygren and

Courtemanche models are that the latter uses a steady-state approximation for the calcium buffers and that the relative sizes of the rapid and slow components of the delayed rectifier are reversed.

Ventricular muscle The first model of ventricular cells [Beeler and Reuter, 1977] consisted of (i) a fast inward sodium current, (ii) a slow inward calcium current, (iii) an inward-rectifying potassium current, and (iv) a voltage-dependent potassium current. A simple linear model of calcium buffering was also included. Drouhard and Roberge [1987] improved the Beeler–Reuter model by varying parameters and the equations for the rate constants for sodium activation and inactivation in order to match experimental results. Noble et al. [1991] constructed a model of the guinea-pig ventricular cell by varying parameters in equations for the atrial cell model of Earm and Noble [1990]. Further refinements including better handling of the fast and slow components of the delayed rectifier current and feedback of length and tension changes on the electrophysiology was incorporated in Noble et al. [1998]. Nordin [1993] modified the DiFrancesco and Noble [1985] equations to model ventricular cells. His model included membrane calcium and potassium pumps and subcompartments inside the cell for sodium and calcium concentrations. Luo and Rudy [1991] brought further improvements by including a plateau potassium current and updating all the current characteristics to match data from whole-cell and patch-clamp experiments. A more detailed model with more accurate descriptions of internal calcium concentration changes has also been constructed [Luo and Rudy, 1994]. The main disadvantage of this effort is the formulation of the calcium release current: it depends on the time of the maximum rate of depolarization and activates with a time delay. This was remedied by the model of Jafri et al. [1998] and also by Priebe and Beuckelmann [1998] for human ventricular cells. A model incorporating a Markov-state model of the transient outward current along with the other ionic currents in Jafri et al. [1998] was described in Greenstein et al. [2000] and a significantly more detailed model comprising a number of stochastically activated calcium release units and a Markov-state model formulation of L-type calcium currents was constructed by Greenstein and Winslow [2002].

Amphibian sinus venosus and atrial cells Rasmusson et al. [1990] have constructed a detailed model of the bullfrog sinus venosus pacemaker cells that includes (i) a delayed rectifier potassium current, (ii) a GHK-type calcium current, linear background, (iii) sodium current (iv) calcium current, (v) a Na/K pump current, (vi) a Na/Ca exchanger current, and (vii) a calcium pump current. Calcium binding to troponin, troponin-Mg, and calmodulin was also included in the model. Furthermore, internal and external sodium, calcium, and potassium were also modeled as time-varying quantities. In addition to the features of the sinus venosus cell, the bullfrog atrial cell [Rasmusson et al., 1990] includes a fast sodium current and an inward-rectifying potassium current.

22.8 Epithelial Cells

A detailed model of the slow processes in principal cells of the cortical collecting tubule of the mammalian kidney was built by Tang and Othmer [1996] and includes: sodium, potassium, and chloride channels; a sodium–potassium pump; a calcium pump; a sodium–potassium–chloride cotransporter; and a sodium–calcium exchanger.

22.9 Smooth Muscle

Smooth muscle cells like many other kinds of cells have significant currents carried by pumps and exchangers. A simple model of smooth muscle cell membrane electrical activity was constructed by Gonzalez-Fernandez and Ermentrout [1994]. This model has the same structure as the Morris–Lecar model of barnacle muscle fibers. Besides model parameter differences, the gating variable m was set to its steady-state value of m_∞ and internal calcium was modeled as a time-varying quantity with a simple linear model of internal buffering. A detailed model of electrical activity in smooth muscle of the small bowel with L- and T-type calcium currents, a calcium-dependent potassium current, a delayed rectifier potassium current, and a background chloride current has been published by Miftakhov et al. [1996].

22.10   Plant Cells

The electrophysiology of a number of plant cells have been studied and characterized. A plasmalemmal proton pump, a hydrogen–chloride symporter, inward- and outward-rectifying K^+ currents, and a chloride channel were modeled in the equations representing electrical activity in *Egeria densa* Planchon by Buschmann et al. [1996].

22.11   Simplified Models

There is a large number of papers investigating the dynamics of cell electrophysiology using simplifications of models listed above. A good reason to use simplified models is that mathematical analysis of such models is tractable.

Hill The model constructed by Hill [1936] was one of the earliest differential equation models of nerve electrical activity. While the behavior of this model was compared with experimental observations in animal preparations, the model is a phenomenological one that only reproduced subthreshold responses. Hill's main focus was the modeling of accomodation and he modeled this using a time-varying "threshold," U.

The basic model is a linear differential equation with time being the independent variable and voltage, V, and threshold voltage, U, being the dependent variables:

$$
\dot{V} = \frac{-1}{k}(V - V_{\text{o}}) + I(t)
$$
$$
\dot{U} = \frac{-1}{\lambda}(U - U_{\text{o}}) + \frac{1}{\beta}(V - V_{\text{o}})
$$

$$(22.31)$$

where V_{o} and U_{o} are some steady-state values of voltage and the threshold function; k, λ, and β are relaxation time-constants (k is a few milliseconds and λ and β are a few hundred milliseconds); and $I(t)$ is some time-varying current source. The above equations can be solved using the variation of constants method and Hill documented the responses of the model to various functions, $I(t)$, and various parameter values. Such a model is only of use if one is not interested in suprathreshold behavior.

FitzHugh–Nagumo The FitzHugh–Nagumo equations are also called the Bonhoeffer–Van der Pol equations and have been used as a generic system that shows excitability and oscillatory activity. FitzHugh [1969] showed that much of the behavior of the Hodgkin–Huxley equations can be reproduced by a system of two differential equations:

$$
\dot{V} = V - \frac{V^3}{3} - U + I(t)
$$
$$
\dot{U} = \phi(V - bU + a)
$$

$$(22.32)$$

where a, b, and ϕ are positive constants (typical values are: $a = 0.7$, $b = 0.8$, and $\phi = 0.08$). With no input current ($I = 0$) the system has a stable resting state and at $I = 0.4$ the system exhibits oscillatory activity. This model reproduces excitability, threshold phenomena, and repetitive firing.

Hindmarsh–Rose models The first model of Hindmarsh and Rose [1982a] was an attempt to improve on the FitzHugh–Nagumo model without increasing the number of state variables. In most neurons undergoing repetitive firing, the time between action potentials is usually much greater than the duration of action potentials; however, the FHN model has an action potential duration that is roughly the same order of magnitude as the inter-spike interval. In addition, FHN does not yield a linear current–frequency relationship. These inadequacies were addressed by Hindmarsh and Rose and in their model the action potential duration and the inter-spike interval are closer to experimental recordings. Their model can be

written as:

$$\dot{V} = -a(f(V) - y - I)$$
$$\dot{y} = b(g(V) - y)$$

(22.33)

where the nonlinearities are defined to be: $f(V) = cV^3 + dV^2 + eV + h$ and $g(V) = f(V) - ge^{rV} + s$. The constants used to model action potentials in snail visceral ganglion neurons were: $a = 5400$ MΩ/sec, $b = 30$ sec^{-1}, $c = 0.00017$, $d = 0.001$, $e = 0.01$, $h = 0.1$, $q = 0.022$, $r = 0.088$, and $s = 0.046$.

A second model [Hindmarsh and Rose, 1982b] sought to include the phenomenon of bursting by adding a third variable. The model had the following form:

$$\dot{V} = -aV^3 + bV^2 + y - z + I$$
$$\dot{y} = c - dV^2 - y$$
$$\dot{z} = r(s(V - V_1) - z)$$

(22.34)

where $a = 1$, $b = 3$, $c = 1$, $d = 5$, $r = 0.001$, $s = 1$, and setting $I = 1$ for a short period triggers the bursting response.

Defining Terms

Action potential: A phenomenon involving temporal changes in the transmembrane potential. An action potential is typically characterized by a fast depolarization follwed by a slower repolarization and sometimes hyperpolarization as well.

Depolarization: Depolarization is a process that is said to occur whenever the transmembrane potential becomes more positive than some "resting" potential.

Hyperpolarization: A deviation of the transmembrane potential in the negative direction from a "resting" state is called hyperpolarization.

Ion Channel: An ion channel is a protein molecule embedded in the cell membrane. It is thought to have the structure of a pipe with obstructions that gate the flow of ions into and out of the cell.

Ion Exchanger: An ion exchanger molecule uses the potential energy in the electrochemical gradients to pump one ionic species into the cell and another species out.

Ion Pump: An ion pump molecule uses energy (in the form of ATP molecules) to pump ions against their electrochemical gradients.

Refractory period: A period of time after an action potential during which the cell is unable to undergo another action potential in response to a second stimulus.

Repolarization: Repolarization is a process that usually follows depolarization and causes the transmembrane potential to return to a polarized state.

Selectivity: This is a property of ion channels where a certain type of channel only allows a specific ionic species to pass through it. Some channels are less specific than others and may allow more than one ionic species to pass through it.

Threshold: There is no satisfactory definition or quantitative description of threshold that will work for all conditions. A working definition of threshold would be the state the cell has to reach in order to produce an action potential. It is usually characterized by the strength of an external stimulus required to bring the cell from some initial state to the threshold state. The problem with this definition is that the threshold stimulus will vary considerably depending on the initial state of the cell: the cell may be in a resting state or it may be undergoing repolarization or depolarization.

Transmembrane potential difference: The potential difference between the inside and the outside of a cell manifests itself very close to membrane. In many cases the potential of the external fluid is

taken to be the reference or ground potential and the transmembrane potential difference is the same as the cell potential otherwise also called the membrane potential.

Voltage clamp: This refers to the experimental procedure of using active electronic circuits to hold the transmembrane potential difference at a fixed value by pumping current into the cell.

Further Information

The best introduction to ion channels and excitable behavior in cells can be found in *Ion Channels of Excitable Membranes*, 3rd ed. by Bertil Hille (Sunderland, MA: Sinauer Associates; 2001).

In the case of neurons, *Principles of Neural Science* by Kandel, Schwartz, and Jessell (New York: Elsevier; 1991) is the bible. Detailed discussions of cardiovascular cell membrane phenomena can be found in *The Heart and Cardiovascular System* edited by Fozzard et al. (New York: Raven Press; 1992).

Mathematical analysis of cell models can be found in Guckenheimer et al. (1997); Bertram et al. (1995); and Koch et al. (1995).

Numerical methods: Most of the models presented in this chapter are systems of first-order nonlinear ordinary differential equations. While the solution of linear ordinary differential equations can be written down explicitly, this is usually impossible for nonlinear systems. The only option to investigate the behavior of these solutions is to compute approximate solutions using numerical time-integration. There are a number of numerical methods with varying degrees of accuracy and they fall into two main classes: explicit and implicit methods. The advantage of explicit methods is that they are simpler to implement whereas implicit methods require the use of a nonlinear solver, which can be extremely complicated. The disadvantage of explicit methods is that the errors of these methods are very sensitive to the time-step used and generally very small time-steps are required to ensure accuracy; implicit methods generally allow much larger time-steps. A general guideline would be to try a variable-step explicit method such as a Runge-Kutta method with tight tolerances to control the error; if this proves to be too slow, an implicit method such as the backward difference formula can be used. A good source of integration packages is http://www.netlib.org.

Databases: A number of databases of membrane models are being constructed. The IUPS Physiome project (Hunter et al., 2002) is an attempt to make mathematical models freely available on the internet although tools to translate the stored models (in XML) into machine executable form are not freely available at the time of this writing.

23

Computational Methods and Software for Bioelectric Field Problems

Christopher R. Johnson
University of Utah

23.1 Introduction

Computer modeling and simulation continue to grow more important to the field of Bioengineering. The reasons for this growing importance are manyfold. First, mathematical modeling has shown to be a substantial tool for the investigation of complex biophysical phenomena. Second, since the level of complexity one can model parallels existing hardware configurations, advances in computer architecture have made it feasible to apply the computational paradigm to complex biophysical systems. Hence, while biological complexity continues to outstrip the capabilities of even the largest computational systems, the computational methodology has taken hold in bioengineering and has been used successfully to suggest physiologically and clinically important scenarios and results.

This section provides an overview of numerical techniques which can be applied to a class of bioelectric field problems. Bioelectric field problems are found in a wide variety of biomedical applications which range from single cells [1], to organs [2], up to models which incorporate partial to full human structures [3–5]. We describe some general modeling techniques which will be applicable, in part, to all the

aforementioned applications. We focus our study on a class of bioelectric volume conductor problems which arise in electrocardiography (ECG) and electroencephalography (EEG).

We begin by stating the mathematical formulation for a bioelectric volume conductor, continue by describing the model construction process, and follow with sections on numerical solutions and computational considerations. We conclude with a section on error analysis coupled with a brief introduction to adaptive methods.

23.2 Problem Formulation

As noted in the chapter on Volume Conductor Theory, most bioelectric field problems can be formulated in terms of either the Poisson or the Laplace equation for electrical conduction. Since Laplace's equation is the homogeneous counterpart of the Poisson equation, we will develop the treatment for a general three-dimensional Poisson problem and discuss simplifications and special cases when necessary.

A *typical* bioelectric volume conductor can be posed as the following boundary value problem:

$$\nabla \cdot \sigma \nabla \Phi = -I_V \quad \text{in } \Omega \tag{23.1}$$

where Φ is the electrostatic potential, σ is the electrical conductivity tensor, and I_V is the current per unit volume defined within the solution domain, Ω. The associated boundary conditions depend on what type of problem one wishes to solve. There are generally considered to be two different types of direct and inverse volume conductor problems.

One type of problem deals with the interplay between the description of the bioelectric volume source currents and the resulting volume currents and volume and surface voltages. Here, the problem statement would be to solve Equation 23.1 for Φ with a known description of I_V and the Neumann boundary condition:

$$\sigma \nabla \Phi \cdot \mathbf{n} = 0 \quad \text{on } \Gamma_T \tag{23.2}$$

which says that the normal component of the electric field is zero on the surface interfacing with air (here denoted by Γ_T). This problem can be used to solve two well-known problems in medicine, the direct EEG and ECG volume conductor problems. In the direct EEG problem, one usually discretizes the brain and surrounding tissue and skull. One then assumes a description of the bioelectric current source within the brain (this usually takes the form of dipoles or multipoles) and calculates the field within the brain and on the surface of the scalp. Similarly, in one version of the direct ECG problem, one utilizes descriptions of the current sources in the heart (either dipoles or membrane current source models such as the FitzHugh Nagumo and Beeler Reuter, among others) and calculates the currents and voltages within the volume conductor of the chest and voltages on the surface of the torso. The inverse problems associated with these direct problems involve estimating the current sources I_V within the volume conductor from measurements of voltages on the surface of either the head or body. Thus, one would solve Equation 23.1 with the boundary conditions:

$$\Phi = \Phi_0 \quad \text{on } \Sigma \subseteq \Gamma_T \tag{23.3}$$

$$\sigma \nabla \Phi \cdot \mathbf{n} = 0 \quad \text{on } \Gamma_T \tag{23.4}$$

The first is the Dirichlet condition, which says that one has a set of discrete measurements of the voltage of a subset of the outer surface. The second is the natural Neumann condition. While it does not look much different from the formulation of the direct problem, the inverse formulations are ill-posed. The bioelectric inverse problem in terms of primary current sources does not have a unique solution, and the solution does not depend continuously on the data. Thus, to obtain *useful* solutions, one must try to

restrict the solution domain (i.e., number of physiologically plausible solutions) [6] for the former case, and apply so-called *regularization* techniques to attempt to restore the continuity of the solution on the data in the latter case.

Another bioelectric direct/inverse formulation poses both the problems in terms of scalar values at the surfaces. For the EEG problem, one would take the surface of the brain (cortex) as one bounded surface and the surface of the scalp as the other surface. The direct problem would involve making measurements of voltage of the surface of the cortex at discrete locations and then calculating the voltages on the surface of the scalp. Similarly, for the ECG problem, voltages could be measured on the surface of the heart and used to calculate the voltages at the surface of the torso, as well as within the volume conductor of the thorax. To formulate the inverse problems one uses measurements on the surface of the scalp (torso) to calculate the voltages on the surface of the cortex (heart). Here we solve Laplace's equation instead of Poisson's equation, because we are interested in the distributions of voltages on a surface instead of current sources within a volume. This leads to the following boundary value problem:

$$\nabla \cdot \sigma \nabla \Phi = 0 \quad \text{in } \Omega \tag{23.5}$$

$$\Phi = \Phi_0 \quad \text{on } \Sigma \subseteq \Gamma_T \tag{23.6}$$

$$\sigma \nabla \Phi \cdot \mathbf{n} = 0 \quad \text{on } \Gamma_T \tag{23.7}$$

For this formulation, the solution to the inverse problem is unique [7]; however, there still exists the problem of continuity of the solution on the data. The linear algebraic counterpart to the elliptic boundary value problem is often useful in discussing this problem of noncontinuity. The numerical solution to all elliptic boundary value problems (such as the Poisson and Laplace problems) can be formulated in terms of a set of linear equations, $A\Phi = \mathbf{b}$. For the solution of Laplace's equation, the system can be reformulated as:

$$A\Phi_{\text{in}} = \Phi_{\text{out}} \tag{23.8}$$

where Φ_{in} is the vector of data on the inner surface bounding the solution domain (the electrostatic potentials on the scalp or heart, for example), Φ_{out} is the vector of data which bounds the outer surface (the subset of voltage values on the surface of the cortex or torso, for example), and A is the *transfer matrix* between Φ_{out} and Φ_{in}, which usually contains the geometry and physical properties (conductivities, dielectric constants, etc.) of the volume conductor. The direct problem is then simply (well) posed as solving Equation 23.8 for Φ_{out} given Φ_{in}. Likewise, the inverse problem is to determine Φ_{in} given Φ_{out}.

A characteristic of A for ill-posed problems is that it has a very large condition number. In other words, the ill-conditioned matrix A is very near to being singular. Briefly, the condition number is defined as $\kappa(A) = \|A\| \cdot \|A^{-1}\|$ or the ratio of maximum to minimum singular values measured in the L_2 norm. The ideal problem conditioning occurs for orthogonal matrices which have $\kappa(A) \approx 1$, while an ill-conditioned matrix will have $\kappa(A) \gg 1$. When one inverts a matrix which has a very large condition number, the inversion process is unstable and is highly susceptible to errors. The condition of a matrix is relative. It is related to the precision level of computations and is a function of the size of the problem. For example, if the condition number exceeds a linear growth rate with respect to the size of the problem, the problem will become increasingly ill-conditioned. See Reference 58 for more about the condition number of matrices.

A number of techniques have arisen to deal with ill-posed inverse problems. These techniques include truncated singular value decompostion (TSVD), generalized singular value decompostion (GSVD), maximum entropy, and a number of generalized least squares schemes, including Twomey and Tikhonov regularization methods. Since this section is concerned more with the numerical techniques for approximating bioelectric field problems, the reader is referred to Reference 8 to Reference 11 to further investigate

the regularization of ill-posed problems. A particularly useful reference for discrete ill-posed problems is the Matlab package developed by Per Christian Hansen, which is available via netlib [12].

23.3   Model Construction and Mesh Generation

Once we have stated or derived the mathematical equations which define the physics of the system, we must figure out how to solve these equations for the particular domain we are interested in. Most numerical methods for solving boundary value problems require that the continuous domain be broken up into discrete elements, the so-called *mesh* or *grid*, which one can use to approximate the governing equation(s) using the particular numerical technique (finite element, boundary element, finite difference, or multigrid) best suited to the problem.

Because of the complex geometries often associated with bioelectric field problems, construction of the polygonal mesh can become one of the most time-consuming aspects of the modeling process. After deciding upon the particular approximation method to use (and the most appropriate type of element), we need to construct a mesh of the solution domain which matches the number of degrees of freedom of our fundamental element. For the sake of simplicity, we will assume that we will use linear elements, either tetrahedrons, which are usually used for modeling irregular three-dimensional domains, or hexahedrons used for modeling regular, uniform domains.

There are several different strategies for discretizing the geometry into fundamental elements. For bioelectric field problems, two approaches to mesh generation have become standard: the *divide and conquer* (or subsequent subdivision) strategy; and the so-called *Delaunay triangulation* strategy.

In using the divide and conquer strategy one starts with a set of points which define the bounding surface(s) in three dimensions (contours in two dimensions). The volume (surface) is repeatedly divided into smaller regions until a satisfactory discretization level has been achieved. Usually, the domain is broken up into eight-node cubic elements, which can then be subdivided into five (minimally) or six tetrahedral elements if so desired. This methodology has the advantage of being fairly easy to program; furthermore, commercial mesh generators exist for the divide and conquer method. For use in solving bioelectric field problems, its main disadvantage is that it allows elements to overlap interior boundaries. A single element may span two different conductive regions, for example, when part of an element represents muscle tissue (which could be anisotropic) and the other part of the element falls into a region representing fat tissue. It then becomes very difficult to assign unique conductivity parameters to each element and at the same time accurately represent the geometry.

A second method of mesh generation is the Delaunay triangulation strategy. Given a three-dimensional set of points which define the boundaries and interior regions of the domain to be modeled, one tessellates the point cloud into an optimal mesh of tetrahedra. For bioelectric field problems, the advantages and disadvantages tend to be exactly contrary to those arising from the divide and conquer strategy. The primary advantage is that one can create the mesh to fit any predefined geometry, including subsurfaces, by starting with points which define all the necessary surfaces and subsurfaces and then adding additional interior points to minimize the aspect ratio. For tetrahedra, the aspect ratio can be defined as $4\sqrt{(3/2)}(\rho_k/h_k)$, where ρ_k denotes the diameter of the sphere circumscribed about the tetrahedron, and h_k is the maximum distance between two vertices. These formulations yield a value of 1 for an equilateral tetrahedron and a value of 0 for a degenerate (flat) element [13]. The closer to the value of 1, the better. The Delaunay criterion is a method for minimizing the occurrence of obtuse angles in the mesh, yielding elements which have aspect ratios as close as possible to 1, given the available point set. While the ideas behind Delaunay triangulation are straightforward, the programming is nontrivial and is the primary drawback to this method. Fortunately, there exist several public domain, two-dimensional (2D) versions, including one from netlib called sweep2.c from the directory Voronoi, as well as at least one three-dimensional (3D) package [14]. For more information on mesh generation and various aspects of biomedical modeling, see References 15 to 23.

23.4 Numerical Methods

Because of the geometrical complexity of, and numerous inhomogeneities inherent in, anatomical structures in physiological models, solutions of bioelectric field problems are usually tractable (except in the most simplified of models) only when one employs a numerical approximation method such as the finite difference (FD), the finite element (FE), boundary element (BE), or the multigrid (MG) method to solve the governing field equation(s).

23.4.1 Approximation Techniques — The Galerkin Method

The problem posed in Equation 23.1 can be solved using any of the aforementioned approximation schemes. One technique which addresses three of the previously mentioned techniques (FD, FE, and BE) can be derived by the Galerkin method. The Galerkin method is one of the most widely used methods for discretizing elliptic boundary value problems such as Equation 23.1 and for treating the spatial portion of time-dependent parabolic problems, which are common in models of cardiac wave propagation. While the Galerkin technique is not essential to the application of any of the techniques, it provides for a unifying bridge between the various numerical methods. To express our problem in a Galerkin form, we begin by rewriting Equation 23.1 as:

$$A\Phi = -I_v \tag{23.9}$$

where A is the differential operator, $A = \nabla \cdot (\sigma \nabla)$. An equivalent statement of Equation 23.9 is, find Φ such that $(A\Phi + I_v, \overline{\Phi}) = 0$. Here, $\overline{\Phi}$ is an arbitrary *test function*, which can be thought of physically as a virtual potential field, and the notation $(\phi_1, \phi_2) \equiv \int_\Omega \phi_1 \phi_2 \, d\Omega$ denotes the inner product in $L_2(\Omega)$. Applying Green's theorem, we can equivalently write,

$$(\sigma \nabla \Phi, \nabla \overline{\Phi}) - \left\langle \frac{\partial \Phi}{\partial n}, \overline{\Phi} \right\rangle = -(I_v, \overline{\Phi}) \tag{23.10}$$

where the notation $\langle \phi_1, \phi_2 \rangle \equiv \int_S \phi_1 \phi_2 \, dS$ denotes the inner product on the boundary S. When the Dirichlet, $\Phi = \Phi_0$, and Neumann, $\sigma \nabla \Phi \cdot \mathbf{n} = 0$, boundary conditions are specified on S, we obtain the *weak form* of Equation 23.1:

$$(\sigma \nabla \Phi, \nabla \overline{\Phi}) = -(I_v, \overline{\Phi}) \tag{23.11}$$

It is understood that this equation must hold for all test functions, $\overline{\Phi}$, which must vanish at the boundaries where $\Phi = \Phi_0$. The Galerkin approximation ϕ to the weak form solution Φ in Equation 23.11 can be expressed as:

$$\phi(\mathbf{x}) = \sum_{i=0}^{N} \phi_i \psi_i(\mathbf{x}) \tag{23.12}$$

The trial functions $\psi_i, i = 0, 1, \ldots, N$ form a basis for an $N + 1$ dimensional space $\mathcal{S}$. We define the *Galerkin approximation* to be that element $\phi \in \mathcal{S}$ which satisfies

$$(\sigma \nabla \phi, \nabla \psi_j) = -(I_v, \psi_j) \quad (\forall \psi_j \in \mathcal{S}) \tag{23.13}$$

Since our differential operator A is positive definite and self adjoint (i.e., $(A\Phi, \Phi) \geq \alpha(\Phi, \Phi) > 0$ for some nonzero positive constant α and $(A\Phi, \overline{\Phi}) = (\Phi, A\overline{\Phi})$, respectively), then we can define a space E with an inner product defined as $(\Phi, \overline{\Phi})_E = (A\Phi, \overline{\Phi}) \equiv a(\Phi, \overline{\Phi})$ and norm (the so-called energy norm) equal to:

$$\|\Phi\|_E = \left\{ \int_\Omega (\nabla \Phi)^2 d\Omega \right\}^{1/2} = (\Phi, \Phi)_E^{1/2} \tag{23.14}$$

The solution Φ of Equation 23.9 satisfies

$$(A\Phi, \psi_i) = -(I_v, \psi_i) \quad (\forall \psi_i \in \mathcal{S}) \tag{23.15}$$

and the approximate Galerkin solution obtained by solving (23.13) satisfies

$$(A\phi, \psi_i) = -(I_v, \psi_i) \quad (\forall \psi_i \in \mathcal{S}) \tag{23.16}$$

Subtracting Equation 23.15 from Equation 23.16 yields

$$(A(\phi - \Phi), \psi_i) = (\phi - \Phi, \psi_i)_E = 0 \quad (\forall \psi_i \in \mathcal{S}) \tag{23.17}$$

The difference $\phi - \Phi$ denotes the error between the solution in the infinite dimensional space V and the $N+1$ dimensional space $\mathcal{S}$. Equation 23.17 states that the error is orthogonal to all basis functions spanning the space of possible Galerkin solutions. Consequently, the error is orthogonal to all elements in $\mathcal{S}$ and must therefore be the minimum error. Thus the Galerkin approximation is an orthogonal projection of the true solution Φ onto the given finite dimensional space of possible approximate solutions. Therefore, the Galerkin approximation is the best approximation in the energy space E. Since the operator is positive definite, the approximate solution is unique. Assume for a moment there are two solutions, ϕ_1 and ϕ_2, satisfying

$$(A\phi_1, \psi_i) = -(I_v, \psi_i) \quad (A\phi_2, \psi_i) = -(I_v, \psi_i) \ (\forall \psi_i \in \mathcal{S}) \tag{23.18}$$

respectively. Then, the difference yields

$$(A(\phi_1 - \phi_2), \psi_i) = 0 \quad (\forall \psi_i \in \mathcal{S}). \tag{23.19}$$

The function arising from subtracting one member from another member in $\mathcal{S}$ also belongs in $\mathcal{S}$; hence, the difference function can be expressed by the set of A orthogonal basis functions spanning $\mathcal{S}$:

$$\sum_{j=0}^{N} \Delta\phi_j (A(\psi_j, \psi_i)) = 0 \quad (\forall \psi_i \in) \tag{23.20}$$

When $i \neq j$, the terms vanish due to the basis functions being orthogonal with respect to A. Since A is positive definite:

$$(A\Phi_i, \Phi_i) > 0 \quad i = 0, \ldots, N \tag{23.21}$$

Thus, $\Delta\phi_i = 0$, $i = 0, \ldots, N$, and by virtue of Equation 23.20, $\delta\phi = 0$, such that $\phi_1 = \phi_2$. The identity contradicts the assumption of two distinct Galerkin solutions. This proves the solution is unique [24].

23.4.2 The Finite Difference Method

Perhaps the most traditional way to solve Equation 23.1 utilizes the FD approach by discretizing the solution domain Ω using a grid of uniform hexahedral elements. The coordinates of a typical grid point are $x = lh, y = mh, z = nh$ (l, m, n = integers), and the value of $\Phi(x, y, z)$ at a grid point is denoted by $\Phi_{l,m,n}$. Taylor's theorem can then be utilized to provide the difference equations. For example:

$$\Phi_{l+1,m,n} = \left(\Phi + h\frac{\partial\Phi}{\partial x} + \frac{1}{2}h^2\frac{\partial^2\Phi}{\partial x^2} + \frac{1}{6}h^3\frac{\partial^3\Phi}{\partial x^3} + \cdots \right)_{l,m,n} \tag{23.22}$$

with similar equations for $\Phi_{l-1,m,n}, \Phi_{l,m+1,n}, \Phi_{l,m-1,n,\ldots}$. The finite difference representation of Equation 23.1 is

$$
\frac{\Phi_{l+1,m,n} - 2\Phi_{l,m,n} + \Phi_{l-1,m,n}}{h^2} + \frac{\Phi_{l,m+1,n} - 2\Phi_{l,m,n} + \Phi_{l,m-1,n}}{h^2}
$$

$$
+ \frac{\Phi_{l,m,n+1} - 2\Phi_{l,m,n} + \Phi_{l,m,n-1}}{h^2} = -I_{l,m,n}(\nu) \tag{23.23}
$$

or, equivalently,

$$
\Phi_{l+1,m,n} + \Phi_{l-1,m,n} + \Phi_{l,m+1,n} + \Phi_{l,m-1,n} + \Phi_{l,m,n+1} + \Phi_{l,m,n-1} - 6\Phi_{l,m,n} = -h^2 I_{l,m,n}(\nu) \tag{23.24}
$$

If we define the vector $\boldsymbol{\Phi}$ to be $[\Phi_{1,1,1} \cdots \Phi_{1,1,N-1}; \cdots \Phi_{1,N-1,1} \cdots \Phi_{N-1,N-1,N-1}]^T$ to designate the $(N-1)^3$ unknown grid values, and pull out all the known information from Equation 23.24, we can reformulate Equation 23.1 by its finite difference approximation in the form of the matrix equation $A\boldsymbol{\Phi} = \mathbf{b}$, where $\mathbf{b}$ is a vector which contains the sources and modifications due to the Dirichlet boundary condition.

Unlike the traditional Taylor's series expansion method, the Galerkin approach utilizes basis functions, such as linear piecewise polynomials, to approximate the true solution. For example, the Galerkin approximation to the sample problem Equation 23.1 would require evaluating Equation 23.13 for the specific grid formation and specific choice of basis function:

$$
\int_{\Omega} \left(\sigma_x \frac{\partial \phi}{\partial x} \frac{\partial \psi_i}{\partial x} + \sigma_y \frac{\partial \phi}{\partial y} \frac{\partial \psi_i}{\partial y} + \sigma_z \frac{\partial \phi}{\partial z} \frac{\partial \psi_i}{\partial z} \right) d\Omega = - \int_{\Omega} I_\nu \psi_i d\Omega \tag{23.25}
$$

Difference quotients are then used to approximate the derivatives in Equation 23.25. We note that if linear basis functions are utilized in Reference 23.25, one obtains a formulation which corresponds exactly with the standard finite difference operator. Regardless of the difference scheme or order of basis function, the approximation results in a linear system of equations of the form $A\boldsymbol{\Phi} = \mathbf{b}$, subject to the appropriate boundary conditions.

23.4.3 The Finite Element Method

As we have seen above, in the classical numerical treatment for partial differential equations — the FD difference method — the solution domain is approximated by a grid of uniformly spaced nodes. At each node, the governing differential equation is approximated by an algebraic expression which references adjacent grid points. A system of equations is obtained by evaluating the previous algebraic approximations for each node in the domain. Finally, the system is solved for each value of the dependent variable at each node. In the FE method, the solution domain can be discretized into a number of uniform or nonuniform finite elements that are connected via nodes. The change of the dependent variable with regard to location is approximated within each element by an interpolation function. The interpolation function is defined relative to the values of the variable at the nodes associated with each element. The original boundary value problem is then replaced with an equivalent integral formulation (such as Equation 23.13). The interpolation functions are then substituted into the integral equation, integrated, and combined with the results from all other elements in the solution domain. The results of this procedure can be reformulated into a matrix equation of the form $A\boldsymbol{\Phi} = \mathbf{b}$, which is subsequently solved for the unknown variable [16,25].

The formulation of the finite element approximation starts with the Galerkin approximation, $(\sigma\nabla\Phi, \nabla\overline{\Phi}) = -(I_\nu, \overline{\Phi})$, where $\overline{\Phi}$ is our test function. We now use the finite element method to turn the continuous problems into a discrete formulation. First we discretize the solution domain, $\Omega = \cup_{e=1}^{E} \Omega_e$, and define a finite dimensional subspace, $V_h \subset V = \{\overline{\Phi} : \overline{\Phi}$ is continuous on Ω, $\nabla\overline{\Phi}$ is piecewise continuous on $\Omega\}$. One usually defines parameters of the function $\overline{\Phi} \in V_h$ at node points $\alpha_i = \overline{\Phi}(x_i)$, $i = 0, 1, \ldots, N$. If we now define the basis functions, $\psi_i \in V_h$, as linear continuous

piecewise functions that take the value 1 at node points and zero at other node points, then we can represent the function $\overline{\Phi} \in V_h$ as

$$\overline{\Phi}(x) = \sum_{i=0}^{N} \alpha_i \Psi_i(x) \qquad (23.26)$$

such that each $\overline{\Phi} \in V_h$ can be written in a unique way as a linear combination of the basis functions $\Psi_i \in V_h$. Now the finite element approximation of the original boundary value problem can be stated as

$$\text{Find } \Phi_h \in V_h \text{ such that } (\sigma \nabla \Phi_h, \nabla \overline{\Phi}) = -(I_v, \overline{\Phi}) \qquad (23.27)$$

Furthermore, if $\Phi_h \in V_h$ satisfies Equation 23.27, then we have $(\sigma \nabla \Phi_h, \nabla \Psi_i) = -(I_v, \Psi_i)$ [26]. Finally, since Φ_h itself can be expressed as the linear combination

$$\Phi_h = \sum_{i=0}^{N} \xi_i \Psi_i(x) \quad \xi_i = \Phi_h(x_i) \qquad (23.28)$$

we can then write Equation 23.27 as

$$\sum_{i=0}^{N} \xi_i(\sigma_{ij} \nabla \Psi_i, \nabla \Psi_j) = -(I_v, \Psi_j) \quad j = 0, \dots, N \qquad (23.29)$$

subject to the Dirichlet boundary condition. Then the finite element approximation of Equation 23.1 can equivalently be expressed as a system of N equations with N unknowns $\xi_i, \dots, \xi_N$ (e.g., the electrostatic potentials). In matrix form, the above system can be written as $A\xi = b$, where $A = (a_{ij})$ is called the global stiffness matrix and has elements $(a_{ij}) = (\sigma_{ij} \nabla \Psi_i, \nabla \Psi_j)$, while $b_i = -(I_v, \Psi_i)$ and is usually termed the load vector.

For volume conductor problems, A contains all of the geometry and conductivity information of the model. The matrix A is symmetric and positive definite; thus, it is nonsingular and has a unique solution. Because the basis function differs from zero for only a few intervals, A is sparse (only a few of its entries are nonzero).

23.4.3.1 Application of the FE Method for 3D Domains

We now illustrate the concepts of the FE method by considering the solution of Equation 23.1 using linear 3D elements. We start with a 3D domain Ω which represents the geometry of our volume conductor and break it up into discrete elements to form a finite dimensional subspace, Ω_h. For 3D domains we have the choice of representing our function as either tetrahedra,

$$\tilde{\Phi} = \alpha_1 + \alpha_2 x + \alpha_3 y + \alpha_4 z \qquad (23.30)$$

or hexahedra,

$$\tilde{\Phi} = \alpha_1 + \alpha_2 x + \alpha_3 y + \alpha_4 z + \alpha_5 xy + \alpha_6 yz + \alpha_7 xz + \alpha_8 xyz \qquad (23.31)$$

Because of space limitations we restrict our development to tetrahera, knowing that it is easy to modify our formulae for hexahedra. We take out a specific tetrahedra from our finite dimensional subspace and apply the previous formulations for the four vertices,

$$\begin{pmatrix} \tilde{\Phi}_1 \\ \tilde{\Phi}_2 \\ \tilde{\Phi}_3 \\ \tilde{\Phi}_4 \end{pmatrix} = \begin{pmatrix} 1 & x_1 & y_1 & z_1 \\ 1 & x_2 & y_2 & z_2 \\ 1 & x_3 & y_3 & z_3 \\ 1 & x_4 & y_4 & z_4 \end{pmatrix} \begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \alpha_3 \\ \alpha_4 \end{pmatrix} \qquad (23.32)$$

or

$$\tilde{\mathbf{\Phi}}_{\mathbf{i}} = \mathbf{C}\alpha \tag{23.33}$$

which define the coordinate vertices, and

$$\alpha = \mathbf{C}^{-1}\tilde{\mathbf{\Phi}}_{\mathbf{i}} \tag{23.34}$$

which defines the coefficients. From Equation 23.30 and Equation 23.34 we can express $\tilde{\Phi}$ at any point within the tetrahedra,

$$\tilde{\Phi} = [1, x, y, z]\alpha = \mathbf{S}\alpha = \mathbf{S}\mathbf{C}^{-1}\tilde{\mathbf{\Phi}}_{\mathbf{i}} \tag{23.35}$$

or, most succinctly,

$$\tilde{\Phi} = \sum_i N_i \tilde{\Phi}_i \tag{23.36}$$

$\tilde{\Phi}_i$ is the solution value at node i, and $\mathbf{N} = \mathbf{S}\mathbf{C}^{-1}$ is the local *shape function* or *basis function*. This can be expressed in a variety of ways in the literature (depending, usually, on whether you are reading engineering or mathematical treatments of finite element analysis):

$$\Phi_j(N_i) = N_i(x, y, z) = f_i(x, y, z) \equiv \frac{a_i + b_i x + c_i y + d_i z}{6V} \tag{23.37}$$

where

$$6V = \begin{vmatrix} 1 & x_1 & y_1 & z_1 \\ 1 & x_2 & y_2 & z_2 \\ 1 & x_3 & y_3 & z_3 \\ 1 & x_4 & y_4 & z_4 \end{vmatrix} \tag{23.38}$$

defines the volume of the tetrahedra, V.

Now that we have a suitable set of basis functions, we can find the finite element approximation to our 3D problem. Our orginal problem can be formulated as

$$a(u, v) = (I_v, v) \quad \forall v \in \Omega \tag{23.39}$$

where

$$a(u, v) = \int_{\Omega} \nabla u \cdot \nabla v \, d\Omega \tag{23.40}$$

and

$$(I_v, v) = \int_{\Omega} I_v \cdot v \, d\Omega \tag{23.41}$$

The finite element approximation to the original boundary value problem is

$$a(u_h, v) = (I_v, v) \quad \forall v \in \Omega_h \tag{23.42}$$

which has the equivalent form

$$\sum_{i=1}^{N} \xi_i a(\Phi_i, \Phi_j) = (I_v, \Phi_j) \tag{23.43}$$

where

$$a(\Phi_i, \Phi_j) = a(\Phi_i(N_j), \Phi_j(N_i)) \tag{23.44}$$

which can be expressed by the matrix and vector elements

$$(a_{ij}) = \int_{\Omega_E} \left(\frac{\partial N_i}{\partial x}\frac{\partial N_j}{\partial x} + \frac{\partial N_i}{\partial y}\frac{\partial N_j}{\partial y} + \frac{\partial N_i}{\partial z}\frac{\partial N_j}{\partial z} \right) d\Omega \tag{23.45}$$

and

$$I_i = \int_{\Omega_E} N_i I_v \, d\Omega \tag{23.46}$$

Fortunately, the above quantities are easy to evaluate for linear tetrahedra. As a matter of fact, there are closed form solutions for the matrix elements (a_{ij}):

$$\int_{\Omega_h} N_1^a N_2^b N_3^c N_4^d \, d\Omega = 6V \frac{a!b!c!d!}{(a+b+c+d+3)!} \tag{23.47}$$

Therefore,

$$(a_{ij}) = \int_{\Omega_E} \frac{b_i b_j + c_i c_j + d_i d_j}{6V^2} \, d\Omega = \frac{b_i b_j + c_i c_j + d_i d_j}{6V} \tag{23.48}$$

and, for the right-hand side (RHS), we have, assuming constant sources,

$$I_i = \int_{\Omega_E} \frac{a_i + b_i x + c_i y + d_i z}{6V} I_v \, d\Omega = \frac{V I_v}{4} \tag{23.49}$$

which have the compact forms

$$a_{ij}^{(n)} = \frac{1}{6V} \left(b_i^{(n)} b_j^{(n)} + c_i^{(n)} c_j^{(n)} + d_i^{(n)} d_j^{(n)} \right) \tag{23.50}$$

and

$$I_i^{(n)} = \frac{V I_v}{4} \quad \text{for constant sources} \tag{23.51}$$

Now we add up all the contributions from each element into a global matrix and global vector.

$$\sum_{n=1}^{\text{Nel}} \left(a_{ij}^{(n)} \right) (\xi_i) = \left(I_i^{(n)} \right) \tag{23.52}$$

where Nel is equal to the total number of elements in the discretized solution domain and i represents the node numbers (vertices). This yields a linear sytem of equations of the form $\mathbf{A\Phi} = \mathbf{b}$, where $\mathbf{\Phi}$ is our solution vector of voltages, $\mathbf{A}$ represents the geometry and conductivity of our volume conductor, and $\mathbf{b}$ represents the contributions from the current sources and boundary conditions.

For the FD method, it turns out that the Dirichlet boundary condition is easy to apply while the Neumann condition takes a little extra effort. For the FE method it is just the opposite. The Neumann boundary condition

$$\nabla \Phi \cdot \mathbf{n} = 0 \tag{23.53}$$

is satisfied automatically within the Galerkin and variational formulations. This can be seen by using Green's divergence theorem,

$$\int_{\Omega} \nabla \cdot \mathbf{A} \, dx = \int_{\Gamma} \mathbf{A} \cdot \mathbf{n} \, dS \tag{23.54}$$

and applying it to the left-hand side (LHS) of the Galerkin finite element formulation:

$$\int_\Omega \nabla v \cdot \nabla w \, d\Omega \equiv \int_\Omega \left[\frac{\partial v}{\partial x_1} \frac{\partial w}{\partial x_1} + \frac{\partial v}{\partial x_2} \frac{\partial w}{\partial x_2} \right] d\Omega$$

$$= \int_\Gamma \left[v \frac{\partial w}{\partial x_1} n_1 + v \frac{\partial w}{\partial x_2} n_2 \right] dS - \int_\Omega v \left[\frac{\partial^2 w}{\partial x_1^2} + \frac{\partial^2 w}{\partial x_2^2} \right] d\Omega$$

$$= \int_\Gamma v \frac{\partial w}{\partial n} \, dS - \int_\Omega v \nabla^2 w \, d\Omega \tag{23.55}$$

If we multiply our original differential equation, $\nabla^2 \Phi = -I_v$, by an arbitrary test function and integrate, we obtain

$$(I_v, v) = -\int_\Omega (\nabla^2 \Phi) v \, d\Omega = -\int_\Gamma \frac{\partial \Phi}{\partial n} v \, dS + \int_\Omega \nabla \Phi \cdot \nabla v \, d\Omega = a(\Phi, v) \tag{23.56}$$

where the boundary integral term, $\partial \Phi / \partial n$ vanishes and we obtain the standard Galerkin finite element formulation.

To apply the Dirichlet condition, we have to work a bit harder. To apply the Dirichlet boundary condition directly, one usually modifies the (a_{ij}) matrix and b_i vector such that one can use standard linear system solvers. This is accomplished by implementing the following steps:

Assuming we know the ith value of u_i:

1. Subtract from the ith member of the RHS the product of a_{ij} and the known value of Φ_i (call it $\bar{\Phi}_i$) this yields the new RHS, $\hat{b}_i = b_i - a_{ij}\bar{\Phi}_j$
2. Zero the ith row and column of A: $\hat{a}_{ij} = \hat{a}_{ji} = 0$
3. Assign $\hat{a}_{ii} = 1$
4. Set the jth member of the RHS equal to $\bar{\Phi}_i$
5. Continue for each Dirichlet condition
6. Solve the augmented system, $\hat{A}\Phi = \hat{b}_v$

23.4.4 The Boundary Element Method

For bioelectric field problems with isotropic domains (and few inhomogeneities), another technique, called the BE method, may be utilized. This technique utilizes information only upon the boundaries of interest, and thus reduces the dimension of any field problem by one. For differential operators, the response at any given point to sources and boundary conditions depends only on the response at neighboring points. The FD and FE methods approximate differential operators defined on subregions (volume elements) in the domain; hence, direct mutual influence (connectivity) exists only between neighboring elements, and the coefficient matrices generated by these methods have relatively few nonzero coefficients in any given matrix row. As is demonstrated by Maxwell's laws [27], equations in differential forms can often be replaced by equations in integral forms; for example, the potential distribution in a domain is uniquely defined by the volume sources and the potential and current density on the boundary. The BE method utilizes this fact by transforming the differential operator defined in the domain to integral operators defined on the boundary. In the boundary element method [28–30], only the boundary is discretized; hence, the mesh generation is considerably simpler for this method than for the volume methods. Boundary solutions are obtained directly by solving the set of linear equations; however, potentials and gradients in the domain can be evaluated only after the boundary solutions have been obtained. As this method has a rich history in bioelectric field problems, the reader is referred to some of the classic references for further information regarding the application of the BE method to bioelectric field problems [31–34].

23.4.5   Solution Methods and Computational Considerations

Application of each of the previous approximation methods to Equation 23.1 yields a system of linear equations of the form $\mathbf{A\Phi} = \mathbf{b}$, which must be solved to obtain the final solution. There are a plethora of available techniques for the solutions of such systems. The solution techniques can be broadly catagorized as *direct* and *iterative* solvers. Direct solvers include Gaussian elimination and LU decomposition, while iterative methods include Jacobi, Gauss-Seidel, successive overrelaxation (SOR),and conjugate gradient (CG) methods, among others. The choice of the particular solution method is highly dependent upon the approximation technique employed to obtain the linear system, upon the size of the resulting system, and upon accessible computational resources. For example, the linear system resulting from the application of the FD or FE method will yield a matrix $\mathbf{A}$ that is symmetric, positive definite, and sparse. The matrix resulting from the FD method will have a specific band-diagonal structure which is dependent on the order of difference equations one uses to approximate the governing equation. The matrix resulting from the FE method will be exceedingly sparse that only a few of the off-diagonal elements will be nonzero. The application of the BE method, on the other hand, will yield a matrix $\mathbf{A}$ that is dense and nonsymmetric and thus requires a different choice of solver.

The choice of the optimal solver is further complicated by the size of the system vs. access to computational resources. Sequential direct methods are usually confined to single workstations and thus the size of the system should fit in memory for optimal performance. Sequential iterative methods can be employed when the size of the system exceeds the memory of the machine; however, one pays a price in terms of performance as direct methods are usually much faster than iterative methods. In many cases, the size of the system exceeds the computational capability of a single workstation and one must resort to the use of clusters of workstations or parallel computers.

While new and improved methods continue to appear in the numerical analysis literature, the author's studies comparing various solution techniques for direct and inverse bioelectric field problems have resulted in the conclusion that the preconditioned CG methods and MG methods are the best overall performers for volume conductor problems computed on single workstations. Specifically, the incomplete Choleski conjugate gradient (ICCG) method works well for the FE method[1] and the preconditioned bi-conjugate gradient (BCG) methods are often utilized for BE methods. When clusters of workstations and parallel architectures are considered, the choice is less clear. For use with some high-performance architectures that contain large amounts of memory, parallel direct methods such as LU decomposition become attractive; however, preconditioned CG methods still perform well.

A discussion of parallel computing methods for the solution of biomedical field problems could fill an entire text. Thus, the reader is directed to the following references on parallel scientific computing [35–37].

23.4.6   Comparison of Methods

Since we do not have space to give a detailed, quantitative description of each of the aforementioned methods, we give an abbreviated summary of the applicability of each method in solving different types of bioelectric field problems.

As outlined above, the FD, FE, and BE methods can all be used to approximate the boundary value problems which arise in biomedical research problems. The choice depends on the nature of the problem. The FE and FD methods are similar in that the entire solution domain must be discretized, while with the BE method only the bounding surfaces must be discretized. For regular domains, the FD method is generally the easiest method to code and implement, but the FD method usually requires special modifications to define irregular boundaries, abrupt changes in material properties, and complex boundary conditions. While typically more difficult to implement, the BE and FE methods are preferred for problems with irregular, inhomogeneous domains, and mixed boundary conditions. The FE method is superior to the

---

[1] This is specifically for the FE method applied to elliptic problems. Such problems yield a matrix which is symmetric and positive definite. The Choleski decomposition only exists for symmetric, positive definite matrices.

BE method for representing nonlinearity and true anisotropy, while the BE method is superior to FE method for problems where only the boundary solution is of interest or where solutions are wanted in a set of highly irregularly spaced points in the domain. Because the computational mesh is simpler for the BE method than for the FE method, the BE program requires less book-keeping than a FE program. For this reason BE programs are often considered easier to develop than FE programs; however, the difficulties associated with singular integrals in the BE method are often highly underestimated. In general, the FE method is preferred for problems where the domain is highly heterogeneous, whereas the BE method is preferred for highly homogeneous domains.

23.5 Adaptive Methods

Thus far we have discussed how one formulates the problem, discretizes the geometry, and finds an approximate solution. We are now faced with answering the difficult question pertaining to the accuracy of our solution. Without reference to experimental data, how can we judge the validity of our solutions? To give yourself an intuitive feel for the problem (and possible solution), consider the approximation of a 2D region discretized into triangular elements. We will apply the FE method to solve Laplace's equation in the region.

First, consider the approximation of the potential field $\Phi(x, y)$ by a 2D Taylor's series expansion about a point (x, y):

$$
\Phi(x + h, y + k) = \Phi(x, y) + \left[h \frac{\partial \Phi(x, y)}{\partial x} + k \frac{\partial \Phi(x, y)}{\partial y} \right]
$$
$$
+ \frac{1}{2!} \left[h^2 \frac{\partial^2 \Phi(x, y)}{\partial^2 x} + 2hk \frac{\partial^2 \Phi(x, y)}{\partial x \partial y} + k^2 \frac{\partial^2 \Phi(x, y)}{\partial^2 y} \right] + \cdots \qquad (23.57)
$$

where h and k are the maximum x and y distances within an element. Using the first two terms (up to first-order terms) in the above Taylor's expansion, we can obtain the standard linear interpolation function for a triangle:

$$
\frac{\partial \Phi(x_i, y_i)}{\partial x} = \frac{1}{2A} [\Phi_i(y_j - y_m) + \Phi_m(y_i - y_j) + \Phi_j(y_m - y_i)] \qquad (23.58)
$$

where A is the area of the triangle. Likewise, one could calculate the interpolant for the other two nodes and discover that

$$
\frac{\partial \Phi(x_i, y_i)}{\partial x} = \frac{\partial \Phi(x_j, y_j)}{\partial x} = \frac{\partial \Phi(x_m, y_m)}{\partial x} \qquad (23.59)
$$

is constant over the triangle (and thus so is the gradient in y as well). Thus, we can derive the standard linear interpolation formulas on a triangle which represent the first two terms of the Taylor's series expansion. This means that the error due to discretization (from using linear elements) is proportional to the third term of the Taylor's expansion:

$$
\epsilon \approx \frac{1}{2!} \left[h^2 \frac{\partial^2 \Phi(x, y)}{\partial^2 x} + 2hk \frac{\partial^2 \Phi(x, y)}{\partial x \partial y} + k^2 \frac{\partial^2 \Phi(x, y)}{\partial^2 y} \right] \qquad (23.60)
$$

where Φ is the exact solution. We can conjecture, then, that the error due to discretization for first-order linear elements is proportional to the second derivative. If Φ is a linear function over the element, then the first derivative is a constant and the second derivative is zero and there is no error due to discretization. This implies that the gradient must be constant over each element. If the function is not linear, or the gradient is not constant over an element, the second derivative will not be zero and is proportional to the error incurred due to "improper" discretization. Examining Equation 23.60 we can easily see that one way to decrease the error is to decrease the size of h and k. As h and k go to zero, the error tends to zero as well. Thus, decreasing the mesh size in places of high errors due to high gradients decreases the error. Besides,

we note that if one divides Equation 23.9 by h/k, one can also express the error in terms of the elemental aspect ratio h/k, which is a measure of the relative shape of the element. It is easy to see that one must be careful to maintain an aspect ratio as close as possible to unity.

The problem with the preceding heuristic argument is that one has to know the exact solution a priori before one can estimate the error. This is certainly a drawback considering the fact that we are trying to accurately approximate Φ.

23.5.1 Convergence of a Sequence of Approximate Solutions

Let us try to quantitfy our error a bit further. When we consider the preceding example, it seems to make sense that if we increase the number of degrees of freedom (DOF) we used to approximate our function, the accuracy must approach the true solution. That is, we would hope that the sequence of approximate solutions will *converge* to the exact solution as the number of DOF increases indefinitely:

$$\|\Phi(x) - \tilde{\Phi}_n(x)\| \to 0 \quad \text{as } N \to \infty \tag{23.61}$$

This is a statement of *pointwise convergence*. It describes the approximate solution as approaching arbitrarily close to the exact solution at each point in the domain as the number of DOF increases.

Measures of convergence often depend on how the *closeness* of measuring the distance between functions is defined. Another common description of measuring convergence is *uniform convergence*, which requires that the maximum value of $\|\Phi(x) - \tilde{\Phi}_n(x)\|$ in the domain vanish as $N \to \infty$. This is stronger than pointwise convergence as it requires a uniform rate of convergence at every point in the domain. Two other commonly used measures are *convergence in energy* and *convergence in mean*, which involve measuring an *average* of a function of the pointwise error over the domain [38].

In general, proving pointwise convergence is very difficult except in the simplest cases, while proving the convergence of an averged value, such as energy, is often easier. Of course, scientists and engineers are often much more interested in assuring that their answers are accurate in a pointwise sense than in an energy sense because they typically want to know values of the solution $\Phi(x)$ and gradients, $\nabla\Phi(x)$ at specific places.

One intermediate form of convergence is called the *Cauchy convergence*. Here, we require the sequences of two different approximate solutions to approach arbitrarily close to each other:

$$\|\Phi_m(x) - \tilde{\Phi}_n(x)\| \to 0 \quad \text{as } M, N \to \infty \tag{23.62}$$

While the pointwise convergence expression would imply the previous equation, it is important to note that the Cauchy convergence does not imply pointwise convergence, as the functions could converge to an answer other than the true solution.

While we cannot be assured pointwise convergence of these functions for all but the simplest cases, there do exist theorems that ensure that a sequence of approximate solutions must converge to the exact solution (assuming no computational errors) if the basis functions satisfy certain conditions. The theorems can only ensure convergence in an average sense over the entire domain, but it is usually the case that if the solution converges in an averge sense (energy, etc.), then it will converge in the pointwise sense as well.

23.5.1.1 Energy Norms

The error in energy, measured by the *energy norm*, is defined in general as [39–41]

$$\|e\| = \left(\int_\Omega e^T L e \, \mathrm{d}\Omega \right)^{1/2} \tag{23.63}$$

where $e = \Phi(x) - \tilde{\Phi}_n(x)$ and L is the differential operator for the governing differential equation (i.e., it contains the derivatives operating on $\Phi(x)$ and any function multiplying $\Phi(x)$). For physical problems this is often associated with the energy density.

Another common measure of convergence utilizes the L_2 norm. This can be termed the average error and can be associated with errors in any quantity. The L_2 norm is defined as

$$\|e\|_{L_2} = \left(\int_\Omega e^T e \, d\Omega \right)^{1/2} \tag{23.64}$$

While the norms given above are defined on the whole domain, one can note that the square of each can be obtained by summing element contributions,

$$\|e\|^2 = \sum_{i=1}^{M} \|e\|_i^2 \tag{23.65}$$

where i represents an element contribution and m the total element number. Often for an *optimal* finite element mesh, one tries to make the contributions to this square of the norm equal for all elements.

While the absolute values given by the energy or L_2 norms have little value, one can construct a relative percentage error that can be more readily interpreted:

$$\eta = \frac{\|e\|}{\|\Phi\|} \times 100 \tag{23.66}$$

This quantity, in effect, represents a weighted RMS error. The analysis can be determined for the whole domain or for element subdomains. One can use it in an adaptive algorithm by checking element errors against some predefined tolerance, η_0, and increasing the DOF only of those areas above the predefined tolerance.

Two other methods, the p and the hp methods, have been found, in most cases, to converge faster than the h method. The p method of refinement requires that one increase the order of the basis function that was used to represent the interpolation (i.e., linear to quadratic to cubic, etc.). The hp method is a combination of the h and p methods and has recently been shown to converge the fastest of the three methods (but, as you might imagine, it is the hardest to implement). To find out more about adaptive refinement methods, see References 23, 26, 37, 38, and 41–43.

23.6 Software for Bioelectric Field Problems

23.6.1 SCIRun

In the past few years, there have been a number of research software systems that have been created for the computational study of biomedical problems, including bioelectric field problems. These include ECGSIM [45], EEGLAB [46], BrainStorm [47], CardioWave[48], SCIRun [49], and BioPSE [50].

In this section, I give a brief overview of the SCIRun and BioPSE problem-solving environments and give examples of their use for the solution of bioelectric field problems.

The SCIRun[2] software system is an integrated, extensible, visualization-driven, open source, problem solving environment that has been developed at the University of Utah's Scientific Computing and Imaging Institute [51].

---

[2] SCIRun is pronounced "ski-run" and derives its name from the Scientific Computing and Imaging (SCI) Institute, which is pronounced "ski" as in "Ski Utah."

For an application developer, SCIRun provides a software platform, upon which other applications can be rapidly constructed. SCIRun provides native support for interprocess communication, resource management (e.g., thread migration, memory management), and parallel computing. These operating system type services enable the dataflow aspects of the system. In addition to these low-level services, SCIRun also provides a number of built-in libraries and data structures that developers can use and can build upon. And at the highest level, SCIRun provides a rich set of algorithms for modeling, simulation, and visualization. All of these levels of functionality can be leveraged by the developer when constructing new algorithms or applications in SCIRun [49].

The application program interface (API) to SCIRun is the visual dataflow environment called the network editor. Within the network editor, programs can be visually assembled from the library of available algorithms. The dataflow network for a sample bioelectric field simulation is shown in Figure 23.1.

The boxes in the network are called *modules*, and the lines connecting them are called *datapipes*. The point of attachment, where a datapipe attaches to a module, is called a *dataport*; the dataports on the tops of the modules are input ports, and the ports on the bottoms of the modules are output ports. In SCIRun, the dataports are color-coded to indicate the type of the data. For example, the blue datapipes are for Matrices, and the yellow datapipes are for Fields. Fields are used to represent 3D geometry, as well as the data values that are defined over that geometry. Taken as a whole, the collection of modules and datapipes in a dataflow application is called a *network*, or *net*. Each module can have an optional user-interface (UI) button on its module; if the user presses the UI button, a separate window appears, with controls for viewing and modifying the state of the module's parameters.

23.6.2 BioPSE

SCIRun comes with a set of general purpose modules that are not specific to any particular application. Modules can also be generated for a specific application, or for adding a set of optional functionality (such as raster data processing), in which case they are organized into a *package*. The package that has been primarily used and extended in this work is called BioPSE [50]. BioPSE stands for biomedical problem solving environment, and contains all of the functionality that is specific to bioelectric field problems.

The example network in Figure 23.1, is solving a bioelectric field problem for a dipolar source in a volume conductor model of a head. The domain is discretized with linear tetrahedral finite elements, with five different conductivity types assigned through the volume. The problem is numerically approximated with a linear system, and is solved using the CG method. A set of virtual electrode points are rendered as pseudocolored spheres, to visualize the potentials at those locations on the scalp, and an iso-potential surface and several pseudocolored electric field streamlines are also shown.

The BioPSE network implements this simulation and visualization with a collection of interconnected modules. The tetrahedral finite element mesh with conductivity values is read in with one of the FieldReaders. That Field is then passed into the SetupFEMatrix module, which produces a stiffness matrix, $\mathbf{A}$, as output. The RHS of the linear system, $\mathbf{b}$, is generated by the ApplyFEMCurrentSource module, which applies the dipole source as a boundary condition. The linear system $\mathbf{A\Phi} = \mathbf{b}$ is then solved by the SolveMatrix module to recover the potentials at all of the nodes in the domain. This solution is then attached to the geometry with the ManageFieldData module, and the results are visualized. A complete description of this application is available in the tutorial section of the SCIRun User's Guide, and can be downloaded from the SCI Institute's website [52].

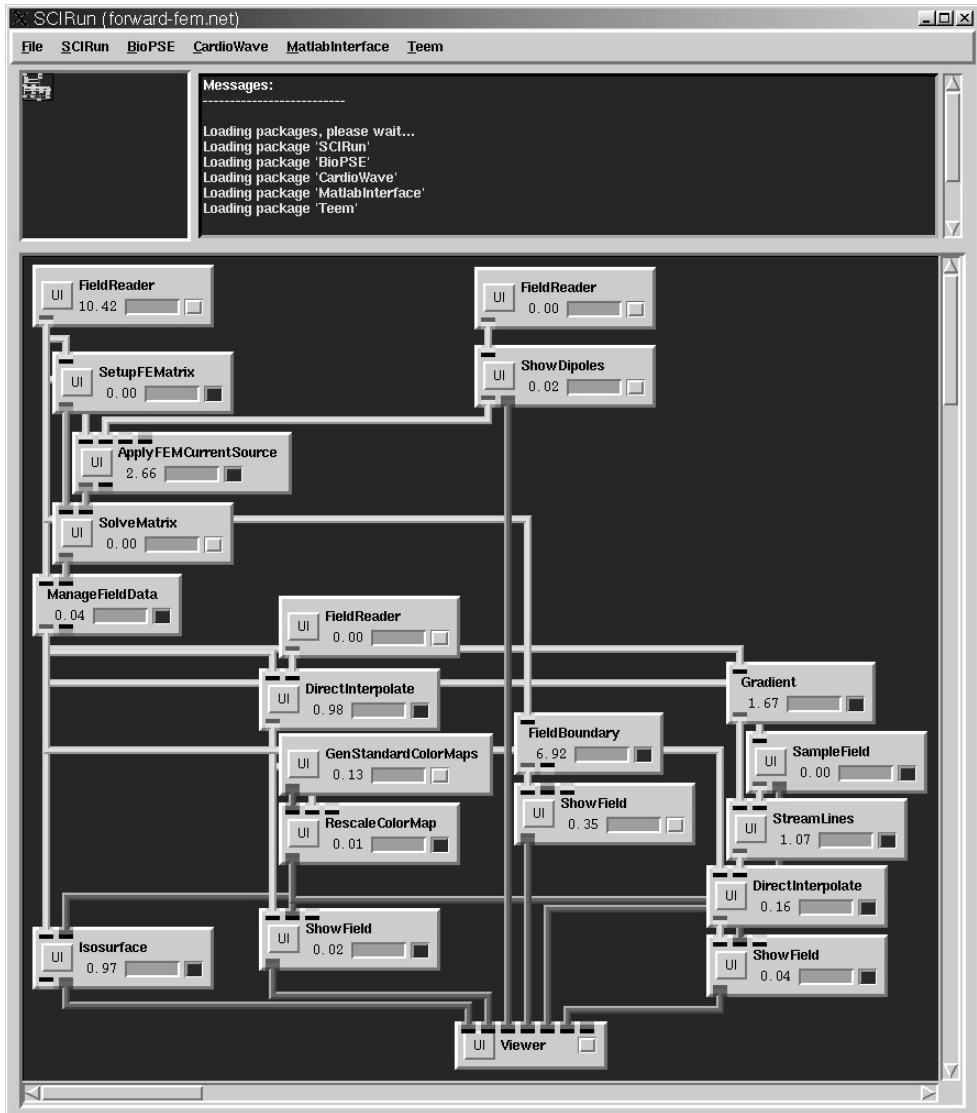
In addition to the BioPSE modules that appear in the above net, BioPSE also contains modules for generating and using finite element lead fields, for constructing separating surfaces from segmented volumes or planar contours, for running BEM simulations, and for visualizing lead potentials over time.


FIGURE 23.1   (See color insert following page 32-14.) BioPSE dataflow network for modeling, simulating, and visualizing the bioelectric field generated in a realistic head model, due to a single dipole source.

23.6.3 PowerApps

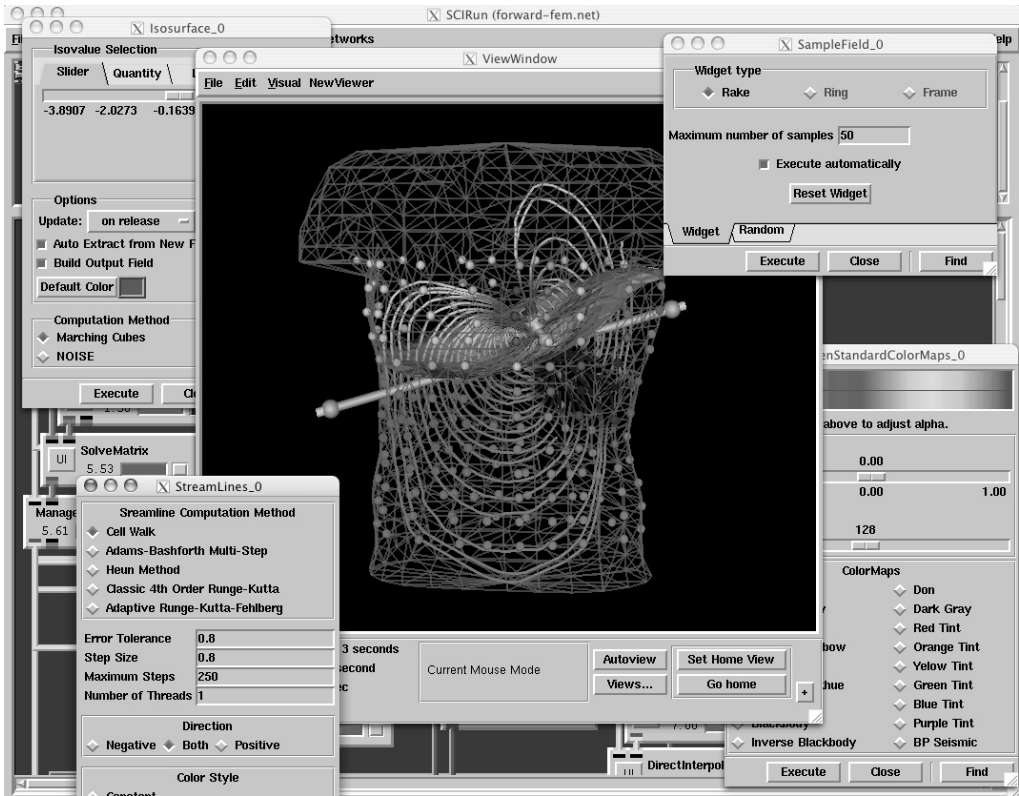
Historically, one of the major hurdles to SCIRun becoming a tool for the scientist as well as the engineer has been SCIRun's dataflow interface. While visual programming is natural for computer scientists and engineers, who are accustomed to writing software and building algorithmic pipelines, it is overly cumbersome for application scientists. Even when a dataflow network implements a specific application (such as the forward bioelectric field simulation network provided with BioPSE and detailed in the BioPSE Tutorial), the UI components of the network are presented to the user in separate UI windows, without any semantic context for their settings. For example, SCIRun provides file browser UIs for reading in data. However, on the dataflow network all of the file browsers have the same generic presentation. Historically, there has not been a way to present the filename entries in their semantic context, for example to indicate that one entry should identify the electrodes input file and another should identify the finite element mesh file.


FIGURE 23.2   (See color insert following page 32-14.) BioPSE dataflow interface to the forward bioelectric field application. The underlying dataflow network implements the application with modular interconnected components called modules. Data are passed between the modules as input and output parameters to the algorithms. While this is a useful interface for prototyping, it is nonintuitive for end-users; it is confusing to have a separate UI window to control the settings for each module. Moreover, the entries in the UI windows fail to provide semantic context for their settings. For example, the text-entry field on the SampleField UI that is labeled "Maximum number of samples" is controlling the number of electric field streamlines that are produced for the visualization.

While this interface shortcoming has long been identified, it has only recently been addressed. With the 1.20 release of BioPSE/SCIRun (in October 2003), we introduced *PowerApps*. A PowerApp is a customized interface built atop a dataflow application network. The dataflow network controls the execution and synchronization of the modules that comprise the application, but the generic UI windows are replaced with entries that are placed in the context of a single application-specific interface window.

With the 1.20 release of BioPSE, we released a PowerApp called BioFEM. BioFEM has been built atop the dataflow network shown in Figure 23.1, and provides a useful example for demonstrating the differences between the dataflow and PowerApp views of the same functionality. In Figure 23.2, the dataflow version of the application is shown: the user has separate interface windows for controlling different aspects of the simulation and visualization. In contrast, the PowerApp version is shown in Figure 23.3: here, the application has been wrapped up into a single interface window, with logically arranged and semantically labeled UI elements composed within panels and notetabs.

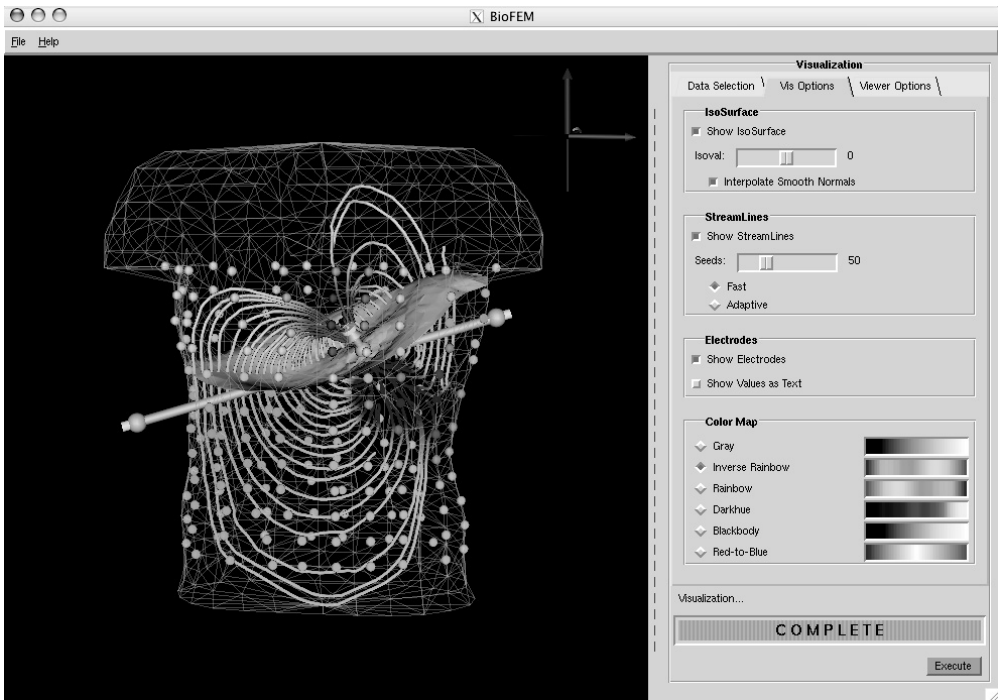
In addition to bioelectric field problems, the BioPSE system can also be used to investigate other biomedical applications. For example, we have wrapped the tensor and raster data processing functionality of the Teem toolkit into the Teem package of BioPSE, and we have used that increased functionality to develop the BioTensor PowerApp, as seen in Figure 23.4. BioTensor presents a customized interface to a 140-module dataflow network. With BioTensor the user can visualize diffusion weighted imaging (DWI) datasets in order to investigate the anisotropic structure of biological tissues. The application supports


FIGURE 23.3 (See color insert following page **32**-14.) The BioFEM custom interface. Though the application is functionality equivalent to the dataflow version shown in Figure 23.1 and Figure 23.2, this PowerApp version provides an easier-to-use custom interface. Everything is contained within a single window; the user is lead through the steps of loading and visualizing the data with the tabs on the right; and generic control settings have been replaced with contextually appropriate labels; and application-specific tooltips (not shown) appear when the user places the cursor over any UI element.
FIGURE 23.4 (See color insert following page **32**-14.) The BioTensor PowerApp. Just as with BioFEM, we have wrapped up a complicated dataflow network into a custom application. In the left panel, the user is guided through the stages of loading the data, co-registering the diffusion weighted images, and constructing diffusion tensors. On the right panel, the user has controls for setting the visualization options. In the rendering window in the middle, the user can render and interact with the dataset.

the import of DICOM and Analyze datasets, and implements the latest diffusion tensor visualization techniques, including superquadric glyphs [53] and tensorlines [54] (both shown).

Principles of Electrocardiography

Edward J. Berbari
Indiana University-Purdue University

24.1 Introduction

The electrocardiogram (ECG) is the recording on the body surface of the electrical activity generated by the heart. It was originally observed by Waller in 1889 [1] using his pet bulldog as the signal source and the capillary electrometer as the recording device. In 1903 Einthoven [2] enhanced the technology by using the string galvanometer as the recording device and using human subjects with a variety of cardiac abnormalities. Einthoven is chiefly responsible for introducing some concepts still in use today including the labeling of the various waves, defining some of the standard recording sites using the arms and legs, and developing the first theoretical construct whereby the heart is modeled as a single time-varying dipole. We also owe the "EKG" acronym to Einthoven's native Dutch language where the root word "cardio" is spelled with a "k."

In order to record an ECG waveform, a differential recording between two points on the body are made. Traditionally each differential recording is referred to as a lead. Einthoven defined three leads numbered with the Roman numerals I, II, and III. They are defined as:

$$I = V_{\text{LA}} - V_{\text{RA}}$$

$$II = V_{\text{LL}} - V_{\text{RA}}$$

$$III = V_{\text{LL}} - V_{LA}$$

where RA = right arm, LA = left arm, LL = left leg. Because the body is assumed to be purely resistive, at ECG frequencies, the four limbs can be thought of as wires attached to the torso. Hence, lead I could be recorded from the respective shoulders without a loss of cardiac information. Note that these are not independent and the following relationship II = I + III holds.

24-1

$$I = V_{RA} - V_{LA}$$

$$II = V_{RA} - V_{LL}$$

$$III = V_{LA} - V_{LL}$$

$$aVL = \frac{2V_{LA} - V_{RA} - V_{LL}}{2}$$

$$aVR = \frac{2V_{RA} - V_{LA} - V_{LL}}{2}$$

$$aVF = \frac{2V_{LL} - V_{LA} - V_{RA}}{2}$$

$$V_i = v_i - V_w$$

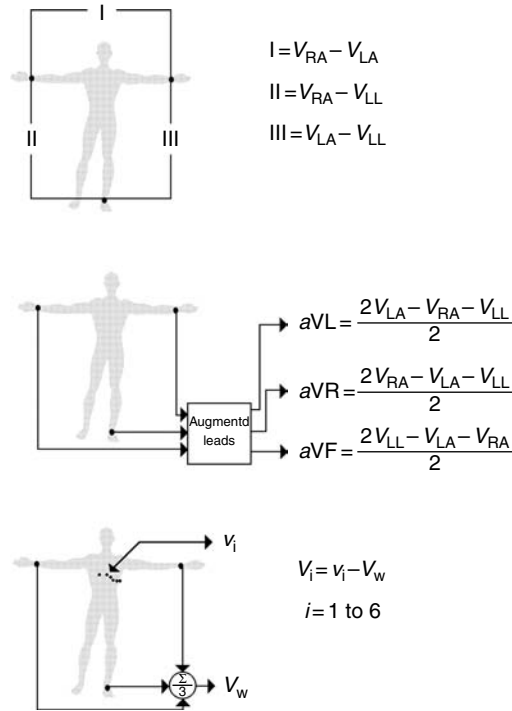
$$i = 1 \text{ to } 6$$


FIGURE 24.1 The 12-lead ECG is formed by the three bipolar surface leads: I, II, and III; the augmented Wilson terminal referenced limb leads: aVR, aVL, aVF; and the Wilson terminal referenced chest leads: V_1, V_2, V_3, V_4, V_5, and V_6.

For 30 years the evolution of the ECG proceeded when F.N. Wilson [3] added concepts of a "unipolar" recording. He created a reference point by tying the three limbs together and averaging their potentials so that individual recording sites on the limbs or chest surface would be differentially recorded with the same reference point. Wilson extended the biophysical models to include the concept of the cardiac source enclosed within the volume conductor of the body. He erroneously thought that the central terminal was a true zero potential. However, from the mid-1930s until today the 12 leads composed of the 3 limb leads, 3 leads in which the limb potentials are referenced to a modified Wilson terminal (the augmented leads [4]), and 6 leads placed across the front of the chest and referenced to the Wilson terminal form the basis of the standard 12-lead ECG. Figure 24.1 summarizes the 12-lead set. These sites are historically based, have a built in redundancy, and are not optimal for all cardiac events. The voltage difference from any two sites will record an ECG, but it is these standardized sites with the massive 90-year collection of empirical observations that has firmly established their role as the standard. Figure 24.2 is a typical or stylized ECG recording from lead II. Einthoven chose the letters of the alphabet from P–U to label the waves and to avoid conflict with other physiologic waves being studied at the turn of the century. The ECG signals are typically in the range of ∀2 mV and require a recording bandwidth of 0.05 to 150 Hz. Full technical specification for ECG equipment has been proposed by both the American Heart Association [5] and the Association for the Advancement of Medical Instrumentation [6].

There have been several attempts to change the approach for recording the ECG. The vectorcardiogram used a weighted set of recording sites to form an orthogonal *XYZ* lead set. The advantage here was minimum lead set but in practice it gained only a moderate degree of enthusiasm among physicians. Body surface mapping refers to the use of many recording sites (>64) arranged on the body so that isopotential surfaces could be computed and analyzed over time. This approach still has a role in research investigations. Other subsets of the 12-lead ECG are used in limited mode recording situations such as the tape-recorded ambulatory ECG (usually 2 leads) or in intensive care monitoring at the bedside
FIGURE 24.2 This is a stylized version of a normal lead II recording showing the P wave, QRS complex, and the T and U waves. The PR interval and the ST segment are significant time windows. The peak amplitude of the QRS is about 1 mV. The vertical scale is usually 1 mV/cm. The time scale is usually based on millimeter per second scales with 25 mm/sec being the standard form. The small boxes of the ECG are 1×1 mm^2.

(usually 1 or 2 leads) or telemetered within regions of the hospital from patients who are not confined to bed (1 lead). The recording electronics of these ECG systems have followed the typical evolution of modern instrumentation, for example, vacuum tubes, transistors, ICs, and microprocessors.

Application of computers to the ECG for machine interpretation was one of the earliest uses of computers in medicine [7]. Of primary interest in the computer-based systems was the replacement of the human reader and the elucidation of the standard waves and intervals. Originally this was performed by linking the ECG machine to a centralized computer via phone lines. The modern ECG machine is completely integrated with an analog front end, a 12–16 bit A/D converter, a computational microprocessor, and dedicated I/O processors. These systems compute a measurement matrix derived from the 12-lead signals and analyze this matrix with a set of rules to obtain the final set of interpretive statements [8]. Figure 24.3 shows the ECG of a heartbeat and the types of measurements that might be made on each of the component waves of the ECG and used for classifying each beat type and the subsequent cardiac rhythm. The depiction of the 12 analog signals and this set of interpretive statements form the final output with an example shown in Figure 24.4. The physician will over-read each ECG and modify or correct those statements that are deemed inappropriate. The larger hospital-based system will record these corrections and maintain a large database of all ECGs accessible by any combination of parameters, for example, all males, older than 50, with an inferior myocardial infarction.

There are hundreds of interpretive statements from which a specific diagnosis is made for each ECG, but there are only about five or six major classification groups for which the ECG is used. The first step in analyzing an ECG requires the determination of the rate and rhythm for the atria and ventricles. Included here would be any conduction disturbances either in the relationship between the various chambers or within the chambers themselves. Then one would proceed to identify features that would relate to the presence or absence of scarring due to a myocardial infarction. There may also be evidence of acute events occurring that would occur with ischemia or an evolving myocardial infarction. The ECG has been a primary tool for evaluating chamber size or enlargement, but one might argue that more accurate information in this area would be supplied by noninvasive imaging technologies.

More recently the high resolution ECG has been developed whereby the digitized ECG is signal averaged to reduce random noise [9,10]. This approach, coupled with postaveraging high-pass filtering, is used to
FIGURE 24.3   The ECG depicts numerous measurements that can be made with computer-based algorithms. These are primarily durations, amplitudes, and areas. (This figure is courtesy of the Hewlett Packard Co., Palo Alto, CA.)
FIGURE 24.4   This is an example of an interpreted 12 lead ECG. A 2.5 sec recording is shown for each of the 12 leads. The bottom trace is a continuous 10 sec rhythm strip of lead II. Patient information is given in the top area, below which is printed the computerized interpretive statements. (Diagram is courtesy of GE Healthcare Technologies, Waukesha, WI.)

detect and quantify low-level signals (1.0 μV) not detectable with standard approaches. This computer-based approach has enabled the recording of events which are predictive of future life-threatening cardiac events [11,12].

24.2 Physiology

The heart has four chambers, the upper two chambers are called the atria and the lower two chambers are called the ventricles. The atria are thin-walled, low-pressure pumps that receive blood from venous circulation. Located in the top right atrium are a group of cells which act as the primary pacemaker of the heart. Through a complex change of ionic concentration across the cell membranes (the current source) an extracellular potential field is established which then excites neighboring cells and a cell-to-cell propagation of electrical events occur. Because the body acts as a purely resistive medium these potential fields extend to the body surface [13]. The character of the body surface waves depends upon the amount of tissue activating at one time and the relative speed and direction of the activation wave front. Therefore the pacemaker potentials which are generated by a small tissue mass are not seen on the ECG. As the activation wave front encounters the increased mass of atrial muscle, the initiation of electrical activity is observed on the body surface and the first ECG wave of the cardiac cycle is seen. This is the P wave and it represents activation of the atria. Conduction of the cardiac impulse proceeds from the atria through a series of specialized cardiac cells (the A–V node and the His–Purkinje system), which again are too small in total mass to generate a signal large enough to be seen on the standard ECG. There is a short relatively isoelectric segment following the P wave. Once the large muscle mass of the ventricles is excited, a rapid and large deflection is seen on the body surface. The excitation of the ventricles causes them to contract and provides the main force for circulating blood to the organs of the body. This large wave appears to have several components. The initial downward deflection is called the Q wave, the initial upward deflection is the R wave, and the terminal downward deflection is the S wave. The polarity and actual presence of these three components depends upon the position of the leads on the body as well as a multitude of abnormalities that may exist. In general the large ventricular waveform is generically called the QRS complex regardless of its makeup. Following the QRS complex is another relatively short isoelectric segment. After this short segment the ventricles return to their electrical resting state and a wave of repolarization is seen as a low-frequency signal called the T wave. In some individuals a small peak occurs at the end or after the T wave and is called the U wave. Its origin has never been fully established but is believed to be a repolarization potential.

24.3 Instrumentation

The general instrumentation requirements for the ECG have been addressed by professional societies through the years [5,6]. Briefly they recommend a system bandwidth between 0.05 and 150 Hz. Of great importance in ECG diagnosis is the low-frequency response of the system because shifts in some of the low-frequency regions, for example, the ST segment, have critical diagnostic value. While the heart rate may only have a 1 Hz fundamental frequency, the phase response of typical analog high-pass filters are such that the system corner frequency must be much smaller than the 3 db corner frequency where only the amplitude response is considered. The system gain depends upon the total system design. The typical ECG amplitude is ± 2 mV and if A/D conversion is used in a digital system, then enough gain to span the only 20% of the A/D converter's dynamic range is needed. This margin allows for recording abnormally large signals as well as accommodating base line drift if present and not corrected.

To first obtain an ECG the patient must be physically connected to the amplifier front end. The patient/amplifier interface is formed by a special bioelectrode that converts the ionic current flow of the body to the electron flow of the metallic wire. These electrodes typically rely on a chemical paste or gel with a high ionic concentration. This acts as the transducer at the tissue–electrode interface. For short-term applications the use of silver-coated suction electrodes or "sticky" metallic foil electrodes are

used. Long-term recordings, such as the case for the monitored patient, require a stable electrode/tissue interface and special adhesive tape material surrounds the gel and an Ag^+/Ag^+Cl electrode.

At any given time, the patient may be connected to a variety of devices, for example, respirator, blood pressure monitor, temporary pacemaker, etc., some of which will invade the body and provide a low resistance pathway to the heart. It is essential that the device not act as a current source and inject the patient with enough current to stimulate the heart and cause it to fibrillate. Some bias currents are unavoidable for the system input stage and recommendations are that these leakage currents be less than $10\,\mu A$ per device. In recent years, there has been some controversy regarding the level of allowable leakage current. The Association for the Advancement of Medical Instrumentation [5] has written its standards to allow leakage currents as high as $50\,\mu A$. Recent studies [14,15] have shown that there may be complex and lethal physiological response to 60 Hz currents as low as $32\,\mu A$. In light of the reduced standards these research results were commented on by members of the American Heart Association Committee on Electrocardiography [16].

There is also $10\,\mu A$ maximum current limitation due to a fault condition if a patient comes in contact with the high voltage side of the AC power lines. In this case the isolation must be adequate to prevent $10\,\mu A$ of fault current as well. This mandates that the ECG reference ground not be connected physically to the low side of the AC power line or its third ground wire. For ECG machines the solution has typically been to AM modulate a medium-frequency carrier signal (400 kHz) and use an isolation transformer with subsequent demodulation. Other methods of signal isolation can be used but the primary reason for the isolation is to keep the patient from being part of the AC circuit in the case of a patient to power line fault. In addition, with many devices connected in a patient-monitoring situation it is possible that ground loop currents will be generated. To obviate this potential hazard a low-impedance ground buss is often installed in these rooms and each device chassis will have an external ground wire connected to the buss. Another unique feature of these amplifiers is that they must be able to withstand the high-energy discharge of a cardiac defibrillator.

Older-style ECG machines recorded one lead at a time, then evolved to three simultaneous leads. This necessitated the use of switching circuits as well as analog weighting circuits to generate the various 12 leads. This is usually eliminated in modern digital systems by using an individual single-ended amplifier for each electrode on the body. Each potential signal is then digitally converted and all of the ECG leads can be formed mathematically in software. This would necessitate a 9-amplifier system. By performing some of the lead calculations with the analog differential amplifiers this can be reduced to an 8-channel system. Thus only the individual chest leads V_1 through V_6 and any two of the limb leads, for example, I and III, are needed to calculate the full 12-lead ECG. Figure 24.5 is a block diagram of a modern digital-based ECG system. This system uses an amplifier per lead wire and a 16 bit A/D converter, all within a small lead wire manifold or amplifier lead stage. The digital signals are sent via a high-speed link to the main ECG instrument. Here the embedded microprocessors perform all of the calculations and a hard copy report is generated (Figure 24.4). Note that each functional block has its own controller and the system requires a sophisticated real-time operating system to coordinate all system functions. Concomitant with the data acquisition is the automatic interpretation of the ECG. These programs are quite sophisticated and are continually evolving. It is still a medical/legal requirement that these ECGs be over-read by the physician.

24.3.1 Applications

Besides the standard 12-lead ECG, there are several other uses of ECG recording technology which rely on only a few leads. These applications have had a significant clinical and commercial impact. Following are brief descriptions of several ECG applications that are aimed at introducing the reader to some of the many uses of the ECG.

24.3.1.1 The Ambulatory ECG

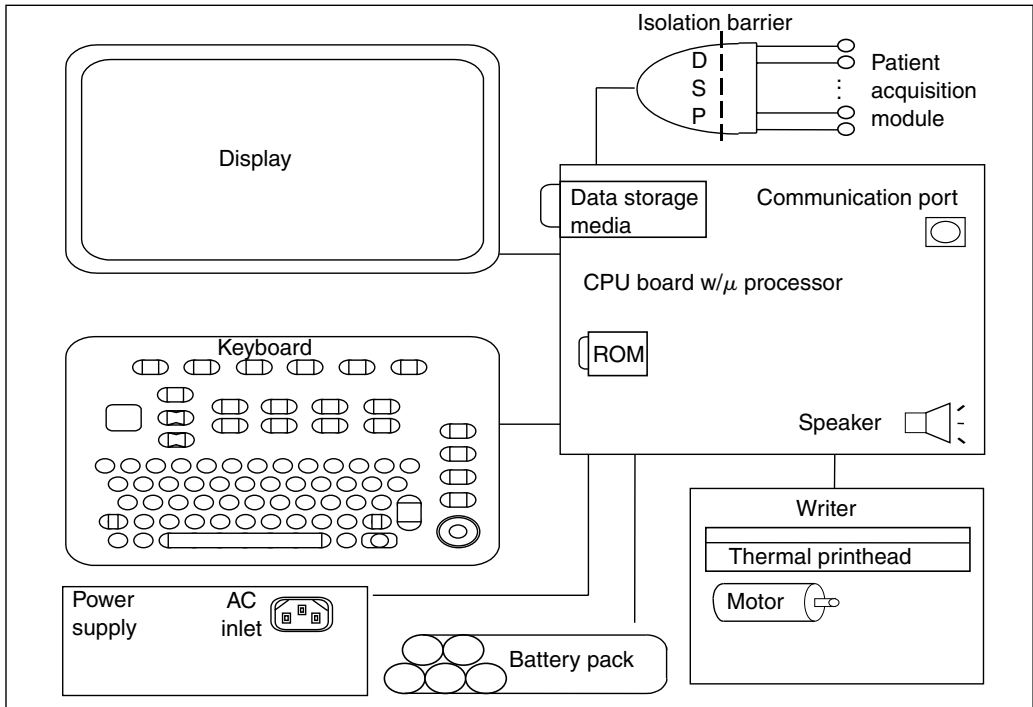
The evolution of the ambulatory or Holter ECG has an interesting history and its evolution closely followed both technical and clinical progress. The original, analog tape-based, portable ECG resembled


FIGURE 24.5 This is a block diagram of microprocessor-based ECG system. (Diagram is courtesy of GE Healthcare Technologies, Waukesha, WI.)

a fully loaded backpack and was developed by Dr. Holter in the early 1960s [17], but was soon followed by more compact devices that could be worn on the belt. The original large-scale clinical use of this technology was to identify patients who developed heart block transiently and could be treated by implanting a cardiac pacemaker. This required the secondary development of a device which could rapidly play back the 24 h of tape-recorded ECG signals and present to the technician or physician a means of identifying periods of time where the patient's heart rate became abnormally low. The scanners had the circuitry to not only playback the ECG at speeds 30 to 60 times real time, but to detect the beats and display them in a superimposed mode on a cathode ray tube (CRT) screen. In addition, an audible tachometer could be used to identify the periods of low heart rate. With this playback capability came numerous other observations such the identification of premature ventricular beats (PVBs) which lead to the development of techniques to identify and quantify their number. Together with the development of antiarrhythmic drugs a marriage was formed between pharmaceutical therapy and the diagnostic tool for quantifying PVBs. ECG tapes were recorded before and after drug administration and drug efficacy was measured by the reduction of the number of PVBs. The scanner technology for detecting and quantifying these arrhythmias was originally implemented with analog hardware but soon advanced to computer technology as it became economically feasible. Very sophisticated algorithms were developed based on pattern recognition techniques and were sometimes implemented with high-speed specialized numerical processors as the tape playback speeds became several hundred times real time [18]. Unfortunately this approach using the ambulatory ECG for identifying and treating cardiac arrhythmias has been on the decline as the rationale of PVC suppression was found to be unsuccessful for improving cardiac mortality. However, the ambulatory ECG is still a widely used diagnostic tool and modern units often have built-in microprocessors with considerable amounts (1.0 Gbyte) of random access memory. Here the data can be analyzed on line with large segments of data selected for storage and later analysis with personal computer-based programs.

24.3.1.2 Patient Monitoring

The techniques for monitoring the ECG in real time were developed in conjunction with the concept of the coronary care unit or CCU. Patients were placed in these specialized hospital units to carefully observe their progress during an acute illness such as a myocardial infarction or after complex surgical procedures. As the number of beds increased in these units it became clear that the highly trained medical staff could not continually watch a monitor screen and computerized techniques were added which monitored the patient's rhythm. These programs were not unlike those developed for the ambulatory ECG and the high-speed numerical capability of the computer was not taxed by monitoring a single ECG. The typical CCU would have 8 to 16 beds and hence the computing power was taken to its limit by monitoring multiple beds. The modern units have the central processing unit (CPU) distributed within the ECG module at the bedside, along with modules for measuring many other physiological parameters. Each bedside monitor would be interconnected with a high-speed digital line, for example, Ethernet, to a centralized computer used primarily to control communications and maintain a patient database.

24.3.1.3 High Resolution Electrocardiography

High-resolution (HR) capability is now a standard feature on most digitally based ECG systems, or as a stand-alone microprocessor based unit [19]. The most common application of the HRECG is to record very low level (1.0 μV) signals which occur after the QRS complex but are not evident on the standard ECG. These "late potentials" are generated from abnormal regions of the ventricles and have been strongly associated with the substrate responsible for a life-threatening rapid heart rate (ventricular tachycardia). The typical HRECG is derived from three bipolar leads configured in an anatomic *XYZ* coordinate system. These three ECG signals are then digitized at a rate of 1000 to 2000 Hz per channel, time aligned via a real-time QRS correlator, and summated in the form of a signal average. Signal averaging will theoretically improve the signal to noise ratio by the square root of the number of beats averaged. The underlying assumptions are that the signals of interest do not vary, on a beat-to-beat basis, and that the noise is random. Figure 24.6 has four panels depicting the most common sequence for processing the HRECG to measure the late potentials. Panel A depicts a 3 sec recording of the *XYZ* leads close to normal resolution. Panel B was obtained after averaging 200 beats and with a sampling frequency of ten times that shown in panel A. The gain is also five times greater. Panel C is the high-pass filtered signal using a partially time-reversed digital filter having a second order Butterworth response and a 3 db corner frequency of 40 Hz [12]. Note the appearance of the signals at the terminal portion of the QRS complex. A common method of analysis, but necessarily optimal, is to combine the filters *XYZ* leads into a vector magnitude, $(X^2 + Y^2 + Z^2)^{1/2}$. This waveform is shown in panel D. From this waveform several parameters have been derived such as total QRS duration, including late potentials, the RMS voltage value of the terminal 40 msec, and the low-amplitude signal (LAS) duration from the 40 μV level to the end of the late potentials. Abnormal values for these parameters are used to identify patients at high risk of ventricular tachycardia following a heart attack.

24.3.1.4 His Bundle Electrocardiography

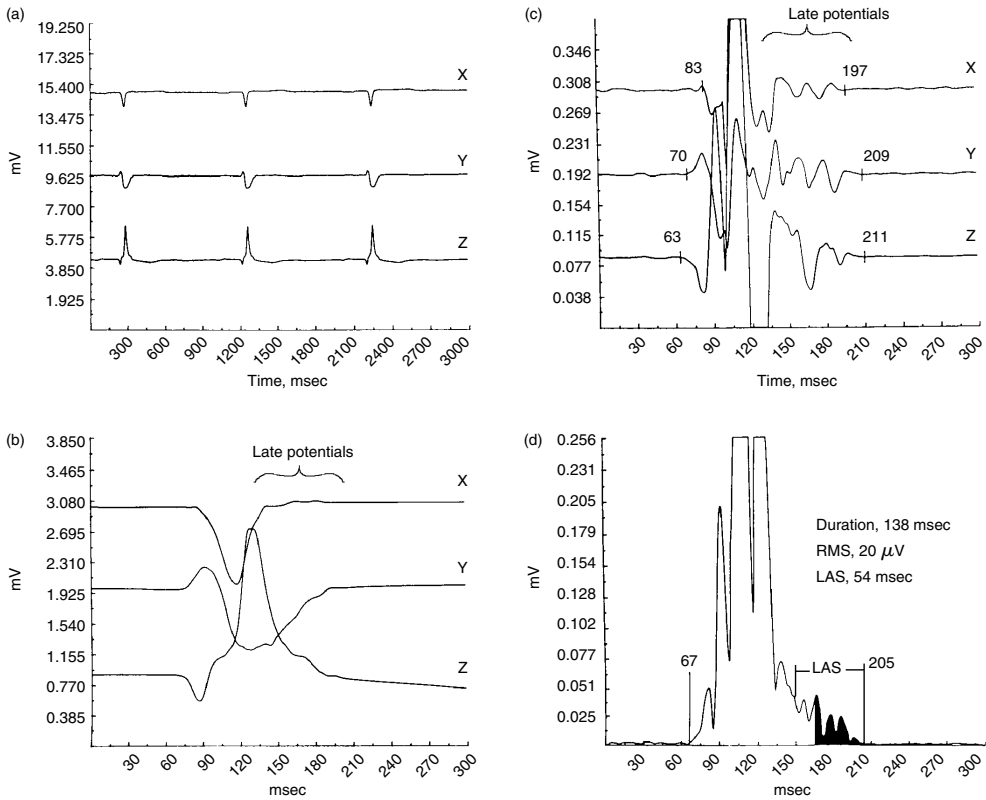
The electrocardiogram can be directly recorded from the heart's surface as in a modern electrophysiology (EP) study where the evaluation of the heart relies on both the body surface ECG and direct recordings obtained from within the heart using electrode catheters. Such catheters are introduced into a leg or arm vein or artery and advanced, under fluoroscopic control, into the interior of one of the four chambers of the heart. An electrode catheter is an insulated set of wires bundled within a polyurethane sheath. The diameters of these catheters range from about 1.0 to 2.5 mm. As many as 16 wires may be in the total assembly with ring electrodes, exposed on the outer surface of the catheter, attached to each internal wire. In addition, there are usually structural internal wires used to stiffen the catheter. With a proper controller at the rear of the catheter a trained operator can flex the catheter in a loop of almost 180 degrees. Together with the torsional properties of the catheter almost every point within the heart can be probed for electrical events. Direct contact recordings are called electrograms to distinguish then from body surface electrocardiograms.


FIGURE 24.6 The signal processing steps typically performed to obtain a high resolution ECG are shown in panels A to D. See text for a full description.

Figure 24.7 shows an example of a His bundle recording. The top two traces are leads II and V_6 of the ECG and the bottom trace is the voltage difference from two electrodes on the indwelling electrode catheter. This internal view of cardiac activation combined with the His bundle electrogram has been referred to as His bundle electrocardiography [20]. Atrial activation on the catheter recording is called the "A" deflection and ventricular activation called the "V" deflection. The His bundle potential is the central "H" deflection. Since the catheter is located very close to the His bundle and AV node, it is assumed that the A deflection arises from atrial muscle tissue close to the AV node. When combined with the surface lead information a number of new intervals can be obtained. These are the PA, AH, and HV intervals. The PA interval is a measure of atrial muscle activation time, the AH interval is a measure of AV nodal activation time, and the HV interval is a measure of the ventricular conduction system activation time.

The modern electrophysiological evaluation, or EP study, may involve as many as 64 individual recordings within the heart. In addition, current can be passed through these electrodes to stimulate the heart. A variety of atrial and ventricular stimulation protocols can be used, which then allows the cardiac electrophysiologist to identify pathways and mechanisms involved in most forms of arrhythmias. Besides this diagnostic function, it is now possible to locate abnormal structures or regions of the heart that are critical to arrhythmogenesis. By passing high-energy radio frequency waves through one or more of the internal electrodes it is possible to cauterize or ablate the suspect tissue without causing any widespread injury to the rest of the heart. In many forms of arrhythmias this ablation therapy can produce a cure for the patient.

In addition to the EP study and ablation therapy internal electrodes are the primary form of signal recording for both the cardiac pacemaker and implantable defibrillator. These devices both sense cardiac activation from permanent indwelling catheters and deliver energy to the heart through them. In the
FIGURE 24.7 The top two traces are ECG leads II and V-2 and the bottom trace is a bipolar catheter recording, properly positioned inside the heart, showing the His Bundle deflection (HB), and intracardiac atrial (A) and ventricular (V) activity.

case of the cardiac pacemaker these are low-level shocks which maintain the patient's heart rhythm. In the case of the implantable defibrillator the device will monitor the patient's rhythm until a serious or life-threatening arrhythmia occurs and then a high-energy pulse will be delivered in order to convert the rhythm back to normal. Both devices rely heavily on continuous monitoring of the cardiac signals obtained from internal catheter recordings using sophisticated implanted microprocessors and accurate means of signal detection and analysis.

24.4 Conclusions

The ECG is one of the oldest, instrument-bound measurements in medicine. It has faithfully followed the progression of instrumentation technology. Its most recent evolutionary step, to the microprocessor-based system, has allowed patients to wear their computer monitor or provided an enhanced, high-resolution ECG which has opened new vistas of ECG analysis and interpretation. The intracardiac ECG also forms the basis of modern diagnostic EP studies and therapeutic devices, such as the pacemaker and implantable defibrillator.

Principles of Electromyography

Kaj-Åge Henneberg
University of Montreal

Movement and position of limbs are controlled by electrical signals traveling back and forth between the muscles and the peripheral and central nervous system. When pathologic conditions arise in the motor system, whether in the spinal cord, the motor neurons, the muscle, or the neuromuscular junctions, the characteristics of the electrical signals in the muscle change. Careful registration and study of electrical signals in muscle (**electromyograms**) can thus be a valuable aid in discovering and diagnosing abnormalities not only in the muscles but also in the motor system as a whole. Electromyography (EMG) is the registration and interpretation of these muscle action potentials. Until recently, electromyograms were recorded primarily for exploratory or diagnostic purposes; however, with the advancement of bioelectric technology, electromyograms also have become a fundamental tool in achieving artificial control of limb movement, that is, functional electrical stimulation (FES) and rehabilitation. This chapter will focus on the diagnostic application of electromyograms, while FES will be discussed in Chapter 30.

Since the rise of modern clinical EMG, the technical procedures used in recording and analyzing electromyograms have been dictated by the available technology. The concentric needle electrode introduced by Adrian and Bronk in 1929 provided an easy-to-use electrode with high mechanical qualities and stable, reproducible measurements. Replacement of galvanometers with high-gain amplifiers allowed smaller electrodes with higher impedances to be used and potentials of smaller amplitudes to be recorded. With these technical achievements, clinical EMG soon evolved into a highly specialized field where electromyographists with many years of experience read and interpreted long paper EMG records based on the visual appearance of the electromyograms. Slowly, a more quantitative approach emerged, where features such as potential duration, peak-to-peak amplitude, and number of phases were measured on the paper records and compared with a set of normal data gathered from healthy subjects of all ages. In the last decade, the general-purpose rack-mounted equipment of the past have been replaced by ergonomically designed EMG units with integrated computers. Electromyograms are digitized, processed, stored on

25-1
FIGURE 25.1   Schematic illustration of different types of muscles: (a) fusiform, (b) unipennate, and (c) bipennate.

removable media, and displayed on computer monitors with screen layouts that change in accordance with the type of recording and analysis chosen by the investigator.

With this in mind, this chapter provides an introduction to the basic concepts of clinical EMG, a review of basic anatomy, the origin of the electromyogram, and some of the main recording procedures and signal-analysis techniques in use.

25.1 The Structure and Function of Muscle

Muscles account for about 40% of the human mass, ranging from the small extraocular muscles that turn the eyeball in its socket to the large limb muscles that produce locomotion and control posture. The design of muscles varies depending on the range of motion and the force exerted (Figure 25.1). In the most simple arrangement (*fusiform*), parallel fibers extend the full length of the muscle and attach to tendons at both ends. Muscles producing a large force have a more complicated structure in which many short muscle fibers attach to a flat tendon that extends over a large fraction of the muscle. This arrangement (*unipennate*) increases the cross-sectional area and thus the contractile force of the muscle. When muscle fibers fan out from both sides of the tendon, the muscle structure is referred to as *bipennate.*

A lipid bilayer (sarcolemma) encloses the muscle fiber and separates the intracellular myoplasma from the interstitial fluid. Between neighboring fibers runs a layer of connective tissue, the endomysium, composed mainly of collagen and elastin. Bundles of fibers, fascicles, are held together by a thicker layer of connective-tissue called the perimysium. The whole muscle is wrapped in a layer of connective tissue called the epimysium. The connective tissue is continuous with the tendons attaching the muscle to the skeleton.

In the myoplasma, thin and thick filaments interdigitate and form short, serially connected identical units called sarcomeres. Numerous sarcomeres connect end to end, thereby forming longitudinal strands of myofibrils that extend the entire length of the muscle fiber. The total shortening of a muscle during contraction is the net effect of all sarcomeres shortening in series simultaneously. The individual sarcomeres shorten by forming cross-bridges between the thick and thin filaments. The cross-bridges pull the filaments toward each other, thereby increasing the amount of longitudinal overlap between the thick and thin filaments. The dense matrix of myofibrils is held in place by a structural framework of intermediate filaments composed of desmin, vimetin, and synemin [Squire, 1986].

At the site of the neuromuscular junction, each motor neuron forms collateral sprouts (Figure 25.2) and innervates several muscle fibers distributed almost evenly within an elliptical or circular region ranging from 2 to 10 mm in diameter. The motor neuron and the muscle fibers it innervates constitute a functional unit, the **motor unit**. The cross section of muscle occupied by a motor unit is called the
FIGURE 25.2 Innervation of muscle fibers. (a) Two normal motor units with intermingled muscle fibers. (b) Reinnervation of muscle fibers. The second and fourth muscle fibers have lost their motor neuron (2) and subsequently have become reinnervated by newly formed sprouts from the motor neuron (1) innervating adjacent muscle fibers. Not drawn to scale.

motor unit territory (MUT). A typical muscle fiber is only innervated at a single point, located within a cross-sectional band referred to as the end-plate zone. While the width of the end-plate zone is only a few millimeters, the zone itself may extend over a significant part of the muscle. The number of muscle fibers per motor neuron (i.e., the innervation ratio) ranges from 3 : 1 in extrinsic eye muscles where fine-graded contraction is required to 120 : 1 in some limb muscles with coarse movement [Kimura, 1981]. The fibers of one motor unit are intermingled with fibers of other motor units; thus several motor units reside within a given cross section. The fibers of the same motor unit are thought to be randomly or evenly distributed within the motor unit territory; however, reinnervation of denervated fibers often results in the formation of fiber clusters (see Figure 25.2).

25.2 The Origin of Electromyograms

Unlike the myocardium, skeletal muscles do not contain pacemaker cells from which excitations arise and spread. Electrical excitation of skeletal muscle is initiated and regulated by the central and peripheral nervous systems. Motor neurons carry nerve impulses from the anterior horn cells of the spinal cord to the nerve endings, where the axonal action potential triggers the release of the neurotransmitter acetylcholine (Ach) into the narrow clefts separating the sarcolemma from the axon terminals. As Ach binds to the sarcolemma, Ach-sensitive sodium channels open, and miniature end-plate potentials arise in the sarcolemma. If sufficient Ach is released, the summation of miniature end-plate potentials, that is, the end-plate potential, reaches the excitation threshold, and sarcolemma action potentials propagate in opposite directions toward the tendons. As excitation propagates down the fiber, it spreads into a highly branched transverse network of tubules (T system) which interpenetrate the myofibrils. The effective radial conduction velocity ($\sim$4 cm/sec) is about two orders of magnitude slower than the longitudinal conduction velocity (2 to 5 m/sec). This is due to the fact that the main portion of the total membrane capacitance is located in the T system and that the lumen of the T system constitutes a higher electrical resistance than the myoplasma.

The slower tubular conduction velocity implies an increasingly delayed onset of tubular action potentials toward the center of the fiber relative to that of the sarcolemmal action potential (Figure 25.3a). However, compared with the time course of the subsequent contraction, the spread of excitation along and within the muscle fiber is essentially instantaneous, thereby ensuring simultaneous release of calcium from the sarcoplasmic reticulum throughout the entire volume of the muscle. If calcium release were restricted to a small longitudinal section of the muscle fiber, only sarcomeres in this region would contract, and sarcomeres in the rest of the fiber would stretch accordingly. Similarly, experiments in detubulated muscle fibers, that is, fibers in which the continuation between the sarcolemmal and the tubular membrane has
FIGURE 25.3 Simulated sarcolemmal and tubular action potentials of frog sartorius muscle fiber. (a) Temporal membrane action potentials calculated in a transverse plane 5 mm from the end-plate zone of a fiber with radius $a = 50 \ \mu$m. Curve 1: Sarcolemmal action potential; curves 2 to 4: action potentials in tubular membrane patches at $r = a$ (2), $r = a/2$ (3), and $r = a/20$ (4). (b) Sarcolemmal action potentials for fibers with radius 70 (1), 50 (2), and 30 (3) μm. The time axes have been expanded and truncated.

been disrupted, have demonstrated that only a thin layer of superficial myofibrils contracts when tubular action potentials fail to trigger calcium release deep in the muscle fiber.

It is well known that the shape of the skeletal muscle action potential differs from that of nerve action potentials with regard to the repolarization phase. In skeletal muscle, the falling phase of the action potential is interrupted by a long, slowly decaying potential known as the afterpotential. This late potential is caused by two opposing forces, the repolarization force due to the efflux of potassium through the sarcolemma and a depolarization force due to an influx of current from the interstitial space into the tubular lumen. The latter current is drawn in through the tubular openings by the repolarizing tubular membrane. Large muscle fibers have a higher tubular-sarcolemma area ratio; hence the inward surge of tubular current increases with fiber size. Figure 25.3b illustrates this by comparing sarcolemmal action potentials for fibers of increasing diameter. The small fiber has only a small amount of tubular membrane; hence the sarcolemmal potassium current has sufficient strength to rapidly repolarize the membrane. For the large fiber, inward tubular current actually depolarizes the sarcolemma slightly during repolarization of the tubular membrane system, thereby producing a small hump on the afterpotential. Since the hump on the *afterpotential* is influenced primarily by fiber size, this feature is more typical for large frog fibers than for smaller human fibers. Experiments have demonstrated that the sarcolemma action potential of detubulated fibers hyperpolarizes in a manner similar to that of a nerve action potential.

In Figure 25.4a, the time course of the sarcolemmal current density is compared with that of the current passing through the tubular mouth during the time course of the sarcolemmal action potential. The positive (outward) peak of the tubular current overlaps in time with the small capacitive sarcolemmal displacement current (initial positive peak) and the negative peak (inward sarcolemmal sodium current). As a result, the net current has a much larger positive peak than that of the sarcolemma alone, and the negative peak of the net current is only about half that of the sarcolemmal current. The outward sarcolemmal potassium current (late positive phase) is almost completely opposed by an antisymmetric inward tubular current, that is, the current drawn into the tubular lumen by the repolarizing T system. The combined effect of the sarcolemmal and tubular interaction is a net current with an almost biphasic waveform and with similar amplitudes of the positive and negative peaks.

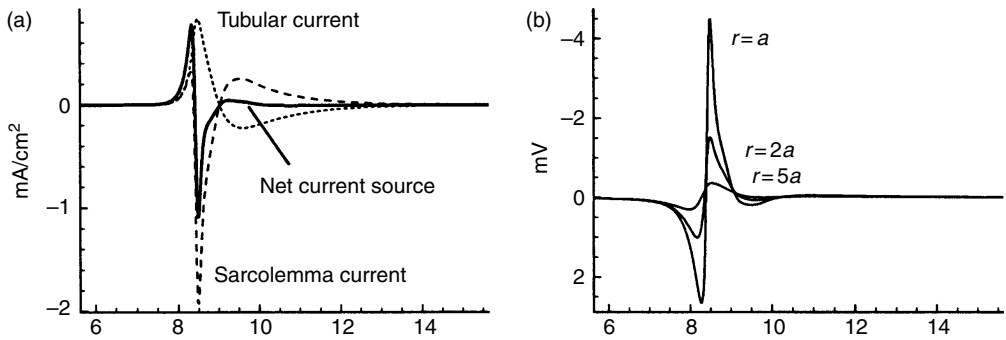
As the net current source propagates toward the tendon, an extracellular potential field arises and follows the action potential complex. At a given field point, this phenomenon is observed as a temporal potential waveform (Figure 25.4b); however, a more complete picture of the phenomenon is obtained by considering the spatial distribution of potentials in the cross section of the motor unit. Figure 25.5 shows schematically how the concentric isopotential lines of individual fibers overlap with those of other fibers in the same motor unit. In a typical healthy motor unit (Figure 14.5a), the mean interfiber distance


FIGURE 25.4 Simulated currents and extracellular potentials of frog sartorius muscle fiber (radius $a = 50\ \mu$m). (a) The net fiber current density is the summation of the current density through the sarcolemma and that passing the tubular mouth. (b) Extracellular action potentials calculated at increasing radial distances (in units of fiber radius) using a bidomain volume conductor model and the net current source in panel (a). The time axes have been expanded and truncated.
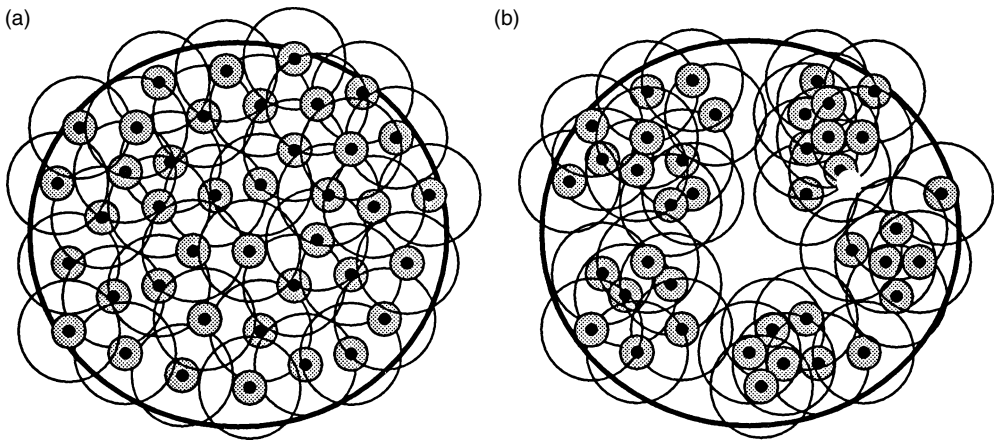

FIGURE 25.5 Schematic cross-sectional view of overlapping single-fiber action potential distributions in a normal (a) and reinnervated (b) motor unit. Muscle fibers are represented by filled black circles. Concentric rings represent axisymmetric isopotential lines of the individual single-fiber potentials at 2 (gray) and 5 radii from the fiber center, respectively. Compare with radial decline of extracellular potentials in Figure 25.4. See text for discussion of simplifying assumptions.

is on the order of a few hundred microns. Taking into account the steep radial decline of the potential amplitudes illustrated in Figure 25.4b, it is evident that **single-fiber action potential (SFAP)** overlapping occurs between low-magnitude isopotential lines. Figure 25.5b illustrates how spatial overlapping between SFAPs might look like in a motor unit with extensive fiber grouping. In this case, higher-level isopotential lines overlap within the clusters, while regions with no fibers would appear as electrically silent.

Several factors ignored in Figure 25.5 need further discussion. All fibers are assumed to be of the same size and with identical, perfectly axisymmetric potential distributions. The net single-fiber current source is an increasing function of fiber size; thus the magnitude of the potential distribution will vary with varying fiber size. Fibers can to a good approximation be considered as constant current sources; hence if the resistivity of the muscle tissue increases, for example, due to increased fiber packing density, the potential difference between an observation point and a reference point also will increase. It follows that local variations in fiber packing density in the region of an active fiber will destroy the axisymmetric appearance of its potential distribution. Muscle fibers are not perfect cylinders, and angular variation in

the shape of the sarcolemma must be expected to create angular variations in the potential distribution. However, due to the relatively high conductivity of the volume conductor, it is plausible that such variations become increasingly insignificant as the distance to the fiber is increased.

A very important factor not considered in Figure 25.5 concerns the degree of longitudinal alignment of SFAPs in the motor unit. As illustrated in Figure 25.2, SFAPs are usually dispersed along the motor unit axis, and their potential distributions do not sum up in a simple manner. SFAPs can be misaligned for several reasons. The end plates are not aligned; hence some SFAPs originate ahead of others. Variations in fiber size and packing density cause variations in conduction velocity; thus the dispersion of SFAPs may actually increase with increasing distance from the end-plate zone. Neuropathologic conditions can affect the alignment of SFAPs. Complete or partial failure of collateral nerve sprouts to conduct nerve action potentials can abolish or delay the onset of action potentials, and immature sprouts formed during reinnervation may cause significant variability (**jitter**) in the onset of muscle action potentials. Denervated muscle fibers shrink; hence a newly reinnervated muscle fiber is likely to have a slower conduction velocity. An increased dispersion of SFAPs creates a very complex and irregular spatial potential distribution. The superimposed temporal potential waveform in a fixed observation point, that is, the **motor unit potential (MUP)**, is therefore comprised of several peaks rather than a simple bi- or triphasic waveform. MUPs with five or more peaks are classified as polyphasic. A **satellite potential** is an SFAP that is so misaligned from the main potential complex that its waveform is completely separated from the MUP.

25.3   Electromyographic Recordings

A considerable amount of information regarding the bioelectrical state of a muscle is hidden in the time-varying spatial distribution of potentials in the muscle. Unfortunately, it is not clinically feasible to obtain high-resolution three-dimensional samples of the spatial potential distribution, since this would require the insertion of hundreds of electrodes into the muscles. In order to minimize the discomfort of the patient, routine EMG procedures usually employ only a single electrode that is inserted into different regions of the muscle. As the SFAPs of an active motor unit pass by the electrode, only their summation, that is, the MUP, will be registered by the electrode. The electrode is effectively integrating out the spatial information hidden in the passing potential complex, leaving only a time-variant potential waveform to be recorded and interpreted. It goes without saying that such a constraint on the recording procedure puts the electromyographist at a considerable disadvantage. To partially circumvent this setback, technical innovations and new procedures have continued to refine EMG examinations to such a level that some of the spatial information originally obscured by the electrode can be extracted intuitively from the temporal waveforms by an experienced electromyographist. With a detailed understanding of the bioelectric principles involved, for example, the bioelectric sources, the volume conductor, and the recording properties of the electrode, the electromyographist can quickly recognize and explain the waveform characteristics associated with various neuromuscular abnormalities.

To increase the amount of diagnostic information, several sets of EMG investigations may be performed using electrodes with different recording characteristics. Figure 25.6 illustrates three of the most popular EMG needle electrodes. The concentric and monopolar electrodes have an intermediate pickup range and are used in conventional recordings. The single-fiber electrode is a more recent innovation. It has a very small pickup range and is used to obtain recordings from only one or two muscle fibers. The macro electrode, which is the cannula of either the concentric or single-fiber electrode in combination with a remote reference electrode, picks up potentials throughout the motor unit territory. This section will review these EMG electrodes, the waveforms they produce, and the signal analysis performed in each case.

25.3.1   Concentric Electrode EMG

Adrian and Bronk developed the concentric electrode (see Figure 25.6) in order to obtain a pickup range that is smaller than that of wire electrodes. The modern version of the concentric electrode consists of a
FIGURE 25.6 Needle electrodes for subcutaneous EMG recordings. For the single-fiber and concentric electrodes, the cannula of the hypodermic needle acts as reference electrode. The monopolar electrode is used with a remote reference electrode.

platinum or stainless steel wire located inside the lumen of a stainless steel cannula with an outer diameter of about 0.5 mm. The tip is beveled at 15 to 20 degrees, thereby exposing the central wire as an oblique elliptical surface of about $150 \times 580 \ \mu$m. The central wire is insulated from the cannula with araldite or epoxy.

The concentric electrode is connected to a differential amplifier; thus common-mode signals are effectively rejected, and a relatively stable baseline is achieved. The cannula cannot be regarded as an indifferent reference electrode because it is located within the potential distribution and thus will pick up potentials from active fibers. Simulation studies [Henneberg and Plonsey, 1993] have shown that the cannula shields the central wire from picking up potentials from fibers located behind the tip. The sensitivity of the concentric electrode is therefore largest in the hemisphere facing the oblique elliptical surface. Due to the asymmetric sensitivity function, the waveshape of the recorded potentials will vary if the electrode is rotated about its axis. This problem is not observed with the axisymmetric monopolar electrode; however, this electrode has a more unstable baseline due to the remote location of the reference electrode. Both the concentric and monopolar electrodes (see Figure 25.6) are used in conventional EMG. Because of the differences in recording characteristics, however, concentric and monopolar recordings cannot be compared easily. A particular EMG laboratory therefore tends to use the one and not the other.

During the concentric needle examination, the investigator searches for abnormal insertional activity, spontaneous activity in relaxed muscles, and motor unit potentials with abnormal appearance. The waveshape of motor unit potentials is assessed on the basis of the quantitative waveform features defined in Figure 25.7:

- *Amplitude* is determined by the presence of active fibers within the immediate vicinity of the electrode tip. Low-pass filtering by the volume conductor attenuates the high-frequency spikes of remote SFAPs; hence the MUP amplitude does not increase for a larger motor unit. However, MUP amplitude will increase if the tip of the electrode is located near a cluster of reinnervated fibers. Large MUP amplitudes are frequently observed in neurogenic diseases.
- *Rise time* is an increasing function of the distance between the electrode and the closest active muscle fiber. A short rise time in combination with a small MUP amplitude might therefore indicate that the amplitude is reduced due to fiber atrophy rather than to a large distance between the electrode and the closest fiber.
- *Number of phases* indicates the complexity of the MUP and the degree of misalignment between SFAPs. In neurogenic diseases, polyphasic MUPs arise due to slow conduction velocity in immature nerve sprouts or slow conduction velocity in reinnervated but still atrophied muscle fibers. Variation in muscle fiber size also causes polyphasic MUPs in myopathic diseases. To prevent noisy baseline fluctuations from affecting the count of MUP phases, a valid baseline crossing must exceed a minimum absolute amplitude criterion.
FIGURE 25.7 Definition of quantitative waveform features of MUPs recorded with a **concentric EMG electrode**. MUP area is defined as the rectified area under the curve in the interval between the onset and end. The number of MUP phases is defined as the number of baseline crossings (□) plus one. MUP turns are marked by a ◊. MUP rise time is the time interval between the 10% and 90% deflection (○) of the main negative-going slope. As by convention, negative voltage is displayed upward.

- *Duration* is the time interval between the first and last occurrence of the waveform exceeding a predefined amplitude threshold, for example, 5 μV. The MUP onset and end are the summation of low-frequency components of SFAPs scattered over the entire pickup range of the electrode. As a result, the MUP duration provides information about the number of active fibers within the pickup range. However, since the motor unit territory can be larger than the pickup range of the electrode, MUP duration does not provide information about the total size of a large motor unit. MUP duration will increase if a motor unit has an increased number of fibers due to reinnervation. MUP duration is affected to a lesser degree by SFAP misalignment.
- *Area* indicates the number of fibers adjacent to the electrode; however, unlike MUP amplitude, MUP area depends on MUP duration and is therefore influenced by fibers in a larger region compared with that of MUP amplitude.
- *Turns* is a measure of the complexity of the MUP, much like the number of phases; however, since a valid turn does not require a baseline crossing like a valid phase, the number of turns is more sensitive to changes in the MUP waveshape. In order to distinguish valid turns from signal noise, successive turns must be offset by a minimum amplitude difference.

Based on the complimentary information contained in the MUP features defined above, it is possible to infer about the number and density of fibers in a motor unit as well as the synchronicity of the SFAPs. However, the concentric electrode is not sufficiently selective to study individual fibers, nor is it sufficiently sensitive to measure the total size of a motor unit. The following two techniques were designed with these objectives in mind.

25.3.2 Single-Fiber EMG

The positive lead of the **single-fiber** electrode (see Figure 25.6) is the end cap of a 25-μm wire exposed through a side port on the cannula of a steel needle. Due to the small size of the positive lead, bioelectric sources, which are located more than about 300 μm from the side port, will appear as common-mode signals and be suppressed by the differential amplifier. To further enhance the selectivity, the recorded signal is high-pass filtered at 500 Hz to remove low-frequency background activity from distant fibers.

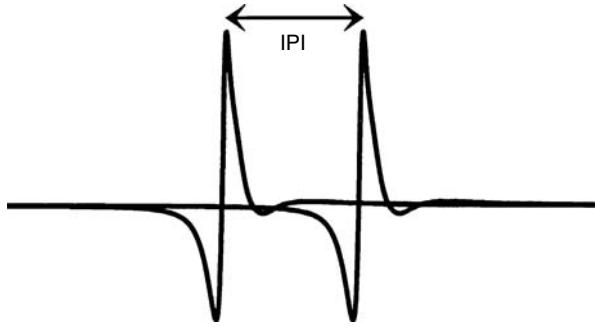
Due to its very small pickup range, the single-fiber electrode rarely records potentials from more than one or two fibers from the same motor unit. Because of the close proximity of the fibers, potentials are of large amplitudes and with small rise times. When two potentials from the same motor unit are picked up, the slight variation in their *interpotential interval* (IPI) can be measured (Figure 25.8). The mean IPI


FIGURE 25.8 Measurement of interpotential interval (IPI) between single-fiber potentials recorded simultaneously from two fibers of the same motor unit.

(jitter) is normally 5 to 50 μsec but increases when neuromuscular transmission is disturbed. When the single-fiber electrode records potentials from an increased number of fibers, it usually indicates that the side port is close to either a cluster of fibers (reinnervation) or that the positive lead is close to fibers in the process of splitting.

25.3.3 Macro EMG

For this electrode, the cannula of a single-fiber or concentric electrode is used as the positive lead, while the reference electrode can be either a remote subcutaneous or remote surface electrode. Due to the large lead surface, this electrode picks up both near- and far-field activity. However, the signal has very small amplitude, and the macro electrode must therefore be coupled to an electronic averager. To ensure that only one and the same MUP is being averaged, the averager is triggered by a SFAP picked up from that motor unit by the side port wire of the single-fiber electrode or by the central wire of the concentric electrode. Since other MUPs are not time-locked to the triggering SFAP, they will appear as random background activity and become suppressed in the averaging procedure. Quantitative features of the macro MUP include the peak-to-peak amplitude, the rectified area under the curve, and the number of phases.

Defining Terms

Concentric electrode EMG: Registration and interpretation of motor unit potentials recorded with a concentric needle electrode.

Electromyograms (EMGs): Bioelectric potentials recorded in muscles.

Jitter: Mean variation in interpotential interval between single-fiber action potentials of the same motor unit.

Macro EMG: The registration of motor unit potentials from the entire motor unit using the cannula of the single-fiber or concentric electrode.

Motor unit: The functional unit of an anterior horn cell, its axon, the neuromuscular junctions, and the muscle fibers innervated by the motor neuron.

Motor unit potential (MUP): Spatial and temporal summation of all single-fiber potentials innervated by the same motor neuron. Also referred to as the *motor unit action potential* (MUAP).

Motor unit territory (MUT): Cross-sectional region of muscle containing all fibers innervated by a single motor neuron.

Satellite potential: An isolated single-fiber action potential that is time-locked with the main MUP.

Single-fiber action potential (SFAP): Extracellular potential generated by the extracellular current flow associated with the action potential of a single muscle fiber.

Single-fiber EMG (SFEMG): Recording and analysis of single-fiber potentials with the single-fiber electrode.

Principles of Electroencephalography

Joseph D. Bronzino
Trinity College

Electroencephalograms (EEGs) are recordings of the minute (generally less that 300 μV) electrical potentials produced by the brain. Since 1924, when Hans Berger reported the recording of rhythmic electrical activity from the human scalp, analysis of EEG activity has been conducted primarily in clinical settings to detect gross pathologies and epilepsies and in research facilities to quantify the central effects of new pharmacologic agents. As a result of these efforts, cortical EEG patterns have shown to be modified by a wide range of variables, including biochemical, metabolic, circulatory, hormonal, neuroelectric, and behavioral factors. In the past, interpretation of the EEG was limited to visual inspection by an electroencephalographer, an individual trained to qualitatively distinguish normal EEG activity from localized or generalized abnormalities contained within relatively long EEG records. This approach left clinicians and researchers alike buried in a sea of EEG paper records. The advent of computers and the technologies associated with them has made it possible to effectively apply a host of methods to quantify EEG changes. With this in mind, this chapter provides a brief historical perspective followed by some insights regarding EEG recording procedures and an in-depth discussion of the quantitative techniques used to analyze alterations in the EEG.

26.1 Historical Perspective

In 1875, Richard Caton published the first account documenting the recording of spontaneous brain electrical activity from the cerebral cortex of an experimental animal. The amplitude of these electrical oscillations was so low (i.e., in the microvolt range) that Caton's discovery is all the more amazing because it was made 50 years before suitable electronic amplifiers became available.

In 1924, Hans Berger of the University of Jena in Austria, carried out the first human EEG recordings using metal strips pasted to the scalps of his subjects as electrodes and a sensitive galvanometer as the

recording instrument. Berger was able to measure the irregular, relatively small electrical potentials (i.e., 50 to 100 μV) coming from the brain. By studying the successive positions of the moving element of the galvanometer recorded on a continuous roll of paper, he was able to observe the resultant patterns in these brain waves as they varied with time. From 1924 to 1938, Berger laid the foundation for many of the present applications of electroencephalography. He was the first to use the word **electroencephalogram** in describing these brain potentials in humans. Berger also noted that these brain waves were not entirely random but instead displayed certain periodicities and regularities. For example, he observed that although these brain waves were slow (i.e., exhibited a synchronized pattern of high amplitude and low frequency, <3 Hz) during sleep, they were faster (i.e., exhibited a desynchronized pattern of low amplitude and higher frequency, 15 to 25 Hz) during waking behaviors. He suggested, quite correctly, that the brain's activity changed in a consistent and recognizable fashion when the general status of the subject changed, as from relaxation to alertness. Berger also concluded that these brain waves could be greatly affected by certain pathologic conditions after noting a marked increase in the amplitude of these brain waves recorded during convulsive seizures. However, despite the insights provided by these studies, Berger's original paper, published in 1929, did not excite much attention. In essence, the efforts of this remarkable pioneer were largely ignored until similar investigations were carried out and verified by British investigators.

It was not until 1934, however, when Adrian and Matthews published their classic paper verifying Berger's findings that the concept of "human brain waves" was truly accepted and the study of EEG activity was placed on a firm foundation. One of their primary contributions was the identification of certain rhythms in the EEG, for example, a regular oscillation at approximately 10 to 12 Hz recorded from the occipital lobes of the cerebral cortex, which they termed the "alpha rhythm." This alpha rhythm was found to disappear when a subject displayed any type of attention or alertness or focused on objects in the visual field. The physiologic basis for these results, the "arousing influence" of external stimuli on the cortex, was not formulated until 1949, when Moruzzi and Magoun demonstrated the existence of pathways widely distributed through the central reticular core of the brainstem that were capable of exerting a diffuse-activating influence on the cerebral cortex. This "reticular activating system" has been called the brain's response selector because it alerts the cortex to focus on certain pieces of incoming information, while ignoring others. It is for this reason that a sleeping mother will immediately be awakened by her crying baby or the smell of smoke and yet, ignores the traffic outside her window or the television playing in the next room. (*Note:* For the interested reader, an excellent historical review of this early era in brain research is provided in a fascinating text by Brazier [1968].)

26.2   EEG Recording Techniques

Scalp recordings of spontaneous neuronal activity in the brain, identified as the EEG, allow measurement of potential changes over time between a signal electrode and a reference electrode. Compared with other biopotentials, such as the electrocardiogram, the EEG is extremely difficult for an untrained observer to interpret, partially as a result of the spatial mapping of functions onto different regions of the brain and electrode placement. Recognizing that some standardization was necessary, the International Federation in Electroencephalography and Clinical Neurophysiology adopted the 10–20 electrode placement system. In addition to the standard 10–20 scalp array, electrodes to monitor eye movement, ECG, and muscle activity are essential for discrimination of different vigilance or behavioral states [Kondraski, 1986; Smith, 1986; Bronzino, 1995, 2000].

Any EEG system consists of electrodes, amplifiers (with appropriate filters), and a recording device. Instrumentation required for recording EEG activity can be simple or elaborate. (*Note:* Although the discussion presented in this section is for a single-channel system, it can be extended to simultaneous multichannel recordings simply by multiplying the hardware by the number of channels required. In cases that do not require true simultaneous recordings, special electrode selector panels can minimize hardware requirements.)

Commonly used scale electrodes consist of Ag–AgCl disks, 1 to 3 mm in diameter, with long flexible leads that can be plugged into an amplifier. Although a low-impedance contact is desirable at the electrode–skin interface ($<10\,k\Omega$), this objective is confounded by hair and the difficulty of mechanically stabilizing the electrode. Conductive electrode paste helps obtain low impedance and keep the electrodes in place. Often a contact cement (collodion) is used to fix small patches of gauze over the electrodes for mechanical stability, and leads are usually taped to the subject to provide some strain relief. Slight abrasion of the skin is sometimes used to obtain lower electrode impedance, but this can cause slight irritation and sometimes infection (as well as pain in sensitive subjects).

For long-term recordings, as in seizure monitoring, electrodes present major problems. Needle electrodes, which must be inserted into the tissue between the surface of the scalp and the skull, are sometimes useful. However, the danger of infection increases significantly. Electrodes with self-contained miniature amplifiers are somewhat more tolerant because they provide a low-impedance source to interconnecting leads, but they are expensive. Despite numerous attempts to simplify the electrode application process and to guarantee long-term stability, no single method has been widely accepted.

Instruments are available for measuring impedance between electrode pairs. The procedure is recommended strongly as a good practice, since high impedance leads to distortions that may be difficult to separate from actual EEG signals. In fact, electrode impedance monitors are built into some commercially available EEG devices. Note that standard DC ohmmeters should not be used, since they apply a polarizing current that can result in a buildup of noise at the skin–electrode interface.

From carefully applied electrodes, signal amplitudes of 1 to 10 μV can be obtained. Considerable amplification (gain $= 10^6$) is required to bring signal strength up to an acceptable level for input to recording devices. Because of the length of electrode leads and the electrically noisy environment where recordings commonly take place, differential amplifiers with inherently high input impedance and high common-mode rejection ratios are essential for high-quality EEG recordings.

In some facilities, special electrically shielded rooms minimize environmental electrical noise, particularly 60 Hz alternating current (AC) line noise. Since much of the information of interest in the EEG lies in frequency bands below 40 Hz, low-pass filters in the amplifier can be used to greatly reduce 60 Hz noise. For attenuating AC noise when the low-pass cutoff is above 60 Hz, many EEG amplifiers employ a notch filter specific only for frequencies in a narrow band centered around 60 Hz.

When trying to eliminate or minimize the effect of 60-Hz sources, it is sometimes useful to use a dummy source, such as a fixed 100-kΩ resistor attached to the electrodes. By employing a dummy source as one of the input signals, the output of the differential amplifier represents only contributions from interfering sources. If noise can be reduced to an acceptable level (at least by a factor of 10 less than EEG signals), it is likely that uncontaminated EEG records can be obtained.

Different types of recording instruments obtain a temporary or permanent record of the EEG. The most common recording device is a pen or chart recorder (usually multichannel), which is an integral part of most commercially available EEG instruments. Recordings are on a long sheet of continuous paper (from a folded stack) fed past the moving pen at one of several selectable constant speeds. Paper speed is selected according to the monitoring situation at hand: slow speed (10 mm/sec) for observing the spiking characteristically associated with seizure activity and faster speeds (up to 120 mm/sec) to identify the presence of individual frequency bands in the EEG.

In addition to (or instead of) a pen recorder, the EEG may be recorded on a multichannel frequency-modulated (FM) analog tape recorder. During such recordings, a visual output device such as an oscilloscope or video display is often used to allow visual monitoring of signals.

Sophisticated FM tape recording and playback systems allow clinicians to review long EEG recordings over a greatly reduced time compared with that required to flip through stacks of paper or to observe recordings in real time. Such systems take advantage of time-compensation schemes, whereby a signal recorded at one speed can be played back at a faster speed. The ratio of playback to recording speed is known, so the appropriate correction factor can be applied to played-back data generating a properly scaled video display. A standard ratio of 60 : 1 is often used. Thus a trained clinician can review each minute of real-time EEG in 1 sec. The display is scrolled at a high rate horizontally across the display

screen. Features of such instruments allow the clinician to freeze a segment of EEG on the display and to slow down or accelerate tape speed from the standard playback as needed. A vertical "tick" mark is usually displayed at periodic intervals by one channel as a time mark to provide a convenient timing reference. Computers also can be used as recording devices. In such systems, one or more channels of analog EEG signal are repeatedly sampled at a fixed time interval (sampling interval), and each sample is converted into a digital representation by an analog-to-digital (A/D) converter. The A/D converter is interfaced to a computer system so that each sample can be saved in the computer's memory. The resolution of the A/D converter is determined by the smallest amplitude that can be sampled. This is determined by dividing the voltage range of the A/D converter by 2 raised to the power of the number of bits of the A/D converter. For example, an A/D converter with a range of ± 5 V and 12-bit resolution can resolve sample amplitudes as small as ± 2.4 mV. Appropriate matching of amplification and A/D converter sensitivity permits resolution of the smallest signal while preventing clipping of the largest signal amplitudes.

A set of such samples, acquired at a sufficient sampling rate (at least twice the highest frequency component of interest in the sampled signal), is sufficient to represent all the information in the waveform. To ensure that the signal is band-limited, a low-pass filter with a cutoff frequency equal to the highest frequency of interest is used. Since physically realizable filters do not have ideal characteristics, the sampling rate is usually set to twice the cutoff frequency of the filter or more. Furthermore, once converted to digital format, digital filtering techniques can be used.

Online computer recordings are only practical for short-term recordings or for situations in which the EEG is immediately processed. This limitation is primarily due to storage requirements. For example, a typical sampling rate of 128 Hz yields 128 new points per second that require storage. For an 8-sec sample, 1024 points are acquired per channel recorded. A 10-min recording period yields 76,800 data points per channel. Assuming 12-bit resolution per sample, one can see that available computer memory quickly becomes a significant factor in determining the length (in terms of time) as well as the number of channels of EEG activity to be acquired in real time by the computer.

Further data processing can consist of compression for more efficient storage (with associated loss of total information content), as in the use of compressed spectral arrays, determination of a reduced features set including only data needed for quantification, as in evoked response recordings, or feature extraction and subsequent pattern recognition, as in automated spike detection during monitoring for epileptic seizure activity.

In addition to the information available from spontaneous EEG activity, the brain's electrical response to sensory stimulation is also important. Due to the relatively small amplitude of a stimulus-evoked potential compared with that of spontaneous EEG potentials, the technique of signal averaging is often used to enhance the characteristics of stimulus-evoked responses. Stimulus averaging takes advantage of the fact that the brain's electrical response is time locked to the onset of the stimulus, while nonevoked, background potential changes are randomly distributed in time. Consequently, the averaging of multiple stimulus-evoked responses results in the enhancement of the time-locked activity, while average random background activity approaches zero. The result is an evoked response that consists of a number of discrete and replicable peaks that occur, depending on the stimulus and recording parameters, at predictable latencies associated with the onset of stimulation.

26.3   Use of Amplitude Histographs to Quantify the EEG

In general, the EEG contains information regarding changes in the electrical potential of the brain obtained from a given set of recording electrodes. These data include the characteristic waveforms with accompanying variations in amplitude, frequency, phase, and so on, as well as the brief occurrence of electrical patterns, such as spindles. *Any analysis procedure cannot simultaneously provide information regarding all these variables.* Consequently, the selection of any analytical technique will emphasize changes in one particular variable at the expense of the others. This observation is extremely important if one is to properly interpret the results obtained using a given technique.

In the computation of amplitude distributions of the EEG, for example, successive EEG amplitudes must be measured and ordered into specific amplitude classes, or *bins*. The amplitude histogram that results from this process is often a symmetrical, essentially Gaussian distribution. The primary characteristics of the Gaussian distribution are summarized simply by specifying its mean and standard deviation, since the higher control moments of the distribution, such as skewness and kurtosis, are equal to zero. However, in non-Gaussian distributions, the measures of skewness and kurtosis assume nonzero values and can be used to characterize that particular amplitude distribution. The four primary statistical measures used to characterize an EEG amplitude histogram include the mean, standard amplitude, skewness, and kurtosis.

26.3.1 Mean

Since the sum of (positive and negative) EEG potential is usually on the order of a few microvolts when the analysis time is not too short, the mean is essentially a constant, although of small value. Any shifts in values of the mean, therefore, are indicative of changes in potential that are of technical origin, such as amplifier drifts, and the like.

26.3.2 Standard Amplitude

The variance of the EEG amplitude distribution is directly related to the total power of the EEG. For example, a flat EEG will provide low variance values, while a widely oscillating EEG will yield high variance values. To avoid confusion and use units that are more familiar to electroencephalographers, the term *standard amplitude* is often used.

26.3.3 Skewness

The degree of deviation from the symmetry of a normal or Gaussian distribution is measured by skewness. This third central moment of the amplitude histogram has a value of zero when the distribution is completely symmetrical and assumes some nonzero value when the EEG waveforms are asymmetrical with respect to the baseline (as is the case in some characteristic sleep patterns, murhythms, morphine spindles, barbiturate spiking, etc.). In general, a nonzero value of the skewness index reflects the presence of monophasic events in the waveform. The following methods can be used to obtain the measure of skewness:

Moment coefficient of skewness:

$$S_{K\mathrm{mc}} = \frac{\sum_{i=1}^{N} (x_i - \bar{x})^3 / N}{\left[\sum_{i=1}^{N} (x_i - \bar{x})^2 / N \right]^{3/2}} \tag{26.1}$$

Pearson's second coefficient of skewness:

$$S_{K_{2c}} = \frac{3(\bar{x}\ \mathrm{median})}{\mathrm{SD}} \tag{26.2}$$

Centile index of skewness:

$$S_{K_{\mathrm{cent}}} = \frac{(\text{number of points} > \bar{x})}{N} \tag{26.3}$$

26.3.4 Kurtosis

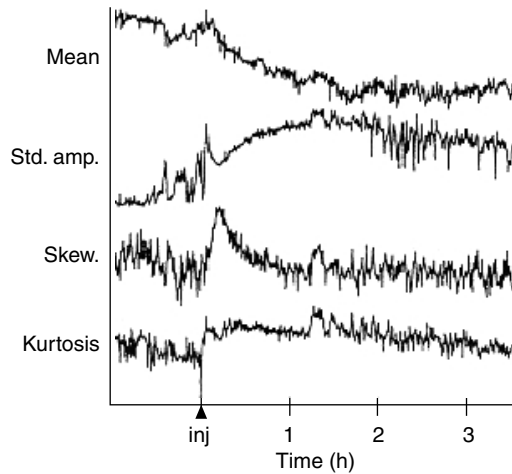
The *kurtosis* measure reveals the peakedness or flatness of a distribution. A kurtosis value greater than that of a normal distribution means that the distribution is leptokurtic, or simply more peaked than


FIGURE 26.1   Plot of the indices of the amplitude distribution, that is, the mean, standard amplitude, skewness, and kurtosis, of the EEG recorded from a rat prior to and for 3 h following intraperitoneal injection of morphine sulfate (30 mg/kg). *Arrow (inj)* indicates time of injection.

the normal curve. A value less than that of a normal distribution indicates a flatter distribution. In clinical electroencephalography, when analyzing EEGs with little frequency and amplitude modulation, one observes negative values of kurtosis. High positive values of kurtosis are present when the EEG contains transient spikes, isolated high-voltage wave groups, and so on. The following methods can be used to obtain the measure of kurtosis.

Moment coefficient of kurtosis:

$$K_{\mathrm{mc}} = \frac{\sum_{i=1}^{N} (x_i - \bar{x})^4 / N}{\left[\sum_{i=1}^{N} (x_i - \bar{x})^2 / N \right]^2} - 3 \tag{26.4}$$

Centile index of lurtosis:

$$K_{\mathrm{cent}} \frac{\text{number of patients such that } |x_i - \bar{x}| \; > \; \text{standard amplitude}}{N} \tag{26.5}$$

A normal distribution will have a value of 0.5 for this measure.

Figure 26.1 illustrates the sensitivity of these measures in analyzing the effect of systemic (IP) administration of morphine sulfate (30 mg/kg) on the cortical EEC. It will be noted that the skewness measure changes abruptly only immediately after the morphine injection, when the EEG was dominated by the appearance of spindles. However, the index of kurtosis characterizes the entire extent of the drug effect from onset to its return to baseline.

The central moments of the EEC amplitude histogram, therefore, are capable of (1) characterizing the amplitude distributions of the EEG and (2) quantifying alterations in these electrical processes brought about by pharmacologic manipulations. In addition, use of the centile index for skewness and kurtosis provides a computer-efficient method for obtaining these measures in real time.

26.4   Frequency Analysis of the EEG

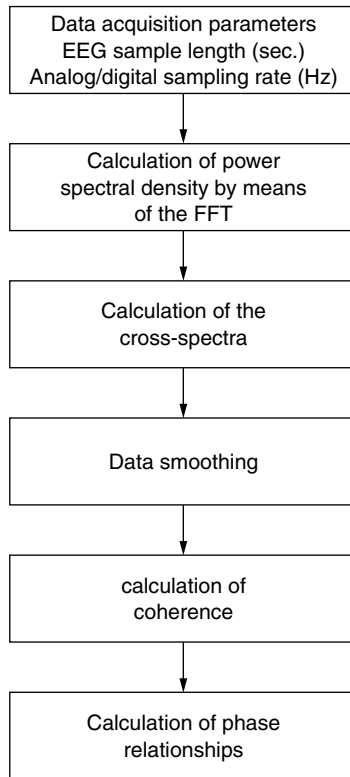
In early attempts to correlate the EEG with behavior, analog frequency analyzers were used to examine single channels of EEG data. Although disappointing, these initial efforts did introduce the use of frequency


FIGURE 26.2   Block diagram illustrating the steps involved in conventional (linear) spectral analysis of EEG activity.

analysis to the study of gross brain wave activity. Although **power spectral analysis**, that is, the magnitude square of the Fourier transform, provides a quantitative measure of the frequency distribution of the EEG, it does so, as mentioned above, at the expense of other details in the EEG such as the amplitude distribution and information concerning the presence of specific EEG patterns.

The first systematic application of power spectral analysis by general-purpose computers was reported in 1963 by Walter; however, it was not until the introduction of the **fast Fourier transform (FFT)** by Cooley and Tukey in 1965 that machine computation of the EEG became commonplace. Although an individual FFT is ordinarily calculated for a short section of EEG data (e.g., from 1 to 8 sec), such signal segmentation with subsequent averaging of individual modified periodograms has been shown to provide a consistent estimator of the power spectrum. An extension of this technique, the compressed spectral array, has been particularly useful for evaluating EEG spectra over long periods of time. A detailed review of the development and use of various methods to analyze the EEG is provided by Bronzino et al. [1995, 2000] and others [Barlow, 1993; Dempster, 1993]. Figure 26.2 provides an overview of the computational processes involved in performing spectral analysis of the EEG, that is, including computation of auto- and **cross-spectra**. It is to be noted that the power spectrum is the *autocorrelellogram*, that is, the correlation of the signal with itself. As a result, the power spectrum provides only magnitude information in the frequency domain; it does not provide any data regarding phase. The power spectrum is computed by Equation 26.6, where $X(f)$ is the Fourier transform of the EEG signal.

$$P(f) = R_e^2[X(f)] + I_m^2[X(f)] \tag{26.6}$$

Power spectral analysis not only provides a summary of the EEG in a convenient graphic form but also facilitates statistical analysis of EEG changes that may not be evident on simple inspection of the records.

In addition to absolute power derived directly from the power spectrum, other measures calculated from absolute power have been demonstrated to be of value in quantifying various aspects of the EEG. Relative power expresses the percentage contribution of each frequency band to the total power and is calculated by dividing the power within a band by the total power across all bands. Relative power has the benefit of reducing the intersubject variance associated with absolute power that arises from subject differences in skull and scalp conductance. The disadvantage of relative power is that an increase in one frequency band will be reflected in the calculation by a decrease in other bands; for example, it has been reported that directional shifts between high and low frequencies are associated with changes in cerebral blood flow and metabolism. Power ratios between low (0 to 7 Hz) and high (10 to 20 Hz) frequency bands have been demonstrated to be an accurate estimator of changes in cerebral activity during these metabolic changes.

Although the power spectrum quantifies activity at each electrode, other variables derivable from the FFT offer a means of quantifying the relationships between signals recorded from multiple electrodes or sites. Coherence (which is a complex number), calculated from the cross-spectrum analysis of two signals, is similar to cross-correlation in the time domain.

The cross-spectrum is computed by

$$\text{Cross-spectrum} = X(f)Y^{*}(f) \tag{26.7}$$

where $X(f)$ and $Y(f)$ are Fourier transforms, and $*$ indicates the complex conjugate.

Coherence is calculated by

$$\text{Coherence} = \frac{\text{cross-spectrum}}{\sqrt{PX(f) - PY(f)}} \tag{26.8}$$

The **magnitude squared coherence (MSC)** values range from 1 to 0, indicating maximum and no synchrony, respectively. The temporal relationship between two signals is expressed by the phase angle, which is a measure of the lag between two signals of common frequency components or bands.

Since coherence is a complex number, the phase is simply the angle associated with the polar expression of that number. MSC and phase then represent measures that can be employed to investigate interactions of cerebral activity recorded from separate brain sites. For example, short (intracortical) and long (corticocortical) pathways have been proposed as the anatomic substrates underlying the spatial frequency and patterns of coherence. Therefore, discrete cortical regions linked by such fiber systems should demonstrate a relatively high degree of synchrony, while the temporal difference between signals, represented by the phase measure, quantifies the extent to which one signal leads another.

26.5 Nonlinear Analysis of the EEG

As mentioned earlier, the EEG has been studied extensively using signal-processing schemes, most of which are based on the assumption that the EEG is a linear, Gaussian process. Although linear analysis schemes are computationally efficient and useful, they only utilize information retained in the autocorrelation function (i.e., the second-order cumulant). Additional information stored in higher-order cumulants is therefore ignored by linear analysis of the EEG. Thus, while the power spectrum provides the energy distribution of a stationary process in the frequency domain, it cannot distinguish nonlinearly coupled frequency from spontaneously generated signals with the same resonance.

There is evidence showing that the amplitude distribution of the EEG often deviates from Gaussian behavior. It has been reported, for example, that the EEG of humans involved in the performance of mental arithmetic tasks exhibits significant non-Gaussian behavior. In addition, the degree of deviation from gaussian behavior of the EEG has been shown to depend on the behavioral state, with the state of slow-wave sleep showing less Gaussian behavioral than quiet waking, which is less Gaussian than rapid eye movement (REM) sleep [Ning and Bronzino, 1989a,b]. Nonlinear signal-processing algorithms such

as bispectral analysis are therefore necessary to address non-Gaussian and nonlinear behavior of the EEG in order to better describe it in the frequency domain.

But what exactly is the bispectrum? For a zero-mean, stationary process $\{X(k)\}$, the bispectrum, by definition, is the Fourier transform of its third-order cumulant (TOG) sequence:

$$B(\omega_1, \omega_2) = \sum_{m=-\alpha}^{\alpha} \sum_{m=-\alpha}^{\alpha} C(m, n)e^{-j(w_1 m + w_2 n)} \tag{26.9}$$

The TOG sequence $[C(m, n)]$ is defined as the expected value of the triple product

$$C(m, n) = E\{X(k)X(k + m)X(k + n)\} \tag{26.10}$$

If process $X(k)$ is purely Gaussian, then its third-order cumulant $C(m, n)$ is zero for each (m, n), and consequently, its Fourier transform, the bispectrum, $B(\omega_1, \omega_2)$ is also zero. This property makes the estimated bispectrum an immediate measure describing the degree of deviation from gaussian behavior. In our studies [Ning and Bronzino, 1989a,b], the sum of magnitude of the estimated bispectrum was used as a measure to describe the EEG's deviation from Gaussian behavior, that is,

$$D = \sum_{(\omega_1 \omega_2)} |B(\omega_1, \omega_2)| \tag{26.11}$$

Using bispectral analysis, the existence of significant **quadratic phase coupling (QPC)** in the hippocampal EEG obtained during REM sleep in the adult rat was demonstrated [Ning and Bronzino, 1989a,b, 1990]. The result of this nonlinear coupling is the appearance, in the frequency spectrum, of a small peak centered at approximately 13 to 14 Hz (beta range) that reflects the summation of the two theta frequency (i.e., in the 6- to 7-Hz range) waves (Figure 26.3). Conventional power spectral (linear) approaches are incapable of distinguishing the fact that this peak results from the interaction of these two generators and is not intrinsic to either.

To examine the phase relationship between nonlinear signals collected at different sites, the cross-bispectrum is also a useful tool. For example, given three zero-mean, stationary processes $\{x_j(n)_j = 1, 2, 3\}$, there are two conventional methods for determining the cross-bispectral relationship, direct and indirect. Both methods first divide these three processes into M segments of shorter but equal length. The direct method computes the Fourier transform of each segment for all three processes and then estimates the cross-bispectrum by taking the average of triple products of Fourier coefficients over M segments, that is,

$$B_{x_1 x_2 x_3}(\omega_1, \omega_2) = \frac{1}{M} \sum_{m=1}^{M} X_1^m(\omega_1) X_2^m(\omega_2) X_3^{m*}(\omega_1 + \omega_2) \tag{26.12}$$

where $X_j^m(\omega)$ is the Fourier transform of the mth segment of $\{x_j(n)\}$, and $*$ indicates the complex conjugate.

The indirect method computes the third-order cross-cumulant sequence for all segments:

$$C_{x_1 x_2 x_3}(k, l) = \sum_{n \in \tau} x_1^m(n) x_2^m(n + k) x_3^m(n + l) \tag{26.13}$$

where τ is the admissible set for argument n. The cross-cumulant sequences of all segments will be averaged to give a resultant estimate:

$$Cx_1 x_2 x_3(k, l) = \frac{1}{M} \sum_{m=1}^{M} C_{x_1 x_2 x_3}^m(k, l) \tag{26.14}$$
FIGURE 26.3 Plots (a) and (b) represent the averaged power spectra of sixteen 8-sec epochs of REM sleep (digital sampling rate = 128 Hz) obtained from hippocampal subfields CA1 and the dentate gyrus, respectively. Note that both spectra exhibit clear power peaks at approximately 8 Hz (theta rhythm) and 16 Hz (beta activity). Plots (c) and (d) represent the **bispectra** of these same epochs, respectively. Computation of the bicoherence index at $f(1) = 8$ Hz, $f(2) = 8$ Hz showed significant quadratic phase coupling (QPC), indicating that the 16-Hz peak seen in the power spectra is not spontaneously generated but rather results from the summation of activity between the two recording sites.

The cross-bispectrum is then estimated by taking the Fourier transform of the third-order cross-cumulant sequence:

$$Bx_1x_2x_3(\omega_1, \omega_2) = \sum_{k=-\alpha}^{\alpha} \sum_{l=-\alpha}^{\alpha} Cx_1x_2x_3(k, l) e^{-j(\omega_1 k + \omega_2 l)} \tag{26.15}$$

Since the variance of the estimated cross-bispectrum is inversely proportional to the length of each segment, computation of the cross-bispectrum for processes of finite data length requires careful consideration of both the length of individual segments and the total number of segments to be used.

The cross-bispectrum can be applied to determine the level of cross-QPC occurring between $\{x_1(n)\}$ and $\{x_2(n)\}$ and its effects on $\{x_3(n)\}$. For example, a peak at $Bx_1x_2x_3(\omega_1, \omega_2)$ suggests that the energy component at frequency $\omega_1 + \omega_2$ of $\{x_3(n)\}$ is generated due to the QPC between frequency ω_1 of $\{x_1(n)\}$, and frequency ω_2 of $\{x_2(n)\}$. In theory, the absence of QPC will generate a flat cross-bispectrum. However due to the finite data length encountered in practice, peaks may appear in the cross-bispectrum at locations where there is no significant cross-QPC. To avoid improper interpretation, the cross-bicoherence index, which indicates the significance level of cross-QPC, can be computed as follows:

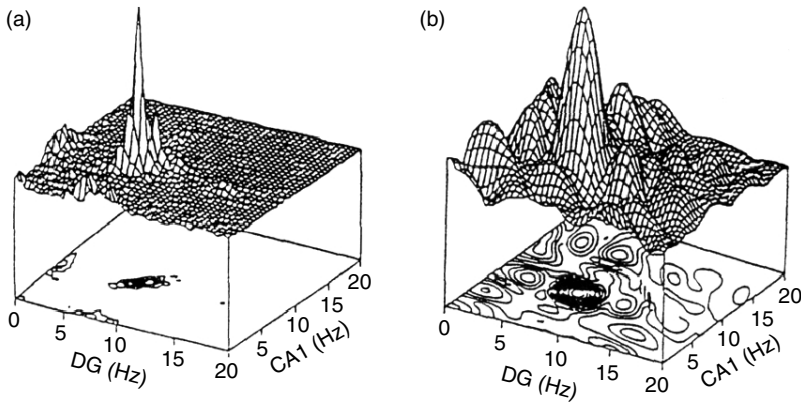
$$bic_{x_1x_2x_3}(\omega_1, \omega_2) = \frac{Bx_1x_2x_3(\omega_1, \omega_2)}{\sqrt{P_{x_1}(\omega_1)P_{x_2}(\omega_2)P_{x_3}(\omega_1 + \omega_2)}} \tag{26.16}$$


FIGURE 26.4 Cross-bispectral plots of $B_{\text{CA1-DG-CA1}}$ (ω_1, ω_2) computed using (a) the direct method and (b) the indirect method.

where $P_{xj}(w)$ is the power spectrum of process $\{x(n)\}$. The theoretical value of the bicoherence index ranges between 0 and 1, that is, from nonsignificant to highly significant.

In situations where the interest is the presence of QPC and its effects on $\{x(n)\}$, the cross-bispectrum equations can be modified by replacing $\{x_1(n)\}$ and $\{x_3(n)\}$ with $\{x(n)\}$ and $\{x_2(n)\}$ with $\{y(n)\}$, that is,

$$B_{xyz}(\omega_1, \omega_2) = \frac{1}{M} \sum_{m=1}^{M} X^m(\omega_1) Y^m(\omega_2) X^{m*}(\omega_1 + \omega_2) \tag{26.17}$$

In theory, both methods will lead to the same cross-bispectrum when data length is infinite. However, with finite data records, direct and indirect methods generally lead to cross-bispectrum estimates with different shapes (Figure 26.4). Therefore, like power spectrum estimation, users have to choose an appropriate method to extract the information desired.

Defining Terms

Bispectra: Computation of the frequency distribution of the EEG exhibiting nonlinear behavior.
Cross-spectra: Computation of the energy in the frequency distribution of two different electrical signals.
Electroencephalogram (EEG): Recordings of the electrical potentials produced by the brain.
Fast Fourier transform (FFT): Algorithms that permit rapid computation of the Fourier transform of an electrical signal, thereby representing it in the frequency domain.
Magnitude squared coherence (MSC): A measure of the degree of synchrony between two electrical signals at specified frequencies.
Power spectral analysis: Computation of the energy in the frequency distribution of an electrical signal.
Quadratic phase coupling (QPC): A measure of the degree to which specific frequencies interact to produce a third frequency.

Biomagnetism

Jaakko Malmivuo
Tampere University of Technology

Since the first detection of the magnetocardiogram (MCG) in 1963 by Baule and McFee [Baule and McFee, 1963], new diagnostic information from biomagnetic signals has been widely anticipated. The first recording of the magnetoencephalogram (MEG) was made in 1968 by David Cohen [Cohen, 1968], but it was not possible to record biomagnetic signals with good signal quality before the invention of the superconducting quantum interference device (SQUID) in 1970 [Zimmerman et al., 1970].

27.1   Theoretical Background

27.1.1   Origin of Bioelectric and Biomagnetic Signals

In 1819, Hans Christian Örsted demonstrated that when an electric current flows in a conductor, it generates a magnetic field around it [Örsted, 1820]. This fundamental connection between electricity

27-1

and magnetism was expressed in exact form by James Clerk Maxwell in 1864 [Maxwell, 1865]. In bioelectromagnetism, this means that when electrically active tissue produces a bioelectric field, it simultaneously produces a biomagnetic field as well. Thus the origin of both the bioelectric and the biomagnetic signals is the bioelectric activity of the tissue.

The following equations describe the electric potential field and the magnetic field of a volume source distribution $\bar{J}^i$ in an inhomogeneous volume conductor. The inhomogeneous volume conductor is represented by a piecewise homogeneous conductor where the regions of different conductivity σ are separated by surfaces S.

$$4\pi\sigma\Phi(r) = \int_v \bar{J}^i \cdot \nabla\left(\frac{1}{r}\right) dv + \sum_j \int_{S_j} (\sigma_j'' - \sigma_j')\Phi\nabla\left(\frac{1}{r}\right) dS_j \tag{27.1}$$

$$4\pi\bar{H}(r) = \int_v \bar{J}^i \cdot \nabla\left(\frac{1}{r}\right) dv + \sum_j \int_{S_j} (\sigma_j'' - \sigma_j')\Phi\nabla\left(\frac{1}{r}\right) dS_j \tag{27.2}$$

The first term on the right-hand side of Equation 27.1 and Equation 27.2 describes the *contribution of the volume source*, and the second term describes the contribution of boundaries separating regions of different conductivity, that is, the *contribution of the inhomogeneities* within the volume conductor. These equations were developed by David Geselowitz [Geselowitz, 1967, 1970].

27.1.2 Measurement of the Biomagnetic Signals

The amplitude of the biomagnetic signals is very low. The strongest of them is the MCG, having an amplitude on the order of 50 pT. This is roughly one-millionth of the static magnetic field of the earth. The amplitude of the MEG is roughly 1% of that of the MCG. This means that, in practice, the MEG can only be measured with the SQUID and that the measurements must be done in a magnetically shielded room. The MCG, instead, can be measured in the clinical environment without magnetic shielding.

27.1.3 Independence of Bioelectric and Biomagnetic Signals

The source of the biomagnetic signal is the electric activity of the tissue. Therefore, the most interesting and most important question in biomagnetism is whether the biomagnetic signals contain new information that cannot be obtained from bioelectric signals; in other words, whether the bioelectric and biomagnetic signals are fully independent or whether there is some interdependence. If the signals were fully independent, the biomagnetic measurement would possibly give about the same amount of new information as the bioelectric method. If there were some interdependence, the amount of new information would be reduced.

Helmholtz's theorem states that "A general vector field, that vanishes at infinity, can be completely represented as the sum of two independent vector fields, one that is irrotational (zero curl) and another that is solenoidal (zero divergence)" [Morse and Feshbach, 1953; Plonsey and Collin, 1961]. The impressed current density $\bar{J}^i$ is a vector field that vanishes at infinity and, according to the theorem, may be expressed as the sum of two components:

$$\bar{J}^i = \bar{J}^i_F + \bar{J}^i_V \tag{27.3}$$

where the subscripts F and V denote *flow* and *vortex*, respectively. By definition, these vector fields satisfy $\nabla \times \bar{J}^i_F = 0$ and $\nabla \times \bar{J}^i_V = 0$. We first examine the independence of the electric and magnetic signals in the infinite homogeneous case, when the second term on the right-hand side of Equation 27.1 and Equation 27.2, caused by inhomogeneities, is zero. The equation for the electric potential may be rewritten

as

$$4\pi\sigma\Phi = \int_{v}\nabla\left(\frac{1}{r}\right)\cdot\bar{J}^{\mathrm{i}}\mathrm{d}v = \int_{v}\frac{\nabla\cdot\bar{J}^{\mathrm{i}}}{r}\mathrm{d}v \tag{27.4}$$

and that for the magnetic field may be rewritten as

$$4\pi\bar{H} = -\int_{v}\nabla\left(\frac{1}{r}\right)\times\bar{J}^{\mathrm{i}}\mathrm{d}v = -\int_{v}\frac{\nabla\times\bar{J}^{\mathrm{i}}}{r}\mathrm{d}v \tag{27.5}$$

Substituting Equation 27.3 into Equation 27.4 and Equation 27.5 shows that under homogeneous and unbounded conditions, the bioelectric field arises from $\nabla\cdot\bar{J}_{\mathrm{F}}^{\mathrm{i}}$, which is the *flow source*, and the biomagnetic field arises from $\nabla\times\bar{J}_{\mathrm{V}}^{\mathrm{i}}$, which is the *vortex source*. For this reason, in the early days of biomagnetic research it was generally believed that the bioelectric and biomagnetic signals were fully independent. However, it was soon recognized that this could not be the case. For example, when the heart beats, it produces an electric field recorded as the P, QRS, and T waves of the ECG, and it simultaneously produces the corresponding magnetic waves recorded as the MCG. Thus the ECG and MCG signals are not fully independent.

There have been several attempts to explain the independence/interdependence of bioelectric and biomagnetic signals. Usually these attempts discuss different detailed experiments and fail to give a satisfying general explanation. This important issue may be easily explained by considering the sensitivity distributions of the ECG and MCG lead systems, and this will be discussed in the next section.

27.2 Sensitivity Distribution of Dipolar Electric and Magnetic Leads

27.2.1 Concepts of Lead Vector and Lead Field

27.2.1.1 Lead Vector

Let us assume that two electrodes (or sets of electrodes) are placed on a volume conductor to form a lead. Let us further assume that inside the volume conductor in a certain location Q there is placed a unit dipole consecutively in the *x*, *y*, and *z* directions (Figure 27.1a). Due to the sources, we measure from the lead the signals c_x, c_y, and c_z, respectively. Due to *linearity*, if instead of the unit dipoles we place in the source location dipoles that are p_x, p_y, and p_z times the unit vectors, we measure signals that are $c_x p_x$, $c_y p_y$, and $c_z p_z$, respectively.

If these dipoles are placed simultaneously to the source location, due to the principle of *superposition*, we measure from the lead a voltage, that is,

$$V = c_x p_x + c_y p_y + c_z p_z \tag{27.6}$$

These dipoles can be considered to be components of a dipole $\bar{p}$, that is, $\bar{p} = p_x\bar{i} + p_y\bar{j} + p_z\bar{k}$. We may understand the coefficients c_x, c_y, and c_z to be components of a vector $\bar{c}$, that is, $\bar{c} = c_x\bar{i} + c_y\bar{j} + c_z\bar{k}$. Now we may express the lead voltage Equation 27.6 as the scalar product of the vector $\bar{c}$ and the dipole $\bar{p}$ as

$$V = \bar{c}\cdot\bar{p} \tag{27.7}$$

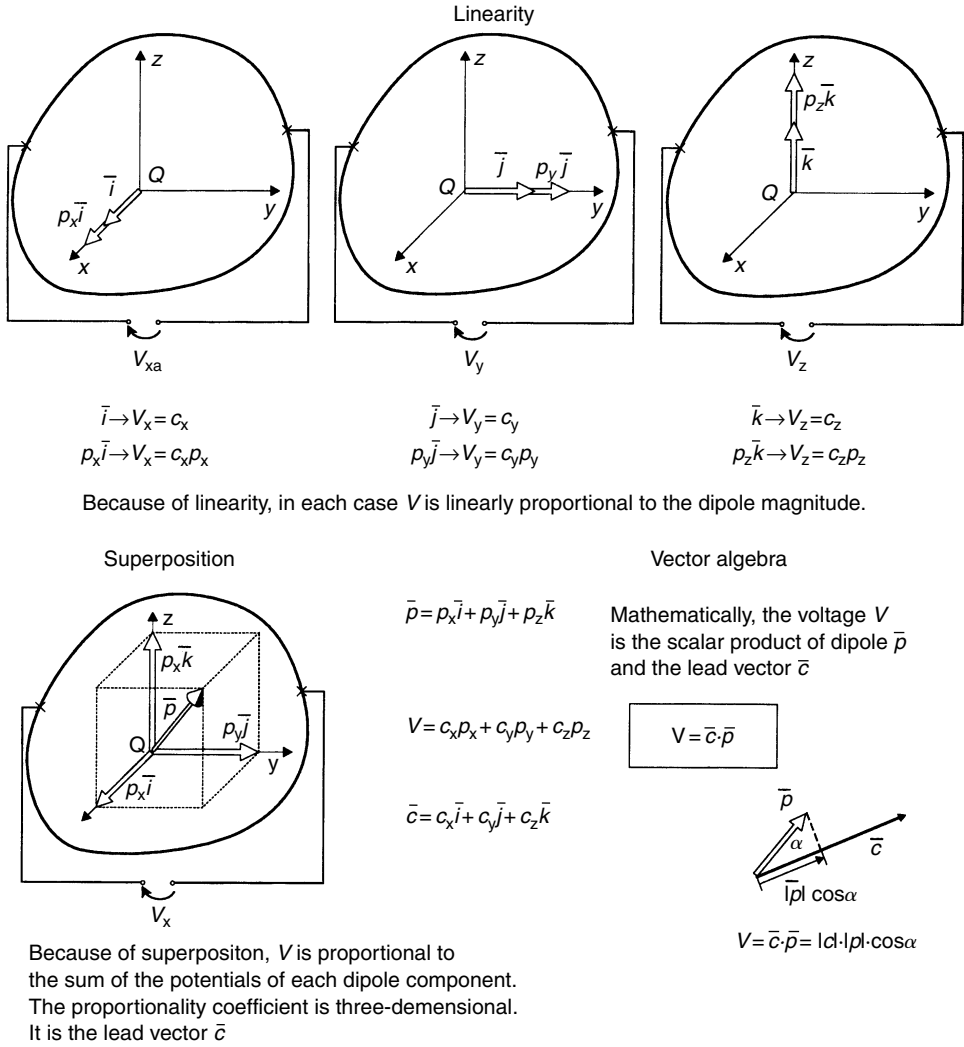
The vector $\bar{c}$ is a three-dimensional transfer coefficient that describes how a dipole source $\bar{p}$ at a fixed point Q inside a volume conductor influences the voltage measured from the lead and is called the *lead vector*.


FIGURE 27.1   The concepts of (a) lead vector and (b) lead field. (See the text for more details.)

The lead vector $\bar{c}$ describes what is the sensitivity of the lead to a source locating at the source location. It is self-evident that for another source location the sensitivity may have another value. Thus the sensitivity, that is, the lead vector, varies as a function of the location, and we may say that it has a certain distribution in the volume conductor. This is called the *sensitivity distribution*.

27.2.1.2   Lead Field

We may define the value of the lead vector at every point in the volume conductor. If we then place the lead vectors to the points for which they are defined, we have a field of lead vectors throughout the volume conductor. This field of lead vectors is called the *lead field* J_L. The lead field illustrates the behavior of the sensitivity in the volume conductor and is a very powerful tool in analyzing the properties of electric and magnetic leads (see Figure 27.1b).

It follows from the *principle of reciprocity*, described by Hermann von Helmholtz in 1853 [Helmholtz, 1853], that the lead field is identical to the electric current field that arises in the volume conductor if a unit current, called reciprocal current I_R, is fed to the lead.

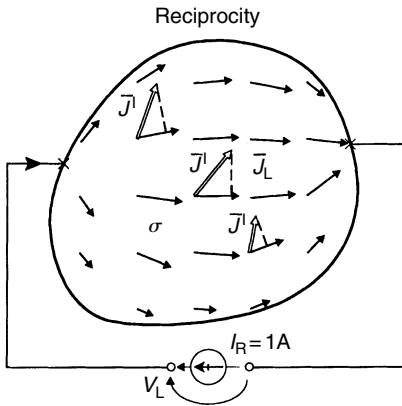
Field of lead vectors
Lead voltage

The field of the lead vectors $\bar{c}_k$ is the lead field $\bar{J}_L$
Each dipole element p_k contributes to the lead voltage by
The toal lead voltage is the sum of the lead voltage elements

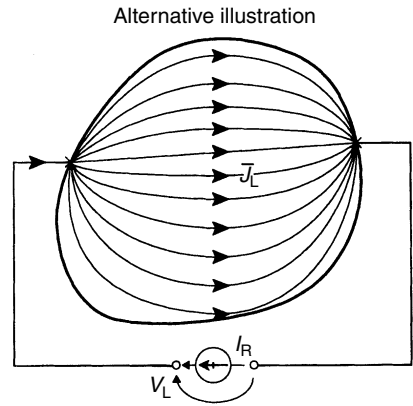
$$V_k = \bar{c}_k \bullet \bar{p}_k$$

$$V_L = \sum_k \bar{c}_k \bullet \bar{p}_k$$

Reciprocity

Alternative illustration


$$V_L = \int \frac{1}{\sigma} \bar{J}_L \bullet \bar{J}^i dv$$

Because of reciprocity, the field of lead vectors $\bar{J}_L$ is the same as the current field $\bar{J}_L$ raised by feeding a reciprocal current of 1A to the lead.


The lead field may also be illustrated with lead field current flow lines.

FIGURE 27.1   Continued.

When we know the lead field $\bar{J}_L$, we can determine the signal V_L in the lead due to the volume source distribution $\bar{J}^i$. For each source element the signal is, of course, proportional to the dot product of the source element and the lead field at the source location, as shown in Equation 27.7. The contributions of the whole volume source is obtained by integrating this throughout the volume source. Thus the signal the volume source generates to the lead is

$$V_L = \int \frac{1}{\sigma} \bar{J}_L \cdot \bar{J}^i dv \tag{27.8}$$

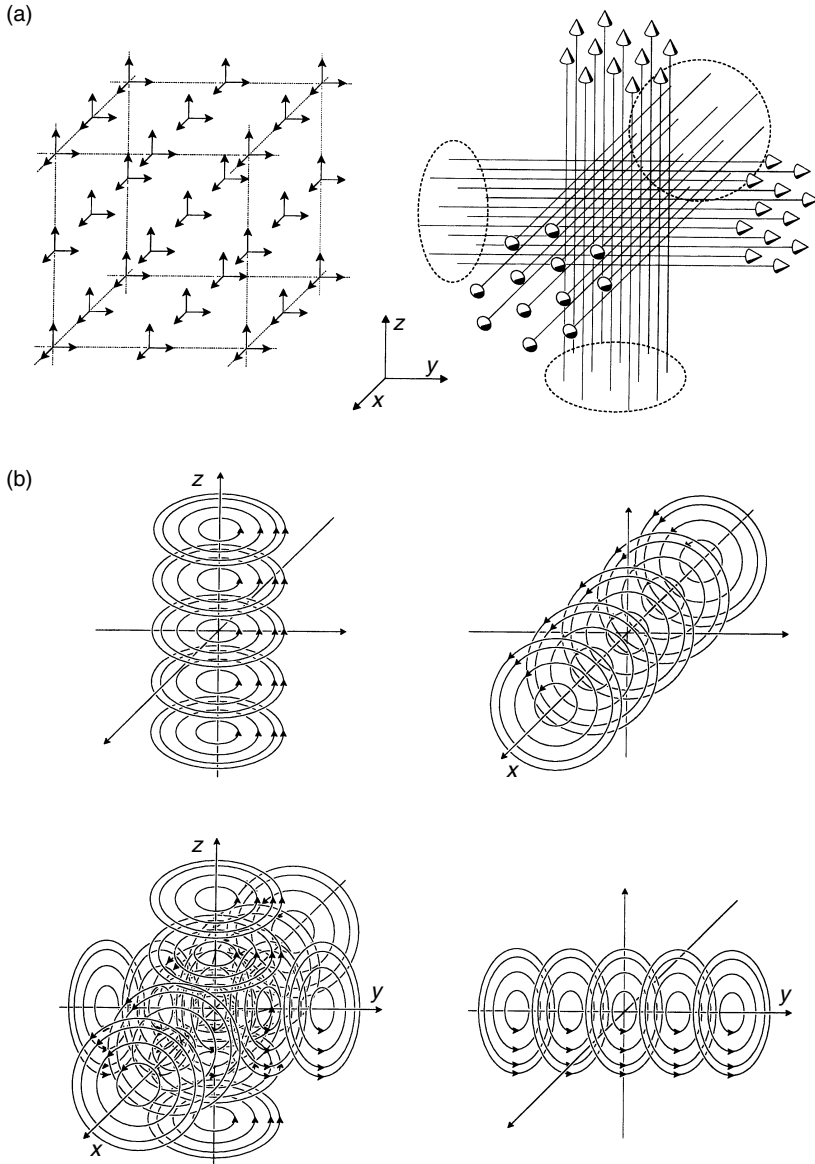
The lead field may be illustrated either with lead vectors in certain locations in the volume conductor or as the flow lines of the distribution of the reciprocal current in the volume conductor. This is called the *lead current field*. In the latter presentation, the lead field current flow lines are oriented in the direction of the sensitivity, and their density is proportional to the magnitude of the sensitivity.


FIGURE 27.2 Sensitivity distributions, that is, lead fields of lead systems detecting (a) electric and (b) magnetic dipole moments of a volume source. The lead field of the electric lead is shown both with vectors representing the magnitude and direction of the lead field (on the left) and with lead field current flow lines (on the right).

27.2.2 Lead Fields of Leads Detecting the Electric and Magnetic Dipole Moments of a Volume Source

27.2.2.1 Electric Lead

The sensitivity of a lead system that detects the electric dipole moment of a volume source consists of three orthogonal components (Figure 27.2a). Each of these is linear and homogeneous. In other words, one component of the electric dipole moment is detected when the corresponding component of all elements of the impressed current density $\bar{J}^i$ are detected with the same sensitivity throughout the source area.

27.2.2.2 Magnetic Lead

The sensitivity distribution of a lead system that detects the magnetic dipole moment of a volume source also consists of three orthogonal components (Figure 27.2b). Each of these has such a form that the sensitivity is always tangentially oriented around the symmetry axis (the coordinate axis). The magnitude of the sensitivity is proportional to the radial distance from the symmetry axis and is zero on the symmetry axis.

27.2.3 Independence of Dipolar Electric and Magnetic Leads

27.2.3.1 Electric Lead

The sensitivity distributions of the three components of the lead system detecting the electric dipole moment of a volume source are orthogonal. This means that none of them can be obtained as a linear combination of the two other ones. (Note that any fourth measurement having a similar linear sensitivity distribution would always be a linear combination of the three previous ones.) Thus the sensitivity distributions, that is, the leads, are orthogonal and thus independent. However, because the three electric signals are only different aspects of the same volume source, they are not (fully) independent.

27.2.3.2 Magnetic Lead

The sensitivity distributions of the three components of the lead system detecting the magnetic dipole moment of a volume source are also orthogonal, meaning that no one of them can be obtained as a linear combination of the two other ones. Thus, similarly, as in measurement of the electric dipole moment, the sensitivity distributions, that is, the leads, are orthogonal and thus independent. However, because the three magnetic signals are only different aspects of the same volume source, they are not (fully) independent.

On the basis of the sensitivity distributions, we also can similarly explain the independence between the electric and magnetic signals. According to Helmholtz's theorem, the electric leads are orthogonal to the three magnetic leads. This means that none of these six leads can be obtained as a linear combination of the other five. However, the six signals, which they measure, are not independent because they arise from the same electrically active volume source.

27.3 Magnetocardiography

27.3.1 Selection of the Source Model for MCG

In ECG and MCG it is the clinical problem to solve the inverse problem, that is, to solve the source of the detected signal in order to get information about the anatomy and physiology of the source. Although the actual clinical diagnostic procedure is based on measuring certain parameters, such as time intervals and amplitudes, from the detected signal and actually not to display the components of the source, the selection of the source model is very important from the point of view of available information.

In clinical ECG, the source model is a dipole. This is the model for both the 12-lead ECG and vectorcardiography (VCG). In 12-lead ECG, the volume conductor (thorax) model is not considered, which causes considerable distortion of the leads. In VCG, only the form of the volume conductor is modeled. This decreases the distortion in the lead fields but does not eliminate it completely. Note that today the display systems used in these ECG and VCG systems do not play any role in the diagnostic procedure because the computerized diagnosis is always based on the signals, not on the display.

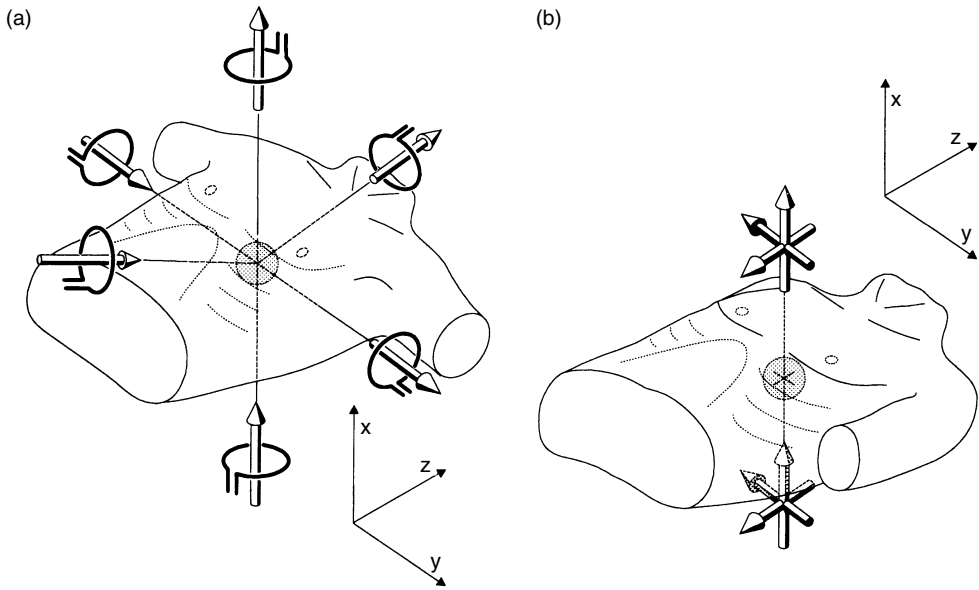
In selection of the source model for MCG, it is logical, at least initially, to select the magnetic source model to be on the same theoretical level with the ECG. Only in this way is it possible to compare the diagnostic performance of these methods. It is clear, of course, that if the source model is more accurate, that is, has more independent variables, the diagnostic performance is better, but when comparing ECG and MCG, the comparison is relevant only if their complexity is similar [Malmivuo and Plonsey, 1995].


FIGURE 27.3 Measurement of the three orthogonal components of the magnetic dipole moment of the heart (a) on the coordinate axis (*xyz* lead system) and (b) at a single location over and under the chest (unipositional lead system).

27.3.2 Detection of the Equivalent Magnetic Dipole of the Heart

The basic detection method of the equivalent magnetic dipole moment of a volume source is to measure the magnetic field on each coordinate axis in the direction of that axis. To idealize the sensitivity distribution throughout the volume source, the measurements must be made at a distance that is large compared with the source dimensions. This, of course, decreases the signal amplitude. The quality of the measurement may be increased considerably if bipolar measurements are used; that is, measurements are made on both sides of the source. Measurement of the magnetic field on each coordinate axis is, however, difficult to perform in MCG due to the geometry of the human body. It would require either six sequential measurements with one magnetometer (dewar) or six simultaneous measurements using six dewars (Figure 27.3).

It has been shown [Malmivuo, 1976] that all three components of the magnetic dipole also can be measured from a single location. Applying this unipositional method symmetrically so that measurements are made on both the anterior and posterior sides of the thorax at the same distance from the heart, only two dewars are needed and a very high quality of lead fields is obtained. Figure 27.4 illustrates the sensitivity distributions in nonsymmetrical and symmetrical measurements [Malmivuo and Plonsey, 1995].

27.3.3 Diagnostic Performance of ECG and MCG

The diagnostic performances of ECG and MCG were compared in an extensive study made at the Ragnar Granit Institute [Oja, 1993]. The study was made using the asymmetrical unipositional lead system, that is, making measurements only on the anterior side of the thorax. The patient material was selected, however, so that myocardial changes were located dominantly on the anterior side.

This study consisted of 290 normal subjects and 259 patients with different myocardial disorders. It was found that the diagnostic performance of ECG and MCG is about the same (83%). Diagnostic parameters were then selected from both ECG and MCG. With this combined method, called *electromagnetocardiogram* (EMCG), a diagnostic performance of 90% was obtained. This improvement in diagnostic
FIGURE 27.4 Sensitivity distributions in the measurement of the magnetic dipole moment of the heart. (a) Non-symmetrical and (b) symmetrical measurements of the *x* component. (c) Symmetrical measurement of the *y* and *z* components.

performance was obtained without increasing the number of parameters used in the diagnostic procedure. Moreover, this improvement is significant because it means that the number of incorrectly diagnosed patients was reduced by approximately 50%.

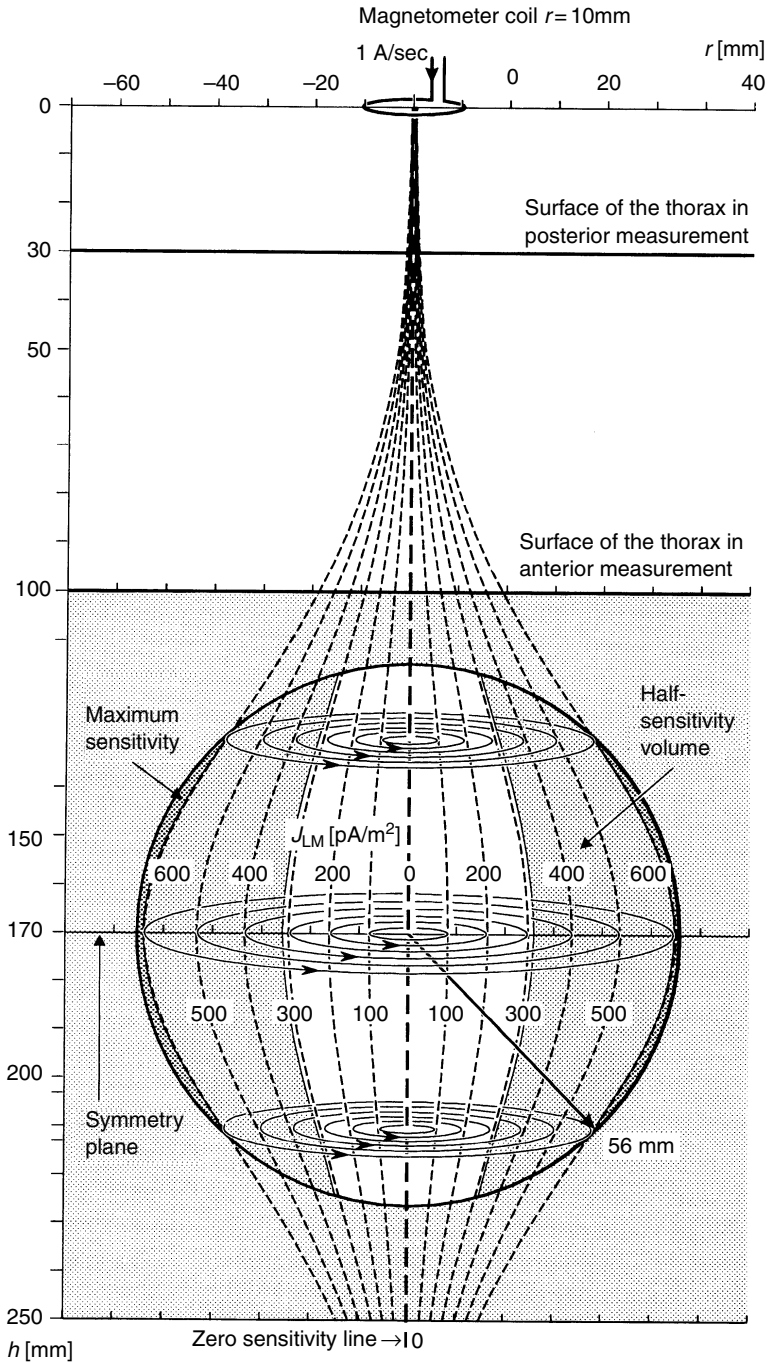
This important result may be explained as follows: The lead system recording the electric dipole moment of the volume source has three independent leads. (This is also the case in the 12-lead ECG system.) Similarly, the lead system detecting the magnetic dipole moment of the volume source has three independent leads. Therefore, the diagnostic performances of these methods are about the same. However, because the sensitivity distributions of electric and magnetic leads are different, the patient groups diagnosed correctly with both methods are not identical.


FIGURE 27.4 Continued.

As stated before, the electric leads are independent of the magnetic leads. If the diagnostic procedure simultaneously uses both the ECG and the MCG leads, we obtain $3 + 3 = 6$ independent leads, and the correctly diagnosed patient groups may be combined. Thus the diagnostic performance of the combined method is better than that of either method alone. This is the first large-scale statistically relevant study of the clinical diagnostic performance of biomagnetism.
FIGURE 27.4 Continued.

27.3.4 Technical Reasons to Use the MCG

The technical differences between ECG and MCG include the MCG's far better ability to record static sources, sources on the posterior side of the heart, monitor the fetal heart, and perform electrodeless recording. As a technical drawback, it should be mentioned that the MCG instrument costs 2 to 3 times more. An important feature of MCG is that, unlike the MEG instrument, it does not need a magnetically

shielded room. This is very important because the shielded room is not only very expensive but also limits application of the technique to a certain laboratory space.

27.3.5 Theoretical Reasons to Use the MCG

It has been shown that MCG has clinical value and that it can be used either alone or in combination with ECG as a new technique called the *electromagnetocardiogram* (EMCG). The diagnostic performance of the combined method is better than that of either ECG or MCG alone. With the combined method, the number of incorrectly diagnosed patients may be reduced by approximately 50%.

27.4 Magnetoencephalography

Similarly as in the cardiac applications, in the magnetic measurement of the electric activity of the brain, the benefits and drawbacks of the MEG can be divided into theoretical and technical ones. First, the theoretical aspects are discussed.

The two main theoretical aspects in favor of MEG are that it is believed that because the skull is transparent for magnetic fields, the MEG should be able to concentrate its measurement sensitivity in a smaller region than the EEG, and that the sensitivity distribution of these methods are fundamentally different. These questions are discussed in the following: The analysis is made using the classic spherical head model introduced by Rush and Driscoll [1969]. In this model, the head is represented with three concentric spheres, where the outer radii of the scalp, skull, and brain are 92, 85, and 80 mm, respectively. The resistivities of the scalp and the brain are 2.22 Ω cm, and that of the skull is 80 times higher, being 177 Ω cm.

The two basic magnetometer constructions in use in MEG are axial and planar gradiometers. In the former, both coils are coaxial, and in the latter, they are coplanar. The minimum distance of the coil from the scalp in a superconducting magnetometer is about 20 mm. The coil radius is usually about 10 mm. It has been shown [Malmivuo and Plonsey, 1995] that with this measurement distance, decreasing the coil radius does not change the distribution of the sensitivity in the brain region. In the following the sensitivity distribution of these gradiometer constructions is discussed.

To indicate the magnetometer's ability to concentrate its sensitivity to a small region, the concept of *half-sensitivity volume* has been defined. This concept means the region in the source area (brain) where the detector sensitivity is one-half or more from the maximum sensitivity. The smaller the half-sensitivity volume, the better is the detector's ability to focus its sensitivity to a small region.

In magnetocardiography, it is relevant to detect the magnetic dipole moment of the volume source of the heart and to make the sensitivity distribution within the heart region as independent of the position in the axial direction as possible. In magnetoencephalography, however, the primary purpose is to detect the electric activity of the cortex and to localize the regions of certain activity.

27.4.1 Sensitivity Distribution of the Axial Magnetometer

In a cylindrically symmetrical volume conductor model, the lead field flow lines are concentric circles and do not cut the discontinuity boundaries. Therefore, the sensitivity distribution in the brain area of the spherical model equals that in an infinite, homogeneous volume conductor.

Figure 27.5 illustrates the sensitivity distribution of an axial magnetometer. The thin solid lines illustrates the lead field flow lines. The dashed lines join the points where the sensitivity has the same value, being thus so-called isosensitivity lines. The half-sensitivity volume is represented by the shaded region.

27.4.2 Sensitivity Distribution of the Planar Gradiometer

Figure 27.6 illustrates the sensitivity distribution of a planar gradiometer. Again, the thin solid lines illustrate the lead field flow lines, and the dashed lines represent the isosensitivity lines. The half-sensitivity
FIGURE 27.5 Sensitivity distribution of the axial magnetometer in measuring the MEG (spherical lead model).

volume is represented by the shaded region. The sensitivity of the planar gradiometer is concentrated under the center of the two coils and is mainly linearly oriented. Further, there exist two zero-sensitivity lines.

27.4.3 Half-Sensitivity Volumes of Electro- and Magnetoencephalography Leads

The half-sensitivity volumes for different EEG and MEG leads as a function of electrode distance and gradiometer baselines are shown in Figure 27.7. The minimum half-sensitivity volume is, of course, achieved with the shortest distance/baseline. For three- and two-electrode EEG leads, the half-sensitivity volumes at 1 degree of electrode distance are 0.2 and 1.2 cm^3, respectively. For 10-mm-radius planar and axial gradiometer MEG leads, these volumes at 1 degree of coil separation (i.e., 1.6-mm baseline for axial gradiometer) are 3.4 and 21.8 cm^3, respectively.

The 20-mm coil distance from scalp and 10-mm coil radii are realistic for the helmet-like whole-head MEG detector. There exist, however, MEG devices for recording at a limited region where the coil distance and the coil radii are on the order of 1 mm. Therefore, the half-sensitivity volumes for planar gradiometers with 1-mm coil radius at 0- to 20-mm recording distances are also illustrated in Figure 27.7. These curves show that when the recording distance is about 12 mm and the distance/baseline is 1 mm, such a planar gradiometer has about the same half-sensitivity volume as the two-electrode EEG.

Short separation will, of course, also decrease the signal amplitude. An optimal value is about 10 degrees of separation. Increasing the separation to 10 degrees increases the EEG and MEG signal amplitudes to
FIGURE 27.6   Sensitivity distribution of the planar gradiometer (half-space model).

approximately 70 to 80% of their maximum value, but the half-sensitivity volumes do not increase considerably from their values at 1 degree of separation.

Thus, contrary to general belief, the EEG has a better ability to focus its sensitivity to a small region in the brain than the whole-head MEG. At about 20 to 30 degrees of separation, the two-electrode EEG lead needs slightly smaller separation to achieve the same half-sensitivity volume as the planar gradiometer. The sensitivity distributions of these leads are, however, very similar. Note that if the sensitivity distributions of two different lead systems, whether they are electric or magnetic, are the same, they detect exactly the same source and produce exactly the same signal. Therefore, the planar gradiometer and two-electrode EEG lead detect very similar source distributions.

27.4.4   Sensitivity of EEG and MEG to Radial and Tangential Sources

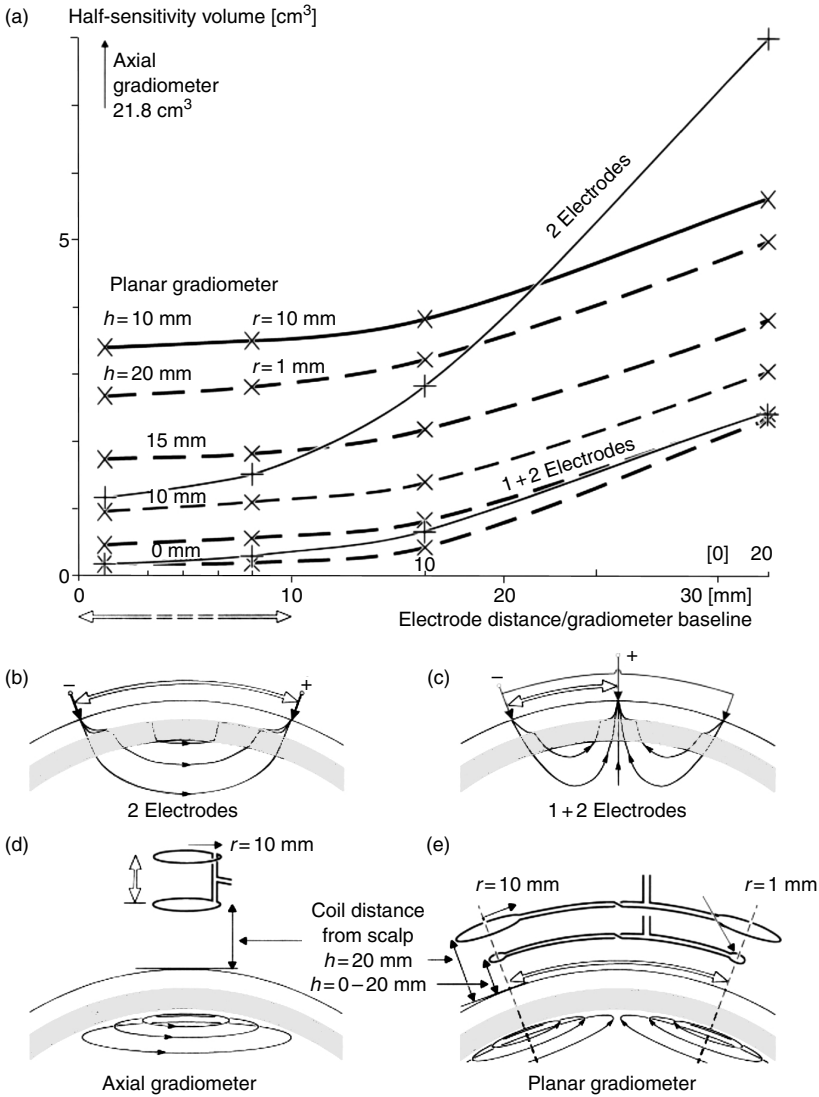
The three-electrode EEG has its maximum sensitivity under that electrode which forms the terminal alone. This sensitivity is mainly directed radially to the spherical head model. With short electrode distances, the sensitivity of the two-electrode EEG is directed mainly tangentially to the spherical head model. Thus with the EEG it is possible to detect sources in all three orthogonal directions, that is, in the radial and in the two tangential directions, in relation to the spherical head model.


FIGURE 27.7   Half-sensitivity volumes of different EEG leads (*dashed lines*) and MEG leads (*solid lines*) as a function of electrode distance and gradiometer baseline, respectively.

In the axial gradiometer MEG lead, the sensitivity is directed tangentially to the gradiometer symmetry axis and thus also tangentially to the spherical head model. In the planar gradiometer, the sensitivity has its maximum under the center of the coils and is directed mainly linearly and tangentially to the spherical head model. The MEG lead fields are oriented tangentially to the spherical head model everywhere. This may be easily understood by recognizing that the lead field current does not flow through the surface of the head because no electrodes are used. Therefore, the MEG can only detect sources oriented in the two tangential directions in relation to the spherical head model.

Electrical Stimulation of Excitable Systems

Dominique M. Durand
Case Western Reserve University

28.1   Introduction

Functional electrical stimulation (FES) of neural tissue provides a method to restore normal function to neurologically impaired individuals. By inserting electrode inside or near nerves, it is possible to activate pathways to the brain or to muscles. Functional nerve stimulation (FNS) is often used to describe applications of electrical stimulation in the peripheral nervous system. Neural prostheses refer to applications for which electrical stimulation is used to replace a function previously lost or damaged.

Electrical stimulation has been used to treat several types of neurological dysfunction with varying amount of success [see Hambrecht, 1979]. For example, electrical stimulation of the auditory nerves to restore hearing in deaf patients has proved to be not only feasible but also clinically useful [Clark, 1990]. Similarly, the phrenic nerve of patients with high-level spinal cord injury can be stimulated to produce diaphragm contractions and restore ventilation [Glenn, 1984]. Electrical stimulation of the visual cortex produces visual sensations called phosphenes [Brindley, 1968] and a visual prosthesis for the blind is currently being tested. Electrical stimulation in the peripheral nerves of paralyzed patients can restore partial function of both the upper extremities for hand function [Peckham and Mortimer, 1977] and lower extremities for gait [Marsolais and Kobetic, 1988]. Several other attempts were not so successful. Electrical stimulation of the cerebellum cortex for controlling epileptic seizures has been tried but was not reliable. However, a new method involving the stimulation of the vagus nerve looks promising [Rutecki, 1990]. There are many other applications of electrical stimulation of the nervous system and many problems associated with each one but it is now clear that the potential and the limits of the technique have not yet been realized.

Stimulation of the nervous system can also be achieved with magnetic field [Chokroverty, 1990]. A coil is placed near the excitable tissue and a capacitor is rapidly discharged into the coil. Large magnetic fluxes are generated and the induced electrical fields can generate excitation. Magnetic stimulation has several advantages over electrical stimulation. Magnetic fields can easily penetrate low-conductivity tissues such as bone and the stimulation it is completely noninvasive. However, magnetic stimulation requires a large amount of energy and the magnetic field is difficult to localize. Magnetic stimulation of excitable tissue shares many aspects with electrical stimulation since the electrical field is, in both cases, the source of the stimulus [Roth and Basser, 1990]. However, there are several important differences [Durand et al., 1989; Nagarajan and Durand, 1993] that are not reviewed below.

What is the basis for the effect of electric stimulation of the nervous system? Clearly, it comes from the fact that a propagated action potential can be triggered by applying a rapidly changing electric field near excitable tissue. This fact was demonstrated early in this century and clinical experimental applications resulted in the 1950s with the highly successful cardiac pacemaker. Other clinical applications have been slow in coming for several reasons that are to be discussed in later sections of this chapter. One of the difficulties is that the fundamental principles of the interaction of electrical fields and neurons is not completely understood. In order to understand how applied currents can generate excitation, it will be necessary to describe the mechanisms underlying excitation (Section 28.1), the distribution of currents inside the volume conductor (Section 28.2), and the interaction between the axon and applied electric fields (Section 28.3).

Another difficulty lies at the interface between electrodes applying the current and neural tissue to be stimulated. Electrons carry current in the wires to the electrodes whereas current in the volume conductor is carried by ions. Chemical reactions at the interface will take place and these reactions are still poorly understood. The waveforms used to apply the current can significantly affect the threshold, the electrochemistry at the electrode site, and tissue damage. These issues are reviewed in Section 28.4.

28.2 Physiology of Excitation

Electrical stimulation of excitable tissue is mediated by artificially depolarizing membrane containing channels capable of producing action potentials. Action potentials are normally elicited by synaptic currents, which in turn produce depolarization of the somatic membrane. The sodium channels are responsible for the generation of the depolarizing phase of the action potential and are sensitive to membrane voltage [Ferreira and Marschall, 1985]. Once initiated in the soma, the action potential is carried unattenuated along the axon to its intended target such as another neuron or neuromuscular junction for muscle contraction (see Figure 28.1). Unmyelinated axons have ionic channels distributed throughout their membrane and the action potential is carried smoothly along their length. The membrane of the axons containing the channels behaves as resistive and capacitive elements limiting the conduction velocity. Myelinated axons are surrounded by an insulation sheath of myelin, which significantly decreases the membrane capacitance, thereby increasing the speed of propagation. Conduction of the action potential is no longer smooth but takes place in discrete steps (saltatory conduction). The myelin sheath is broken at regularly spaced intervals (nodes of Ranvier) to allow the current to flow through the membrane [Aidley, 1978].

Action potential can be artificially generated by placing electrodes directly inside a cell. Current flowing from the inside to the outside will produce depolarization followed by excitation provided that the current amplitude is large enough. This technique cannot be used for functional stimulation since we do not yet have the technology to interface electrodes with large numbers of single axons. Therefore electrodes must be placed in the extracellular space near the tissue to be excited. It is then possible to activate simultaneously many cells. However, stimulation must be selective. Selectivity is defined as the ability of a stimulation system to activate any chosen set of axons. For example, the nervous system chooses to recruit small fibers connected to small motor units followed by large fibers connected to large motor units for smooth motor
FIGURE 28.1 Electrical stimulation of a myelinated fiber. An electrode is located near the axon and a cathodic stimulus is applied to the electrode. The current flow in and around the axon is described in this chapter and causes depolarization of the membrane at the sites closest to the electrodes. Action potentials are generated underneath the electrode and propagate orthodromically and antidromically.

control. Applied current pulses activate first large fibers and then small fibers with increasing current (reverse recruitment) for reasons described in Section 28.4. The reverse recruitment order as well as our inability to recruit a chosen set of axons within a nerve bundle makes electrical stimulation a powerful but difficult-to-control tool for the activation of the nervous system.

28.3 Electric Fields in Volume Conductors

The excitable tissue to be stimulated (peripheral nerves, motor neurons, CNS neurons, etc.) are in all cases surrounded by an extracellular fluid with a relatively high conductivity (80 to 300 Ω cm). The electrodes used for electrical stimulation are always placed in this "volume conductor" and it is essential to understand how the currents and the electric fields are distributed [Heringa et al., 1982]. The calculation of the current density and electric fields can be easily done in simple cases such as a homogenous conductivity (the same everywhere) and isotropic conductivity (the same in all directions).

Quasi-static formulation: The calculation of the electric fields generated by an electrode located in a conducting volume conductor can be done by solving Maxwell equations. The frequencies used for electric stimulation are generally under 10 kHz, and therefore a simplified set of equations known as the quasi-static formulation can be used [Plonsey, 1969]:

$$\text{Conservation of charge:} \quad \nabla \cdot J = 0 \tag{28.1}$$

$$\text{Gauss' law:} \quad \nabla \cdot E = \frac{\rho}{\varepsilon} \tag{28.2}$$

$$\text{Ohm's law for conductors:} \quad J = \sigma E \tag{28.3}$$

$$\text{Electric field:} \quad E = -\nabla \phi \tag{28.4}$$

where E is the electric field (V/m) defined as gradient of the scalar potential ϕ, J the current density (defined as the current crossing a given surface in A/m^2), σ the conductivity (inverse of resistivity) in S/m, ρ the charge density in C/m^3, ε the permittivity of the medium, and $\nabla \cdot \mathbf{A}$ the divergence of vector $\mathbf{A}$.

Equivalence between dielectric and conductive media: Assuming an infinite homogeneous conducting medium with conductivity σ with a single point source as shown in Figure 28.2a, the current density
FIGURE 28.2   Voltage and electric field along an axon. (a) The current density J within an infinite, homogenous, and isotropic volume conductor is radial and is inversely proportional to the square of the distance. (b) Voltage along an axon located 1 cm from an anode with 1 mA of current. (c) Electric field along the same axon.

J at any point is the sum of a source term J_s and an ohmic term σE.

$$J = \sigma E + J_s \tag{28.5}$$

Using Equation 28.1:

$$\nabla \cdot J = \nabla \cdot \sigma E + \nabla \cdot J_s = 0 \tag{28.6}$$

Since the volume conductor is homogeneous, $\nabla \cdot (\sigma E) = \sigma \nabla \cdot E$ and we then have:

$$\sigma \nabla \cdot E = -\nabla \cdot J_s \tag{28.7}$$

Since $E = -\nabla \phi$ and $\nabla \cdot (\nabla \mathbf{A})$ is by definition the Laplacian of $\mathbf{A}$, $\nabla^2 \mathbf{A}$, we then have

$$\nabla^2 \phi = \nabla \cdot \frac{J_s}{\sigma} = -\frac{I_v}{\sigma} \tag{28.8}$$

where I_v is a source term in A/m^3. The source term I_v is zero everywhere except where the sources are located. This equation is nearly identical to the Poisson equation derived from Equation 28.2

[Kraus and Carver, 1973]:

$$\nabla^2 \phi = -\frac{\rho}{\varepsilon} \tag{28.9}$$

derived for dielectric media. Using the following equivalence:

$$\rho \to I_{\mathrm{v}}$$

$$\varepsilon \to \sigma$$

the solution of the Poisson equation for dielectric problems can then be used for the solution of the current in volume conductors.

Potential from a monopole source: Given a point source (monopolar) in an infinite homogeneous and isotropic volume conductor connected to a current source I, the potential and currents anywhere can be easily derived. Using spherical symmetry, the current density J at a point P located at a distance r from the source is equal to the total current crossing a spherical surface with radius r (see Figure 28.2).

$$J = \frac{I}{4\pi r^2} \mathbf{u}_{\mathrm{r}} \tag{28.10}$$

where $\mathbf{u}_{\mathrm{r}}$ is the unit radial vector, r the distance between the electrode and the measurement point. The electric field is then obtained from Equation 28.3:

$$E = \frac{I}{4\pi \sigma r^2} \mathbf{u}_{\mathrm{r}} \tag{28.11}$$

The electrical field is the gradient of the potential. In spherical coordinates:

$$E = -\frac{\mathrm{d}\phi}{\mathrm{d}r} \mathbf{u}_{\mathrm{r}} \tag{28.12}$$

Therefore the potential at point P is obtained by integration:

$$\phi = \frac{I}{4\pi \sigma r} \tag{28.13}$$

It can be easily shown that this solution satisfies the Poisson equation. For a monopolar electrode, the current distribution is radial and is inversely proportional to the conductance of the medium and the distance to the source. The potential decays to zero far away from the electrode and goes to infinity on the electrode. The singularity at $r = 0$ can be eliminated by assuming that the electrode is spherical with finite radius a. Equation 28.13 is then valid on the surface of the electrode $r = a$ and for $r > a$ [Nunez, 1981].

Equation 28.13 can be generalized to several monopolar electrodes. Assuming n electrodes with a current I_i located at a distance r_i from the recording point, the voltage is then given by:

$$\phi = \frac{1}{4\pi \sigma} \sum_{n} \frac{I_i}{r_i} \tag{28.14}$$

For an axon located in the volume conductor as shown in Figure 28.2, the voltage along the axon located 1 cm away from an anode with a 1-mA current source is given by the following equation and is plotted in

$$\phi = \frac{I}{4\pi\sigma\sqrt{d^2 + x^2}} \tag{28.15}$$

The electric field along the axon can be obtained by taking the spatial derivative of Equation 28.15 and is plotted in Figure 28.2b.

Potential from bipolar electrodes and dipoles: In the derivation of the potential generated by a monopolar electrode, the current enters the volume conductor at the tip of the electrode and exits at infinity. However, in the following example (salt water tank), a current is applied through two monopolar electrodes separated by a distance d as shown in Figure 28.3a. The potential generated by this bipolar configuration can be calculated at point P (assuming that the voltage reference is at infinity) as follows:

$$\phi = \frac{I}{4\pi\sigma}\left(\frac{1}{r_1} - \frac{1}{r_2}\right) \tag{28.16}$$

When the distance d between the two electrodes is small compared to the distance r, the equation for the potential is given by the following dipole equation valid for $r \gg d$:

$$\phi = \frac{Id\cos\theta}{4\pi\sigma r^2} \tag{28.17}$$

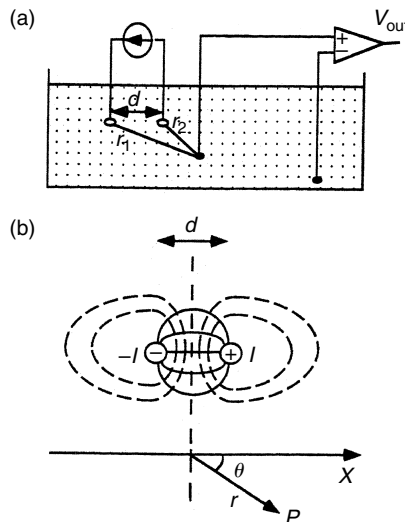
where the angle θ is defined in Figure 28.3. The current distribution for a current dipole is no longer radial and is shown in Figure 28.3b. The voltage along the line perpendicular to the axis of the dipole and passing through a point equidistant from the electrodes is zero. Therefore an axon located in that region would not be excited regardless of the current amplitude. The potential generated by a dipole is inversely proportional to the square of the distance and therefore decays faster than the monopole. Therefore,


FIGURE 28.3 Voltage generated by bipolar electrodes. (a) Salt water tank. Two electrodes are located within a large tank filled with a conduction solution. The voltage generated by the bipolar arrangement can be measured as shown provided that the reference electrode is located far away from the stimulation electrode. The effect of the stimulation electrode on the reference potential can also be taken into account. (b) Current lines and equipotential voltage distributions (dashed lines) for a dipole. The distance r between the observation P and the electrodes is much greater than the distance d between the electrodes.
FIGURE 28.4 Method of images. The method of images can be used to calculate the voltage generated by an electrode in a homogenous volume conductor. The two semi-infinite volume conductors with conductivities σ_1 and σ_2 (a) are replaced by a single infinite volume conductor with conductivity σ_1 and an additional image electrode (b).

the dipole configuration will have a more localized excitation region. However, the excitation thresholds are higher since most of the current flows around the electrode. For an observation point located at a distance r from a dipole or monopole with the same current, the ratio of the monopole voltage to that of the dipole voltage is proportional to r/d. Since r is assumed to be much larger than d, then the monopole voltage is much larger than the voltage generated by the dipole.

Inhomogenous volume conductors: For practical applications of electrical stimulation, electrodes are placed in various parts of the body. The volume conductors are clearly not homogenous since we must consider the presence of bone with a conductivity significantly higher than that of extracellular space or even air above the skin with a conductivity of zero. How do those conductivities affect the potentials generated by the electrode? This question can usually only be answered numerically by computer models, which take into account these various compartments such as finite differences, finite elements, or boundary elements methods. A simple solution, however, can be obtained in the case of a semi-infinite homogeneous volume conductor using the method of images. Consider two volume conductors with conductivities σ_1 and σ_2 separated by an infinite plane as shown in Figure 28.4. A monopolar stimulating electrode is placed in region 1. Potential recordings are made in that same region. It can be easily shown that the inhomogenous volume conductor can be replaced by a homogenous volume by adding another current located on the other side of the plane (see Figure 28.4) with an amplitude equal to [Nunez, 1981]:

$$I' = \frac{\sigma_1 - \sigma_2}{\sigma_1 + \sigma_2} I \tag{28.18}$$

The voltage at point P is then given by Equation 28.13. The mirror image theory is only applicable in simple cases but can be useful to obtain approximations when the distance between the recording electrode and the surface of discontinuity is small, thereby approximating an infinite surface [Durand et al., 1992].

28.4 Electric Field Interactions with Excitable Tissue

When axons are placed inside a volume conductor with a stimulation electrode, current flows according to equations derived in the previous section. Some of the current lines enter and exit the axon at different locations and will produce excitation or inhibition. An example of this current distribution is shown in Figure 28.5a for a monopolar anodic electrode. A length Δx of the axonal membrane can be modeled at rest by a capacitance C_m in parallel with a series combination of a battery (E_r) for the resting potential and a resistance R_m simulating the combined resistance at rest of all the membrane channels (see Figure 28.5b).
FIGURE 28.5 Effect of extracellular current on axon membrane polarization. (a) A monopolar anode is located near an axon and current enters and exits the membrane. (b) At rest the membrane can be modeled by a simple RC network. (c) When current enters the membrane, charge is added to the membrane capacitance and additive membrane polarization is generated. Therefore the membrane is hyperpolarized. (d) When current exits the axon, the membrane is depolarized.

Nonlinear ionic channels conductances can be added in parallel with the membrane resistance and capacitance. Their contribution at rest is small and becomes significant only around threshold. Since we are interested mainly how to drive the membrane potential toward threshold from resting values, their contribution is ignored. When current enters the membrane flowing from the outside to the inside, the membrane is hyperpolarized (moved closer to threshold) as illustrated in Figure 28.5c. Similarly, when the current exits the membrane, depolarization is generated (the membrane voltage is moved closer to the threshold). In the case of an anodic electrode illustrated in Figure 28.5, stimulation should not take place directly underneath the electrode but further along the axon where the membrane is depolarized.

A more quantitative approach to this problem can be obtained by modeling the interaction of the model with the applied current. The applied current I generates a voltage distribution in the extracellular space, which can be calculated using Equation 28.15 assuming a homogeneous and isotropic medium. An unmyelinated fiber is modeled as a one-dimensional network by linking together electrical models of the membrane with a resistance R_a to account for the internal resistance of the axon as shown in Figure 28.6a. The circuit can be simulated using numerical methods [Koch and Segev, 1989] or by using already available general software packages such as Pspice or neuronal simulation packages such as Neuron [Hines, 1984]. The variable of interest is the transmembrane potential V_m since the sodium channels are sensitive to the voltage across the membrane. V_m is defined as the difference between the intracellular voltage V_i and the extracellular voltage V_e minus the resting potential E_r in order the reflect the change from resting values. Stimulation of the fiber can occur when the extracellular voltage difference between two nodes is large enough to generate transmembrane voltage greater than the firing threshold. Applying Kirchoff's law at
FIGURE 28.6 Model of extracellular voltage and axon interactions. (a) The effect of the extracellular voltage generated by the stimulating electrode on the axon can be modeled by connecting directly the membrane compartment to the extracellular source. The effect of the ion channels can be taken into account by adding nonlinear conductances and an equilibrium battery (not shown). (b) The axon with an extracellular voltage in (a) is equivalent to an axon inside an infinite conductance medium (zero voltage) and an equivalent voltage source inside the membrane.

each node and taking the limit when the length of membrane Δx goes to zero, one obtains the following inhomogenous cable equation [Clark and Plonsey, 1966; Rall, 1979; Altman, 1988; Ratty, 1989]:

$$\lambda^2 \frac{\partial^2 V_\mathrm{m}}{\partial x^2} - \tau_\mathrm{m} \frac{\partial V_\mathrm{m}}{\partial t} - V_\mathrm{m} = -\lambda^2 \frac{\partial^2 V_\mathrm{e}}{\partial x^2} \tag{28.19}$$

V_m and V_e are the transmembrane and extracellular voltage, respectively. λ is the space constant of the fiber and depends only on the geometric and electric properties of the axon:

$$\lambda = \frac{1}{2}\sqrt{\frac{R_\mathrm{m}^\mathrm{s} d}{R_\mathrm{a}^\mathrm{s}}} \tag{28.20}$$

where R_m^s is the specific membrane resistance, R_a^s the axoplasmic specific resistance, and d the diameter of the axon. τ_m is the time constant of the axon and is given by:

$$\tau_\mathrm{m} = R_\mathrm{m} C_\mathrm{m} \tag{28.21}$$

The term on the right side of Equation 28.21 is called the source term or forcing function and is the product of the square of the space constant with the second spatial derivative of the extracellular voltage. In order to explain the significance of this term, it can be easily shown that the model in Figure 28.6a is equivalent to a model in which the extracellular space with its electrode and voltage has been replaced by
FIGURE 28.7 Equivalent source voltage (V_{eq}). A positive value of the V_{eq} indicates membrane depolarization and a negative value indicates membrane hyperpolarization. (a) Equivalent source voltage plotted along the axon for an anodic stimulus. The peak value is negative and therefore the membrane is hyperpolarized underneath the electrode. Depolarization occurs at the sites of maximum value of V_{eq} (arrows). (b) Cathodic stimulation generates depolarization underneath the electrode and the amplitude of V_{eq} is larger than that for anodic stimulation. Therefore, a cathodic stimulus has a lower threshold than an anodic stimulus. (c) V_{eq} is larger for fibers with larger diameter; therefore large diameter fibers are recruited first.

a set of equivalent voltage sources inside the nerve given by:

$$V_{eq} = \lambda^2 \frac{\Delta^2 V_e}{\Delta x^2} = \lambda^2 \frac{d^2 V_e}{dx^2}\bigg|_{\Delta x \to 0} \tag{28.22}$$

The amplitude of the equivalent voltage sources is plotted in Figure 28.7a for a 10-μm axon stimulated by a 1-mA anodic current located 1 cm away from the axon. A positive value for the equivalent indicates membrane depolarization while negative value indicates hyperpolarization. The peak value of the depolarization indicates the excitation site. Therefore, one would predict that for anodic stimulation, excitation would take place at the peak of the two depolarized regions and two action potentials would propagate toward the ends of the axon away from the electrode. Note that the shape of V_{eq} calculated is similar to that predicted by simply examining the current flow and out of the axon in Figure 28.5. This analysis is valid only at the onset of the pulse, since during the pulse, currents will be distributed throughout the cable and will affect the transmembrane potential [Warman et al., 1993]. However, it has been shown that for short pulses, these effects are small and the shape of the transmembrane voltage can be predicted using the source term of the cable equation.
FIGURE 28.8 Discrete model for myelinated fibers. The resistance R_n and capacitance C_n of the node of Ranvier is modeled with an additional internodal resistance R_a. The resistance of the myelin is assumed to be infinite in this model. Extracellular voltages are calculated or measured at each node and the transmembrane voltage can be estimated.

Discrete cable equation for myelinated axons: Electrical stimulation of myelinated fibers is significantly different from unmyelinated fibers since the presence of myelin sheath around the axon forces the current to flow in and out of the membrane only at the nodes (see Figure 28.1). The action potential propagates from one node to the next (saltatory conduction). The effect of an applied electrical field on a myelinated fiber can be described using a discrete model of the axon and extracellular voltage [McNeal, 1976; Rattay, 1989]. Such a model is shown in Figure 28.8 in which voltages are applied at each node. The resistance R_n represents the membrane resistance at the node of Ranvier only since the myelin resistance is considered very high for this model and is neglected. C_n is the capacitance at the node of Ranvier. R_a represents the resistance between two nodes. The battery for the resting potential is removed for simplification by shifting the resting potential to zero. R_n, C_n, and R_a are given by:

$$R_n = \frac{R_n^s}{\pi \, dl} \tag{28.23}$$

$$R_a = \frac{4 R_a^s L}{\pi \, d^2} \tag{28.24}$$

$$C_n = C_n^s \pi \, dl \tag{28.25}$$

where d is the inner fiber diameter, l the width of the node, and L the internodal distance R_n^s and R_a^s are the specific membrane and axosplasmic resistance at the node respectively (Figure 28.8). The cable equation for this model can be derived using Kirchoff's law:

$$\frac{R_n}{R_a} \Delta^2 V_m - R_n C_n \frac{\partial V_m}{\partial t} - V_m = -\frac{R_n}{R_a} \Delta^2 V_e \tag{28.26}$$

Δ^2 is the second difference operator: $\Delta^2 V = V_{n-1} - 2V_n + V_{n+1}$. Using Equation 28.23 to Equation 28.25 one can show that $R_n C_n$ and R_n / R_a is independent of the diameter since $L/D = 100$ and $d/D = 0.7$ and l is constant. Therefore, the left part of Equation 28.26 is independent of the diameter. The source term, however, does depend on the diameter but only implicitly. As the distance between the node increases

with the diameter of the fiber, the voltage across the nodes also increases suggesting that fiber with larger diameters are more easily excitable since they "see" larger potentials along the nodes.

Equivalent cable equation for myelinated fibers: The fiber dependence of these fibers can be expressed explicitly by using an equivalent cable equation recently derived [Basser, 1993] and adapted here to take into effect the extracellular voltage:

$$\lambda_{\text{my}}^2 \frac{\partial^2 V_{\text{m}}}{\partial x^2} - \tau_{\text{my}} \frac{\partial V_{\text{m}}}{\partial t} - V_{\text{m}} = -\lambda_{\text{my}}^2 \frac{\partial^2 V_{\text{e}}}{\partial x^2} \tag{28.27}$$

where λ_{my} is the equivalent space constant for the case of an axon with myelin sheath of infinite resistance and is defined as:

$$\lambda_{\text{my}} = \frac{1}{2} \sqrt{\frac{R_{\text{n}}^{\text{s}} \, dL}{R_{\text{a}}^{\text{s}} l}} \tag{28.28}$$

Unmyelinated/myelinated fibers: The equivalent cable equation for the myelinated fibers is similar to Equation 28.20 derived for unmyelinated axons. The forcing function is also proportional to the first derivative of the extracellular electrical field along the nerve. The dependence on the diameter can directly be observed by expressing the equivalent voltage source for myelinated fibers (V_{eqmy}) as a function of the inner diameter d:

$$V_{\text{eqmy}} = 35.7 \frac{R_{\text{n}}^{\text{s}}}{R_{\text{a}}^{\text{s}}} \frac{d^2}{e} \frac{d^2 V_{\text{e}}}{dx^2} \tag{28.29}$$

Equation 28.29 shows that V_{eqmy} is proportional to the square of the diameter of the fiber d while the equivalent voltage source for unmyelinated fiber is proportional to its diameter (Equation 28.22).

Anodic/cathodic stimulation: It has been demonstrated experimentally that in the case of electrical stimulation of peripheral nerves, cathodic stimulation has a lower threshold (less current required) than anodic stimulation. This experimental result can be directly explained by plotting V_{eq} for a cathodic and anodic electrode (1 mA) located 1 cm away from an 10-μm unmyelinated fiber (Figure 28.7). The maximum value of V_{eq} for anodic stimulation is 0.05 mV at the two sites indicated by the arrow. However, the maximum depolarization for the cathodic electrode is significantly larger at 0.2 mV with the site of excitation located directly underneath the electrode. In special cases, such as an electrode located on the surface of a cortex, cathodic stimulation can have a higher threshold [Ranck, 1975].

Large/small diameter axons: The equivalent voltage source of the cable equation is proportional to the square of the space constant λ. λ^2 is proportional to the diameter of the fiber (Equation 28.20) for myelinated fibers and to the square of the diameter (Equation 28.29) for myelinated fibers. Therefore, in both cases, V_{eq} is higher for fibers with larger diameter (see Figure 28.7c) and large diameter fibers have a lower threshold. Since the physiological recruitment order by the central nervous system (CNS) is to first recruit the small fibers followed by large ones, electrical stimulation produces a reverse recruitment order. However, techniques have been developed to recruit small fiber before large fibers by using a different stimulation waveform [Fang and Mortimer, 1991 and Lertmanorat and Durand, 2004a, b]. Since λ^2 is also dependent on the electrical properties of the axons, it is then possible to predict that fibers with a larger membrane resistance or lower axoplasmic resistance will also have lower thresholds.

Spatial derivative of the electrical field: The first spatial derivative (or the second spatial derivative of the voltage along the nerve) is responsible for electrical excitation of the nerve. Therefore, an electrical field with a nonzero second spatial derivative is required for excitation. An axon with a linearly decreasing voltage distribution would not be excited despite the presence of a large voltage difference along the axon.

This is due to the fact that a linear voltage distribution gives a constant electrical field and therefore the spatial derivative of the field is zero.

Activating function: The second spatial derivative term of the equivalent voltage source is also known as the activation function [Rattay, 1990]:

$$f_{\text{unmy}} = \frac{\mathrm{d}^2 V_e}{\mathrm{d}x^2} \tag{28.30}$$

This function can be evaluated from knowledge of the extracellular voltage alone and can be used to predict the location of excitation. For unmyelinated fibers, the activation function does not contain any information about the axon to be stimulated. In the case of myelinated fibers where the voltage is evaluated at the nodes of Ranvier, the activating function becomes:

$$f_{\text{my}} = \frac{\Delta^2 V_e}{\Delta x^2} \tag{28.31}$$

The new function contains implicit information about the fiber diameter since the distance L between the nodes of Ranvier is directly proportional to fiber diameter D ($L = 100 \times D$). The diameter dependence can be made explicit in Equation 28.29.

Net driving function: The equivalent voltage source or the activating function represent only the source term in the electrical model of the axon (Figure 28.6). However, the transmembrane voltage is determined by a weighted sum of the currents flowing at all the nodes. A net driving function which takes into account both the source term at each node and the passive redistribution from sources at other nodes has been defined and found useful for accurate prediction of the excitation threshold for any applied field [Warman et al., 1992].

Current–distance relationship: The amount of current required to activate a fiber with a given diameter depends of its geometry but also on its distance from the electrode. The farther away the fiber, the lower the voltage along the fiber (Equation 28.15); therefore larger current will be required to reach threshold. This effect is illustrated in Figure 28.9 for myelinated fibers. The distance as a function of current amplitude at threshold is plotted for several experiments [Ranck, 1975]. With a current of 1 mA, all fibers within 2 mm are activated. The calculated current–distance relationship for a 10-μm fiber has been shown to approximate well the experimental data (see dashed line in Figure 28.9) [Rattay, 1989]. The current–distance relationship is linear only for small distances. For distances above 1 mm, doubling the distance will require four times the current amplitude.

Longitudinal/transverse field: The equivalent voltage source is also proportional to the second spatial derivative of the potential present at each point along the axon. It is important to note that it is the longitudinal component of the electrical field, which is responsible for exciting the nerve. Therefore, electrodes placed longitudinally generate the most efficient stimulus since this placement would produce a large longitudinal electric field component. Conversely, electrodes placed transversely (on each side of the axon) require a much higher current since the largest component of the field does not contribute to the excitation of the nerve (Figure 28.10a).

Anodal surround block: As shown by the current–distance relation, the current amplitudes required for excitation decrease with distance. This is not entirely true for cathodic stimulation. Cathodic stimulation produces membrane depolarization underneath the electrode and membrane hyperpolarization on both sides of the electrodes (Figure 28.7b). As the current amplitude is increased, the hyperpolarization also increases and can block the propagation of the action potential along the axon. This effect is known as anodal surround block and is shown in Figure 28.10b. It is possible to identify three regions around the electrode each giving different responses. There is a spherical region close to the electrode (I) in which no
FIGURE 28.9 Current–distance relationship for monopolar cathodic stimulation of myelinated axons. The distance between the axon and the electrode is plotted as a function of current threshold amplitude for many experiments from several authors. The dashed line shows the current–distance relation calculated for 10-μm fiber stimulated with a 200-μsec pulse. (From Rattay F. *IEEE Trans. Biomed. Eng.* 36:676–681, 1989. With permission.)
FIGURE 28.10   (a) Longitudinal/transverse electrode placement. (b) Anodal surround block.

excitation will take place due to the surround block. Fibers located in the region (II) are excited and fibers still further away (III) from the electrode are below threshold and are not excited.

Unidirectionally propagated action potentials: Electrical stimulation of nerves with electrodes normally depolarizes the membrane to threshold producing two action potentials propagating in opposite directions

as shown in Figure 28.1. Stimulation techniques have been developed to generate action potential propagating in one direction only [Sweeney and Mortimer, 1981]. The techniques rely on the fact that bipolar stimulation generates depolarization under the cathode and hyperpolarization under the anode. By increasing the amount of hyperpolarization relative to the depolarization, the action potential generated underneath the cathode and traveling toward the anode can be blocked while the action potential traveling in the other direction can escape.

28.5 Electrode–Tissue Interface

At the interface between the electrode and the tissue, the shape of the waveform can influence the threshold for activation as well as the corrosion of the electrode and the tissue damage generated.

28.5.1 Effect of Stimulation Waveform on Threshold

Strength–duration curve: It has been known for a long time that it is the time-change in the applied current and not the continuous application of the external stimulus which can excite. DC currents cannot excite and even in small amplitudes can cause significant tissue damage. It has also been observed experimentally that the relationship between the pulse width and the amplitude suggests that it is the total charge injected which is the important parameter. This relationship between the amplitude and the width of a pulse required to bring an excitable tissue to threshold is shown in Figure 28.11a. The amplitude of the current threshold stimulus (I_{th}) decreases with increasing pulse width (W) and can be modeled by the following relationship derived experimentally [Lapicque, 1907]:

$$I_{th} = \frac{I_{rh}}{1 - \exp(-W/T)} \tag{28.32}$$

The smallest current amplitude required to cause excitation is known as the rheobase current (I_{rh}). T is the membrane time constant of the axon if the axon is stimulated intracellularly. For extracellular stimulation, T is a time constant which takes into account the extracellular space resistance. The relationship between current amplitude and pulse width can also be derived theoretically using the cable equation by assuming that total charge on the cable for excitation is constant [Jack et al., 1983].

Charge duration curve: The threshold charge injected $Q_{th} = I_{th} \times W$ is plotted in Figure 28.11b and increases as the pulse width increases.

$$Q_{th} = \frac{I_{rh} W}{1 - \exp(-W/T)} \tag{28.33}$$

The increase in the amount of charge required to fire the axon with increasing pulse width is due to the fact that for long pulse duration, the charge is distributed along the cable and does not participate directly to raising the membrane voltage at the excitation site. The minimum amount of charge Q_{min} required for stimulation is obtained by taking the limit of Q_{th} (Equation 28.33) when W goes to zero is equal to $I_{rh} \times T$. In practice, this minimum charge can be nearly achieved by using narrow current pulses.

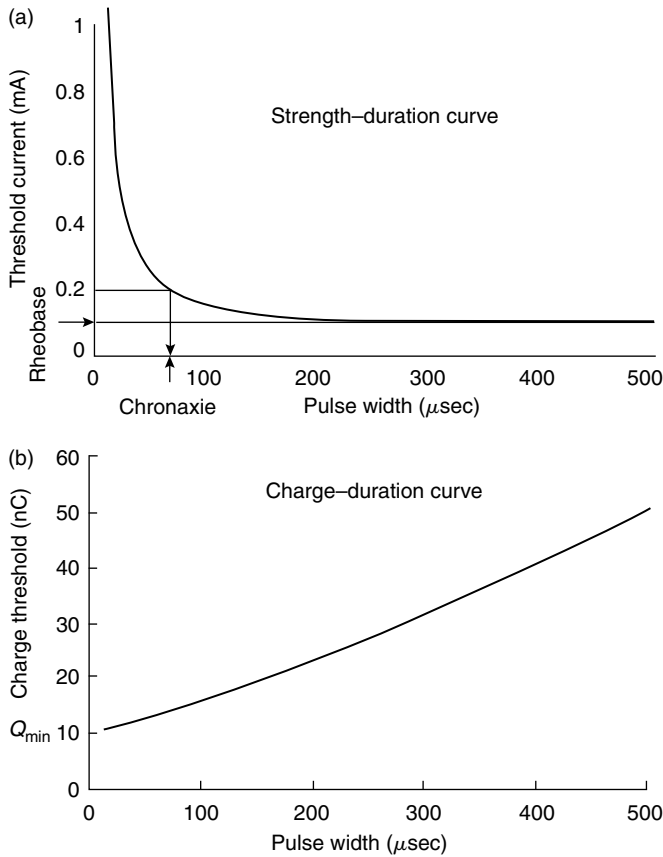
Anodic break: Excitation generated by cathodic current threshold normally takes place at the onset of the pulse. However, long-duration, subthreshold cathodic or anodic current pulses have been observed experimentally to generate excitation at the end of the pulse. This effect has been attributed to the voltage sensitivity of the sodium channel. The sodium channel is normally partially inactivated at rest. However, when the membrane is hyperpolarized during the long-duration pulse, the inactivation of the sodium channel is completely removed. Upon termination of the pulse, an action potential is generated since the inactivation gate has a slow time constant relative to the activation time constant and cannot recover fast enough [Mortimer, Chapter 3 in Agnew and McCreery, 1990]. This effect can be observed with an anodic


FIGURE 28.11 Effect of pulse width on excitation threshold. (a) Strength–duration curve. The amplitude of the current required to reach threshold decreases with the width of the pulse. This effect can be derived theoretically by assuming that the charge on the cable at threshold is constant. (b) The threshold charge (amplitude × pulsewidth) injected into the tissue increases with the pulse width. Narrow pulse are recommended to minimize charge injection.

or cathodic pulse since both can generate hyperpolarization. Anodic break can be prevented by avoiding abrupt termination of the current. Pulse shapes with slow decay phases such as exponential or trapezoidal decay shapes have been successfully used [Fang and Mortimer, 1991].

Electrochemistry of stimulation: Conduction in the metal is carried by electrons; while in the tissue, current is carried by ions. Although capacitive mechanisms have been tested, electrodes have not yet been developed which can store enough charge for stimulation. Therefore most electrical stimulation electrodes rely on Faradaic mechanisms at the interface between the metal and the tissue. Faradaic mechanisms require that oxidation and reduction takes place at the interface [Roblee and Rose, chapter 2 in Agnew and McCreery, 1990]. Faradaic stimulation mechanisms can be divided into reversible and nonreversible mechanisms. Reversible mechanisms occur at or near the electrode potential and include oxide formation and reduction, hydrogen plating. Irreversible mechanisms occur when the membrane is driven far away from its equilibrium potential and include corrosion, hydrogen, or oxygen evolution. Those irreversible processes can cause damage to both the electrode and the tissue since they alter the composition of the electrode surface and can generate toxic products with pH changes in the surrounding tissue. During charge injection, the electrode potential is modified by an amount related to the charge density (total charge divided by the surface area). In order to maintain the electrode potential within regions producing only minimal irreversible changes, this charge density must be kept below some values. The maximum

charge density allowed depends on the metal used for the electrode [Merrill et al., 2005], the stimulation waveform, the type of electrode used, and the location of the electrode within the body.

Stimulation of brain tissue: Electrodes can be placed on the surface of the brain and directly into the brain to activate CNS pathways. Experiments with stimulation of electrodes arrays made of platinum and placed on the surface of the brain indicate that damage was produced for charge density between 50 and 300 $\mu C/cm^2$, but that the total charge/phase was also an important factor and should be kept below 3 μC [Pudenz, 1975a, b]. Intracortical electrodes with small surface area can tolerate a charge density as high as 1600 $\mu C/cm^2$ provided that the charge/phase remains below 0.0032 μC [Agnew, 1986]. More recently, studies have shown that prolonged stimulation by electrode cortical arrays can significantly decrease the excitability of the neural tissue [McCreery et al., 2002].

Stimulation of the peripheral nerve: The electrodes used in the peripheral nerves are varied and include extraneural designs such as the spiral cuffs or helix electrode [Naples et al., 1991] with electrode contacts directly on the surface of the nerve or intraneural designs placing electrodes' contacts directly inside the nerve [Nannini et al., 1991; Rutten et al., 1991]. Intraneural electrodes can cause significant damage since electrodes are inserted directly into the nerve through the perineurium. However, these electrodes can display good selectivity. Extraneural electrodes are relatively safe since the newer designs such as those at the spiral or helix are self-sizing and allow swelling without compression but display poor selectivity. Damage in peripheral nerve stimulation can be caused by the constriction of the nerve as well as neuronal hyperactivity and irreversible reactions at the electrode [McCreery et al., 1992]. New electrode designs aimed at producing selective stimulation by recruiting only small portions of the nerve have been proposed [Veraart et al., 1993; Tyler and Durand, 1994]. An electrode array has been designed to place electrodes directly into the nerve through the epineurium and the perinerium [Branner et al., 2001]. Another design takes advantage of the plasticity of the nerve and reshapes the nerve cross section into a flatter configuration. With this flat interface nerve electrode (FINE) design, electrodes can be placed close to the fascicles without damaging the perineurium [Tyler and Durand, 2002, 2003].

Stimulation of muscle tissue: Muscle tissue can be best excited by electrodes located on the nerve supplying the muscle [Popovic, 1991]. However, for some applications, electrodes can be placed directly on the surface of the skin (surface stimulation, Myklebust et al., 1985), directly into the muscle (intramuscular electrode, Caldwell and Reswick, 1975), or on the surface of the muscle (epimysial electrode, Grandjean and Mortimer, 1986). The current thresholds are higher when compared to nerve stimulation unless the electrode is carefully placed near the point of entry of the nerve [Mortimer, 1981]. Stainless steel is often used for these electrodes and is safe below 40 $\mu C/cm^2$ for coiled wire intramuscular electrodes [Mortimer, 1980].

Corrosion: Corrosion of the electrode is a major concern since it can cause electrode damage, metal dissolution, and tissue damage. However, corrosion occurs only during the anodic phase of the stimulation. Therefore, by using monophasic waveform as shown in Figure 28.12b, corrosion can be avoided. Conversely, the monophasic anodic waveform (Figure 28.12a) must be avoided since it will cause corrosion. (This not true, however for capacitive electrode metals such as tantalum for which a dielectric layer of tantalum pentoxide is formed during the anodic phase and reduced during the cathodic phase.) For most applications, cathodic stimulation has a lower threshold than that of anodic stimulation. It appears, therefore, that monophasic cathodic waveforms (Figure 28.11a) would be a preferred stimulation waveform since it minimizes both the current to be injected and the corrosion. However, since the current only flows in one direction, the chemical reactions at the interface are not reversed and the electrode is driven in the irreversible region.

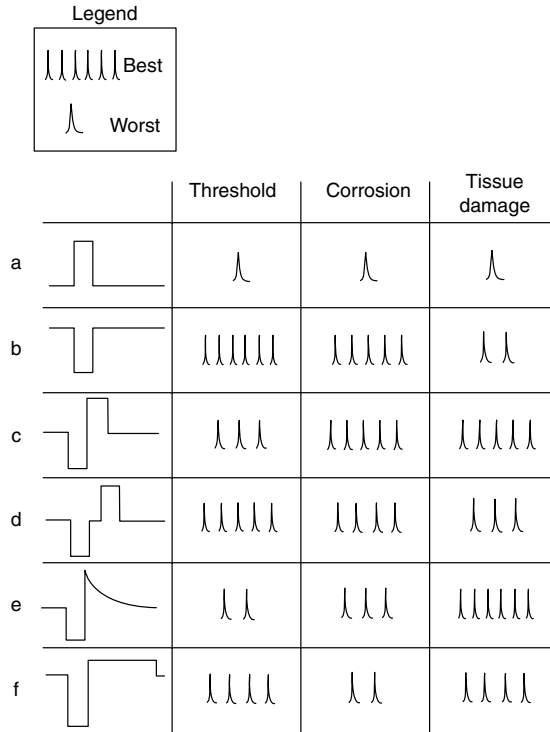
Tissue damage: Electrodes operating in the irreversible region can cause significant tissue damage since irreversible process can modify the pH of the surrounding tissue and generate toxic products. Balanced biphasic waveforms are preferred since the second phase can completely reverse the charge injected into the tissue. Provided that the amplitude of the current is small, the electrode voltage can then be maintained within the reversible region. Waveforms that have the most unrecoverable charge are the most likely to induce tissue damage. Tissue damage can also be caused by generating high rate of neural activity


FIGURE 28.12 Comparison of stimulation waveforms. The waveforms are ranked for their ability to generate low threshold stimulation, low corrosion, and low tissue damage.

[Agnew et al., chapter 6 in Agnew and McCreery, 1990]. The mechanisms underlying this effect are still unclear but could include damage to the blood–nerve barrier, ischemia, or a large metabolic demand on the tissue leading to changes in ionic concentration both intra- and extracellularly.

Biphasic waveforms: Common biphasic waveforms for stainless steel or platinum use a cathodic pulse followed by anodic phase. An example of a square-balanced biphasic waveform is shown in Figure 28.12c. Another commonly used biphasic waveform easily implemented with capacitor and switches is shown in Figure 28.12e. This waveform ensures that the charge is exactly balanced since a capacitor is inserted in series with the tissue to be stimulated and the charge injected is then reversed by discharging the capacitor [Mortimer, 1981]. Biphasic cathodic-first waveforms have a higher threshold than monophasic waveforms since the maximum depolarization induced by the cathodic pulse is decreased by the following anodic pulse [Mortimer, chapter 3 in Agnew and McCreery, 1990]. A delay can then be inserted between the cathodic and anodic phase as shown in Figure 28.12d. However, the time delay can also prevent adequate charge reversal and can be dangerous to the electrode and the tissue. An alternative method is to decrease the maximum amplitude of the anodic phase but increase its length as shown in Figure 28.12f. However, this can also be damaging to the electrode since the charge is not reversed fast enough following the cathodic pulse. The various waveforms shown in Figure 28.12 are ranked for their effect on tissue damage, corrosion, and threshold of activation [See also Merrill et al, 2005].

28.6 Conclusion

Electrical stimulation of excitable tissue has been used for over a century and important discoveries have been made concerning the mechanisms underlying the interactions between the applied fields with the

tissue and the electrochemistry at the electrode–tissue interface. It is now clear that electrical stimulation is a powerful technique, which could potentially activate any excitable tissue in the body and replace damaged functions. It is also clear, however, that if our goal is to provide intimate interfacing between excitable tissue and electrodes in order to reproduce the normal function of the nervous system, present technology is not adequate. The electrodes are too large relative to the size of the axons and can only access either a few elements separately or a large number of elements simultaneously. Moreover, it is also clear that our understanding of the electrochemistry at the interface between the electrode and tissue is limited as well as the mechanisms underlying tissue damage. However, the substantial gains to be made are worth the efforts required to solve these problems.

W E ARE AT THE CUSP OF A TECHNOLOGICAL REVOLUTION that holds promise to have more of an impact on human health, disease, and quality of life than any other development in history. Based on a foundation of fundamental science and empirical observation, engineering research and design has brought us into an era where it is no longer boastful to expect that the blind will see and the paralyzed will walk. We have seen how the development of implantable pacemakers and defibrillators over the last half century has redefined life for patients with heart disease. We are about to witness a far more dramatic revolution. The convergence of decades of neuroscience research and technology development has now reached critical mass and is propelling the neural engineering field into the commercialization phase. First-generation pacemakers, *surface stimulators* and *single-channel* neural prosthetic implants were essentially miniaturized benchtop pulse generators, and the engineering challenges involved in their production were encapsulation, battery life, and component reliability. Now we are conceiving and implanting multichannel implants with closed-loop feedback and autonomous control systems, and the engineering challenges push the limits of medical knowledge and human creativity. We are developing a depth knowledge of neural function never before dreamed of . . . as we must, if we are to be successful in our charge to augment and ultimately to replace neural function. *The payoff is huge: improved quality-of-life and functional restoration following stroke, spinal cord injury, and traumatic brain injury, with extension into deafness, blindness, paralysis, and movement disorders, and even some mental illness and seizure disorders.*

Neural Engineering has taken longer to reach the cusp of commercialization than many other medical device fields, such as that of pacemakers, largely because of the number and complexity of the multiple fields of knowledge in neuroscience, biomaterials, and engineering required to achieve acceptable efficacy. But Neural Engineering has the potential for impact on many disease states that are far from the realm of the neurologist or neurosurgeon, because excitable and hence stimulatable, tissue is implicated in the functioning of virtually every organ system in the body.

This volume represents contributions from a sampling of thought leaders in industry, academia, and clinical medicine and provides an understanding of the history, physiology, and some of the most promising engineering technologies in the industry. An exhaustive compilation is beyond the scope of this volume and is the subject of a planned separate text. DiLorenzo and Gross relate the extraordinary breadth and duration of investigation and discovery that has led up to the current flood of innovation. *Grill, an early leader in functional electrical stimulation (FES), describes the theoretical foundation for stimulation of cells of the nervous system. Graupe, an early pioneer in the research and clinical application of noninvasive FES for gait restoration discusses the research and commercialization efforts behind ParaStep. Davis et al. have outlined the development, success, and difficulties of a multichannel wired-linked stimulating system for functional restoration in paraplegia.* Kennedy, a pioneer in neural interfacing and the first to chronically record neural signals from a human, describes and compares various neural recording technologies. Schulman, a cofounder of Pacesetter systems and now president of The Alfred Mann Foundation, and colleagues describe the BION, a broadly applicable platform technology for minimally invasive neural stimulation and sensing. Greenberg, president of Second Sight, provides insight into the development of a breathtaking technology which offers hope to the blind. Velasco et al., leaders in the field of neurostimulation for the treatment of epilepsy, describe their experiences with seizure control. Roth and Zangen describe

promising innovations in the noninvasive transcranial magnetic stimulation technology, which is being commercialized for a number of promising indications.

The convergence of disciplines described herein is becoming apparent to researchers, engineers, clinicians, established medical device companies, early stage venture capital investors, and a wave of startup companies. We are witnessing the transition of Neural Engineering from basic research to intense commercialization and widespread clinical application and acceptance. The impact of this industry on medicine and on society promises to be as dramatic as that of the development of antibiotics. We are entering an era in which the nervous system is replaceable and augmentable . . . the Neurological Age. The future is upon us.

29.1 Background

Recent years have witnessed remarkable advances in the development of technology and its practical applications in the amelioration of neurological dysfunction. This encompasses a wide variety of disorders and their treatment has been the purview of different, partially overlapping, medical and scientific specialties and societies. As a result of these advances, three somewhat independent and long-standing fields with unique origins — stereotactic and functional neurosurgery, neuromodulation, and functional electrical stimulation — are experiencing increasing convergence and overlap and the distinctions separating them are beginning to blur.

Stereotactic and functional neurosurgery — which takes its origins at the beginning of neurosurgery in the late 19th century, but which as a society dates to the 1940s — has mainly concerned itself with the surgical treatment of nervous system conditions that manifest as disordered function, including movement disorders (Parkinson's disease [PD], tremor, dystonia), pain, epilepsy, and psychiatric illnesses. In the first part of the last century, the surgical treatment of these disorders usually involved ablation of nervous tissue but this has almost completely been supplanted by the advent of electrical neurostimulation. Other modalities within the purview of stereotactic and functional neurosurgery include pharmacological and biological therapies that are delivered via surgical techniques.

29-1

Neuromodulation broadly involves alteration of the function of the nervous system. The International Neuromodulation Society was established in the 1990s and dedicated itself to the treatment of nervous system disorders — mostly pain and spasticity — with implantable devices, including pumps and stimulators. However, with the advances in the field, this society has broadened its scope to include implantable devices used to treat disorders of sensory and motor functions of the body. This society has been driven by both anesthesiologists and neurosurgeons, but has mainly been clinical in its purview.

Functional electrical stimulation has pertained mostly to the restoration of upper and lower limb function (after injury and ischemia), bowel, bladder and sexual function, and respiratory function. This field, represented by the International Functional Electrical Stimulation Society, also is interested in auditory and visual prostheses, and has — in contrast to the two other societies — a distinctly engineering bias, limited as it has been to electrical stimulation.

It is quite clear that each of these areas has strong overlap, both clinically as well as technologically. While one or the other may have been more clinical or basic in its scientific approach, with the progress in both technology development and its translation into the clinic, these distinctions are becoming increasingly blurred. Advances in functional neurosurgery have been driven by clinical empiricism and advances in pathophysiological understanding of the target disorders, but also by technological advancement (e.g., the development of the stereotactic frame and then frameless image guidance stereotactic technology and the development of implantable neurostimulation systems). Neuromodulation — based as it is on the use of implantable devices — has been driven by technical and pharmacological innovation coupled to increased understanding of neurophysiology and the pathophysiological manifestations in states of disease. Finally, functional electrical stimulation (FES) has mostly been an undertaking driven by engineering technology, since from the outset the goals have been restoration of motor function using controlled electrical stimulation. Clinical application has always been the long-term objective and with the current synergy of technological innovation and increasing clinical experimentalism (e.g., motor prosthesis trials for spinal cord injury) the field is making great strides.

The technology that is a main driver behind each of these overlapping disciplines can be coined "neural engineering." Although this domain might seem like a relatively recent innovation, a view into the historical underpinnings of neuromodulation in the 18th century reveals that in fact from the start, technological innovation and neuromodulation developed hand in hand, and some of this pioneering foundation building of the last several centuries might reasonably be called neural engineering.

29.1.1 The Early History of Electrical Stimulation of the Nervous System

The use of electricity for therapeutic purposes can arguably be said to date back even to the use of amber and magnetite in jewelry around 9000 BC [1]. The use of the torpedo fish or electric eel was advocated by Scribonius Largus — one of the first Roman physicians in the first millennium — for the treatment of headache and gout [2]. The patient would apply the fish to the painful region until numb (but not too long) [3]. Its use continued into the 16th century by which time the indications were broadened to include melancholy, migraine, and epilepsy.

By the 17th century electricity was identified as a form of energy and primitive devices to induce electric current were developed. The first electrostatic generator was constructed in 1672, but electrical sparks from a modified electrostatic generator were first used therapeutically to treat paralysis in 1744 [3] (the first example of neural engineering?). In 1745 in Leyden, the capacity of an electrified glass jar and tin foil — the Leyden jar — to store electrical charge was inadvertently discovered when its discharge caused a physiological effect so severe that the experimenter took two days to recover [4]. Electricity and the nervous system were intricately associated early on because the most sensitive electrical detector at the time was in fact the nervous system. The new phenomenon was quickly embraced by the medical field, and "cures" of paralysis and other ailments rapidly proliferated, yielding many fantastic books from "electrotherapists" such as John Wesley the divine [3,4]. By 1752, even Benjamin Franklin was using it, to treat a 24-year-old woman with convulsions [5], and various palsies, but he at least was not convinced of any persistent benefits from the electrical treatments [4].

Albrecht von Haller felt that nerves and muscles were sensitive to the effects of electrical current, but he and others did not believe that electricity played a role in normal functioning [6]. In 1791, Galvani published his famous experiments in which he induced muscular contractions in frog leg muscle using a metallic device constructed of dissimilar metals [7]. He reasoned that the electrical current was being "discharged" from the muscle, a view which was countered by Volta who felt that the electrical current flowed from the dissimilar metals [8] and which led him to develop the voltaic bimetallic pile — the first battery — based on this insight [9]. Electrophysiological experiments using voltaic piles to generate "Galvanic current" rapidly proliferated, including important experiments by Aldini, Galvani's nephew, who was interested in, among other things, the therapeutic applications of galvanism [6] (more examples of neural engineering). His particular interest was in "reanimation" especially following near-drowning, and this work included electrically stimulating both animals and men — the latter following the not infrequent hangings and decapitations [10]. He was successful at provoking muscular contractions of the somatic musculature, but was disappointed that he could not get similar results with the heart [6]. In fact, Aldini was likely the first to induce facial muscle contractions with direct brain electrical stimulation in both oxen and human cadavers, predating Fritsch and Hitzig's influential work by many years [11]. A particularly dramatic demonstration on a hanged criminal in England garnered widespread lay coverage, possibly contributing to the inspiration behind the *Frankenstein* myth [6]. He also used the voltaic piles to treat "mental disorders" including depression — a precursor to electroconvulsive therapy — after first applying the pile safely to his own head [10].

The next major advance arose from Faraday's invention of the first electric generator in 1831, which induced alternating or "Faradic current" by rotating wires inside a magnetic field. Dubois-Reymond in 1848 demonstrated that the time-varying nature of Faradic current was important in efficient stimulation, and he formulated an early expression of the strength–duration curve relating the threshold for activating the neuromuscular system to the intensity and duration of the current pulse [3]. G.B. Duchenne — regarded as the father of "electrotherapy" — established it as a separate discipline ("De l'Electrisation localisee," 1855) [3]. He used Faradic current applied through moistened electrode pads, preferring it to Galvanic current because of its warming properties. In 1852 he stimulated the facial nerve for palsy [12]. With Duchenne's influence and the proliferation of induction coils and batteries, therapeutic electrical stimulation spread widely. By 1900, according to McNeal, most physicians in the United States had an "electrical machine" for the treatment of a plethora of ailments — many neurological, including pain. Many different and interesting devices were constructed, for use in every part of the body (literally), including the "hydroelectric bath" (not recommended!) [3]. Called the "Golden Age of Medical Electricity," the close of the 19th century would only be eclipsed by the close of the following century in the proliferation of the use of electricity in medical therapeutics.

Fritsch and Hitzig [11] are said to have been the first to stimulate the cortex in living animals and systematic mapping of cerebrocortical function was described in animals by Ferrier [13]. The first time the human brain was directly stimulated in a conscious patient was in 1878 by Barthlow, who introduced a stimulating needle into a patient's brain through an eroding scalp and skull tumor [14]. Low amplitude Faradic current elicited contralateral muscle contractions and an unpleasant tingling feeling, initiating the field of cerebral localization using electrical stimulation. Cushing observed the effects of intraoperative faradic stimulation in 1909 [15], and Forester's intraoperative work in the 1930s influenced Wilder Penfield [16], culminating in Penfield and Jasper's seminal publication of *Functional Anatomy of the Human Brain* in 1954.

29.2 Neural Augmentation — Neural Prostheses

29.2.1 Origins of the Field of Neural Prostheses

The field of neural prostheses encompasses the set of technologies relevant to the restoration of neurological and neuromuscular function and this includes both motor prostheses and sensory prostheses. The early motor work focused on technologies for restoration of limb motor function, these having

clinical relevance to the treatment of both paralyzed and amputee patients. In the last several decades, as microelectronic and microfabrication technologies have progressed, sensory prostheses have reached the state of practicality and cochlear implants have become a standard of care in the treatment of sensorineural deafness. Research and commercialization efforts continue in remaining areas, including restoration of the motor and sensory functions of the limbs, motor functions of the bladder, bowel, and diaphragm, and sensory functions including tactile, visual, and vestibular.

In the 1950s, a human study showing sound perception arising from electrode implantation inspired researchers across the world to investigate the possibility of a cochlear prosthesis, which, after several decades of development in academia and industry, became the first FDA approved neural prosthesis [17].

The Neural Prosthesis Program, launched in 1972 and spearheaded by F. Terry Hambrecht, MD, brought funding, focus, and coordination to the multidisciplinary effort to develop technologies to restore motor function in paralyzed individuals. The initial efforts were in electrode–tissue interaction, biomaterials and neural interface development, cochlear and visual prosthesis development and control of motor function using implanted and nonimplanted electrodes.

In his 1980 UC Davis Ph.D. thesis, David Edell [18,19] demonstrated chronic recording from peripheral nerve using a multichannel micromachined silicon regeneration electrode array . This was a major achievement, as it proved that chronic recording from the nervous system was possible. Furthermore, his silicon-based implant was proof of concept that biocompatible recording interfaces could be made from silicon using existing etching and microfabrication technology and could therefore be made to incorporate electrodes, preamplifiers, processing, memory, and telemetry elements on the same silicon substrate implanted in the nervous system.

29.2.2 Neural Augmentation — Motor Prostheses

29.2.2.1 Neuromuscular Stimulation for Control of Limb Movement

Liberson and coworkers [20] are credited as being the first to utilize FES to restore functional control of movement to a paralyzed limb. They treated over 100 hemiplegic patients with foot-drop using a transistorized stimulator and conductive rubber electrodes placed on the skin overlying the peroneal nerve. A switch under the sole triggered stimulation during the swing phase of gait causing contraction of the tibialis anterior and dorsiflexion of the foot [21]. All patients were reported to have received some benefit but acceptance was limited due to skin irritation from the electrode, need for precise electrode placement, hassle in applying the device compared to functional benefit, and electrode lead breakage. Liberson termed this "functional electrotherapy." However, this term did not gain widespread acceptance; rather, "functional electrical stimulation," coined by Moe and Post did [22].

Long and Masciarelli [23], intrigued by Liberson's lower extremity work, devised a system for upper extremity functional restoration in high cervical quadriplegic patients. Using FES controlled finger extension, via extensor digitorum stimulation, coupled with spring loaded thumb and finger flexion, the device enabled control of grasp in the paralyzed limb. Though patients tolerated it very well it did not gain widespread clinical acceptance.

Peckham and colleagues [24] at Case Western Reserve University used chronic percutaneous stimulation of forearm muscles to provide hand grasp, including both palmar and lateral prehension and release, in C5 quadriplegic patients.

Restoration of some form of assisted gait in spinal cord injured patients has been the focus of several research groups. In 1960, Kantrowitz [25] reported the use of surface stimulation of quadriceps and gluteal muscles to effect rising and standing for several minutes from a sitting position in a paraplegic patient. In 1973, Cooper [26] reported bilateral implantation of the femoral and sciatic nerves in a T11-12 paraplegic and claimed ambulation of up to 40 feet using a walker for balance assistance.

Using implanted stimulators and electrodes on the femoral nerves bilaterally, Brindley [27] was able to achieve in a paraplegic the movement of rising from a sitting position and limited gait assisted

FIGURE 29.1 Series of still images from 4-channel FES gait sequence performed by author (DJD) at MIT in 1990. (A) Subject bracing to stand, (B) Standing under FES control with computer controlled stimulator on the far left (L to R: author DJD, subject, Allen Wiegner, PhD), (C) First step, (D) Second step, (E) Third step, (F) Fourth step, (G) Preparing to sit, (H) Sitting down, (I) Seated in wheelchair after walking, (J) Repositioning feet, (K) Smiling.

with elbow crutches but not requiring a walker, braces, or other support. Several more sophisticated devices followed. Kralj et al. [28,29] described a 4- to 6-channel skin surface electrode FES systems in which patients ambulated with the assistance of parallel bars or a roller walker. At MIT in 1990, DiLorenzo and Durfee [30] implemented a computer-controlled 4-channel skin surface electrode FES system with bilateral quadricep stimulation and peroneal nerve withdrawal reflex stimulation and achieved 60 feet of handrail balance-assisted gait in a thoracic spinal cord injured patient and developed adaptive closed-loop controllers which compensated for time-varying muscle performance, including gaint changes due to muscle fatigue [31,32]. Figure 29.1 shows a sequence of still frames from a gait sequence using this 4-channel surface FES configuration [30]. Convinced of the greater potential for clinical efficacy and market success with implanted technologies, DiLorenzo [30,33–36] pursued related implanted FES work, and Goldfarb and Durfee [37] continued this line of surface FES work to include a long-legged brace with a computer-controlled friction brake for improved energy efficiency and control.

Marsolais [38] reported improved motor function in patients with intramuscular stainless steel electrodes implanted in the quadriceps, hip flexors, extensors, and abductors. Though significant motor torque improvement was achieved in some of these patients, all of whom had some motor function preimplantation, patients required supervision for ambulation.

Dan Graupe [39,40] extended the surface FES technology developed by Lieberson and Kralj to include a patient borne and controlled system. Graupe then commercialized this technology for clinical use as the ParaStep system. The history of the field of FES for ambulation and the commercialization of ParaStep is described in more detail in the chapter by Graupe in this volume.

The first generation of implanted FES systems for upper extremity functional restoration were developed at Case Western Reserve University and Cleveland Veterans Affairs Medical Center for the restoration of hand grasp to patient with cervical spinal cord injury [41]. This system allowed the paraplegic patient to control hand grasp on an otherwise paralyzed limb by generating movement commands using contralateral shoulder movements. This technology was commercialized by NeuroControl Corporation, which was founded by Hunter Peckham, Ph.D., Ronald Podraza, and colleagues at Case Western Reserve University in Cleveland, Ohio. NeuroControl received FDA approval in 1997 to market the grasp restoration device, known as the FreeHand System.

29.2.2.2 Chronically Implanted Neuroelectric Interfaces (Recording Arrays)

29.2.2.2.1 Basic Neuroscience

Separate but concurrent research efforts by many investigators in basic neurophysiology were making significant advancements in developing an understanding of how cortical and spinal neural systems control motor function. Extensive research on control of movement by hundreds of neuroscientists has revealed correlations between parameters of limb movement and neural activity in many motor centers, including the primary motor cortex, premotor and supplementary motor cortex, cerebellum, and spinal cord.

The motor cortex was the first area to undergo detailed quantitative study of neuronal activity during whole-arm reaching movements in an awake behaving primate [42]. Georgopoulos et al. [42] first demonstrated a relation between neural cell activity and movement direction. They found that cell firing rates are directionally sensitive in a graded manner, that is, the firing rate is maximal in a so-called preferred direction and the firing rate tapers off gradually as the direction of movement deviates form this preferred direction. In 1984, Georgopoulos et al. [43] demonstrated the presence of cells in both primary motor cortex and in area 5, the firing rates of which correlate linearly with position of the hand in two-dimensional space. Subsequent work expanded this knowledge to include additional movement parameters and limb movement in three-dimensional space [44–48].

Later research, beginning in the 1990s focused on control using neural signals, in both nonhuman primate and human subjects, lending credence to the notion that sufficient information may be extracted from neural signals to be used as a control signal for a prosthetic system. Schwartz extended this work and characterized neural firing patterns associated with limb movement in three-dimensional space [46] and with Talyor and Tillary developed a real-time adaptive prediction algorithm with which a primate was able to control robot arm movement [49]. Donoghue et al. [50] pursued similar lines of research and characterized patterns of behavior from large populations of cells. DiLorenzo [51] showed evidence for the presence of real-time motor feedback error signals in the primate motor cortex, suggesting the presence of feedforward and feedback signals in primary motor cortex. Using the 100 channel intracortical array developed by Richard Normann, Donoghue characterized additional information content in correlations between neuronal activity [52]. Using wire electrode arrays, Nicolelis also characterized real-time prediction of limb trajectory using neural ensembles and in collaboration with Srinivasan showed remote control of robot movement by a nonhuman primate [53].

29.2.2.2.2 Initial Application to Humans

Kennedy and Bakay [54–56] demonstrated human 2-D control of cursor movement by a paralyzed human patient using the cone neurotrophic electrode. This novel electrode facilitates regeneration of neural processes into an insulating glass cone where a stable electrical and mechanical interface forms, providing a long-term high signal to noise ratio. In 1987, Kennedy founded Neural Signals to develop the cone electrode for clinical use; however, the company has refocused its direction on the commercialization of a less invasive EMG driven system for locked-in patients.

A spinout from Donoghue's and Normann's research efforts, Cyberkinetics Neurotechnology Systems, Inc., has demonstrated in pilot studies human control of cursor movement using a 4 × 4 mm 96-channel intracortical microelectrode array chronically implanted into the primary motor cortex [57]. As of this writing, they have demonstrated the ability to record over 6 months postimplantation.

29.2.3 Neural Augmentation — Sensory Prostheses

29.2.3.1 Sensory Stimulation — Auditory (Cochlear Implant)

Auditory prostheses, which provide patterned stimulation of the eighth cranial nerve, were the first commercially available sensory neural prosthesis. As of this writing, it is the only approved sensory prosthesis; however, visual prostheses are already in clinical trials and are likely to be available in the not too distant future.

An experiment published in 1957 by Djourno and Eyries [17] is credited with inspiring the development of the cochlear implant. Paris otologist C. Eyries, and neurophysiologist A. Djourno implanted wires in the inner ear of a deaf patient and were able to elicit sensations of sound with electrical stimulation. This experiment was reproduced in 1964 by Doyle et al. [58] in Los Angeles.

Inspired by this 1957 Djourno article, William House, MD, joined with Jack Urban, president of an electronics company, in Los Angeles to develop a cochlear implant and they published results on their first patients in 1973 [59]. Working with investigators at the House Ear Institute, founded by his brother Howard House [60], MD, also an otolaryngologist, William House pioneered the development of the single-channel cochlear implant and achieved its approval by the FDA.

Blair Simmons of Stanford University first evaluated multichannel cochlear stimulation, placing four wires into the auditory nerve [61]. Several years later, Dr. Robin Michelson, an otolaryngologist at the University of California San Francisco (UCSF), implanted a multichannel cochlear implant placed in the scala tympani [62]. Michael Merzenich, also of UCSF, lead the research and development of this and subsequent multichannel cochlear implants [63]. Al Mann founded Advanced Bionics® Corporation in 1993, licensed the UCSF cochlear implant technology, and recruited Joe Schulman, Ph.D. and Tom Santogrossi to develop this technology into the CLARION cochlear implant [64–67].

In parallel with developments in the United States, in Melbourne, Australia, Graeme Clark initiated a large and extremely productive clinical and research program at the University of Melbourne in Australia [68–71]. The implants developed under Clark are manufactured by Cochlear Ltd., a subsidiary of Nucleus Pty. Ltd. in Sydney and Cochlear has the largest worldwide population of implanted patients, with over 65,000 patients having been implanted with the Nucleus worldwide [72].

In 1975, Ingeborg and Erwin Hochmair began development of a multichannel cochlear implant, which was implanted in Vienna 2 years later [73,74]. They continued development of the device for nearly a decade and in 1989 founded MED-EL, which has since become the third major manufacturer of cochlear implants.

There are several factors that have contributed to the success of the cochlear implant. (1) Well-developed foundation of basic science, particularly in the area of auditory neurophysiology. (2) Focused and coordinated research programs and funding including that of the NIH Neural Prosthesis Program. (3) Clinician champions who were active in the research and facilitated its clinical acceptance as early adopters themselves and as thought leaders. (4) Cochlear anatomy, including the tonotopic arrangement of sensory receptors and their protection by a bony encasement, facilitating stable chronic neuro-electric interfacing. Because of this surgically accessible anatomy, an electrode array may be placed and press chronically against a rigid surface while being in close proximity to neural cells, without the risk of damage to or migration through soft neural tissues. This neural interfacing problem is a major hurdle in the development of visual, somatosensory, and motor prostheses, which generally must interface directly with soft neural tissues, which are subject to perpetually changing forces and displacements.

29.2.3.2 Sensory Stimulation — Visual

The restoration of vision has captivated the imagination of man since biblical times. Now, after 4 decades of modern research, beginning with the stimulation of the visual cortex by Giles Brindley in 1966 [75], visual prostheses are making the transition from basic science research to commercialization. William Dobelle, Ph.D. achieved similar results using cortical stimulation to evoke phospheses in 1974 [76,77], and he was a pioneer in the drive to commercialize the visual cortex prosthesis. In 1983, he acquired Avery Labs, a manufacturer of electrodes for brain stimulation. From this and other ventures he derived funds to advance his vision prosthesis research and developments efforts at the Dobelle Institute, located in Portugal. An excellent historical review is provided in this volume by Greenberg.

29.2.3.3   Sensory Stimulation — Tactile

Electrocutaneous nerve stimulation was discovered in 1745 by von Kleist who described a shock from an electrostatically charged capacitor [79]. Studies published by von Frey in 1915 [80] and Adrian in 1919 [81] demonstrated the spectrum of sensations elicited by electrocutaneous stimulation, ranging from vibration to prickling pain and stinging pain. In 1966, Beeker [82] described an artificial hand with electrocutaneous feedback of thumb contact pressure. Initial results, although qualitative, were positive. In 1977, Schmidl [83] reported that electrocutaneous sensory feedback of grip strength improved control of an experimental hand. He found electrocutaneous feedback to be less susceptible to adaptation than vibrotactile feedback. In 1979, Shannon showed that electrocutaneous feedback on the skin above the median nerve is used to encode gripping force in a myoelectrically controlled prosthesis and patients reported an improved level of confidence when using the prosthesis [84].

In 1974 at Duke University, Clippinger implanted a sensory feedback system incorporating an electrode pair to stimulate the median nerve. He provided a frequency-modulated signal that transmitted gripping force at the terminal hook. Patients were able to perceive grip force as well as object consistency [85]. In 1977, Clippinger [86] reported a system using implanted electrodes to provide afferent sensory feedback for upper extremity amputees. The same year, he reported that postoperative stimulation of the sciatic nerve by a lower-extremity prosthesis offered the additional benefit of postoperative pain reduction, and in 1982, he reported 6 year success in a lower-extremity amputee using sciatic nerve stimulation to transmit heel strike force and leg structure bending movement on a single channel [87]. No further work on implanted sensory feedback prostheses is published by Clippinger.

In 1995 at MIT, DiLorenzo and Edell demonstrated functionality of a chronically implanted multichannel intrafascicular peripheral electrode array in an animal model using behavioral and neurophysiological recording, including eye blink reflexes and somatosensory evoked potentials. These studies demonstrated the functionality of sensory afferent fibers following transaction as well as the functionality of a chronically implanted intrafascicular stimulating neuroelectric interface [33–35,78] (Figure 29.2). Horch et al. [88–90] have developed percutaneous flexible microwires for intrafascicular stimulation of neural tissue.

29.3   Neuromodulation

29.3.1   Chronic Electrical Stimulation of the Nervous System for Functional Disorders

The early history of the use of electrical stimulation of the nervous system was limited to the acute setting because of the lack of availability of implantable stimulators for chronic use. The first progress

in this regard was in the area of cardiac pacing, which only recently has come to be viewed, rightfully, as neuromodulation. Although Aldini was motivated to "reanimate" the heart with Galvanic stimulation [6], the first successes were by Albert Hyman who used faradic stimulation to resuscitate the heart in animals and apparently some patients as well after cardiac arrest [3]. It was not until 1952 that an artificial pacemaker was successfully used by Paul Zoll, and in 1958, a chronic pacemaker was used for 96 days (although it had to be wheeled around on a table!) [91]. An implantable device that had to be charged through the skin was implanted the next year in Sweden [92], followed by a radio-frequency coupled pacemaker [93,94], and the first fully implantable, self-powered device was implanted in 1960 [95].

29.3.2 Early Development of Deep Brain Stimulation for Psychiatric Disorders and Pain

The availability of implantable pacemakers paved the way for their use in treating nervous system disorders of "function," including movement disorders (tremor, PD, dystonia), pain, epilepsy, and psychiatric disorders. Until this time, a common procedure in the 1950s was subfrontal leucotomy for various psychiatric indications and in fact Spiegel and Wycis developed their stereotactic frame mainly for use in this surgery. J. Lawrence Pool at the Neurological Institute at Columbia University was the first to reason that electrical stimulation might provide a nondestructive, reversible alternative to ablative procedures; in this case for psychiatric indications. He had previously — in 1945 — implanted the first patient with an induction coil for stimulating the femoral nerve for paraparesis (the first example of true functional electrical stimulation) [96] and in 1948 he placed a silver electrode in the caudate nucleus of a patient with PD afflicted with intractable depression, coupled to a permanent mini induction coil placed in the skull. His intent was to activate the caudate with electrical stimulation (although his reasoning is not made clear) and indeed he reported that the patient had some benefits from daily stimulation (with an external primary coil?) for 8 weeks, but a wire broke and therapy was discontinued. Pool also implanted a psychotic patient in 1948 with a cingulate gyrus stimulator.

Neural ablation within the pain-mediating pathways of the brain and spinal cord was the standard treatment for deafferentation (neuropathic) or cancer-related (nociceptive) pain, which was refractory to medical treatment. Thus the nonablative treatment of pain was advanced when in 1954, R.G. Heath at Tulane reported pain relief in schizophrenic patients following electrical stimulation of the septal nuclei via a stereotactic approach (first done in 1950) [97], and similar results were reported by Pool using Heath's technique in a patient treated exclusively for pain (with an externalized electrode wire) [98]. In his 1954 monograph, Pool reported that "focal electrical stimulation of deep midline frontal lobe structures is a new technique that is now being used more and more frequently" [98], which apparently included both himself and Heath in patients with psychiatric disease and pain. By this time, Spiegel and Wycis [99] were also implanting chronic electrodes for stimulation through a stereotactic approach. However, there were as yet no reports of the use of chronic stimulation for the treatment of movement disorders. In the 1960s, levo-dopa for the treatment of PD arrived, and virtually eliminated — for the next several decades — the surgical treatment of PD, except for severe tremor. Moreover, by this time, public outcry eliminated the surgical treatment of psychiatric disorders, which, although mainly directed against leucotomy and lobotomy, also included electrical brain stimulation. Thus, the next advances occurred exclusively in the treatment of pain.

By 1960 Heath and colleagues were stimulating the septal nuclei for pain (without concurrent psychiatric disorder) and in 1961 Mazars and colleagues [100,101] introduced the sensory thalamus as a target with the idea that stimulation of the deafferented neurons in the thalamus following amputation or stroke, for example, would relieve neuropathic pain. In these and other reports of brain stimulation for pain (septal region [102]; caudate [103]), only acute stimulation through externalized wires was used. However, Glenn pioneered the use of his RF-coupled device — first introduced for cardiac pacing in 1959 [94] — to pace the phrenic nerve in a paralyzed patient in 1963 [104]. Shortly thereafter, Sweet and Wepsic [105] implanted an RF stimulator to suppress pain in the peripheral nervous

system, and it was used in the first dorsal column stimulator implantation in 1967 by Shealy [106], based on the Melzack and Wall "gate control" theory of pain transmission in the spinal cord [107]. In 1982 at Duke, Nashold et al. [108] demonstrated a technique for intraoperatively mapping peripheral nerve bundles in order to accurately place electrodes on individual fasciculi to relieve chronic limb pain.

Pursuing an anatomically more central approach, Hosobuchi and colleagues [109] reported successful chronic stimulation of the sensory thalamus for facial pain in 1973 and this was followed by chronic stimulation of sensory thalamus by Mazars [110] and of other regions as well. Notable amongst these is the periventricular gray region which — based on the findings of analgesia induced by electrical stimulation in the rat by Reynolds [111] — was chronically stimulated in patients in 1973 by Hosobuchi and colleagues [112] and Richardson and Akil [113,114]. Ultimately, the fully implantable battery-powered stimulator was developed for cardiac pacing [95] and then adapted for use in the treatment of pain [14].

29.3.3   The Dawn of Deep Brain Stimulation for Movement Disorders

The earliest use of chronic therapeutic stimulation for movement disorders appears to be that of Bechtereva and colleagues in the erstwhile U.S.S.R. They implanted 24 to 40 electrodes in 4 to 6 bundles into the "thalamic — striopallidal nuclei" for patients with hyperkinesias as a result of PD, torsion dystonia, and other causes [115,116]. Benefits of intermittent stimulation were seen for as long as 3 years, although no implantable stimulator was used. Other early results were from electrical stimulation of sensory thalamus [110,117] or centromedian-parafascicular complex (CM/Pf) [118] for thalamic deafferentation pain, when improvements in the often associated dyskinesia were noted. Another avenue was that of Cooper and colleagues in the 1970s [119] who stimulated the anterior lobe of the cerebellum to treat various movement disorders, including spasticity and dystonia. Davis and colleagues performed cerebellar stimulation on 316 patients between 1974 and 1981 for spastic motor disorders with good success [120].

By the 1970s, when PD was mostly being treated pharmacologically, the usual indication for stereotactic surgery in movement disorders was tremor and hyperkinesias (e.g., in dystonia) and the preferred operation was thalamotomy of the ventral intermediate (Vim) nucleus. It had long been appreciated that acute high-frequency, but not low-frequency electrical stimulation of Vim led to immediate tremor arrest, which was used as a final check prior to radio-frequency ablation [121,122]. The first chronic stimulator implantations directed at movement disorders per se were by Mundinger in 1975 [123]. Brice and McLellan [124] implanted deep brain stimulator (DBS) leads in the subthalamic region (a common site for subthalamotomy at the time) in 3 patients for severe intention tremor resulting from multiple sclerosis. The latter paper is of special interest in that it anticipates by decades the idea of a contingent, on-demand system. Andy [125] implanted 9 patients with stimulating electrodes in the thalamus but concluded that the likely target was CM/Pf.

At about the same time in 1987, Benabid [126,127] and Seigfried [128] began implanting DBSs into Vim of the thalamus for tremor from PD and essential tremor. Benabid's report of his large series of Vim stimulators in 1996 [129], followed shortly thereafter by the North American series [130] brought international attention to the field of electrical brain stimulation. The field came full circle as a result of other important trends. The limitations and complications of levo-dopa treatment for PD began to become apparent by the 1980s and as a result Laitinen — a student of Leksell, a leader in functional neurosurgery in the 1950s during which time pallidotomies were performed — began to revisit ablative surgery for PD. His influential report in 1992 of the results of pallidotomy refocused attention on the surgical treatment of PD [131]. With a large experience by then in DBS, Siegfried performed the first implantation of a stimulator electrode into the posteroventral internal globus pallidus for PD in 1992 [132]. The next advance resulted from new insights into the pathophysiology of PD: the report of DeLong and colleagues of the amelioration of experimental PD in nonhuman primates by the ablation of the subthalamic nucleus, whose glutamatergic driving actions on the globus pallidus interna was elucidated [133]. Benabid then targeted this novel region for deep brain stimulation in 1993 (the subthalamic region,

including white matter projections, had been the target for "subthalamotomies," but never before had the subthalamic nucleus per se been targeted because of concerns over the development of hemiballism) [134].

29.3.4 The Efforts toward Neurostimulation for Epilepsy

In the 1950s Cooke [135] and Dow [136] described their work in rats and primates showing that stimulation of the cerebellum had effects on the electroencephalogram and the frequency of seizures. On this basis, in 1973 Cooper and colleagues reported the use of chronic cerebellar stimulation in patients with epilepsy. They also reported benefits for spasticity [119]. Unfortunately, several subsequent clinical series were unable to replicate Cooper's results with epilepsy [137]. Also in the 1970s, Chkhenkeli reported preliminary results of stimulating the caudate nucleus for epilepsy (followed in 1997 by a larger series) (Chkhenkeli and Chkhenkeli, 1997).

Based on the idea that anterior nucleus of the thalamus (ANT) has widespread connections with and therefore possible modulatory effects on the cortex, Cooper also investigated and reported the results of stimulation of the anterior nucleus of the thalamus for epilepsy [138]. Also around that time Mirski and Fisher began providing experimental evidence for a role of the anterior nucleus in epilepsy [139,140] and that electrical stimulation can mitigate seizure activity [141]. This has provided the impetus to revisit this target for epilepsy [142,143] and current trials are underway. Meanwhile, Velasco reported that DBS of the centromedian nucleus (CM) — an intralaminar nucleus with widespread connections to the striatum and cortex — reduced seizure frequency in medically refractory patients [144]. Although not replicated in a limited clinical trial [145], results continue to be good for generalized epilepsy [12].

Also during the 1980s, the groups of Gale [146] and Moshe [147] independently began to report a role for the basal ganglia in regulating seizures. These and other lines of investigation paved the way for two small clinical series involving electrical stimulation of the subthalamic nucleus [148,149] which, although providing mixed results, have led to a larger clinical trial currently underway.

As early as the 1960s, the role of electrical stimulation of vagal nerve afferents on the electroencephalogram was appreciated [150]. This observation led Jacob Zabara, a physiologist at Temple University, to investigate the effect of vagal afferent stimulation on seizures in animal models [151,152]. These preclinical findings were the basis for launching Cyberonics, founded by Jacob Zabara and Reese S. Terry Jr. in 1987, which developed an implantable vagus nerve stimulator (VNS). Cyberonics conducted trials of vagal nerve stimulation for epilepsy in human patients beginning in 1988 [153,154] and achieved clinical approval for its use as an adjuvant therapy in 1997.

In the 1990s, Lesser [155] discovered the phenomenon of afterdischarges in the cortex, following electrical stimulation and he found that subsequent electrical stimulation can terminate these afterdischarges.

In 1997, Robert Fishell founded NeuroPace to develop an implant that applies the principle of afterdischarge termination to the treatment of seizures. In 2001, NeuroPace licensed seizure detection technology developed by Brian Litt, Ph.D. Frank Fisher and Ben Pless were recruited as CEO and CTO of NeuroPace and as of this writing, the company is in clinical trials for its Responsive Neurostimulator (RNS) device.

In the 1990s, DiLorenzo designed a closed-loop Neuromodulation technology, and in 2002 he founded NeuroBionics Corporation. In 2004, he recruited John Harris and Kent Leyde to join the company which was renamed BioNeuronics Corporation and as of this writing they are in development of a proprietary technology addressing this market.

Several trials of deep brain stimulation are currently underway. In addition, direct electrical stimulation of the epileptic focus in the cortex or hippocampus, in some cases coupled to contingent and others to closed-loop stimulation algorithms are being examined by a number of investigators.

29.3.5 Current State of the Art of Neurostimulation

Electrical stimulation of the central, peripheral, and autonomic nervous systems has reached the point of standard clinical practice for an expanding list of indications (see table). New indications are under active

investigation, such as Tourette's syndrome [156] and cluster headache [157]. Vagal nerve stimulation is routinely performed for epilepsy but deep brain stimulation and cortical stimulation are actively being studied. As a nondestructive alternative, electrical stimulation is spurring a judicious resurgence of psychosurgery for obsessive compulsive disorder (OCD) (internal capsule, nucleus accumbens) and depression (same targets as for OCD, plus vagus nerve, and area 25 [158]) which disable a large number of patients and are treatment-resistant. The treatment of pain continues to lag behind even though it was one of the earliest indications for DBS studies. Spinal cord stimulation is frequently performed for various types of peripheral pain as is peripheral nerve stimulation. Motor cortex stimulation is under active investigation for neuropathic deafferentation pain (as well as for movement disorders [159] and for rehabilitation after stroke [160]).

In addition to advancing the field through expanding indications, technological and scientific advances are promising to increase effectiveness in certain settings. Most promising is the development of closed-loop strategies for the treatment of the epilepsies, and perhaps other disorders (recall the early work of Brice and McClellan [124] with tremor, discussed earlier). The ability to detect and predict [161] seizures is being capitalized on to tailor stimulation or other neuromodulatory interventions. This promises to increase effectiveness and decrease cellular injury, adaptation, or habituation, and to decrease battery drain as well. Other advances may include new electrode designs and stimulation strategies aimed at optimizing activation (or inhibition) of selected neural elements, such as axons over cell bodies. This work will be advanced by increasing understanding of the mechanisms of neurostimulation, which has lagged behind empirical, clinically based progress. Of course, progress in battery technology, including rechargeability and miniaturization, will increase long-term ease-of-use and tolerability of neurostimulation devices. With the more sophisticated neurostimulators on the drawing board and in development at several companies, the battery lifetime becomes an even more important issue than in first generation devices.

At the turn of the 20th century, the remarkable results seen with deep brain stimulation in movement disorders (historically, the last indication for which it was tried) have led to the great resurgence in the use of electrical stimulation for the treatment of a wide variety of neurological disorders. Not since the turn of the 19th century has interest in this therapy been so widespread. The difference, hopefully, is that we are now also in the age of evidence-based medicine so that the seemingly striking benefits of electrical neuromodulation have been and will continue to be subjected to objective standards of evaluation and that the enormous potential neural engineering holds will be responsibly harnessed for the patient's best interest.

Electrical Stimulation of the Central Nervous System

Warren M. Grill
Duke University

30.1 Introduction

Electrical stimulation is a widespread method to study the form and function of the nervous system and a technique to restore function following disease or injury. The central nervous system (CNS) includes the brain and spinal cord (Figure 30.1). Both the spinal cord and brain include regions primarily populated by cell bodies (somas) of neurons, and termed gray matter for its color, and regions primarily populated by axons of neurons, and termed white matter. The diversity of neuronal elements and complexity of the volume conductor make understanding the effects of stimulation more challenging in the case of CNS stimulation than in the case of peripheral stimulation. Specifically, it is unclear, in many cases, what neuronal elements (axons, cell bodies, presynaptic terminals; Figure 30.1) are activated by stimulation [Ranck, 1975]. Further, it is unclear how targeted neural elements can be stimulated selectively without coactivation of other surrounding elements. This chapter presents a review of the properties of CNS stimulation as required for rational design and interpretation of therapies employing electrical stimulation.

Electrical stimulation has been used to determine the structure of axonal branching [Jankowska and Roberts, 1972], examine strength of connections between neurons, and determine the projection patterns of neurons [Lipski, 1981; Tehovnik, 1996]. Examples of application of CNS stimulation from treatment
FIGURE 30.1 Structure of the central nervous system (CNS). (a) The CNS includes the brain and the spinal cord. (b) The gray matter of the CNS contains the cell bodies of neurons as well as dendritic and axonal processes. (c) When an electrode is placed within the heterogeneous cellular environment of the CNS it is unclear which neuronal elements are effected by stimulation.

of neurological disorders include the treatment of pain by stimulation of the brain [Coffey, 2001] and spinal cord [Cameron, 2004], treatment of tremor and the motor system symptoms of Parkinson's disease [Gross and Lozano, 2000], as an experimental treatment for epilepsy [Velasco et al., 2001; Hodaie et al., 2002], as well as a host of other neurological disorders [Gross, 2004]. In addition CNS stimulation is being developed for restoration of hearing by electrical stimulation of the cochlear nucleus [Otto et al., 2002] and for restoration of vision [Brindley and Lewin, 1968; Schmidt et al., 1996; Troyk et al., 2003].

A nerve cell or a nerve fiber can be artificially stimulated by depolarization of the cell's membrane. The resulting action potential propagates to the terminal of the neuron leading to release of neurotransmitter that can impact the postsynaptic cell. Passage of current through extracellular electrodes positioned near neurons creates extracellular potentials in the tissue. The resulting potential distribution can result in an outward flowing transmembrane current and depolarization. Alternately, extracellular potentials may modulate or block ongoing neuronal firing depending on the magnitude, distribution, and polarity of the potentials.

The objective of this chapter is to present the biophysical basis for electrical stimulation of neurons in the CNSs. The focus is on using fundamental understanding of both the electric field and its effects on neurons to determine the site of neuronal excitation or modulation in the CNS where electrodes are placed among heterogeneous populations of neuronal elements including cells, axons, and dendrites.

30.2   Generation of Potentials in CNS Tissues

Passage of current through tissue generates potentials in the tissue (recall Ohm's Law: $V = IR$). The potentials are dependent on the electrode geometry, the stimulus parameters (current magnitude), and the electrical properties of the tissue. For example, the potential generated by a monopolar point source can be determined analytically using the relationship $V_e(r) = I/4\pi\sigma r$ where I is the stimulating current, σ is the conductivity of the tissue medium (Table 30.1), and r is the distance between the electrode and the measurement point. The point source model is a valid approximation for sharp electrodes with small

tips [McIntyre and Grill, 2001]. Larger electrodes are typically used for chronic stimulation of the CNS, and the spatial distribution of the potentials in the tissue differs from those produced by a point source electrode (Figure 30.2). Examples of the spectrum of electrode types used for CNS stimulation (and recording) are shown in Figure 30.3.

The extracellular potentials generated by the passage of current are dependent on the electrical properties of the tissue. The electrical properties of the CNS are both inhomogeneous and anisotropic (Table 30.1), and the distribution of potentials within the tissue will depend strongly on the tissue and electrode geometries. In general, biological conductivities have a small reactive component [Ackman and Seitz, 1984; Eisenberg and Mathias, 1980], and thus a relatively small increase in conductivity at higher frequencies [Ranck, 1963; Nicholson, 1965; Ranck and BeMent, 1965].

Spatial variations in the electrical properties of the tissue can cause changes in the patterns of activation [Grill, 1999]. In most cases, to calculate accurately the extracellular potentials generated by extracellular stimulation requires a numerical solution using a discretized model, for example with the finite element method [e.g., Veltink et al., 1989; McIntyre and Grill, 2002].

30.3 Response of Neurons to Imposed Extracellular Potentials

As described in the previous section, the distribution of extracellular potentials is dependent on the electrode geometry, the electrical properties of the extracellular tissue, and the stimulation amplitude. The effect of the potentials on neurons is dependent on the nerve cell type, its size and geometry, as well as the temporal characteristics of the stimulus. During stimulation of peripheral nerves it is clear that it is the axons in the vicinity of the electrodes that are activated. However, the CNS contains a heterogeneous population of neuronal elements including local cells projecting locally around the electrode as well as those projecting away from the region of stimulation, axons passing by the electrode, and presynaptic terminals projecting onto neurons in the region of the electrode (Figure 30.1c). Effects of stimulation can be mediated by activation of any or all of these elements and include both direct effects of stimulation of postsynaptic elements, as well as indirect effects mediated by electrical stimulation of presynaptic terminals that mediate the effects of stimulation via synaptic transmission.

From this complexity arise two principal questions during stimulation of the CNS [Grill and McIntyre, 2001]: what neuronal elements are activated by extracellular stimulation? and how can targeted elements be stimulated selectively? Computational modeling provides a powerful tool to study extracellular excitation of CNS neurons. The volume of tissue stimulated, both for fibers and cells, and how this changes with electrode geometry, stimulus parameters, and the geometry of the neuronal elements is quite challenging to determine experimentally. Using a computer model enables these parameters to be examined under controlled conditions and enables determination of the effects of stimulation on all the different neural
FIGURE 30.2   (See color insert following page 32-14.) Electric fields generated by passage of current in CNS tissue. The first step in determining the response of CNS neurons to extracellular stimulation is to calculate the electric potentials generated in the tissue by passage of current through the electrode. Potentials produced by passage of current into a homogenous region of the CNS ($\sigma = 0.2$ S/m) using a point source electrode (a), a cylindrical electrode (b), as used for deep brain stimulation, and a disk electrode (c), as used for epidural or cortical surface stimulation. (d) Although a simple analytical solution exists for the potentials generated by a point source electrode, they differ substantially from the potentials generated by larger cylindrical or disk electrodes.

elements around the electrode simultaneously. Computational modeling of the effects of extracellular stimulation on neurons involves a two-step approach. The first step is to calculate the electric potentials generated in the tissue by passage of current through the electrode. The second step is to determine the effect of those potentials on the surrounding neurons.

30.4   From Cell to Circuit — Construction of Models of CNS Neurons

Electrical circuits are used to model the electrical behavior of neurons. These electrical-equivalent circuits, often referred to as cable models, represent the neuron as a series of cylindrical elements. Each cylinder is in turn replaced by a "compartment," representing the neuronal membrane, and a resistor representing the intracellular space. Thus the model becomes a series of membrane compartments, connected by resistors. Each compartment is itself an electrical circuit that includes a capacitor representing the membrane capacitance of the lipid bilayer, resistors representing the ionic conductances of the transmembrane
FIGURE 30.3 (See color insert following page 32-14.) Electrodes for central nervous system stimulation. (a) Single iridium microwire electrode developed at Huntington Medical Research Institutes that can be used for extracellular recording from single units or extracellular microstimulation of small populations of neurons [McCreery et al., 1997]. (b) Multisite silicon microprobe developed at the University of Michigan. Inset shows higher magnification view of two electrode sites near the tip (Images courtesy of J.F. Hetke, University of Michigan). (c) Three-dimensional assembly of multisite silicon microprobes [Bai et al., 2000]. The array is four probes, 256 sites on 400 μm centers in 3D. There are 16 parallel stimulating channels (16 sites active at any time) with off-chip current generation. The array is fed by a 7-lead ribbon cable at a data rate of up to 10 Mbps. It operates from $\pm$5V supplies. (Image courtesy of K.D. Wise, University of Michigan). (d) Arrays of up to 128 microwires enable simultaneous extracellular recording from multiple single neurons. Each wire is 50 μm diameter stainless steel, insulated with Teflon [Nicolelis et al., 2003]. (e) Multielectrode silicone array developed at the University of Utah [Normann et al., 1999]. (g) Quadrapolar electrode used for deep brain stimulation (Medtronic Inc., Minneapolis, MN).

proteins (ion channels), and batteries representing the differences in potential (Nernst potential) arising from ionic concentration differences across the membrane. The process of constructing an equivalent electric-circuit model of a CNS neuron is illustrated in Figure 30.4.

The values of circuit elements can be readily calculated from the geometry of the neurons and the specific values of neuron electrical properties. Consider a cylindrical representation of a segment of
FIGURE 30.4 Construction of models of central nervous system (CNS) neurons. (a) Examples of stained neurons in the CNS. (b) The morphology of stained neurons can be reconstructed in three dimensions. (c) The morphology is then converted into a series of equivalent cylindrical elements. (d) The cylindrical elements are subsequently replaced by electrical equivalent circuits with resistive elements representing the intracellular space and compartmental models representing the membrane. (e) Each cylindrical segment includes a representation of the membrane and the intracellular space and the values of the equivalent circuit elements can be calculated from the geometry of the cylinder and specific parameter values. (f) Each compartment model of the membrane may contain several nonlinear ionic conductances (g_i, g_j) and linear ionic conductance (g_L) representing various ionic channels in the membrane, batteries representing the Nernst potential arising from the difference in concentration of ions on the inside and outside of the membrane (E_i, E_j, E_L), and a capacitor (C_m) representing the capacitance arising from the lipid bilayer of the cell.

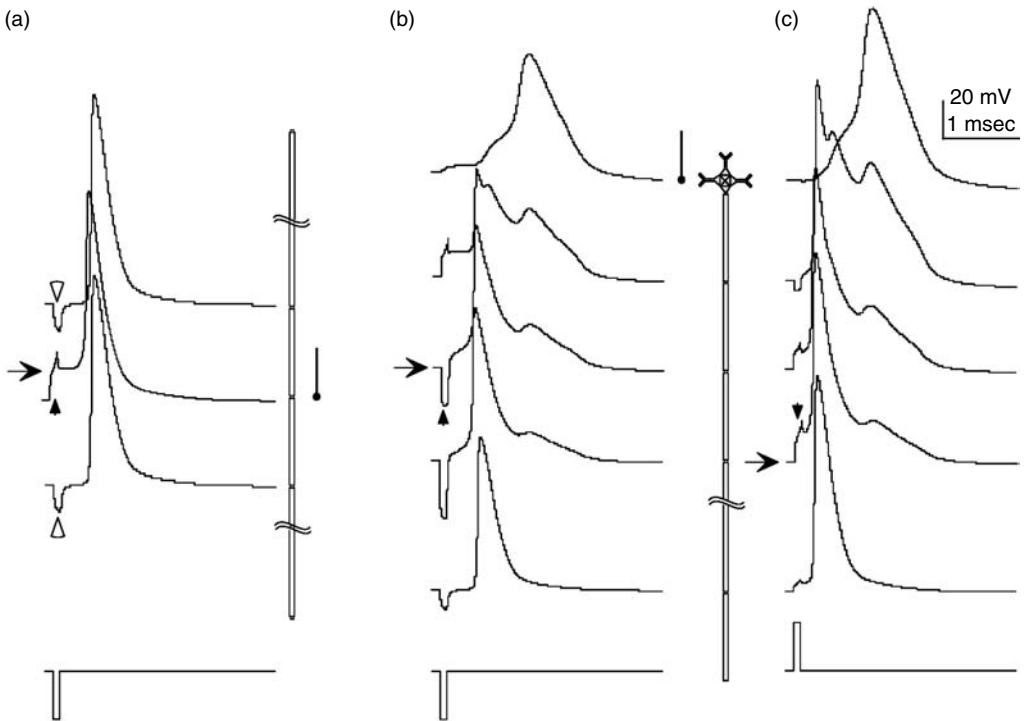
neuronal element, with diameter d and length l (Figure 30.4e). If we cut and "unroll" the cylinder then the membrane resistance, R_m, can be calculated as: R_m = specific membrane resistance/area of segment = $r_m/\pi \times l \times d$, where typical values for the specific membrane resistance are from 1000 to 5000 Ω-cm^2. The membrane resistance is nonlinear, where the value of the membrane resistance depends on the voltage across the membrane (transmembrane potential). Further, separate elements (typically calculated as conductances) are used to represent the transmembrane paths for different ionic species, and the model of a patch of membrane includes several of these in parallel (Figure 30.4e). Similarly, the membrane capacitance, C_m, can be calculated as: C_m = specific membrane capacitance × area of segment = $c_m/\pi \times l \times d$, where typical values of the specific membrane capacitance are from 1 to 2 μF/cm^2. The intracellular resistance, R_i, can be calculated as: R_i = intracellular resistivity × segment length/cross sectional area of segment = $\rho_i \times l/(\pi \times (d/2)^2)$, where typical values of the intracellular resistivity are from 50 to 400 Ω-cm.


FIGURE 30.5 Action potential initiation by extracellular stimulation of CNS neurons by cathodic and anodic stimuli. Each trace shows transmembrane voltage as a function of time for different sections of the neuron. (a) Stimulation with a monophasic cathodic stimulus pulse from an electrode positioned 1 mm over a node of Ranvier of the axon. Depolarization occurs in the node directly beneath the electrode (solid arrowhead) and hyperpolarization occurs in the adjacent nodes of Ranvier (open arrowhead). Action potential initiation occurs in the node of Ranvier directly under the electrode (arrow) and the action potential propagates in both directions. (b) During threshold stimulation with an electrode positioned 1 mm over the cell body, action potential initiation occurs at a node of Ranvier of the axon. With cathodic stimuli (duration 0.1 msec) action potential initiation occurred at the second node of Ranvier from the cell body (arrow). (c) With anodic stimuli (duration 0.1 msec) action potential initiation occurred in the third node of Ranvier from the cell body (arrow).

30.5 Sites of Action Potential Initiation in CNS Neurons

The response of a cable model, representing a CNS neuron, to extracellular electrical stimulation is shown in Figure 30.5. The transmembrane potential as a function of time, in different segments of the neuron, is shown for a cathodic electrode positioned over the axon (Figure 30.5a), for a cathodic electrode positioned over the cell body (Figure 30.5b), and for an anodic electrode positioned over the cell body (Figure 30.5c).

During stimulation over the axon with a cathodic current the axon is depolarized immediately beneath the electrode, and hyperpolarized in regions lateral to the electrode (arrowheads Figure 30.5a). Action potential initiation occurs in the most depolarized node of Ranvier, immediately beneath the electrode (arrow) and then propagates in both directions.

The response of a CNS neuron is more complex. With both cathodic and anodic stimuli delivered through an electrode placed 1 mm above the cell body, action potential initiation occurred in the axon, even though the electrode is positioned directly over the soma. With 0.1 msec duration cathodic stimuli action potential initiation occurred at the second node of Ranvier from the cell body (arrow), and with 0.1 msec duration anodic stimuli action potential initiation occurred in the third node of Ranvier from the cell body (arrow). During the cathodic stimulus pulse, the node of Ranvier where action potential initiation occurred was hyperpolarized by the stimulus (arrowhead). Following termination of the stimulus, the cell

body and dendritic tree discharged through the axon, leading to action potential initiation [McIntyre and Grill, 1999]. This finding in a computational model is consistent with contemporary in vitro results from cortex [Nowak and Bullier, 1998a, b]. Thus, with cathodic stimuli action potential initiation occurred in a part of the neuron that was hyperpolarized by the stimulus, and this indirect mode of activation increases the threshold for activation of local cells with cathodic stimuli. Conversely, with anodic stimuli, the site of action potential initiation was at the node that was most depolarized by the stimulus (arrowhead). These position dependent thresholds are reflected in exciting populations of neurons, as well (see Section 30.6.3).

30.6 Excitation Properties of CNS Stimulation

The finding that action potential initiation occurs in the axon has several important implications for CNS stimulation. First, since excitation occurs in the axon there is little difference in the extracellular chronaxie times for excitation of local cells and excitation of passing axons (see "Strength–Duration Relationship," in Section 30.6.1). Therefore, chronaxie time is not a sensitive indicator of the neuronal element that is activated by extracellular stimulation [Miocinovic and Grill, 2004]. Second, since action potential initiation occurs at some distance from the site of integration of synaptic inputs, the effects of coactivation of presynaptic fibers may be less than expected and the axon may still fire even when the cell body is hyperpolarized, for example by inhibitory synaptic inputs (see "Indirect Effects," Section 30.6.4). Therefore, extracellular unit recordings of cell body firing may not accurately reflect the output of the neuron [Grill and McIntyre, 2001; McIntyre et al., 2004]. Finally, the difference in the mode of activation of local cells by cathodic stimuli and anodic stimuli is the basis for the difference in threshold between cathodic and anodic stimuli (see "Effect of Stimulus Polarity," Section 30.6.3).

30.6.1 Strength–Duration Relationship

The stimulus amplitude necessary for excitation, I_{th}, increases as the duration of the stimulus is decreased. The strength–duration relationship describes this phenomena and is given by

$$I_{th} = I_{rh}\left[1 + \frac{T_{ch}}{PW}\right]$$

where the parameter I_{rh} is the rheobase current, and is defined as the current amplitude necessary to excite the neuron with a pulse of infinite duration, and the parameter T_{ch} is the chronaxie and is defined as the pulse duration necessary to excite the neuron with pulse amplitude equal to twice the rheobase current.

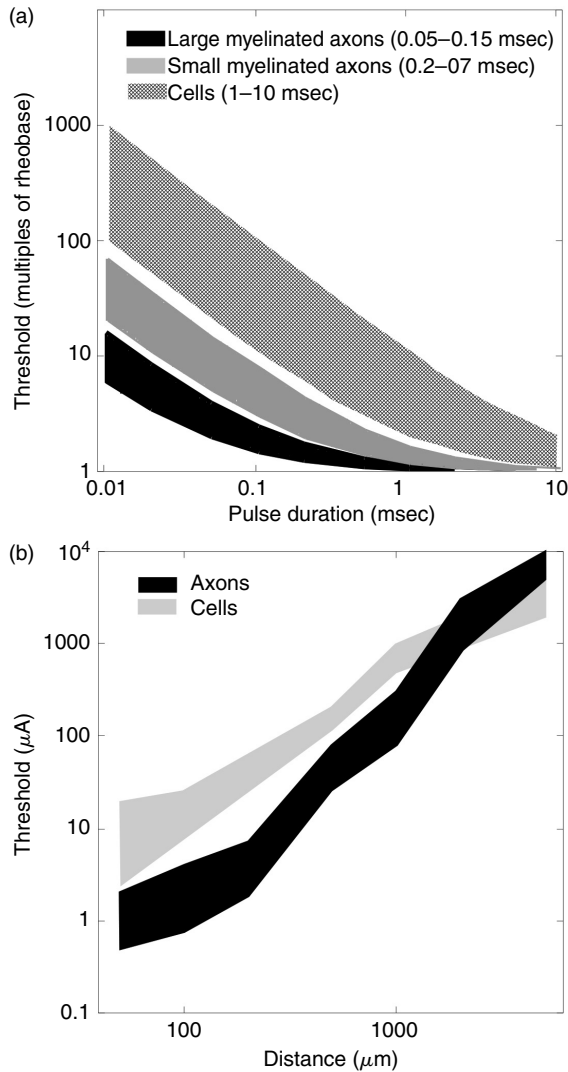
Measurements with intracellular stimulation have demonstrated that the temporal excitation characteristics, including chronaxie (T_{ch}) and refractory period, of cells and axons differ (Figure 30.6a). However, during extracellular stimulation of neurons, action potential initiation occurs in the axon, even with the stimulating electrode positioned over the cell body or dendrites (see above). Although with intracellular activation the chronaxies of many cell bodies exceed 1 msec, with extracellular activation they are below 1 msec [Stoney et al., 1968; Ranck, 1975; Asanuma, 1976; Swadlow, 1992] and lie within the ranges determined for extracellular activation of axons [Ranck, 1975; Li and Bak, 1976; West and Wolstencroft, 1983]. For stimulation of cortical gray matter, the mean T_{ch} for *intracellular* stimulation of cells (15 msec) was substantially longer than T_{ch} for *extracellular* stimulation of axons (0.27 msec), but the mean T_{ch} for *extracellular* stimulation of local cells (0.38 msec) was comparable to that for extracellular stimulation of axons [Nowak and Bullier, 1998a]. Further, the chronaxies measured with extracellular stimulation were dependent on a number of factors other than the neuronal element that was stimulated [Miocinovic and Grill, 2004]. The chronaxies of different neuronal elements determined with extracellular stimulation overlap and do not enable unique determination of the neuronal element stimulated.


FIGURE 30.6 Properties of central nervous system stimulation. (a) The strength–duration relationship describes the amplitude required for stimulation as a function of the stimulation pulse duration. Strength–duration curves for intracellular stimulation of different neural elements were constructed from data summarized in Ranck, 1976. (b) The current–distance relationship describes the threshold intensity required for stimulation as a function of the distance between the electrode and the neuron. Current–distance curves for axons and cells were constructed from data summarized in Ranck, 1976.

30.6.2 Current–Distance Relationship

The threshold current required for extracellular stimulation of neurons, I_{th}, increases as the distance between the electrode and the neuron, r, increases. This is described by the current–distance relationship [Stoney et al., 1968]:

$$I_{th} = I_R + k \cdot r^2$$

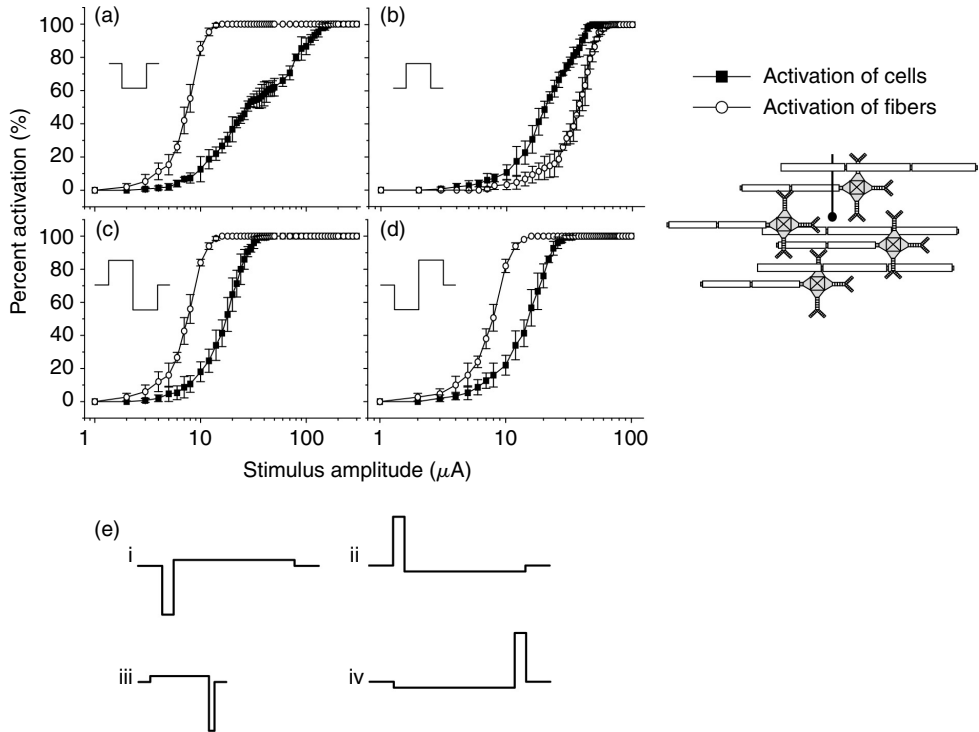
where the offset, I_R, determines the absolute threshold and the slope, k, determines the threshold difference between neurons at different distances from the electrode. Current–distance relationship for excitation of


FIGURE 30.7 Effect of stimulus polarity and waveform on excitation of populations of local cells and passing axons. (a)–(d) Input–output curves from a population model containing 50 passing axons and 50 local cells randomly positioned around a point source stimulating electrode. The curves are the percent of neurons (passing axons, local cells) activated as a function of the stimulation amplitude for excitation with (a) 0.2 msec duration monophasic cathodic pulses, (b) 0.2 msec duration monophasic anodic pulses, (c) anodic-phase-first biphasic symmetric pulses (0.2 msec per phase), and (d) cathodic-phase-first biphasic symmetric pulses (0.2 msec per phase) [modified from McIntyre and Grill, 2000]. (e) Examples of asymmetric charge-balanced biphasic pulses. Cathodic-phase-first (i) and anodic-phase-first psuedomonophasic pulses have a low-amplitude second phases and exhibit excitation properties similar to monophasic cathodic and anodic stimuli, respectively. Novel asymmetric pulses manipulate neuronal excitability via a subthreshold first that also balances the charge. The anodic prepulse (0.2 msec) followed by a cathodic stimulus phase (0.02 msec) enables preferential excitation of passing axons, while a cathodic prepulse (1.0 msec) followed by an anodic stimulus pulse (0.1 msec) enables preferential excitation of local cells [McIntyre and Grill, 2000].

axons and cells in the CNS have been measured in a large number of preparations, and current–distance curves for these two populations are summarized in Figure 30.6b.

30.6.3 Effect of Stimulus Polarity and Stimulus Waveform on CNS Stimulation

During excitation of axons in the peripheral nervous system different stimulus polarities produce changes in the threshold as well as changes in the site of action potential initiation, and similar, but more pronounced effects occur during CNS stimulation. In Figure 30.7 are shown the results of a computational study to determine which neuronal elements are activated by extracellular stimulation in the CNS. A model including populations of local cells and axons of passage, randomly positioned around a point source stimulating electrode, was used to compare activation of local cells to activation of passing fibers with different stimulation waveforms [McIntyre and Grill, 2000]. Using cathodic pulses the threshold for activation of passing axons was less than the threshold for activation of local neurons, and when 70%

of the axons were activated approximately 10% of the local cells were also activated. When using anodic pulses, the threshold for activation of local cells is less than the threshold for activation of passing axons, and the stimulus amplitude that activated 70% of the local cells also activated 25% of the passing axons. The basis for this effect can be understood by comparing action potential initiation in local cells using cathodic and anodic stimuli described earlier.

To prevent possible degradation of the stimulating electrodes or damage to the tissue, chronic stimulation is conducted with biphasic stimulus pulses [Lilly et al., 1955; Robblee and Rose, 1990]. The response of passing axons and local cells to symmetric biphasic pulses is shown in Figure 30.7c and Figure 30.7d. Using either anodic-phase-first or cathodic-phase-first pulses, the threshold for activation of passing axons was less than the threshold for activation of local neurons, and the relative selectivity for axons was lower with either pulse than with monophasic cathodic pulses.

These results and previous experimental evidence demonstrate that different neuronal elements have similar thresholds for extracellular stimulation [Roberts and Smith, 1973; Gustafsson and Jankowska, 1976] and illustrates the need for design of methods that enable selective stimulation. Stimulus waveforms can be designed explicitly to take advantage of the nonlinear conductance properties of neurons and thereby increase the selectivity between activation of different neuronal elements. Biphasic asymmetrical stimulus waveforms capable of selectively activating either local cells or axonal elements consist of a long-duration low-amplitude prepulse followed by a short-duration high-amplitude stimulation phase. The long-duration prepulse phase of the stimulus is designed to create a subthreshold depolarizing prepulse in the nontarget neurons and a hyperpolarizing prepulse in the target neurons [Grill and Mortimer, 1995; McIntyre and Grill, 2000]. Recall that during cathodic stimulation, the site of excitation in axons is the depolarized node of Ranvier, while the site of excitation in local cells is a node of Ranvier that is hyperpolarized by the stimulus (Figure 30.5). Conversely, with anodic stimuli, the site of excitation in local cells is a depolarized node of Ranvier, and the most polarized node of passing axons is hyperpolarized by the stimulus. Thus, the same polarity prepulse will produce opposite polarization at the sites of excitation in local cells and passing axons. The effect of this subthreshold polarization is to decrease the excitability of the nontarget population and increase the excitability of the target population via alterations in the degree of sodium channel inactivation [Grill and Mortimer, 1995]. Therefore, when the stimulating phase of the waveform is applied, the neuronal population targeted for stimulation will be activated with greater selectively [McIntyre and Grill, 2000]. Asymmetrical charge-balanced biphasic cathodic-phase-first stimulus waveforms result in selective activation of local cells, while asymmetrical charge-balanced biphasic anodic-phase-first stimulus waveforms result in selective activation of fibers of passage. Further, charge balancing is achieved as required to reduce the probability of tissue damage and electrode corrosion. Note that these prepulse waveforms differ from the pseudomonophasic waveforms used in some stimulators in that the low-amplitude long-duration phase of the waveform precedes rather than follows the high-amplitude short-duration phase of the waveform (Figure 30.7e).

30.6.4 Indirect Effects of Extracellular Stimulation

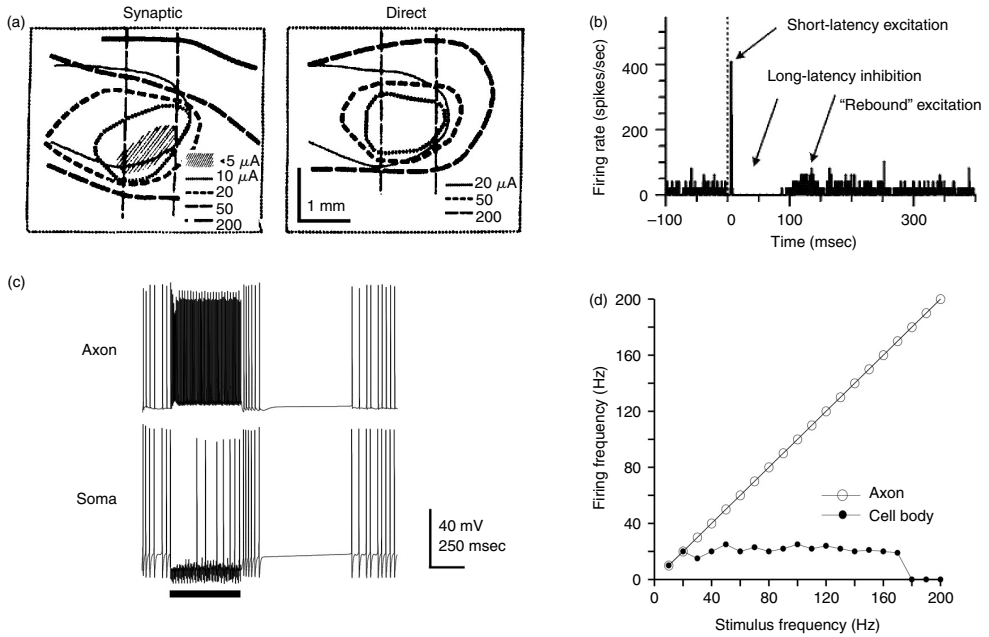
The thresholds for excitation of presynaptic terminals and subsequent indirect effects on local neurons (mediated by synaptic transmission) are similar to thresholds for direct effects (mediated by stimulus current) during extracellular stimulation (Figure 30.8a) of spinal cord motoneurons [Gustafsson and Jankowska, 1976], rubrospinal neurons [Baldissera et al., 1972], and corticospinal neurons [Jankowska et al., 1975]. Further, the chronaxie of presynaptic terminals (~0.14 msec in frog spinal cord, Tkacs and Wurster, 1991; 0.06 to 0.54 msec in rat subthalamic nucleus, Hutchison et al., 2002) is comparable to that of passing axons, and thus effects may be attributed to activation of passing axons when in fact they arise from activation of presynaptic elements. These "indirect" effects of stimulation must be considered when electrodes are placed within the heterogeneous environment of the CNS. During extracellular stimulation, release of inhibitory and excitatory neurotransmitters from presynaptic terminals can result in complex polyphasic changes in the firing rate of postsynaptic neurons (Figure 30.8b) [Butovas and Schwarz, 2003] and modulate the threshold for excitation of the postsynaptic neuron


FIGURE 30.8 Central nervous system (CNS) stimulation results in direct effects and indirect effects on CNS neurons. (a) Two-dimensional maps of thresholds for indirect (synaptic) and direct activation of neurons in the red nucleus [from Baldissera et al., 1972]. (b) Complex polyphasic changes in the firing rate of a cortical neuron in response to extracellular stimulation [from Butovas and Schwarz, 2003]. (c) Transmembrane potential in the axon (top trace) and cell body (bottom trace) of a model thalamocortical neuron before, during (black bar at bottom), and after extracellular stimulation [from McIntyre et al., 2004]. Extracellular stimulation results in simultaneous inhibition of the cell body, as a result of activation of presynaptic terminals and subsequent indirect effects, and excitation of the axon, as a result of direct action potential initiation in a node of Ranvier. (d) Firing rate in the cell body and axon during extracellular stimulation of a model thalamocortical neuron [modified from McIntyre et al., 2004]. The firing rate in the cell body is lower than that in the axon, as a result of simultaneous indirect synaptic effects on the soma, and direct excitation of the axon.

[Swadlow, 1992; McIntyre and Grill, 2002]. Thus, indirect effects mediated by synaptic transmission may alter the direct effects of stimulation on the postsynaptic cell. Further, antidromic propagation of action potentials originating from activation of axon terminals can lead to widespread activation or inhibition of targets distant from the site of stimulation through axon collaterals. However, recall that action potential initiation occurs at some distance from the soma, where integration of synaptic inputs occurs, and thus the axon may be excited even when the cell body is hyperpolarized (Figure 30.8c). Therefore, extracellular unit recordings of firing in the soma may not accurately reflect the output of the neuron (Figure 30.8d) [Grill and McIntyre, 2001; McIntyre et al., 2004].

30.7 Summary

This chapter described electrical activation of neurons within the CNS. Electrical stimulation is used to study the form and function of the nervous system and a technique to restore function following disease or injury. Successful application of electrical stimulation to treat nervous system disorders as well as interpretation of the results of stimulation requires understanding of the cellular level effects of stimulation. Quantitative models provide a means to understand the response of neurons to extracellular stimulation. Further, accurate quantitative models provide powerful design tools that can be used to engineer stimuli that produce a desired response.

The fundamental properties of excitation of CNS neurons were presented with a focus on what neural elements around the electrode are activated under different conditions. During CNS stimulation action potentials are initiated in the axons of local cells, even for electrodes positioned over the cell body. The threshold difference between cathodic and anodic stimuli arises due to differences in the mode of activation. Anodic stimuli cause depolarization of the axon and excitation via a "virtual cathode," while cathodic stimuli cause hyperpolarization at the site of excitation and the action potential is initiated during repolarization. The threshold for activation of presynaptic terminals projecting into the region of stimulation is often less than or equal to the threshold for direct excitation of local cells, and indirect effects mediated by synaptic transmission may alter the direct effects of stimulation on the postsynaptic cell. The fundamental understanding provided by this analysis enables rational design and interpretation of studies and devices employing electrical stimulation of the brain or spinal cord.

Transcutaneous FES for Ambulation: The Parastep System

Daniel Graupe
University of Illinois

31.1 Introduction and Background

31.1.1 Historical Background

Functional electrical (neuromuscular) stimulation, denoted as FES (or FNS) has its origins in Luigi Galvani's experiment on electrically exciting a frog's leg in the 1780s as described by him in "De Viribus Electricitatis in Motu Muscular" (1791), which despite some faults due to the state of scientific knowledge at its time, can be shown to lay the foundation to two great disciplines, electrical engineering and neurophysiology [1].

The first demonstrated modern application of FNS to a human patient for functional movements of extremities was reported by Lieberson in 1960 [2] in the case of a hemiplegic patient, whereas the first application to a paraplegic patient is that by Kantrowitz [3].

Unbraced short-distance ambulation by transcutaneous FNS of a complete paraplegic was first described in 1980 by Kralj et al. [4].

In early 1982, the first patient-controlled ambulation for a complete paraplegic as necessary for independent ambulation was achieved by Graupe et al. [5–7] employing EMG (electromyograph) control. A manually controlled system, known as the Parastep FNS system was tested from 1982 and received FDA approval in 1994 to become the first FNS ambulation system to be so approved and to be commercially available for use by individuals beyond research environments.

The systems of Graupe et al. [5,7] employ a walker for balancing support. It was commercialized by Sigmedics, Inc. (founded for this purpose in 1987) as the Parastep System (Parastep-I System) and was the first (and still is the only) FES ambulation system to have received FDA approval in 1994 [8] and approval by Medicare/Medicid for reimbursement 2003 [9,10].

In parallel, work was carried out since the early 1980s on percutaneous FNS, especially at Case Western Reserve University [11,12] in Vienna, Austria [13], and in Augusta, Maine [14].

FNS as above is applicable for traumatic complete (or near-complete as far as sensation, leg extension, and hip flexion are concerned) upper-motor-neuron thoracic level paraplegics. To date, approximately 1000 such patients are or have been able to ambulate over short distances with the FDA-approved Parastep system. They have been trained in over 20 hospitals or rehabilitation centers in the USA and in Europe, with no known detrimental effects. These patients can ambulate independently between 20 and several hundred meters (some up to one mile) without sitting down. The number of complete paraplegic patients who ambulate with implanted (percutaneous) electrodes is very small — about a dozen. The latter patients must undergo surgery (often of several hours) and they require occasional repeat surgery to correct electrode breakage or slippage, which are still unresolved problems. They also experience infections at the sites of electrode penetration through the skin. Consequently, at the present state of implantation, and noting the performance of the transcutaneous Parastep FNS users, it appears that for some time to come, the transcutaneous approach will be the more common one, and not just due to it being the only one available outside the research lab. It is for these reasons and since it is the only system for which there exists a body of independent source published material on clinical experience and data collection that this chapter concentrates on the Parastep ambulation system. Still, for completeness of this chapter, a very brief discussion on the major other ambulation systems is discussed.

31.1.2 Brief Review of FES Systems for Ambulation by Paraplegics

A very brief discussion on the major other FES ambulation systems is discussed here, for completeness.

1. *Noninvasive (Transcutaneous) FES systems:* The only other transcutaneous FES system (but for the PARASTEP) or both standing and ambulation that has been used outside their inventors' laboratory is the *Ljubljana FES system*, which is based on the work of Kralj et al. [15,16] and which emanated from that group's earlier pioneering work [4] on FES (related to the still earlier work of Lieberson et al. [2] concerning hemiplegia). The bench-model of the Ljubljana system was the first to achieve ambulation via FES by a complete thoracic-level paraplegic [4]. Its principles are similar to those of the Parastep system in their purpose and in their general function, which can, in part, already be found in the principles of the earlier Ljubljana work on hemiplegia and in Lieberson's work. It differs from the Parastep system in that it was not designed to maximize walking distance and it also differs in its control and in its channel coordination (to result in a bulkier system than the Parastep system). Its patient-borne version is usually a four-channel system. Its signal generation is essentially a two-channel signal generator, such that the four-channel system is a double two-channel system. The Ljubljana system is not yet commercially available (at least, not outside the use in research programs, mainly in Europe) and is presently not FDA-approved. No independent multi-patient ambulation-performance studies and statistics and no multi-patient medical evaluations or psychological evaluations were published on that system.

Other noninvasive (transcutaneous) FES systems for standing and ambulation, apart from the Ljubljana system and the Parastep system, are essentially all *bench-devices*, as developed in various research laboratories for the purpose of their own research (see D. Popovic et al. [17], Mayagoitia et al. [18], and the Stanmore system of Phillips et al. [19]). Whereas all FES ambulation systems can be and are used for *standing*, there are several transcutaneous FES systems for standing alone (see Jaeger [20]; Kralj and Bajd [21];

the Odstock standing system of Taylor et al. [22]). These are obviously limited in scope and are not within the main theme of this review. None is commercially available.

2. *Hybrid FES-Long-Leg Brace Ambulation Systems:* Hybrid FES-Long-Leg-Brace or FES-Body-Brace systems, which combine trascutaneous FES with a long-leg brace or with a body brace for standing and ambulation by paraplegics, have been developed since the 1970s ([8,23,24], Solomonow et al. [the LSU system] [25]). These systems are also intended for upper-motor-neuron (thoracic level) LSI. They represent a regression from FES, since they give up one of the major goals of FES ambulation, namely, patient's independence. Since hybrid systems use a body brace or long-leg braces, they are far heavier and far more cumbersome than, say, the 10.5 ounce Parastep. They require 30 min to don and a long time to doff, requiring help from an able-bodied person in donning and in doffing the system. This also affects patient compliance and regular use of the system, while the system's weight reduces ambulation distances [25].

3. *Implanted FES Ambulation Systems:* As stated earlier in this section, research on implanted FES for standing and ambulation has been carried out in parallel with the work on transcutaneous noninvasive FES, the latter being the subject of the present review. It is however important for the completeness of this review to comment briefly on implanted FES.

Work on both invasive FES and noninvasive FES started in the late 1970s and early 1980s. Also, the first applications to thoracic-level complete traumatic paraplegic were reported for both approaches in the early 1980s [4–6,11,13]. Also, both approaches are based on the fundamental user by Lieberson et al. [2]. However, invasive methods, both *percutaneous* [11,13] and fully implanted systems [26] always involve major surgery in contrast to the noninvasive transcutaneous methods on which this review concentrates. It is not just the surgery (and its cost). Furthermore, so far all noninvasive methods encounter loss of contact of electrodes, wire breakage, and sometimes even tearing of nerve fibers. Such occurrences then require resurgery. Fully implanted FES [27] does not encounter infections at locations where wires penetrate the skin as it happens with percutaneous methods. (In fully implanted systems, a radio-frequency [RF] receiver is implanted that receives RF signals through the skin, from a transmitter attached above the skin and the received RF is rectified to provide electric power.) All invasive systems require some kind of patient control from a nonimplanted device, as do noninvasive systems. Also all invasive systems require similar patient training and muscle strengthening. Of course, an implanted device requires no electrode placement each morning and removal each evening. However, with the Parastep system, donning time is 5–8 min for a trained user and doffing time is 3–4 min. Connection and disconnection of the FES control device and, in percutaneous systems, connection of wires to the implanted electrodes from outside, also takes a few minutes. It is therefore not surprising that the Parastep system was the first and is still the only FES system for standing and ambulation that has received (1994) FDA approval and is commercially available. We note that there are presently some 600 users of the Parastep and it is used both at home and at workplace. In contrast, there are presently only a few (in the order of a dozen) users of even the most advanced percutaneous system (based on Marsolais work and that of his colleagues in Cleveland, as mentioned above), whereas the fully implanted system is not yet complete to allow out-of-clinic ambulation.

We comment that the work on implanted FES has resulted in great advances in implantation techniques and materials that are of value in situations where there is no alternative to implantation (unlike the case of FES for standing and ambulation). However, the difficulties in implanted systems are still with us and they will always require surgery.

31.2 The Parastep System

31.2.1 System's Electric Charge and Charge Density Parameters

The FNS consists of sequences (trains) of electrical impulses that are applied transcutaneously so that stimulation reaches peripheral motor neurons at selected sites. Stimulation serves only to trigger action
FIGURE 31.1   Action potential in response to stimulation at a quadriceps stimulated site.

FIGURE 31.2   The parastep unit.

potentials at these motor units. The resultant action potentials produced in the motor neurons concerned, in response to these triggers (stimulation impulses), subsequently cause contraction of muscle fibers that are associated with these motor neuron [27,28], see Figure 31.1.

Comment: This action potential (AP) is a summation of many synchronous action potentials produced in response to a stimulation signal. It is recoded by surface electrodes at the stimulation site. The sharp peak at the beginning of each AP is an artifact of the stimulus.

31.2.1.1   Parameters of Stimulation Signals and safety Standard Constraints

The stimulation trains that are employed are trains of impulses of 120–150 μsec in duration (width) and their rate is of 20–25 pulses/sec. The pulse duration above is selected to be as low as possible while still allowing full contractions [27,29]. This is necessitated by considerations of minimizing the electrical charge density applied to the stimulation site for the patient's safety: it, therefore, also minimizes battery power, to result in a compact light-weight portable system (Figure 31.2). The system is powered by a 9.6 VDC battery pack consisting of 8 AA or AAA Ni-Cad rechargeable batteries, to power the stimulator and its computer.

The maximal current per pulse is limited [27] in our system to 0.3 A $= Io$. As per the 1985 ANSI standard, Section 3.2.2.2 of the Association for Advancement of Medical Instrumentation and the American National Standard Institute [30], stimulation should be limited to below 10 mA average current. Hence, stimuli of
FIGURE 31.3 Parastep system with battery pack and walker.

$T = 150$ μsec duration (pulse-width) at $f = 24$ pulses/sec, result in average current I_{ave} of

$$I_{ave} = Io \times T \times f \tag{31.1}$$

namely $0.3 \times 24 \times 0.00015 = 0.00108$ A or 1.08 mA, as is well below the ANSI limit. Another critical ANSI parameter is that of maximal electrical charge per pulse of 75 μC/pulse. The Parastep system's maximal output electrical charge value is given by

$$Q = IoT \tag{31.2}$$

or 0.3×0.00015 C $= 45$ μC $=$ Q. Thus the current density I_{ave}/S is for electrodes of 1.75×3.75 in.^{2} (namely $S = 40$ cm$^2 = 4000$ mm^2). The current density in the case of the Parastep system is therefore:

$$I_{ave}/S = 0.00108/4000 \text{ A/mm}^2 = 0.25 \text{ } \mu\text{C/mm}^2 \tag{31.3}$$

which is well below the ANSI limit of 10 μC/sq.mm.

31.2.2 System Parameters and Design

The Parastep system is based on a single microprocessor [27,29] which is its main component and where the stimulation signals of all channels are shaped and controlled and where synchronization between channels is performed for the four different stimulation operational menus. The microprocessor generates and shapes trains of stimulation pulses that are multiplexed and directed by the algorithm imbedded in that microcomputer to 6 output channels, which are individually controlled by the microcomputer, in response to menu selection by the patient to avoid robot-like movements. Channel separation is performed by a timing program, which is passed from the microcomputer to an array of microcomputer-controlled opto-isolators and then appropriately amplified, thus providing the system's outputs to 12 surface electrodes that are attached to the skin at appropriate placements. These skin electrodes are self-adhesive and are reusable for 14 days. They are to be attached by the patient himself in the morning and removed each evening or as desired at locations that the patient has been taught to remember. The stimulator unit weighs 7.6 ounces (Figure 31.2), excluding a battery pack of six AA 1.5 V rechargeable alkaline (or 8 rechargeable NiMH) batteries to allow at least 60 min of standing or walking [27]. The system is shown in Figure 31.3 and Figure 31.4.
FIGURE 31.4   Parastep system in use during walk by paraplegic patient.

TABLE 31.1   Stimulation Frequency vs. Rate of Muscle Fatigue

Stimulation frequency (Hz)	% Drop in isometric moment at ankle joint		
	After 10 min	After 20 min	After 30 min
20	<2	<2	3
30	4	14	40
50	17	53	71

Pulse duration: 300 μsec throughout.

The same microchip also controls optic isolation chips to allow using a single power amplifier for all channels. This allows the Parastep to employ six stimulation channels (12 electrodes) rather than the usual four stimulation channels and to integrate them to reduce system's weight, while facilitating full patient control of all channels. Furthermore, it facilitates considerable battery power savings. The additional two stimulation channels (at the paraspinals for trunk stability) play a major role in enhancing standing time, ambulation distances, and speeds as compared with four channel systems.

31.2.2.1 Pulse Width and Pulse Repetition-Rate (Frequency)

Pulse durations (widths) are set to be of 120 to 150 μsec [27]. Higher durations are undesirable and unnecessary. Higher pulse width speeds up the rate of muscle fatigue and therefore reduces the maximal ambulation distance (see Table 31.1) and the maximal time a patient can stand or walk via FES. It also sends into the body more electrical charge than is needed and requires higher battery power and hence higher battery weight.

The inter-pulse repetition rate (frequency) is set higher than the average pulse rate in the able-bodied individual, but is still kept as low as possible (22 to 24 pulses/sec) to reduce rate of fatigue (see Table 31.1). It is determined by considerations of fatigue, tetanization, and force (note that while standing or walking, the body weight dampens vibrations considerably). At even lower frequencies, muscle vibrations are observed that are no more dampened and that may affect the patient's balance when standing or walking. Higher frequencies also imply that a higher electrical charge enters the body and requires higher battery power and heavier batteries. Furthermore higher pulse rates speed up the rate of muscle fatigue to reduce duration and range of ambulation. Both pulse widths and rates, while constant, can be adjusted if necessary (see Figure 31.5).

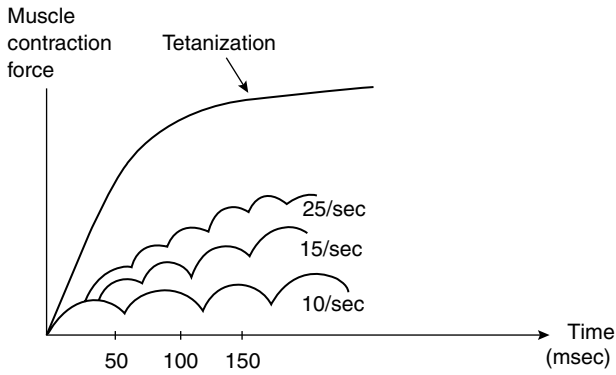
Therefore, a combination of a short pulse duration, low stimulation levels, and low pulse rate is essential to reduce muscle fatigue, thus extending walking distance (walking time) per walk [5]. The consequences of lower battery power needs, of lower system weight, and of the resultant effect on compactness are of course also significant for a patient-borne system and for user friendliness, especially, in a body-borne system.


FIGURE 31.5 Muscle contraction force vs. stimulation rate and time.
FIGURE 31.6 Placement of quadriceps stimulation electrodes (right leg, lateral side view).

31.2.2.2 Menus for Pulse Shaping and Synchronization

Pulse amplitude shaping is a major aspect of the pulse shaping algorithm and it is the subject of four different menus within that algorithm. The menus are patient selectable, through touch of finger-touch switches located on the Parastep's walker or on the Parastep's elbow-support canes. The menus are those for standing up, for right step, for left step, and for sitting down (see Figure 31.6). Pulse-amplitude shaping is dynamic and varies for each of the six stimulation channels and as per each menu, as does the distribution of output signal to each output channel [5,11]. The time variation of the pulse amplitudes in each menu and per each channel, as in Figure 31.6, is therefore unique and is based on considerations of the executions of the given menu's function (say, taking a right step) and of doing so safely, efficiently, and smoothly.

31.2.2.3 Stimulation Sites

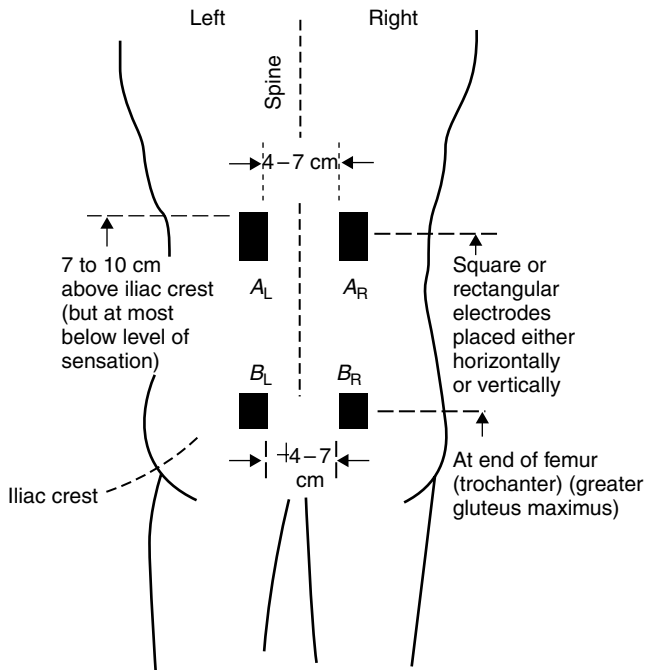
The stimulation electrodes are self-adhesive electrodes (12 in total), placed at six stimulation sites [27], two electrodes per site, as follows: two over the right quadriceps and two over the left quadriceps, to stimulate knee extension; two over the common peroneal nerve right and left (to activate dorsi-flexion and to elicit a hip flexion reflex via sensory neural feedback). Finally, two electrodes are placed over the right paraspinals at right and two at left, for upper trunk stability in patients with lesions at T7 or higher (to be placed approximately 1 in. below the level of start of sensation, but not too close to the heart). Patients with SCI lesions at lower levels will have electrodes placed over the gluteus medius and maximus for improved stability, whereas patients with lesions at T-l 0 or lower usually do not require paraspinal stimulation at all (Figure 31.6 to Figure 31.8). We comment that improved trunk stability affects not
FIGURE 31.7   Placement of peroneal nerve electrodes (to elicit step via hip flexion reflex).


FIGURE 31.8   Paraspinal electrodes placement (patient's back).

just patient safety, but helps to reduce fatigue, thus improving ambulation performance and appearance (which is not just an esthetic aspect but also a psychological one).

As shown in Figure 31.8, alternatives to the peroneal nerve placements are possible in some cases (see Chapter 7 of Reference 5). These alternatives involve other branches of the sciatic nerve, which trigger the hip flexion reflex.

The number of channels (of electrode pairs) to be used is a matter of trade-off. Obviously, with more channels more muscle groups (at below the SCI lesion) can contract. However, when increasing the number of channels, say from six to eight, the patient must place (every morning) 16 electrodes instead of 12 and for a paraplegic patient this involves a lot of additional effort and time. Furthermore, the six channels that are stimulated by the Parastep system, as discussed above are the ones that are the easiest to be reached by the user and the ones where there is the greatest tolerance in terms of error in placement's localization, while additional sites will require more care in exact placement. It is our experience that with
FIGURE 31.9 Synchronization scheme of envelopes of stimulation signals at various channels. (*Note:* Broken vertical lines divide between the four Parastep menus. Paraspinal signal envelopes correspond in shape to quadriceps channels except for peaks.)

more than 6 channels, most patients will soon stop using the system. Hence, human factor considerations imply to limit the system to the most important functions (channels) as far as performance is concerned. The resulting performance, as discussed later in this review (Section 31.5) appears to justify this choice and to result in a rather smooth walk that can be viewed in a 15-min movie of a walk of a complete thoracic-level paraplegic using the Parastep system (see http://www.ece.uic.edu/∼graupe).

31.2.2.4 Sequencing-Control Menus for the Stimulation Signals

Pulse-amplitude shaping is a major aspect of the pulse-shaping algorithm and it is the subject of four different menus within that algorithm. The menus are patient selectable, through touch of finger-touch switches located on the Parastep's walker or on the Parastep's elbow-support canes. The menus are those for standing up, for right step, for left step, and for sitting down (see Figure 31.9). Pulse-amplitude shaping is dynamic and varies for each of the six stimulation channels and per each menu, as does the distribution of output signal to each output channel [6,27]. The time variation of the pulse amplitudes in each menu and per each channel, as in Figure 31.9, is therefore unique and is based on considerations of the executions of the given menu's function (say, taking a right step), and of doing so safely, efficiently, and smoothly.

The stimulation signals are sequenced at the system's microcomputer chip as in Figure 31.9, where the envelope patterns of the stimulation impulses (and not the individual pulses) are illustrated. This pattern is automatically sequenced by the stimulator's computer to give a ramp increase of impulse levels for stand-up to be followed by a lower constant level while the patient is standing, both being applied to the right and left quadriceps electrodes and to the right and left paraspinal/gluteal electrodes. When a left step menu is selected, either manually or through above-lesion (chest-level) EMG (as described later), then stimulation is stopped at the left quadriceps and paraspinals/gluteus while at the same time the common peroneal nerve is being stimulated to elicit a step. This lasts for a fixed duration of $T = 0.4$ to 1.0 sec, as is preselected for the convenience of the patient. At the end of this period T, stimulation to the left common peroneal stops and the left quadriceps and left paraspinals/gluteus are stimulated. However, during the step period, the level of stimulation at the right quadriceps is automatically increased by the sequencing program to compensate for the fact that full body weight is borne by the right leg over that period. If a right step is selected, then the same menu is employed, with a reversal of roles of right and left. When a sit-down menu is selected, then the sequencing program first triggers an audible and a visual warning to allow the patient to abort the sit-down if he is not ready to sit and to allow for time to

reach a chair and to comfortably sit down. Also, at that time, stimulation to the quadriceps is increased to compensate for possible weakening of the quadriceps that may have caused the patient to decide to sit.

The microchip also controls optic isolation chips to allow using a single power amplifier for all channels. This allows the Parastep to employ six rather than the usual four stimulation channels and to integrate them to reduce system weight, while facilitating full patient control of all channels. Furthermore, it facilitates considerable further battery power savings. The additional two stimulation channels (at the paraspinals, for trunk stability) play a major role in enhancing standing time, ambulation distances, and speeds as compared to four channel systems.

Control of the FES is performed by the stimulation signal's sequencing program of the Parastep's microcomputer, while selection of menus of that program is performed either manually (as in the Parastep commercial system) or via an above-lesion EMG control algorithm for menu selections [5,7,29].

31.2.2.5 Finger-Touch Menu Selection

Menu-selection finger-touch switches [27,29] are located on the walker's handlebars for easy finger reach while normally holding the walker (or cane). They require only a light single and quick (short) finger touch without changing hand position on the bars. Adaptation and learning of balancing and of menu selection (only two menus during walking; of right and of left step, activated at right or left handlebar), is very easy and fast. Only finger-touch selection is available in the commercial Parastep system.

31.2.2.6 Above-Lesion EMG-Controlled Menu Selection

While the commercial PARASTEP system employs only manual touch buttons for menu selection, the laboratory Parastep system, that was tested on 14 patients at Michael Reese Hospital, Chicago, IL, allowed for above-lesion surface-EMG (electromyographic) menu selection too with good results [7,27,29]. However, menu-selection EMG-control was not incorporated in the commercial system (and is not covered by its FDA approval), since training is far lengthier and requires the donning of four more electrodes (for EMG pickup). This was felt to greatly limit the number of users. We comment that EMG electrode placement is much more critical than that of placing the stimulation electrodes themselves.

The above-lesion EMG-based menu selections employ surface-EMG signals from electrodes placed at above-lesion locations on the patient's chest. The thus obtained EMG signal (see Figure 31.8) serves to map a pattern of upper-trunk posture that has been shown [5,7,27], to predict intended body function, corresponding to the four menus above (stand, left step, right step, and sit menus), with an accuracy of better than 99.8%. In this case, no finger controls are needed.

We emphasize that the relevant information from the above-lesion EMG signal is NOT based on the EMG level (power), but on the whole stochastic time-series pattern of that signal [27,29]. Therefore, the patient does not have to produce a specific produce upper-body above-lesion (shoulder) movement to select a particular menu. The patient's natural walk and the natural changes in the above-lesion muscles as are needed to move the walker and to otherwise balance when intending a particular step (or to stand up or to sit down) causes dynamic changes in the whole EMG stochastic pattern. These pattern changes are then recognized in the microchip's algorithm as a command to select a particular menu (from the menus above). In this way, the above-lesion EMG control differs from others that require unnatural pulling of shoulders or of arms to produce an EMG-based command. Such intentional and unnatural movements divert patient's concentration and yield an unnatural walk.

The mapping of the upper-trunk posture considers the above-lesion EMG signal, dented as $y(k)$, to satisfy a pure autoregressive (AR) time-series model [7,29]:

$$y(k) = a(1)y(k-1) + a(2)y(k-2) + \cdots + a(n)y(k-n) + w(k) \qquad (31.4)$$

where k is discrete time, such that $k = n+1, n+2, n+3, \ldots$, and $w(k)$ denotes a discrete white-noise process.

We comment that both under finger-touch control (menu selection) and under EMG menu selection, the direction of step (and hence, of a walk) is determined by the shoulder movement of the patient as naturally performed when intuitively moving the walker to any desired direction.

31.2.2.7 Stimulation Signal's Level Control

The stimulation level is adjusted at the Paraestep's microcomputer chip, in accordance to either the patient's single finger-touch menu switching command or *t* in response to an above-lesion EMG signal from the patent's chest that is interpreted in the same microchip.

31.2.2.8 Finger-Touch Force Level Control

The degree of recruitment of motor neurons determines the contraction force exerted by the muscle fibers that are associated with these neurons [27,29]. The degree of recruitment is, in turn, dependent on the level of the stimulation signal when the motor neurons are triggered by FES stimuli. In the commercial Parastep, the stimulation level is controlled by the touch buttons at the left and right hand side of the walker. Each finger touch raises the level by a single increment. Out of 10 possible level increments that are color marked most patients use one of the 3 lowest levels to start their walk, in order to minimize rate of fatigue. During a half-hour walk a patient will usually have to adjust FES level only 2 to 3 times by a single discrete increment. The range of levels can be factory-set to suit special needs (patients).

31.2.2.9 Below-Lesion Response-EMG FES Level Control

Alternatively, in the Parastep lab system tried at Michael Reese Hospital, a below-lesion surface-EMG Stimulation-Level Control, denoted as Response-EMG Level Control, was successfully tested on some patients [27,29].

Obviously, in complete upper-motor neuron paraplegics (thoracic level SCI patients), no EMG occurs below the level of the lesion, since the lower-extremity neurons do not fire. However, under FES, action potentials arise at the stimulated motor neurons. These produce action potentials similar to those in nonimpaired situations. Furthermore, since any stimulation electrode-pair activates many hundreds of motor neurons simultaneously, all resultant action potentials are fully synchronized and appear as one very strong action potential due to this combined and synchronized firing (see Figure 31.1). This is in contrast to the surface-EMG above the lesion, which results from unsynchronized firing of hundreds of neurons. Furthermore, the resulting response-EMG increases with the degree of recruitment. It can thus serve to detect progression of fatigue and serve to adjust stimulation levels accordingly. The commercial system uses only finger-touch level control, since the reliability in calibration of relations between response-EMG level (and shape) against desired FES stimuli strength (to counter the fatigue) is still not sufficiently reliable. It is also not covered by the Parastep's FDA approval. However, when using opto-isolators, the stimulation electrodes can simultaneously serve as response-EMG electrodes. This is due to the very short duration of the Parastep's stimulus in relation to the duration of a single action potential (which is given by the stimulation of low pulse-rate used by the Parastep system).

31.2.2.10 Peripheral Equipment

The Parastep FES system uses a walker (see Figure 31.3 and Figure 31.4), or in a few cases, a pair of elbow-support (Canadian) canes [27,29]. Walkers are employed in all other FES ambulation systems, invasive or not. Walkers (or elbow-support canes) serve mainly for balance. Walkers carry (in the Parastep system) only 5% or less of body weight in trained FES users during standing and are crucial during the standing-up mode. Their balancing role is due to the fact that complete SCI paraplegics have no sensation (in addition to having no motor functions below their lesion). Hence, indirect sensation coming through their arms and hands, while holding the walker's handlebars, lets the users sense the ground to provide a certain psychological security. It thus allows the users to balance their body by slight shoulder and arm movements to better balance during standing and walking. The users are able to easily and rather naturally change direction of walking, at will, through shoulder positioning by which they turn their steps. One major function of the walker is during the stand-up phase from a seated position. The patient then gets up

with the arms leaning on the walker. All these reasons indicate the crucial role of walkers toward achieving independent standing and walking.

The Parastep system is described in further detail in Graupe and Kohn [27,28].

31.3 Patient Admissibility, Contraindications, and Training

31.3.1 Patient Admissibility Criteria

The cardiovascular status of the patients must be good. Hence, the criteria for a patient to be admitted to train and to use the Parastep standing/ambulation system are as follows [7,27,29]:

1. The patient must be in good general health and with a complete traumatic spinal cord lesion at levels no higher than C-7 and no lower than T-12.
2. Intact lower motor units (lumbar level L-1 and below).
3. Must have a complete/near-complete SCI lesion that do not allow the patient to stretch his/her knees for standing up and where the patient has no substantial sensation (pain) of the stimuli.
4. Surgery/wound following SCI must have healed, or as determined by the surgeon.
5. Stable ortho-neuro-metabolic systems.
6. No recent history of long bone stress fractures, osteoporosis, or severe hip or knee joint disease. A bone density test is advisable in case of women over 40 or patients who are many years (10 or more) beyond date of injury. The author had a patient 40 years postinjury who had no problem and was accepted to the FES ambulation program.
7. No history of cardiac or respiratory problems.
8. Adequate trunk stability so that once quadriceps are stimulated, the patient can hold his upper trunk upright while supporting himself with a walker.
9. The patient demonstrates appropriate muscle contractions in response to stimulation (absence of such response usually implies some lesions below T-12).
10. Standing tolerance: The patient has adequate fatigue tolerance to practice and perform standing and walking functions after initial training.
11. Balance and trunk control (at least when paraspinals are stimulated).
12. The patient must have adequate hand and finger control or VOICE control to manipulate the system controls. Future systems may circumvent the need for finger control via speech recognition to allow patients lacking hand/finger control to use the system.
13. Sufficient upper body and arm strength to lift oneself up to the walker for a second or two without stimulation and to grasp chair when stimulation is stopped for any reason.
14. No severe scoliosis.
15. No irreversible contractures.
16. No morbid obesity.
17. Patient is not pregnant.
18. Motivation: The patient demonstrates and expresses appropriate desire and commitment to the training program.

Also, interference of stimulation signal with an electronic cardiac pacemaker must be avoided.

31.3.2 Contraindications

Once the admission criteria of Section 31.3.1 are followed, no contraindications are known to the author from his personal observations or training experience with approximately 100 patients. Also, none are known to have been reported in the literature.

31.3.3 Patient Training

The author's experience of over 23 years of working with patients and of observing Parastep training programs outside his own training program in the use of the Parastep FES system for standing indicates that once the patient satisfies the criteria as above the patient is able to stand and to ambulate, if trained properly. Distances and speed vary widely and even distances (and speeds) well below the averages mentioned in this chapter may be a major achievement for some patients, depending on their general health, level of lesion, age, and any other limitations they may have. The author had trained a 62-year-old T-3/T-4 complete paraplegic patient (gunshot wounds) who was in the wheelchair for 40 years and never been stimulated. This patient stood up in his first session and took 12 steps in his third one-hour session. Motivation is the definite key factor and this also implies family/friends' and (and physician's) encouragement and support. Family/friends' support is crucial. This should not just be verbal, but also in terms of helping the candidate stand/walk at home after or between training sessions by walking next to him/her to be able to prevent the patient from a possible fall, and moving (sharp) obstacles from the way. The patient should have at least one strong armchair (possibly a metal chair) with arm rests at an adequate height for the patient to be able to get up and sit down independently of the walker. Some patients do initially need help in placing the lower paraspinal or gluteus electrodes on the skin. It is very advisable that a family member or friend should observe at least part of one training session. The skin electrodes need be replaced once every 2 weeks (or less, if contact to skin is inadequate). Bad electrodes or broken electrode connectors are the main reasons for stimulation failure.

Training programs vary widely and so do their respective results. This author is familiar with Parastep training programs that involve 5 to 6 h a day of supervised training for 5 or 10 consecutive days, of Parastep programs of one hourly session every week or every 2 weeks for over 1 year, of Parastep programs of three 1-h sessions a week for 11 weeks (Klose et al. [31], the University of Miami program), and of Parastep programs of 2 h per day, 5 days a week for over 4 months (Cerrel-Bazo et al. [32], the Vicenza program, Italy). Since all these programs use the same FES system (the Parastep system) only the performance results shed a light on their efficiency. However, they differ widely in cost and in the required commitment of time by the patient. Therefore, the decision on which kind of program to attend is usually not a matter of choice.

Regardless of the training program, it is of utmost importance that the patient complements each supervised training session with after-hour home exercise of at least 15 min (many programs require much more).

In almost all training programs, training starts with reconditioning and strengthening of the muscles involved and also of arm muscles. First, the quadriceps muscles, which are those that are the most involved in stand-up and in standing require strengthening. Treadmill exercises in walking are often used. In many programs, monitoring of heart rate and of blood pressure is done during treadmill training. Parallel-bar standing and walking are sometimes used at the initial stages, during a muscle-strengthening phase. But parallel-bar exercise does not help in learning to rely on and to balance oneself with the walker and may therefore be counter productive. Muscle strengthening while seated is a very major part of the home exercise throughout training, but takes place only in the first or second supervised sessions. It is psychologically most important to stand a patient up, even for 20 to 30 sec (as long as is safe) even in the first session. This and taking of the first few steps (even 2 or 3) early on are great motivators. Hence, the first step should be taken after the patient can stand safely (with a walker) for about 3 min. Eventually, training and muscle strengthening should aim at standing for 10 min or more and walking for as long as is possible. These sessions should start with treadmill standing and walking. At the last stages of training, patients should be taught to fall, by sudden power shutdown (they will learn to avoid an actual fall through proper use of walker). They will also learn to lift themselves up from the ground with no help, to walk on rough ground, and on reasonable slopes. They will train in getting in and out of a car unaided. The most advanced T-9 to T-12 patients can then train on using elbow-support cane.

Continuous walking after end of training on a near-daily basis, for at least 45 min a day (not necessarily in one session per day) is essential for progress and for improved performance.

The first training session must involve getting sufficient quadriceps contraction to have each leg lift while the patient is in a seated position. Psychologically and motivationally, it is desired that the patient gets up (to a walker, not to parallel bars) in the first or second session. However, this should not defer rigorous muscle strengthening in future sessions (actually, until end of the training program). For best results, daily (5 days/week) training of 1–2 h/day, followed by home exercises, yields far better outcomes at end of training than a 3 h/week program and even more, if the whole training program is condensed over only 1–2 weeks. Still, whatever the training program, if after completion of training, the patient continues to walk daily for 30–45 min he will continue improving and his performance will equal the best program (of course, considering his individual status, lesion level, age, and general health).

Home exercising while undergoing training should be done when the patient stimulates while seated — except when, later in training (and with trainer's explicit permission) the patient is permitted to take a walker home and stands/takes steps WHILE an able-bodied person is close at hand.

31.4   Walking Performance, and Medical and Psychological Benefits Evaluation Results

31.4.1   Walking Performance Data

Walking distances covered by Parastep users vary with the individual user's level of injury, training, learned skills, and physical condition. Distance walked will vary and increase with practice and training. Individual goals are established for each user by the physical therapist. Studies conducted in different clinical settings reported distances walked by individual users ranging from a few feet to over a mile at a time, with the average distance being around 1450 ft (450 m/walk) for fully trained patients in certain training programs [32,33].

Performance is influenced by the training program, but mostly by how rigorously the patient continues to actively stand and walk with the FES system after end of training. Improvements in performance will be very noticeable 1 or 2 years after end of formal training. Approximately 5% of the Parastep users known to the author (from several U.S. training programs) can ambulate one mile per walk on occasions (usually one year or more after end of formal training). The author expects this to be the case too for the Vicenza (Italy) training program.

The Miami Project to Cure Paralysis of the University of Miami reports average ambulation distances for Parastep users of 115 m/walk at a mean pace of 5 m/min, at the end of the training program of 33 sessions over 11 weeks [31]. For the Parastep training program of daily sessions over 4 months at the Centro di Rehabilitazione di Villa Margherita in Argugnano, Vicenza, Italy, an average distance of 444 m per walk was reported, at a mean speed of 14.5 m/min and with mean daily walk time of 90 min [32]. See also Chaplin [33]. These performance differences are very significant.

Still, there is no reason to assume that persistent FES users in the 11-week program cannot do as well as those in the 4-month program at 1 year after end of training. However, continuous use may be higher for patients whose performance at end of training is considerably higher. This is the author's experience in his own (once weekly over 1-year program). The Vicenza program reports zero dropout 14 to 39 months after end of training [32]. The author is not aware of other training programs with similar results.

We comment that the averages given are for patients whose SCI lesion levels are more or less evenly distributed between T-1 and T-12. Usually, performance is better if the LSI lesion is lower (toward T-12). However, motivation and persistence often makes up for level of lesion. Still, patients who for various medical or age reasons cannot walk more than 10 m (per walk) at end of training should still continue exercising, since benefits of FES exercise are more than just a matter of distance or speed, as is discussed later. Kralj et al. [15] give the general utilization statistics on the Ljubljana FES system for performance tests carried out by its developers.

However, these do not include performance data or medical or psychological patient evaluation on that system. The data given here on the Parastep system, are from independent centers (University of

TABLE 31.2 Ambulation Performance Results (Parastep Users)

Miami Medical School, the Vicenza Rehabilitation Center, Italy) that are not connected with the system's manufacturers or its developers.

Table 31.2 gives further ambulation performance data.

A 14 min video of complete thoracic-level paraplegic patients, while walking with the Parastep system, is shown in www.ece.uic.edu/~graupe.

31.4.2 Evaluation Results on Medical Benefits for Walking with the Parastep System

The benefits in using the Parastep system go well beyond the benefits in the ability of walking, as discussed in Section 31.4.1. Medical and psychological evaluation that were published on Parastep users, show several medical and psychological benefits to walking with the Parastep. These are discussed in this and in the next section. Most important medically is the major improvement in circulation at below the level of the SCI lesion. We discuss the medical and physiological evaluation results here, while psychological evaluation outcomes are summarized in Section 31.4.3.

1. *Lower-Extremity Blood Flow:* A study performed as a part of the Miami Project, to Cure Paralysis of the Departments of Neurological Surgery and of Orthopedics and Rehabilitation of the University of Miami, authored by Nash et al. [34] and involving 12 Parastep users, reports an average increase of lower-extremity blood inflow volume f 56% (from 417 to 650 ml/min) after 12 weeks (32 sessions) of Parastep training. Dr. Cerrel-Bazo reported (verbally) to this author similar improvements (at the Vicenza program in Italy). It is noted that, after paralysis due to thoracic level SCI, blood flow to the lower extremities decreases considerably, with detrimental subsequent effects on kidney function and eventual cardiovascular effects. Hence, such improvement is of major significance.

2. *Other Cardiovascular Effects:* The above 12-patient study at the Miami Project of the University of Miami [34] has shown that the average resting heartbeat of Parastep users decreased from 70.1 (prior to FES training) to 63.2 (posttraining). Also, the Common Femoral Artery cross-sectional area increased by 50%, from 0.36 cm^2 (pretraining) to 0.48 cm^2 (post-FES training).

3. *Physiological Responses to Peak Arm Ergometry:* A study on physiological responses by 15 Parastep users [27] to peak-arm ergometry exercises have shown that average time to fatigue has improved from 15.3 min prestart of FES training to 19.2 min after 33 sessions of training. Also, the peak workload increased from 48.1 to 60 W. Oxygen uptake at peak-arm ergometry increased from 20.02 ml/kg/min pretraining to 23.01 ml/kg/min posttraining, while the respiratory exchange ratio dropped from 1.26 pretraining to 1.18 posttraining, to indicate improvement in all these parameters. The patients (12 men, 3 women) ranged in age from 21 to 45, in years from injury from 0.7 to 8.8, and in body weight from 53.6 to 83.5 kg.

4. *Muscle Mass:* A significant increase (10 to 22%) in high circumference was measured on Parastep users after 3 to 6 months of training at the University of Illinois/Michael Reese Hospital training program in Chicago [5].

5. *Spasticity:* Spasticity is common to all SCI patients with upper-motor lesions. In the authors experience in 19 years of observing well over 100 patients training with or using the Parastep system, almost all patients who complained of spasticity commented on either considerable or some improvement in spasticity. This improvement was usually observed after the first 2 to 3 training sessions. Usually,

TABLE 31.3 Medical and Physiological Evaluation Data (Parastep Users)

	Pre-FES-training (Ave.)	Post-FES-training (Ave.)	
Lower-extremity blood flow	417 ml/min	650 ml/min (improv.)	12 patient data/ U. of Miami [34]
Heart rate	70.1	63.2 (improv.)	12 patients/Miami [34]
Time to fatigue (at peak-arm ergometry test)	15.3 min	19.2 min (improv.)	15 patients/Miami [35]
Peak workload heart rate (pk arm ergom. test)	188.5	183.1 (improv.)	15 patients/Miami [35]
Oxygen uptake (pk arm ergom. test)	20 ml/kg/min	23 ml/kg/min (improv.)	15 patients/Miami [35]
Spasticity		Usually improvement, especially for very spastic pre-training	Michael Reese Hospital, Chicago [6,27,29]
		Training, where no significant change was reported	

the higher the degree of spasticity, the greater was the improvement that was reported. This improvement was often reported as one of the reasons for participating in the FES program. The improvement in spasticity is important with regard to the detrimental effect of medications (Baclofen, Valium, Lioresal) on alertness and fatigue as medication doses can then be reduced in many cases [5].

6. *Bone Density:* Practically all paraplegics suffer from reduced bone density. This happens right after injury and may be aggravated when the patient does not put weight on the legs. One of the Parastep patients in the author's program recorded a 50% bone density prior to training (but no bone injuries) with no improvement after one year though he continued to walk and reached 1 mile/walk. The only study published till now (Needham-Shropshire et al. [36]) does not show any improvement in bone density due to FES ambulation. However, this study refers to the end of 11 weeks of training. No study exists on patients who have consistently walked via FES for several years.

7. *Pressure Ulcers (Decubitus Ulcers):* Almost all paraplegics suffer from decubitus ulcers. However, all but one patient at the author's FES program (at Michel Reese Hospital, Chicago), had no occurrence of a new ulcer while regularly using FES. Improved blood circulation at below the lesion is most likely the cause for this [27]. The exception was due to a cut from a sharp object.

The medical and physiological evaluation data are summarized in Table 31.3.

31.4.3 Psychological Outcome Evaluation Results

1. *Psychological Evaluation Results — Self-Concept Scores:* A study on 14 Parastep users after 11 weeks of training at the Miami program [37] concerning physical self-concept using the Tennessee Self-Concept Scale (TSCS), compares TSCS scores before the beginning of Parastep training against the score at the end of the 11-week program. It shows that the average TSCS score improved in a statistically significant manner from 44.3 to 52.0. Furthermore, all patients with a score below 50 prior to FES-training, have improved, whereas no patient with an initial score above 50 dropped to below 50.

2. *Psychological Observations – Depression scores:* The same study [37] as in Section 31.4.3 reports on comparing Beck Depression Inventory (BDI) scores for measuring depression before and after 11 weeks of Parastep training. BDI scores of below 9 refer to no depression and scores below 18 to mild depression, whereas scores from 18 to 29 point to moderate depression. The results of the study show that all five patients who were initially at the mild or moderate depression score levels (one was initially even beyond the moderate range) did improve significantly. The patient who was initially beyond the moderate depression range (31 DBI score) improved to 24 (mild depression range). One of the two patients, who were initially

TABLE 31.4   Psychological Evaluation Results — For Parastep Users

	Pre-FES-Training (Ave.)	Post-FES-Training (Ave.)	
Physical Self Concept (TSCS scores)	43.2 TSCS	52 TSCS (improv.)	15 patients/Miami [37]
Depression Scores (BDI scores)	8.8 BDI	5.4 BDI (improv.)	15 patient data [37]

in the moderate range, improved to the low-mild range and the other to the no-depression range. All patients who were initially in the low-depression range stayed in that range.

The psychological evaluation results, as in the present section, are summarized in Table 31.4.

31.5   Regulatory Status

The Parastep-I functional neuromuscular (electrical) system (referred to throughout this chapter as the Parastep system) for standing and for ambulation by thoracic-level paraplegics received FDA approval on April 20, 1994 [8]. It was the first and is still the only noninvasive FES ambulation system to have received FDA approval. Furthermore, effective April 1, 2003 the Centers for Medicare and Medicaid Services (CMS) made a National Coverage Determination extending coverage to the Parastep-I System for qualifying Medicare beneficiaries. Specific HCPCS codes have been assigned to cover costs associated with both the acquisition of the Parastep-I equipment [9] and for the physical therapy training services Parastep-I [10]. Medicare covers approximately 80% of equipment acquisition costs. Following the CMS example, most major medical insurers in the United States have already amended their policies to cover the Parastep system. The Parastep's manufacturer, Sigmedics, Inc. of Fairborn, Ohio, physical therapy training services has set up its own Patient Case Management Department for the purpose of facilitating insurance reimbursement process.

31.6   Concluding Comments

This chapter discusses the Parastep system, which is the first and still, the only FDA-approved transcutaneous (noninvasive) FES system for ambulation by complete or near-complete thoracic-level paraplegics. It describes what this system can already do for the thoracic-level (complete) paraplegic patient in noninvasive FES. It gives concrete data from many studies on how that system performs. It also discusses its design, operation, admission criteria, contraindications, and training.

We thus conclude that a totally noninvasive FES for independent standing and mobility is already a reality for complete upper-motor-neuron thoracic-level traumatic paraplegics. Furthermore, it is commercially available and it received (2003) approval for reimbursement by the Center for Medicare and Medicaid Services (CMS) that regulates Medicare and Medicaid reimbursements policies in the United States and subsequently, by practically all medical insurance companies in the United States. Training programs for that system exist in many hospitals and rehabilitation centers. As was discussed above, upon completion of 4 months of daily training, ambulation distances for the Parastep system were reported to average 444 [32] or 115 m/walk in a 33-session 11-week program [31]. Medical benefits have been documented, in terms of greatly increased blood flow to the lower extremities [34], reduced spasticity [29], reduced incidence of decubiti [27], increased thigh circumference [27], and of psychological benefits (improved self-concept and depression scores) [37].

However, even 10 years after FDA approval of such a noninvasive FES system and 2 years after reimbursement was approved by Medicare, Medicaid, and by most insurers, there is great ignorance in the paraplegics community about the availability of such a system and of its performance and benefits. In Reference [38], a statement by a patient is quoted (made in a recent symposium of prospective FES users, funded by the Whitaker Foundation), that "in 3 to 4 different rehabilitation facilities and (having) talked to over 200 patients…none of them ever mentioned FES." These indicate ignorance, regarding the role

of FES in paraplegia, among physicians involved in caring for paraplegics, and among the (physical and occupational) therapists and other related staff.

The consensus of the Symposium above (and which agrees with what this author repeatedly hears from patients) was that desire to stand upright independently and to ambulate even short distances is the prime desire of paraplegics long-term compliance and long-term use of FES is also a problem. However, the circulatory benefits and the other medical and psychological befts should play an important role, for patients, for physicians, and for insurance companies involved.

All this does not detract in any way from the urgent need to repair the spinal cord through regeneration. Neither the Parastep nor any other FES approach can substitute for this, since FES does not heal. It is an aid, just like eyeglasses or a hearing aid. It is hoped that regeneration will be a reality for human SCI patients. In the meantime, a realistic aid does exists that is already FDA-approved and reimbursable. It can always be and will be improved, but its performance even now is usually pretty good.

Comparing Electrodes for Use as Cortical Control Signals: Tiny Tines, Tiny Wires, or Tiny Cones on Wires: Which Is Best?

Philip R. Kennedy
Emory Uiversity

In the fields of neural prosthetics and neural engineering there are several viable contenders for the prize of best long-term electrode to access cortical control signals for restoration of communication and movement in humans. These contenders can be classified into three main groups. The first group includes those who have developed tiny tines that are driven into the cortex and provide signals for months and sometimes years [1–3]. The second group produces flexible wires that are inserted into the cortex and provide signals also for months and sometimes years [4]. The third type of electrode is also a wire configuration but allows for growth of the brain's neuropil into the hollow glass tip of the electrode. Robust signals have been recorded for years from this neurotrophic electrode (NE) [5]. Thus, these electrodes can be classified into (1) those that protrude toward neurons and (2) the NE that welcomes the neurites into its tip and thus fuses with the neuropil.

The holy grail of all these efforts is the restoration of movement to the paralyzed. For example, quadriplegics need to use their hands, and cortical control of functional neuromuscular stimulation devices would appear to be the answer to this need. These systems, though they will provide access to cortical control signals, may not alone restore movement to those with spinal cord injury; instead, I suspect these recording technologies will be hybridized with spinal cord regeneration efforts to restore movement to

TABLE 32.1   Characteristics of Electrodes

	Tines	Tines	Tines	Wires	Neurotrophic
Investigators	Anderson	Donoghue	Schwartz	Nicholelis	Kennedy

N/T = Not tested, yrs = years.

those paralyzed by spinal cord injuries. Similarly for amputees, robotic technologies will be wed with cortical control signal technologies for successful control of artificial limbs.

Herculean efforts have been expended by all workers in this field to provide single unit recordings in the belief that the precision needed for control of digits is found only in the firing patterns of cortical single units recorded from primates. While not doubting this conclusion, less precise control may be sufficient for some prosthetic applications. An example of less precision is found in local field potential recordings (LFPs), which are simply an aggregate of single unit recordings. These LFPs may prove very useful as prosthetic controllers [1,6–8]. Furthermore, this chapter will conclude with the surmise that not only precision, but plasticity too, may be the unique (and a very necessary) feature available from single unit recordings and not from LFPs. Yet LFPs may provide some degree of prosthetic control, which though less precise, may be useful.

First, let us look more closely at these three electrode categories and discuss the pros and cons. Conflict of Interest statement: yes, it is true that this author is the developer of the NE. Nevertheless, I will try to be as impartial as I can and assess the facts as published and known to me. Table 32.1 summarizes electrode similarities and differences. I apologize in advance if any worker in this field is underrepresented.

The first three investigators use tine type electrodes that are either the 100-pin array (devised by Dick Norman), and used by Donoghue and colleagues [2], or the Michigan probe used by Schwartz et al. [3]. Anderson and colleagues use their version of the array [1]. Nicholelis et al. use micro wires they have devised [4]. Let us take these characteristics point by point. Kennedy is the only one to use the NE so far [5,9,10].

1. Longevity is of prime importance in a chronic electrode that is to be implanted in a young adult human for a lifetime that can extend beyond 50 years. Clearly, the NE is ahead in this respect so far [5], though recent reports from Donoghue's lab show a few signals enduring for years [2]. In all animals and human subjects, the signals from the NE continued until the preparation was destroyed or the subject died. The NE has endured in two humans for over 4 years (in preparation).

2. Stability of signal is of great importance too. This is difficult to assess over long time periods especially if the subject is totally paralyzed because in that case there is no behavior or electromyographic (EMG) activity available for correlation. Stability has been shown in the NE [5,9–11] and to some extent in Donoghue's recordings [2]. One can argue, however, that stable single units may not be of great importance now with the advent of LFPs' recordings. Because the LFP signals are inherently more stable, the loss of a few single units may not matter to the overall quality of the LFP. Nevertheless, there is yet no firm evidence of that, so stability still remains important.

3. Plasticity is one important feature of single units that is probably not available from LFPs. It ought to be easier to train one unit, than an unruly classroom of poorly correlated units. The expectation is

that perhaps any unit recorded from anywhere in the brain can be trained to control a specific output. If this plasticity expectation is to be fulfilled, however, there must be a priori stability of the unit. Without stability and longevity, repeated sessions of retraining would be required. So far, the NE is unique in achieving the goals of plasticity, stability, and longevity [5,10 in prep.].

4. Directionality has been tested by all investigators and found to be present. Schwartz and colleagues are the only ones to have shown directionality in three dimensions using a virtual reality environment [3]. In these trials the cursor was driven under the influence of the single units into all eight corners of the virtual cube space. There does not seem to be any overwhelming reason why other electrode configurations should be deficient in this task. Directionality with the NE was achieved without resort to the firing rate, but was deduced from the initial direction of depolarization of the action potentials [11].

5. Force has been tested by the Nicholelis group who found that force and direction can be controlled by the monkey [4]. This feature has not been tested by others. Again, there is no overwhelming reason why force relationships could not be found with other electrode configurations.

6. Local field potentials have been studied by Anderson et al. [1], Kennedy et al. [6,7] and Leuthardt [8] and found to be useful. Anderson's group found that LFPs indicate cognitive state of the monkey and has also indicated directionality. The Kennedy group also found directionality within the LFPs [5], and in addition used them to control a cursor and a cyber hand on the computer monitor. The subject was able to flex the cyber digits under control of the LFPs with reasonable speed [5]. Again, there is no overwhelming reason why other electrode configurations should be deficient in recording LFPs. In fact, it may minimize the impact of unit instability inherent in other electrodes and thus improve their functional longevity.

7 and 8. Units per contact and per electrode have been presented by all authors. Tines and wires usually have only a few units, but have many tines or wires, thus providing a large number of units overall. This makes processing of the signal outputs per electrode relatively straightforward, but implies that a large number of electrodes are needed to provide many signals. On the other hand, the NE has 5 to 10 signals per electrode and up to 19 in one subject (in preparation), which means that fewer electrodes are required. Processing of these signals using spike-sorting technologies is complicated but very achievable with today's systems [2, in prep.]. The NE advantage is that fewer electrodes, and hence implantable amplifiers, are needed.

9. Relatedness to EMG Activity. Electromyographic activity has been studied by the Kennedy group in one almost paralyzed subject. They found that EMG was related to movement onsets, and poorly related to single unit recording, though fairly well related to LFP onsets (in preparation). Though interesting, these results are not essential to the success of any of the electrodes. After all, the subjects to be implanted will be paralyzed a priori. Furthermore, there is no overwhelming reason why other electrode configurations should be deficient in this task.

10. Stimulation of the underlying cortex can be achieved by all electrodes except the NE. The NE is not designed for stimulation. Its design constraints do not preclude it from being used as a stimulation electrode. Tests cannot be carried out in the human for technical reasons (no implantable stimulating electronics, subjects are paralyzed) and ethical reasons (implants are allowed so as to provide communication with the external world). In animal studies, stimulation was attempted and no response, such as limb movement, was seen. It would have been surprising if a response was seen because the NE contains a limited number of axons within its tip (see below) and stimulation with conventional electrodes affects a large number of neurons (with or without passing fibers) to produce a measurable response. If it can never be shown to produce a response with stimulation, then it has the disadvantage of being used only for recording.

Let us now look more closely at the evidence for some functional advantages of the NE in humans. Disadvantages will be enumerated and discussed at the end of this section. Published data have

FIGURE 32.1   (See color insert following page 32-14.) Neurotrophic electrode configuration.

shown the following:

1. Subjects drove a cursor in 2D for communication using single action potentials (APs) and LFPs [5,11]
2. Plasticity was demonstrated for single APs, but not attempted with LFPs [5,11]
3. Directionality was detected in single APs [5,11] and LFPs [6]
4. LFPs were used to drive simulated cyber digits [6]
5. Binary switch control was obtained from single APs [10] and LFPs [7]

32.1   A Brief Description of the NE

First, let us understand the unusual configuration of the NE. Figure 32.1 illustrates the salient features of the NE. The glass tip is 1 to 2 mm in length with a 50 μm diameter at the lower end where the neurites enter. The upper end is about 300 μm wide to allow at least two wires to enter. They are held in place by methylmethacrylate glue. The wire ends are usually 500 μm.

from each other and from the each end of the glass. The amplifier is connected to the wires. Because the ingrown neurites become myelinated, the neural signals recorded must be considered as APs (see histology discussion below). The APs shown have opposite initial depolarization directions. This is because the amplifier has fixed polarity with positive and negative wires. So axons close to one wire will have initial AP depolarizations opposite in direction to the AP depolarizations recorded at the other wire. This has important implications for directionality as discussed later.

A brief description of implantation techniques is required. Prior to surgery, localization of an active cortical site is essential and this is achieved using functional magnetic resonance imaging (MRI). An example of active areas is shown in red in Figure 32.2. The subject imagines movement of digits for example, and the scanner detects this as blood flow changes. We will describe this in detail in a further publication [in prep.]. All subjects undergo fMRI prior to implantation.

The implantation site is chosen based on stereotaxic 3D guidance using a system such as Stealth. Figure 32.3 shows the white pointer wand that is registered in 3D with the computer that contains the subject's MRI. The pointer indicates the active area by moving it over the active area of the fMRI.

Histological processing has shown that there are myelinated neurites inside the cone tip of the electrode as shown in this electron microscopic image. The tissue contains normal neuropil except for the lack

FIGURE 32.2 (See color insert following page 32-14.) Three-dimensional reconstruction of implantation target site.

FIGURE 32.3 (See color insert following page 32-14.) Surgical implantation site.

FIGURE 32.4 Electron microscopic histology.

of neurons [10]. There are myelinated neurites, axo-dendritic synapses, blood vessels, and dendroglial cells but no microglial scavenger cells, no gliosis, and no neurons. Our interpretation is that the neurons sprouted neurites that grew into the cone tip and became myelinated. Thus, the NE records APs from axons, and because there are usually many axons close together, we appear to be recording compound APs when the firing rates are high. *Long lasting (1) and stability (2)* signals have persisted in two subjects for over 4 years when the subjects died from their underlying diseases (Figure 32.4).

32.2 Functionality of the APs Recorded from the NE

32.2.1 Cursor Control

Subject JR was the world's first cyborg because he was the first to control a computer directly from his brain. Our first subject MH only provided binary signals and did not demonstrate control of a computer. JR was implanted on March 24th, 1998 and by mid-summer was controlling the cursor [10]. We thresholded his signals and separated them into large and small amplitude APs. One set drove the cursor in the horizontal and the large units drove the cursor in the vertical direction. The firing rate or the APs was directly proportional to the cursor movement above a user-determined threshold firing. Gain of firing rate to cursor velocity was also user determined but held fixed during trials. Results of testing on days 120, 121, and 122 after implantation demonstrated that within five trials he could control the cursor as shown in Figure 32.5. The cursor was placed at the top left of the screen and he had to move it across and down the screen as quickly as possible, thus forcing him to fire the large units that drove the cursor vertically downward.

   When asked to drive the cursor to a particular icon about half way across the screen, he succeeded quite well as shown in Figure 32.6 for day 243. Target 4 (on the ordinate) was the requested target which he hit repeatedly after initial inaccurate hitting of target 3 for five trials. Gaps between bars indicate rest
FIGURE 32.5 Learning curve for cursor control.
FIGURE 32.6 Learning curve for two-dimensional cursor control.

periods. Thus subject JR demonstrated cursor control in two dimensions even before it was demonstrated in monkeys [5].

3. Plasticity: In JR, we implanted area 4, hand representation, as determined by the functional MRI. We realized that he was moving facial muscles, specifically eyebrow movements, to produce neural activations. We preferred of course that he use neural activity that was not related to face or other residual movements. We asked JR not to use face movements of any kind during cursor driving. He appeared to comply with this request. To ensure that he did not move, we placed electrodes over his eyebrows to measure EMG activity. This activity would have driven the cursor in the vertical direction. This would have upset his performance in a task that required him to move horizontally to hit icons. Thus he had to maintain relaxation of his eyebrow muscles. The neural activity that drove the cursor is shown in Figure 32.7 with the target icon entry point on the right above, and the EMG activity shown below over a 10-sec timebase. Note the neural bursts that are not accompanied by the EMG activity.

His performance during this task is shown in Figure 32.8. When he tried to perform too quickly (less than 20 sec) he produced errors as shown by the grey bars. Trial 5 was error free with a time of 22 sec, whereas trials 3 and 4 performed in 11 or 12 sec produced errors. Thus he could perform without activating his face muscles.

When asked what he was thinking during these trials, he spelled out "nothing" [5]. However, the next day he admitted he was thinking of the cursor. He was focused on the cursor alone. He was driving the
FIGURE 32.7 Neural signal activity during cursor movement with no EMG phasic activity.
FIGURE 32.8 Learning curve while using neural signals alone.

cursor simply by thinking about it. Thus we concluded that what had once been hand-related cortex, was now cursor-related cortex. This is the first demonstration of plasticity in human cortical recording.

4. Directionality: In other electrode configurations, directionality is detected by the firing rate of a neuron in a specific direction [3]. With the NE however, fdirectionality is independent of firing rate. Instead, it is determined by the initial depolarization direction of the AP as shown in Figure 32.9. We noted that individual action potentials can be discrete depolarizations in positive or negative directions or can appear to be a single biphasic unit, which is in reality the overlying of positive and negative depolarizing directions.

Deflections in one direction are shown in the upper panel of Figure 32.10 where most APs have initial deflections in the negative or downward direction at rest. The subject JR was then requested to think of moving the cursor in the horizontal direction and all APs were thresholded as a group to drive the cursor. JR saw the cursor moving horizontally. The lower panel of Figure 32.10 shows the resultiing action potential directions, namely, upward or positive. Later recordings when all the action potentials were used to drive the cursor vertically downward, resulted in AP deflections in the opposite direction. Thus the initial direction of depolarization allows detection of directionality.

Directionality was also detected during LFP recordings as shown in Figure 32.11. In these recordings, LFPs were recorded separately from each wire inside the cone tip of the electrode. The wires are in the rows with 5 sec of recording in each panel. In the left column, the subject JR was moving the cursor
FIGURE 32.9 Action potentials.
FIGURE 32.10 Directionality detected by phase relationships.

horizontally, and in the right column he was moving it vertically. Note the clearly distinct separation of activity for each wire that depended on the direction of cursor movement.

5. Force. Clearly, we cannot test force relationships in paralyzed people. Force relationships were not tested in animals.

6. Local field potentials (LFPs). Intracortical LFPs were tested in two subjects JR and TT as published [6]. Intracortical LFPs have large amplitudes as can be seen in the previous Figure 32.11. In one subject, JR, a cyber hand was developed with digits that moved with firing rate as shown in Figure 32.12. The subject received feedback visually, auditorially, and sensorially (with a finger tap) with each AP firing. He was instructed to move a digit on receiving a verbal "Go" signal. The latency between the "go" signal and movement onset is plotted in Figure 32.13. After 6 trials, he usually performed this task in under 5 sec. This performance improvement indicated that LFPs could be used in this crude manner for movement control.

Extracortical LFPs were recorded in two subjects, RR and GT [7]. The signal amplitudes were low in this mode and thus detection methods other than voltage thresholds were sought. Thus we analyzed the data using the frequency domain as shown in Figure 32.14. In this subject a stainless steel skull screw was implanted over the leg area of motor cortex. At rest, the dominant frequency was the resting 8 Hz (alpha waves) and a 16- to 20-Hz signal. During attempted (and very slight) foot movements, the 8-Hz

20 mV
1 sec
FIGURE 32.11   Directionality detected in LFPs.
FIGURE 32.12   LFP control of cyber digit movements.

signal shifted lower and the lowest frequency increased in amplitude near 2 Hz. Changes such as these can provide a binary switch signal. In this subject, this binary output was used to operate a light switch as recently published [7].

Thus, LFPs can be used as binary outputs and for controlling crude movements.

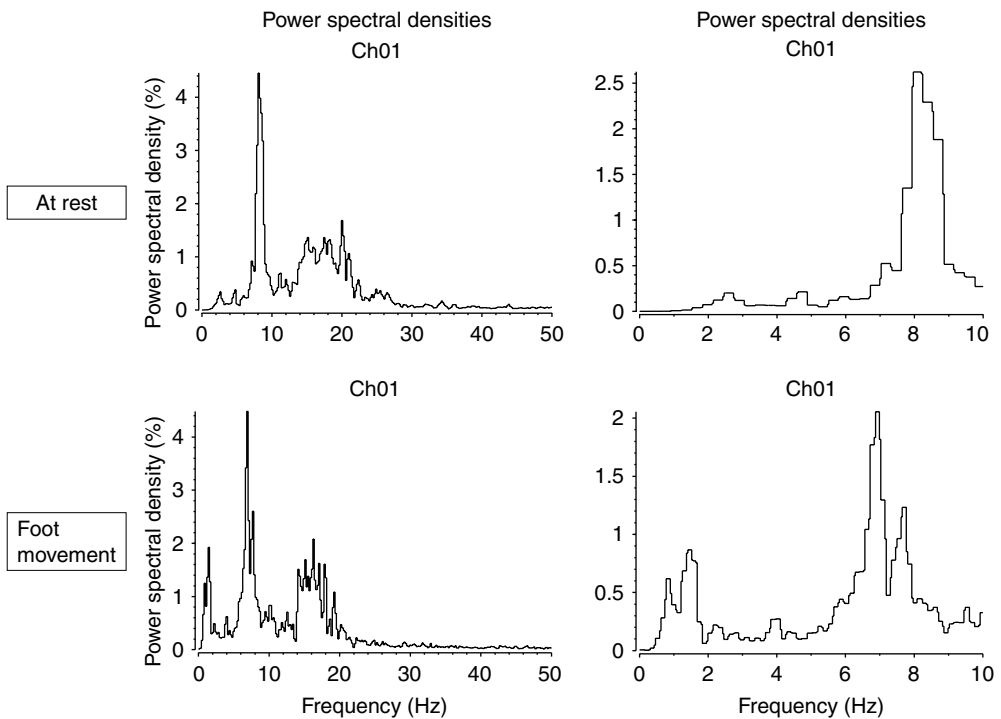
7 and 8. Units per contact and per electrode. One of the misconceptions about the NE is that only one or two can be implanted and thus only one or two signals can be obtained. It is true that only a few can be implanted, and that is due to the bulk of the implanted electronics. Once the electronics can be further miniaturized, many electrodes can be implanted. Even with one electrode however, recent off-line analysis of human recorded data has revealed as many as 19 units from one electrode in subject JR as
FIGURE 32.13 Learning curve for LFPs.


FIGURE 32.14 Differences in LFP spectrum during movement and rest.

shown in Figure 32.15. About half are not correlated and thus are expected to be independent channels of communication [in prep.]. Therefore it is not unrealistic to expect that each electrode will yield between 5 and 10 useful signals that the patient can control. Such control remains to be tested in subsequent subjects.

These large numbers of units per electrode are in sharp contrast to other electrodes where about one, maybe two, units are recorded at each electrode tip. With 100 tines on the Cyberkinetic's probe this is indeed impressive [2]. In fact, over time, this number drops to 40% or less of tines that continue to record unit activity. Furthermore, each unit varies due to micromovements, so the stability of units is questionable.

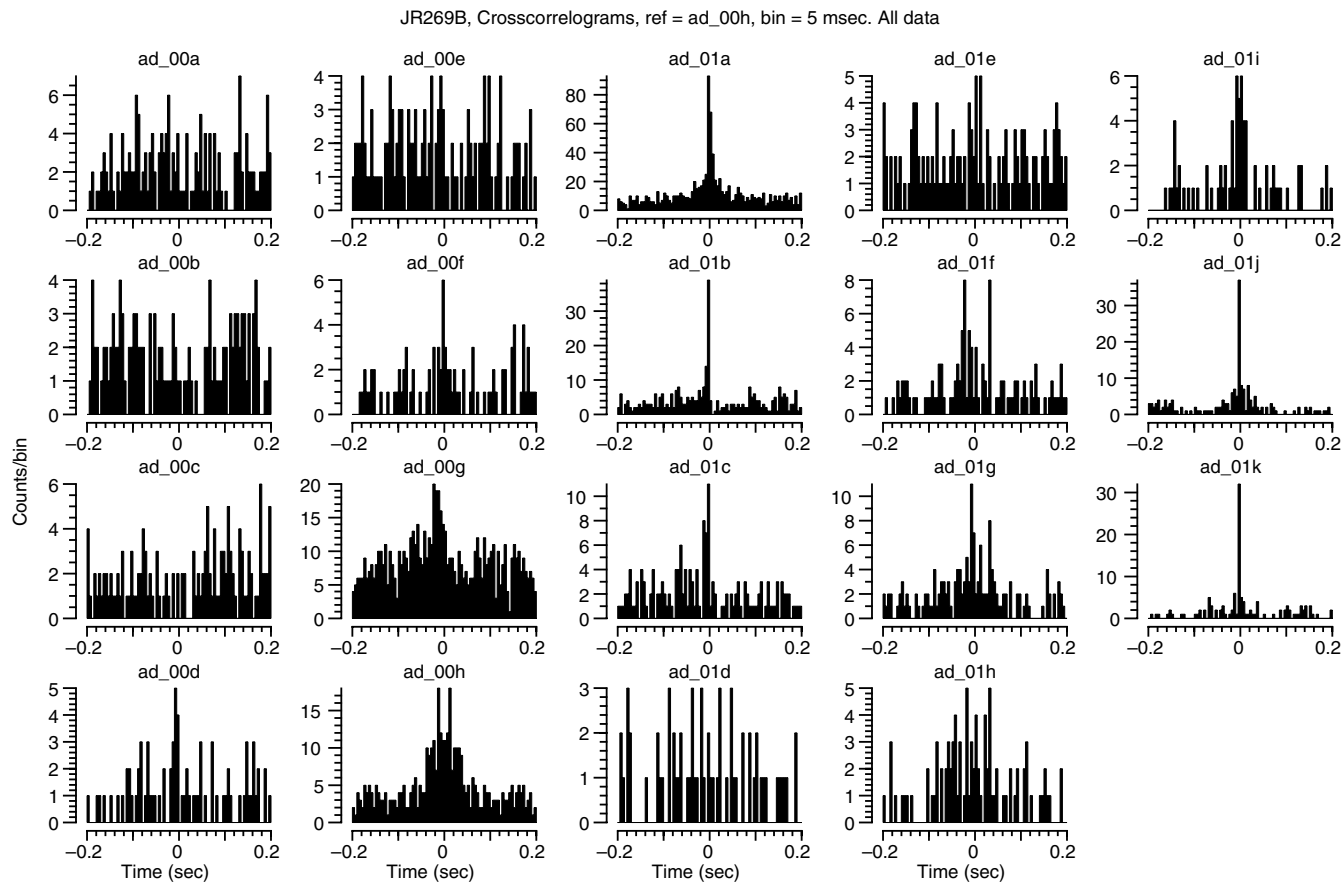
9. ElectroMyoGraphic (EMG) relatedness. In one subject, DJ, we were able to record EMG from the forearm as he made minute movements. The EMG was correlated with LFPs and APs recorded from


FIGURE 32.15 Cross correlograms of single action potentials.

the electrode implanted in the contralateral area 4 motor cortex [in prep.]. The LFPs were correlated and the APs had weak correlations as expected. Recording EMG in near paralyzed subjects is unique to our project but would be feasible with any of the electrodes.

10. Stimulation. Attempts at microstimulation in rats through the NE implanted in the leg area did not produce movement. Evoked movements would have been surprising because only a few tens of axons could have been stimulated and usually an observable movement of a leg in response to stimulation would be produced in response to a large area of stimulated neurons and passing axons. Increasing the stimulating current was not an option due to the danger of electrolytically destroying the axons inside the electrode tip. All other electrodes, whether wires or tines, have safely provided stimulation. Thus for stimulation, the other electrodes are preferred.

32.3 Conclusions

In nine of the 10 characteristics discussed earlier, the NE shines. The one exception is stimulation as discussed. Thus, it could be the outright winner in this race except that it has some unique problematic characteristics.

1. Accurate histological reconstruction of recorded units is not possible due to the destruction inherent in placing it in the cortex and the trophic changes that take place as the tissue grows into the cone tip. This is not, however, of importance in neural prosthetics where functionality is paramount.
2. Manufacture of the electrode at present is difficult and requires many months of practice.
3. Implantation of the electrode is also difficult and requires much practice by someone with microsurgical skills.
4. There is a delay of 3 or 4 months before the tissue has grown in and signals stabilize.
5. Replacement of the electrode in the exact same area would hardly produce the same signals unless many months passed to allow healing and reconstitution of the tissue.
6. Training time may be prolonged since plastic changes may be needed to produce useful function.

Thus for successful usage, skill in manufacture and implantation is required. The delay in signal acquisition of 3 months is surely tolerable for someone who requires a lifetime of use. Replacement is hardly going to be needed if it continues recording as studies strongly suggest. Training time again is hardly a problem when used for the lifetime of the subject.

We will allow the reader to judge for himself or herself as to who the winner will eventually be because I cannot be considered unbiased. The LFPs discussed earlier may allow other electrodes to produce useful signals even though they may not be able to retain single units over the required lifetime of the subject. LFPs may prove adequate when crude control is needed, but will hardly prove adequate for precise control. Only time and effort will tell which electrode and recording technique will be instrumental in providing cortical control of prosthetic devices.

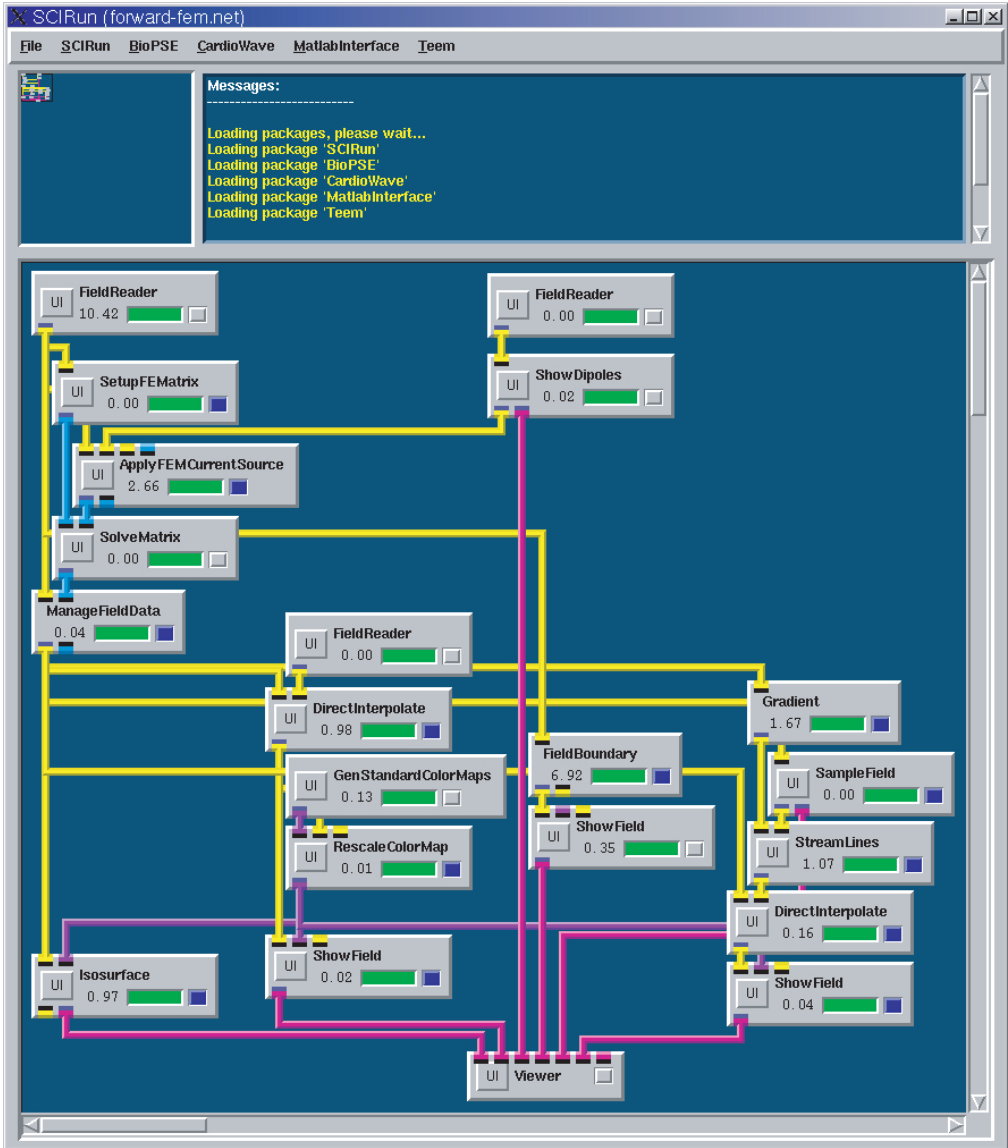

FIGURE 23.1 BioPSE dataflow network for modeling, simulating, and visualizing the bioelectric field generated in a realistic head model, due to a single dipole source.
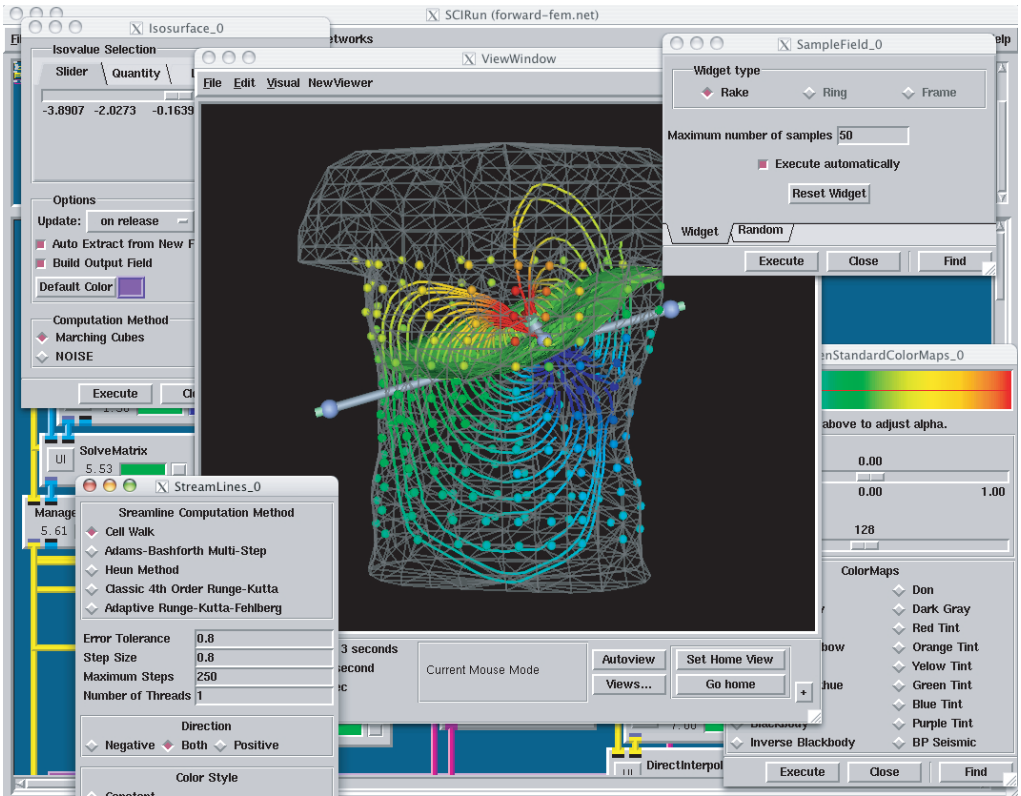

FIGURE 23.2 BioPSE dataflow interface to the forward bioelectric field application. The underlying dataflow network implements the application with modular interconnected components called modules. Data are passed between the modules as input and output parameters to the algorithms. While this is a useful interface for prototyping, it is nonintuitive for end-users; it is confusing to have a separate UI window to control the settings for each module. Moreover, the entries in the UI windows fail to provide semantic context for their settings. For example, the text-entry field on the SampleField UI that is labeled "Maximum number of samples" is controlling the number of electric field streamlines that are produced for the visualization.

FIGURE 23.3 The BioFEM custom interface. Though the application is functionality equivalent to the dataflow version shown in Figures 23.1 and 23.2, this PowerApp version provides an easier-to-use custom interface. Everything is contained within a single window; the user is lead through the steps of loading and visualizing the data with the tabs on the right; and generic control settings have been replaced with contextually appropriate labels; and application-specific tooltips (not shown) appear when the user places the cursor over any UI element.
FIGURE 23.4 The BioTensor PowerApp. Just as with BioFEM, we have wrapped up a complicated dataflow network into a custom application. In the left panel, the user is guided through the stages of loading the data, co-registering the diffusion weighted images, and constructing diffusion tensors. On the right panel, the user has controls for setting the visualization options. In the rendering window in the middle, the user can render and interact with the dataset.
FIGURE 30.2 Electric fields generated by passage of current in CNS tissue. The first step in determining the response of CNS neurons to extracellular stimulation is to calculate the electric potentials generated in the tissue by passage of current through the electrode. Potentials produced by passage of current into a homogenous region of the CNS ($s = 0.2$ S/m) using a point source electrode (a), a cylindrical electrode (b), as used for deep brain stimulation, and a disk electrode (c), as used for epidural or cortical surface stimulation. (d) Although a simple analytical solution exists for the potentials generated by a point source electrode, they differ substantially from the potentials generated by larger cylindrical or disk electrodes.

33.1   Introduction

The authors' aim has been to develop a generic functional electrical stimulation (FES) implant for the restoration of functions in spinal cord injured (SCI) paraplegic individuals, the functions or modes of which can be matched to an individual's requirements: upright functional mobility, pressure relief and lower extremity exercise, bladder and bowel control [1–6]. In addition, for bladder control, less invasive

33-1

surgical procedures were proposed to avoid posterior conus rhizotomy, and sacral laminotomy in order to access the sacral nerve roots for stimulation [7,8]. It was hoped that this system would offer more functions and less surgery to patients with a cost–benefit ratio. This approach was termed "Multi-Functional."

Simple locomotor functions can complement the use of a wheelchair and be helpful in overcoming obstacles to wheelchair access specially doorsteps and unadapted bathroom facilities. In addition, being able to stand up to reach objects and perform prolonged manual tasks would be convenient for many work-place and home situations [3–5]. Five paraplegic volunteers (two at the Neural Engineering Clinic (NEC) in Augusta, ME and three at the Shriners Hospital for Children (SHC) in Philadelphia, PA) have participated in this device's evolution.

During 1983, R.D. (NEC) became aware of the possibilities of modifying and using the 22-channel cochlear implant technology (Cochlear Ltd., Lane Cove, N.S.W., Australia) as the basis for an implantable FES system for the restoration of multiple functions in SCI paraplegics.

The state of FES in paraplegia has been extensively reviewed [1–5]. These SCI individuals are unable to move their lower extremities or control bladder and bowel function. They must regularly self-catheterize (∼3 to 6 times/day). Secondary medical problems are prone to occur, such as pressure sores, osteoporosis, muscular atrophy in the lower limbs, muscle spasticity, deep vein thrombosis, cardiovascular disease, and depression. Although considerable FES achievements have been made, there has yet to be developed a safe, practical FES system for these multiple functions that is completely independent of the laboratory and is an energy-efficient mobility aid for prolonged use at home and in the workplace. The reason lies in the fact that FES is addressing complex problems requiring not only interdisciplinary knowledge from muscle and nerve physiology and electrical stimulation technology, but also implementation of biomechanical and control principles [6].

Other reasons that limit clinical application may also be significant, for example cost-benefit considerations (especially for implanted systems). Although spinal injury results in loss of multiple physiological systems, neural implants to date have been developed to restore only specific functions. An approach was proposed to develop a generic FES implant the functions or modes of which can be matched to an individual patient's requirements. In addition, less invasive surgical procedures were proposed to avoid the posterior conus rhizotomies, and sacral laminectomy associated with existing implanted bladder implants [7,8].

Since 1984, three FES implant models have evolved from the Cochlear's technology and its subsidiary: Neopraxis Pty. Ltd. The initial Nucleus FES-22 Stimulator was implanted in 1991 after animal and human studies, and with the U.S. Food and Drug Administration's approval (IDE# G87014) and Institutional Review Board (IRB) approval in a 21 yr. Paraplegic Subject (ASIA: T10).

33.2 Historical Aspect

In 1984, the Veterans Administration (VA) funded the initial animal studies at the Togus VA Medical Center (Augusta, ME). These were aimed at determining what changes would be required to use a modified cochlear implant with a maximum pulse output of 4.3 mA and 0.4-msec pulse width, to be suitable for FES use in humans. An initial decision was taken to utilize epineurally placed electrodes (2.5-mm diameter platinum disks) in preference to epimysial or intramuscular electrodes because it was known that the stimulation currents would be lower and that there would be less movement of the electrodes. In order to determine exactly how low the stimulation currents would be and to determine the stimulation sites, initial anesthetized rabbits studies were conducted [9]. The threshold found for each branch of the split sciatic nerves was of 0.1 to 0.2 mA at 0.2 msec with 50 pps. Maximal stimulation was achieved usually between 0.5 and 1.0 mA. Simultaneous dorsiflexion of both paws as well as co-contraction in the anterior and posterior muscle groups could be achieved.

At the Togus VA Medical Center, with the approval of their IRB and volunteer patients undergoing lower extremity amputation, stimulation studies were carried out at 0.2-msec pulse duration with 20-pps frequency, with a portable, battery-operated, calibrated constant-current unit (Cordis Corp Miami, Fl.,

Nucleus FES-22   Praxis FES-24A

(a)   (b)

Implanted 1991   Implanted 1998
FIGURE 33.1 (a) The first 22-channel RF FES System (Nucleus FES-22) implanted in Subject A in 1991. (b) The second developed RF FES-24A Praxis System, implanted in Subject B in 1998.

Model 910 A). The pulse amplitudes for producing maximal stimulation and contraction in the largest of the nerves (medial sciatic) ranged from 0.6 to 2.5 mA, which falls well within the range of the Cochlear receiver-stimulating unit to be used [9,10]. Using the *Color Atlas of Human Anatomy*, First Edition edited by R.M.H. McMinn and R.T. Hutchings (Yearbook Medical Publishers, Inc., Chicago IL), whose dissections were reproduced as life-size photographs, allow measurements of the diameters to be made at different points along the nerves. These measurements were in relatively close agreement with the amputated nerve diameters of the nine volunteer patients [10].

33.3 Neural Engineering Clinic: 2 Male Subjects

33.3.1 Nucleus FES22 Stimulating System

As a first device, the FES22 stimulator was only intended to provide its recipient with enhanced mobility functions. During 1985, Roger Avery (Custom Med Laboratories, Durham, NH) started work on the design and manufacture for the implantable leads and electrodes. Because of the need for higher output currents it was also necessary to design a new transmitter coil capable of delivering the higher power. To make each of the 22 output channels individually available a circular epoxy housing was designed with 22 sockets around the perimeter (Figure 33.1a) with the diameter of the housing being determined by the diameter of the coil. During November/December 1991, the Nucleus FES-22 system was implanted in Subject A (21-year-old male paraplegic subject; ASIA: A T10) in 3 sessions at the Kennebec Valley Medical Center (now Maine General Medical Center), Augusta, ME. The receiver–stimulator was placed subcutaneously at the lower right anterior intercostal margin with 11 connecting leads subcutaneously tunneled to the right and another 11 to the left hip areas. Following this, 2.5-mm diameter platinum disc electrodes were placed epineurally on the individual branches of the right and left femoral nerves by suturing the silicone elastomer ring around each electrode to the connective tissues on each side of the nerve branches. In the second and third procedures, electrodes were attached over gluteal, posterior tibial, peroneal, and sciatic nerves bilaterally [11]. A total of 20 electrodes were implanted epineurally, with one electrode placed subcutaneously in a Teflon bag in each of the femoral triangles, as spare lead.

Six weeks following surgery (January 1992), the FES-22 system did produce threshold and maximal muscle contractions as tested in all 20 channels. At the second testing session in February 1992, the implanted system did not function properly owing to a suspected electrostatic damage in the implant resulting in the loss of 7 channels. Hardware and software changes were made allowing the remaining 15 channels to work. In December 1992, the 15 channels were retested for threshold and maximal muscle

contractions; the multivariate analysis did not show any change with time or body side, but a significant effect was seen with the electrode locations [12].

Subject A exercised his lower extremity muscles at home using a PC computer to control the implanted stimulator. In January 1997, he was provided with a battery-operated external portable conditioning system ($19 \times 11 \times 6$ cm^3), which he uses at home and at work sitting in his wheelchair. The exercise protocol stimulates the right and left knee extensors and ankle plantar/dorsi flexors alternately 4 sec ON/4 sec OFF, for a total of 20 min. After the muscles have been conditioned, dynamometric testing (isometric mode) has shown that implanted FES stimulation produces bilateral knee extension torque of 45 to 55 Nm at 30° and 65 Nm at 60° of knee flexion. Subject A exercised at least 3 days a week, and found if he did not do so the spasticity in the lower extremities increased.

The laboratory PC-based FES-22 System implements a 10-msec duty-cycle state machine for open- and closed-loop control for use in prolonged standing mode. The controller is divided into three phases (1) open-loop "sit-to-stand"; (2) closed-loop stand; and (3) closed-loop "stand-to-sit." To initiate standing up and sitting down, the subject uses a remote switch on a hand glove. The sensors used for closed-loop control are electrogoniometers across both knees, which respond to a 10° knee buckle, and accelerometers attached to the back at T6 level.

Controlled Nucleus FES-22 stimulation to the motor nerves of the quadriceps and gluteal muscles has resulted in uninterrupted standing for over 60 min [12]. This has been achieved by use of the bilateral knee-angle goniometer sensors with the Andrews stabilizing anterior floor reaction orthosis (AFRO), which is an ankle–foot brace. With the knee goniometers sensing for a 10 degree, the stimulator would come "ON" to correct the buckle; usually this occurred between 3 and 8% of the standing time. On recovery, the automatic switch "OFF" occurs when knee flexion has returned to less than 5 degrees. Otherwise, lower extremity muscle activation is not required to maintain the upright posture [13].

33.4   Praxis FES24-A System

In 1998, Cochlear Ltd formed a subsidiary company: Neopraxis Pty. Ltd., which decided to build on the knowledge gained from the FES22 implant and to produce the Praxis FES24A System. This system was designed to provide multiple functions, bladder and bowel control, enhanced mobility, and seated pressure relief, in order to provide recipients with a cost-effective device that addresses their most important needs.

33.4.1   Bladder Control

The traditional bladder stimulator, Finetech–Brindley Stimulator, and now the "Vocare" (NeuroControl Corp., Cleveland, OH) operates by stimulating the sacral anterior roots [8]. This system has two primary drawbacks, which the Praxis system was designed to eliminate: (a) posterior sacral rhizotomies are done, via a laminectomy, in order to achieve an areflexive bladder with increased capacity; (b) a sacral laminectomy is done to access the anterior sacral roots for fitting cuff type electrodes. The rhizotomy procedure eliminates reflex erection in male recipients. Further, Creasey [8] states that "a patient who has the rhizotomies but does not use the implant (stimulator) would therefore be expected to become more constipated."

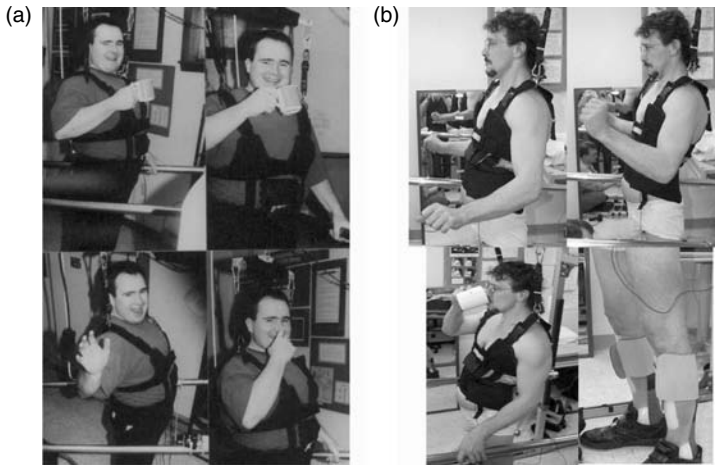
In August 1998, the Praxis FES24-A stimulator (Figure 33.1b) was developed by Neopraxis Pty. Ltd., and implanted in Subject B (35 year-old male paraplegic subject; ASIA: A, T10). Eighteen channels were used for stimulating individual nerves or branches for muscle contractions and limb movements, including exercise, pressure relief, and standing and stepping. The electrodes implanted for epineural stimulation were ten thin flexible platinum cuffs (Flexi-Cuff) that were sized, cut, and sutured closed with at least twice the diameter of encircled nerve. The other 8 electrodes were 3-mm-diameter, platinum buttons which were placed on the epineurium. Each button has an attached Dacron mesh surround that was sutured to the adjacent connective tissue on each side of the nerve.


FIGURE 33.2   Prolonged standing (1 h): controlled FES + Andrews' AFO.

Three channels for bilateral sacral root stimulation (S2-4) for bladder control (bowel control and erection, if possible) were provided. Sacral root stimulation was achieved by three pairs of LPR electrodes (10-mm long, solid platinum tubing of 1.0-mm diameter) inserted into the external sacral foramina in a lateral direction to follow and to stimulate the nerve roots epidurally. One further channel was connected to an epidural spinal cord stimulating electrode (Pisces Quad: Medtronic Inc., Minneapolis, MN) for conus medullaris modulation of spastic bladder and bowel reflexes.

33.4.2 Praxis System Clinical Results

For the year prior to his implantation, Subject B was able to stand without knee bracing using a combination of the Andrews' AFRO and closed-loop skin surface FES applied directly over the femoral nerves, 2 to 3 cm below the inguinal ligament. With closed-loop control of stimulation, he would typically stand uninterrupted for 30 min, and up to 70 min. With training, Subject B did achieve the "C" posture and stood with the stimulation "OFF" for more than 50% of the standing time [14]. In December 1997, muscle strength tests done on the Biodex dynamometer (isometric mode) showed that surface stimulation of the right quadriceps (femoral nerve) was capable of eliciting 50 Nm of knee extension at 30° of knee flexion and 45 Nm at 45° [13–15].

After implantation of the Praxis FES 24-A system in August, 1998, Subject B carried out an FES exercise routine, which stimulated three separate sequences (quadriceps group, buttocks and posterior thigh group, and ankle group), each running initially for 5 min and extending to 15 min over a 2-week period. Each muscle in the sequence would be stimulated sequentially for 4 sec on and off. Subject B found that daily stimulation decreased his muscle spasms and spasticity level.

When standing with the implanted system, he was able to perform a variety of one-handed tasks including reaching for and holding a 2.2-kg object at arm's length. These tasks were achieved while in the "C" posture with closed-loop activation to the lower extremity muscles and balance maintained by the other upper extremity (Reference 15; Figure 33.2b).

33.4.3 Bladder Results

On September 4th 1998, in the Urodynamic Testing Laboratory, Subject 2 had his sacral roots (S3 and 4) bilaterally stimulated intermittently. This showed on three occasions the bladder contracted with recorded pressures of between 45 and 50 cm of water. On December 14th 1998, urodynamic testing again showed consistent results from S3 and 4 sacral root stimulation producing three sustained bladder contractions
FIGURE 33.3   SCI: Bladder voiding: Bilateral S3 + 4 stimulation.

with pressures of 40 to 55 cm water and urination (Figure 33.3) with each stimulation pattern (5 sec on/5 sec off, 20 Hz, 8 bursts). On April 2nd 1999, urodynamic testing was repeated with two bladder reflex activations from each pattern of stimulation (5 sec on/5 sec off, 20 Hz, 8 to 14 bursts). Pressures of 50 to 70 cm of water were recorded.

In April 1999, the internal FES24-A unit's connecting wire between the internal antenna and the stimulator module broke as a result of subject B's repeated bending at the waist [15]. The Receiver/Stimulator unit was removed in 1999, as subject B complained of discomfort from the two connectors under the abdominal skin. The network of leads and electrodes were left for a possible replacement of the newly designed System.

33.5   Praxis FES24-B System

This third iteration system: FES24-B System (Figure 33.4), which eliminates this internal wire breakage possibility and consists of:

- A body-worn controller "Navigator" capable of executing a wide variety of software control Strategies.
- A skin surface stimulator "ExoStim" to mimic an implant and to provide simple exercise functions prior to implantation.
- Sensor packs incorporating accelerometers and a gyroscope to provide feedback information to control Strategies.
- A new implant receiver/stimulator was based on the latest cochlear implant control integrated circuit (IC), the "CIC3."
- A range of implantable electrode leads suitable for the system's multiple functions.

  The FES24-B System provides a maximum current output of 8 mA in a constant-current mode. Stimulation is achieved using biphasic (negative and positive phases, closely charge-matched) current pulses. Pulse widths can be varied from 25 to 500 μsec and a per channel pulse frequency of 0 to 400 Hz on each of the 22 channels can be obtained, which were designed as cathodes while the rear surface plate of the receiver/stimulator was connected to be the anode. The stimulator provides real time data telemetry functions including the ability to measure the impedance of the current path through each electrode and the ability to transmit voltage measurements from each electrode [16].

33.6 Experience at Shriners Hospitals for Children

Three males with paraplegia, ages 18, 21, and 21 years, underwent surgical implantation of the Praxis FES24-B System (Figure 33.4) between January 2002 and May 2003 at Shriners Hospital for Children, Philadelphia. Eighteen epineural electrodes (Table 33.1) were implanted for upright mobility in all three subjects, and three pairs of bifurcated linear pararadicular electrodes were placed extradurally on the bilateral S2, S3, and S4 mixed nerve roots for bladder and bowel function in the first 2 subjects.

33.6.1 Upright Mobility

Four weeks postimplantation, the subjects participated in 4 weeks of strengthening and conditioning of the implanted muscles followed by 17 to 22 weeks in which the focus was on programming of the upright mobility strategies and training for their functional use. Goals included achievement of the transitions between sitting and standing, swing through and reciprocal gait with a walker or crutches, and prolonged standing. For reciprocal gait, swing was achieved through stimulation to the iliopsoas, biceps femoris, and the tibialis anterior to create a flexor withdrawal response. Additional training goals

FIGURE 33.5 Two subjects using the Praxis System for functional activities (a) Subject 2 uses forearm crutches to descend stairs. (b) Subject 3 reaches for items on a shelf using a walker to support himself with one upper extremity.

include advanced activities, such as ascending and descending stairs (Figure 33.5a) and achievement of subject specific goals (Figure 33.5b). Bilateral ankle foot orthoses were worn for all upright mobility activities.

Following training, data were collected for a variety of mobility activities, including transitions between sitting and standing, a short (6 min) and a long (6 min) walk, ascending and descending stairs, and maneuvering in an inaccessible bathroom stall. All subjects chose to use a swing-through gait pattern for the tested activities, except Subject 2 who chose a reciprocal pattern for ascending stairs only. Subjects 1 and 3 each used a walker with wheels to perform the mobility activities and Subject 2 used forearm crutches. None of the subjects required physical assistance to complete the activities. Subjects 1 and 3 required supervision for all tested activities, and Subject 2 was independent for all activities except stairs where he required supervision. Data for ascending and descending stairs were not collected with Subject 1 as the activity was felt to be unsafe for him. Several activities could not be performed by Subject 3 secondary to complaints of shoulder pain related to poor scapular muscle control.

33.6.2 Sensors

Closed-loop standing using sensor packs incorporating accelerometers and a gyroscope was attempted with Subject 1. Sensor packs were attached externally on the thigh and the calf (Figure 33.6) to detect the position of the knee while standing. Stimulation would decrease until a change in the knee joint angle was detected, at which time stimulation would again increase to prevent a knee buckle.

Figure 33.7 demonstrates the use of the sensors for closed-loop feedback to the right quadriceps muscles during quiet standing. Using closed-loop control, the subject was able to stand with less stimulation to the quadriceps than what he had been using while standing with open-loop control. He was also able to stand for a longer period of time before the muscle fatigued, requiring him to sit. The algorithm for increasing and decreasing stimulation to the quadriceps did not create any balance disturbances for this subject.

33.6.3 Bladder and Bowel

Neuromodulation was attempted with Subject 1 and acute suppression of reflexive bladder contractions during bladder filling was observed. When using stimulation to both S3 nerve roots throughout the day, this subject maintained a catheterize schedule (every 6 h) comparable to that used when he

took anti-cholenergic medication. This suggested that neuromodulation may have helped to suppress reflexive bladder activity on a daily basis during the control period (without the neuromodulation or medication) he catheterized more frequently, on an average of every 4 h. The ability to improve bowel evacuation was examined in Subject 2, using two different stimulation paradigms: low-frequency electrical stimulation (20 Hz, 350 μsec, 8 mA) and a combination of low frequency and high frequency (500 Hz, 350 μsec, 8 mA). The daily use of electrical stimulation appeared to cause a reduction in the time to complete defecation by 40% with the first stimulation strategy and by 60% with the second strategy.

Despite numerous attempts with varying stimulation parameters to the sacral nerve roots, neither subject could obtain detrusor pressures sufficient to provide voiding with stimulation. Both subjects continued to catheterize for bladder emptying.

33.6.4 Electrode Stability

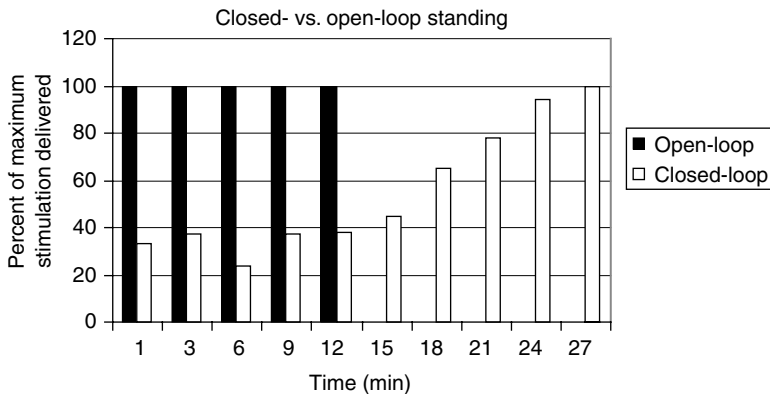
Three of the 52 electrodes placed for lower extremity stimulation experienced changes in the responses of the muscles. One of these was due to a disconnection at the connector site between the implant and the electrode lead. This was repaired and the electrode continued to function without further problems. The remaining two electrodes (biceps femoris and tibial nerve) were not replaced, as they did not impact function for the subjects involved.
FIGURE 33.6 Sensor packs used for closed-loop standing.


FIGURE 33.7 Using open-loop control, the stimulation remained at 100% for 12 min of standing after which the subject's muscles were too fatigued for him to remain upright. Using closed-loop control, stimulation could be maintained at a lower level, increasing over time as needed. With closed-loop control, standing time was more than doubled to 27 min.

33.7   Complications

Follow-up of the first two implanted at the NEC site, Subjects (A & B.): In 2002, Subject A accidentally cut his left foot, which was treated superficially. In 3 to 4 days, his left lower extremity was swollen with an infection, which immediately was treated with intravenous antibiotics for 2 weeks. The swelling resolved, but 6 weeks later the tissues around the Nucleus FES-22 system were swollen and inflamed. After 3 days of I.V. antibiotics, the implanted system was explanted taking as much time as when it was implanted. The most difficult part was finding and dissecting the small 2.5 mm platinum electrodes and their silastic backing. He recovered well without further complications.

In 2001, Subject B was experiencing intermittent severe pain in the T7-8 vertebra at the post-fractured site, after conservative treatment failed; the spine was fused in this area. By the time that he was ready for implanting the Praxis FES24-B stimulator in 2003, the Neopraxis Company was closed by Cochlear Ltd. However, he was offered the stimulator for implantation, but without further support by the Company, he decided not to continue and did have the leads and electrodes removed.

At the SHC site: During the training period Subject 2 sustained a stress fracture of the left proximal first metatarsal, which he believed happened when his left leg experienced greater impact at initial contact due to his poor control of swing for that step. The subject was immobilized for 6 weeks in a soft boot after which he was able to return to training without further problems. At the end of June 2002, Subject 1 sustained an abrasion near his ankle and antibiotics were started once this was reported. Then at the beginning of August 2002, he began experiencing high fever and complained of heat and inflammation around one of his surgical incisions. Despite treatment with intravenous antibiotics, this subject continued to experience problems with inflamed incisions, some of which resulted in open skin and fluid drainage. Antibiotic treatment appeared to temporarily suppress these reactions but problems continued. Due to this, the majority of the system has been removed with future surgeries planned to remove the remainder.

33.8   Conclusion

In the developing field of FES and implantable neural prosthetic devices, there has been a need for reliable and safe, multichannel implantable stimulating systems to restore multiple functions in neurologically impaired patients. In paraplegic individuals, the stimulating systems' functions should be designed to modulate spasticity and precisely activate individual muscles for joint movement and control of bladder and bowel functions. The more channels available, the more nerves can be activated and the more modes of functionality can be restored. Our contribution to this aim has been continuous since 1983, and the two Praxis FES Systems [11–16], have provided hope for a new rehabilitation aid for restoration of function in spinal cord injury paraplegia. Providing more functions with an FES system with a greater number of channels introduced new challenges to the subjects and research teams including the need for multiple surgical procedures, new surgical approaches to placing electrodes, increased risk of infection, and greater hospitalization and rehabilitation time. Importantly, these challenges are being addressed through multiple research efforts [17] at various centers.

34.1 Introduction

Functional electrical stimulation (FES) is a rehabilitation technique for the restoration of lost neurological function, resulting from conditions such as stroke, spinal cord injury, cerebral palsy, head injuries, and multiple sclerosis. FES utilizes low-level electrical current applied in programmed patterns to different nerves or reflex centers in the central nervous system to produce functional movements. The stimulation may be triggered by a single switch (open-loop) or from sensor(s) or neuronal activity (closed-loop).

While FES has been used successfully to pace the heart [1] and to restore hearing [2] in the past, it has not been widely adopted as a means of reanimating paralyzed limbs that result from stroke and spinal cord injury (SCI). It is estimated by the U.S. National Institutes of Health (NIH) that there are about 700,000 people who experience a stroke each year in the United States, with an associated comprehensive cost of $57.9 billion per year [3]. Of the more than 4 million stroke survivors alive today, many experience permanent impairments of their ability to move, think, understand and use language, or speak — losses that compromise their independence and quality of life. Furthermore, stroke risk increases with age, and as the American population is growing older, the number of persons at risk for experiencing a stroke is increasing. There is also an estimation of 250,000 Americans living with spinal cord injuries with 10,000 to 12,000 new spinal cord injuries reported every year in the United States. The cost of managing the care of SCI patients approaches $4 billion each year [4].

The potential of FES to restore function in these areas has been largely unfulfilled mostly due to the limitations of the FES devices currently available. FES could also be used in limb loss applications to reduce phantom pain and to restore functional movement of prosthetic limbs. In 2000/2001, about 130,000 lower-limb amputations were performed each year in the United States [5,6].

An optimal FES system should have the following fundamental characteristics. It should (1) provide both stimulating and sensing capabilities, (2) be fully implantable, (3) be minimally invasive, (4) have real-time communication capability, (5) allow a practically unlimited number of stimulation and sensing channels, and (6) function without external equipment or interconnected leads between components.

This chapter describes a network of wireless implantable microstimulators/microsensors, also known as Battery-Powered BION®[1] (BIOnic Neuron) devices for FES and Sensing (FES–BPB System). This new platform was designed to overcome the limitations of the current FES technology by providing:

1. Microdevices that can be programmed as either stimulators or sensors for use in closed-loop applications.
2. Minimally invasive implantation procedures to reduce labor intensive surgery and associated patient risks and to provide rapid recovery.
3. Wireless bidirectional communications and telemetry to all stimulators and sensors, which eliminates the use of both transcutaneous leads (which are susceptible to infection), and surface applied coils and stimulators.
4. Real-time communication between the stimulators, sensors, and control unit, to maintain continuous closed-loop control.
5. Flexibility and functional expandability since there are no leads and each implant has a full complement of programmable stimulators and sensors.
6. A large number of channels, which allows the same system to be used for a variety of applications without interference in the same patient.
7. Self-powered operation using rechargeable batteries to power the implantable devices. External equipment (e.g., power antennas) are only needed during battery recharging.
8. Wireless sensors capable of measuring biopotentials, angle, position, pressure, temperature, and permanent magnet fields.

34.2 Evolution of the Implantable BION Devices

In 1988, G. Loeb proposed and W.J. Heetderks mathematically showed that the concept of a wireless network of injectable microstimulators powered by an external antenna/coil, was possible [7]. It was thought that these microstimulators would eliminate many of the problems associated with the use of percutaneous electrodes, since they do not incorporate leads. J.H. Schulman, G.E. Loeb, and P.R. Troyk, under support contracts from the U.S. NIH (contract N01-NS-9-2327), the Alfred Mann Foundation (AMF, Santa Clarita, CA), and the Canadian Network for Neural Regeneration and Functional Recovery, developed an injectable, glass-enclosed microstimulator (Figure 34.1a) that is powered and controlled by an external alternating magnetic field generated by a coil connected to a control unit. This first 255-channel stimulating system, later called the radio frequency (RF) BION device, allowed instantaneous control of stimulation pulse amplitude, frequency, pulse width, pulse position timing, and pulse charge-recovery current [8].

The AMF continued to develop and improve the wireless RF BION device. As a result of these efforts, a second-generation RF BION device, which incorporates a ceramic case, an output capacitor, and zener diodes to protect the device against electrostatic discharges was developed (Figure 34.1b) [9]. These RF BION devices are currently being used or have been used in several clinical studies being conducted by the AMF and its affiliated organizations, the Alfred Mann Institute (University of Southern California, Los Angeles, CA) and Advanced Bionics Corporation (Santa Clarita, CA). As of September, 2004, 33 patients have been implanted with RF BION devices for treatment of urinary incontinence, obstructive sleep apnea, pain associated with shoulder subluxation, knee osteoarthritis, forearm contracture, and foot drop applications [10–13].

While the wireless RF BION device eliminates the need for the leads associated with the percutaneous electrodes, it requires the patient to wear an external coil during use, to transmit power and data to the implanted device. Both to improve patient acceptance of this technology, and to increase the reliability of the system, it was necessary to eliminate the need to constantly use an external coil to power and control the device. Thus, the idea for a battery-powered BION device (hereinafter BPB) was conceived at the AMF.

The AMF, with guidance from Jet Propulsion Lab (JPL), developed a small cylindrical lithium ion rechargeable battery. A new company (Quallion, Inc.) was formed and financed by Alfred Mann to manufacture and improve these unique highly reliable batteries. Today, these batteries can be safely recharged if discharged to zero volts and are expected to operate for over 10 years. These batteries were designed specifically for the BPB (Figure 34.2).

The AMF licensed the BPB technology to Advanced Bionics Corp., which designed and implemented the first BPB (stimulator only) for urinary incontinence (referred to as the UI-BPB). This was the first BION to have a two-way telemetry (Figure 34.1c). The telemetry receiver in this UI-BPB turns on for a

FIGURE 34.2   (See color insert following page 32-14.) Quallion battery for the BPB.

very short time interval every 1.5 sec, to conserve battery power. Thus, rapid synchronization for limb control is not feasible with the UI-BPB. As of January 2006, over 100 patients have been implanted with the UI-BPB for the treatment of urinary incontinence, urinary frequency and migraine headaches [14]. Due to its lack of sensing capabilities, and slow communication response time, the UI-BPB is not well suited for FES applications.

The AMF is currently developing the next generation of the BPB. This BPB (Figure 34.1d) allows the creation of a wireless FES network including: both stimulation and sensing in each BPB for fully implantable closed-loop applications; data processing for sensed signals; high-speed bidirectional telemetry; wireless oscilloscope monitoring for fitting purposes, via back telemetry of voltage-sensed signals; a rechargeable battery (enabling prolonged operation without external power); and capability of communications with over 850 BPBs simultaneously (effectively 100 communications/sec/BPB) [15].

The ceramic BION devices (Figure 34.1b through Figure 34.1d) use an extremely strong Zirconia with 3% Ytrium ceramic case. The FDA pointed out that long-term immersion in water significantly weakens this ceramic [16]. Over a three-year period, the AMF came up with a process to improve the longevity of this ceramic. Today, accelerated life testing has shown that this ceramic will retain 80% of its strength after 40 years of soaking in saline solution [17–19].

34.3 Battery-Powered BION System for FES and Sensing

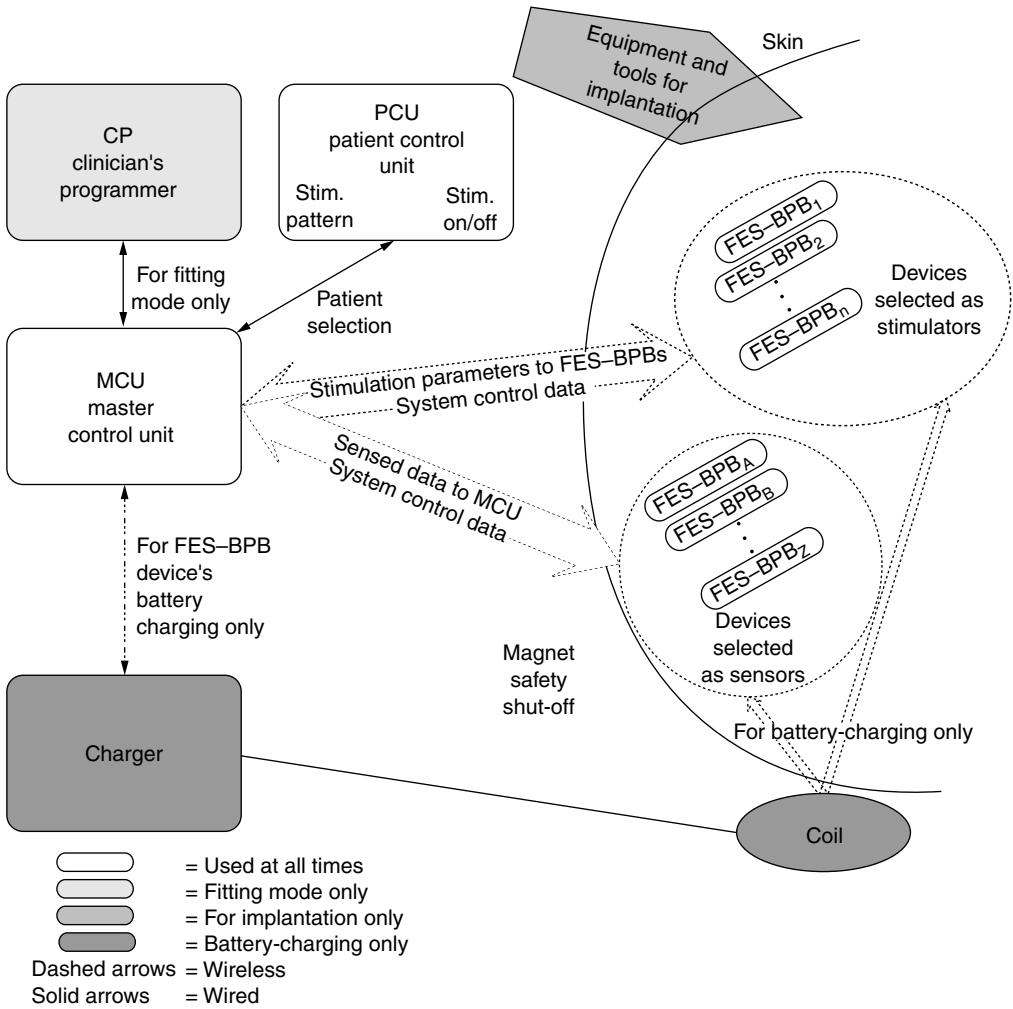
The FES–BPB System is a wireless, multichannel network of separately implantable battery-powered BION devices that can be used for both stimulation and sensing. The System is comprised of a master control unit (MCU), a Clinician's Programmer, a recharging subsystem (charger and coil), and BPBs. Additional equipment, dissolvable suture material, and surgical insertion tools (used only during the implantation procedure) are also part of the System. The FES–BPB System can be set up for use in two configurations: fitting mode and stand-alone mode. A block diagram of the FES–BPB System is shown in Figure 34.3.


FIGURE 34.3   Functional electrical stimulation and sensor system (FES–BPB).

The MCU is the communication and control hub for the FES–BPB System. The MCU transmits commands to and receives data from all the BPBs and the recharging subsystem. There are two versions contemplated for the MCU packaging (1) an external MCU, which will be outside the body and have a few controls accessible to the patient; and (2) an implantable MCU, which will be implanted in a convenient location in the body. The implantable MCU version will have a small patient control unit (PCU).

The Clinician's Programmer consists of software loaded on a computer that allows the clinician to configure and test the FES–BPB System for each patient.

The recharging subsystem (charger and coil) is used when the rechargeable battery of the BPB needs to be recharged. The charging process requires the placement of the coil close to the area on the patient's body where the BPB is implanted. Recharging is mandatory when the battery of the BPB is low. Depending on the frequency of use and stimulation levels delivered by the BPB, the battery could potentially run down in 1–8 days. Under normal stimulation conditions (nerve stimulation of 1- to 2-mA pulse amplitude, 15- to 100-μsec pulse width, and 20 pulses/sec), charging for about 5–20 min/day is required to charge the battery. The BPB's maximum stimulation capability (20-mA pulse amplitude at 14 V compliance with 200-μsec pulse width and 125 pulses/sec) can rapidly discharge the battery in a very short

time and would result in the need to recharge the battery for longer periods of time and much more frequently.

The external charger coil transmits only power to the implanted devices. Charging and battery status are transmitted by each BPB to the MCU. Each BPB can accept a charging field 20 times the nominal field to recharge, without overheating. Upon completion of the charging process, the MCU then issues a stop-charging command to the charger.

The BPB has a sensor to detect the field from a permanent magnet. The function of the magnet is to hold the stimulation off. This is a safety feature in case the BPB is stimulating in an undesired manner and the patient does not have access to his control unit. When the magnet is positioned on the patient's body over the area where the BPB is implanted, a magnetic sensor inside the BPB detects the external magnetic field and holds the stimulation off. When the magnet is removed the stimulation turns back on. This is the default mode of the magnetic detector. Other modes can be programmed during fitting.

The BPB implantation is performed in a minimally invasive procedure and is accomplished using a combination of specially designed insertion tools and commercially available items.

The functional description of the FES–BPB System components is presented in the following sections.

34.3.1   Master Control Unit

The MCU is the communication and control hub for the FES–BPB System. The MCU transmits commands to and receives data from each one up to a total of 850 BPBs in the system within one hundredth of a second. When the patient uses the FES–BPB System (stand-alone mode), the MCU coordinates the activity of the BPBs by receiving data from implanted devices programmed as sensors, transmitting stimulation commands, and monitoring overall System status. It also serves as the basic user interface for the patient, providing System ON/OFF control and alarms, as well as program selection and limited parameter control. During fitting, the MCU acts as a conduit between the Clinician's Programmer and the rest of the System, enabling the transparent setup of each BPB and the coordination needed among BPBs to implement the desired functional movement.

The MCU also manages the recharging subsystem. The charger communicates with the System in the same manner as that of the BPBs, and it can be turned ON/OFF or checked for correct operation via the MCU.

The MCU contains the following safety mechanisms:

- An emergency STOP button on the external MCU, which when depressed, immediately issues a "stop stimulation" command to all BPBs.
- During recharging, if any BPB overheats or overcharges and cannot protect itself, it would communicate this information to the MCU, which would issue a "stop charging" command to the charger and alert the patient. If an external MCU is being used, it would produce a sound to alert the patient. In the case where an implantable MCU is being used, the MCU would send a command to the BPBs to produce a specific stimulation pattern to alert the patient and would also communicate with the external PCU, if it is within communication range. The PCU would then generate an audible alert.

The MCU also stores patient usage data for the clinician. This data can be used to verify compliance and to analyze the stimulation and sensing parameters of each session. The approximate location of each BPB in the body is also maintained in this database.

34.3.2   Software and Firmware

The software for the FES–BPB System is divided into two components. One component is the Clinician's Programmer application, which runs on a laptop computer. The other component is the firmware running on the MCU. The PC with the Clinician's Programmer interfaces with the MCU via a serial
FIGURE 34.4 (See color insert following page 32-14.) Battery-powered BION internal components.

communication link. During the fitting of the System to a particular patient, the two components work in concert to facilitate measurement and storage of the stimulation and sensor calibration parameters. Once these parameters have been gathered in a fitting session, the essential information can be stored in the MCU, so that the MCU can operate in stand-alone mode to facilitate the desired functional movement. Ultimately, the MCU will modulate the stimulation output in response to information it receives from the BPBs programmed as sensors.

The Clinician's Programmer uses a graphical interface, which contains screens to perform the following essential functions:

- Gather basic personal information for the patient, including information about the location in the body of his/her BPBs.
- Establish the stimulation range for each implanted BPB and allow selection of the stimulation parameters.
- Specify the details of the activity sequences that will be involved in the FES algorithm.
- Gather the trigger information that will be used to generate transitions between activity sequences in response to the sensor inputs.
- Compose the Finite State Machine functions that will drive a routine and download the complete program to the MCU for either immediate execution or later use.

34.3.3 Battery-Powered BION Device (BPB)

The BPB is a battery-powered microdevice that is capable of both delivering electrical stimulation and acting as a general-purpose sensor for recording biopotential signals, pressure, distance or angle between two BPBs, and temperature. The following sections describe the functional building blocks of the BPB, battery, and packaging. The specifications of the BPB are provided in Table 34.1. Figure 34.4 shows the internal components of the BPB and Figure 34.5 shows a cross section of an assembled BPB.
FIGURE 34.5 (See color insert following page 32-14.) Battery-powered BION device cross section.
FIGURE 34.6 MCU–BPB communication protocol.

The BPB has the following subsystems:

34.3.3.1 Stimulation

The BPB is a single-channel, constant-current, charge-balanced stimulator. The stimulation output is capacitance-coupled, which also prevents direct connection between the battery or battery-generated DC voltages and the tissue. Stimulation pulse amplitude, width, and frequency can be independently adjusted. In addition, triggering events can cause the stimulation to be delivered continuously or in a pulse burst, which can be ramped up and down with a variety of Start/Stop times.

34.3.3.2 Communication

The bidirectional propagated wave RF communication between the MCU and the BPBs is established through a dipole antenna (Figure 34.5). This link operates at a frequency in the band 100 to 500 MHz, using quad phase modulation with a 5-MHz bandwidth. The BPB communication module includes a crystal-controlled transmitter, receiver, and digital processing unit that synchronizes with and processes the MCU transmissions. The digital processing unit in the BPB also corrects small numbers of errors in the received data, decodes the MCU commands, and generates the responses to the MCU including the reporting of higher numbers of communication errors that cannot be mathematically corrected. In this latter situation, the MCU would resend the message.

The communication protocol between the MCU and BPBs is shown in Figure 34.6. The timing of the frame is completely controlled by the MCU and every BPB will synchronize to its MCU's clock.

The header and trailer fields are used for frame synchronization and for carrying frame control data intended for all BPBs and for other MCUs. When an MCU detects another MCU, the one with the higher ID number shifts the time slots of all the BPBs it is controlling, to avoid communication interference. Once the MCU assigns the time slots for the downlink and uplink data packets to each one of the BPBs in the net, each BPB turns on its receiving or transmitting circuitry for only a few microseconds at the assigned times in each frame in order to save battery. The downlink data packets contain stimulation or sensing control data or both and forward error correction (FEC) bits to correct up to four or five bit errors. Bit errors beyond that number are reported to the MCU, which will then resend the message. If some messages are vital, the message would be sent twice or the value would be sent back to the MCU for the MCU to verify and authorize the command. Uplink data packets are transmitted by each of the BPBs and are used to carry information to the MCU (e.g., sensed data). The FEC in the uplink data packet only corrects one or two bit errors.

34.3.3.3 Power (Battery and Charging)

The main power source for the BPB is a 10-mW-Hr rechargeable lithium-ion battery that allows the implanted device to operate as a stand-alone stimulator/sensor. Its special nonflammable lithium ion chemistry provides long life and permits the voltage to go to zero and be recovered safely without damage to the battery. The recharge process is achieved via a low-frequency (127 kHz) magnetic link with an external coil worn or placed nearby when charging. Assuming continuous stimulation pulses at 20 pps with 100-μsec pulse width and 2-mA pulse amplitude into a 2-kΩ load, the battery of a BPB selected as a stimulator will provide 100 h of continuous operation. For a BPB selected as sensor, the battery will also provide 100 h of continuous operation.

The lithium ion battery is specified to have a cycle life of 2000 cycles for a standard charge/discharge cycle, which is a fairly deep discharge of the battery before recharge occurs. The nominal stimulation/sensing requirements in many applications are such that the battery would not be discharged to the standard low level (if recharged daily). Thus, the 2000 cycles represent a lifetime of over 10 years if the battery is recharged daily.

34.3.3.4 Safety

The BPB includes the following safety features:

- A miniature magnetic sensor that detects the magnetic field from an external magnet and holds off the stimulation if, for some reason, it needs to be turned off.
- A temperature sensor that communicates with the charger, via the MCU, to terminate charging, if appropriate and disconnects the battery when the temperature rises above a predetermined threshold.
- Battery safety circuitry that protects the battery from overvoltage, overdischarging, and overcharging.
- BPBs can protect themselves from magnetic fields in excess of 20 times the field necessary for maximum charging and, for a short time, for fields in excess of 50 times the field for maximum charging. This short time is more than sufficient for the BPB to send a message to the MCU to turn off the charger and to alert the patient of risk.

34.3.3.5 Biopotential Sensing, Data Display, and Data Analysis

The biopotential function is implemented to record neural or muscular electrical signals (EMG signals). Biopotential sensing is accomplished using a low-noise amplifier and band-pass filter circuit, followed by a digital postprocessing circuit. The amplifier is adjustable from a gain of 10 to a gain of 1000. The low-frequency setting of the band-pass filter is adjustable from below 1 to 300 Hz. The high-frequency setting is adjustable from 300 Hz to 10 kHz. Input referred noise is less than 5 μV rms (20 μV peak).

34.3.3.5.1 Data Display: Oscilloscope Mode

During fitting, the analog signal from the amplifier/filter section can be digitized and transmitted from the BPB to the MCU to the Clinician's Programmer screen at the rate of 40,000 samples per second. This "oscilloscope mode" (Figure 34.7) can be used when evaluating the placement of the BPB and during fitting, but it is not suitable for long-term use due to its high power demands.
FIGURE 34.7 Biopotential sensing module, oscilloscope display mode.
FIGURE 34.8   Data analysis with the BPB biopotential sensing module. (a) Counting pulses above threshold line. (b) Rectify and integrate neural signal.

FIGURE 34.9   Use of BPBs for distance/angle measurements.

34.3.3.5.2 Data Analysis

The analog output of the biopotential sensor also passes to a programmable window detection circuitry that can be set by the clinician (1) count pulses that fall within (or above or below) the set thresholds (Figure 34.8a); or, (2) rectify and integrate the sensed signal (Figure 34.8b). (1) Counting pulses: The neuronal pulses that occur are accumulated every 10 msec and relayed to the MCU. (2) Rectify and integrate: Every 10 msec, if required, the circuit can rectify the amplitude of the biopotential sensor's analog output and sum up the average rectified signal. An output between 0 and 255 will be generated indicating the average energy occurring every 10 msec.

34.3.3.6   Pressure Sensing

Some BPBs will be fabricated with a pressure transducer mounted at one end. The initial version of this sensor is about 3 mm in diameter and is sensitive to pressures along the axial dimension of the BPB. Future versions will be sensitive to lateral pressure, and may be mounted remotely from the BPB. The present full-scale absolute pressure range is 400 to 900 mmHg. This signal can be read out either AC or DC coupled. When DC-coupled, it reads the absolute pressure. Since ambient pressure varies with altitude changes, this offset can be accounted for by placing a reference sensor of the same type in the MCU, then subtracting off this baseline.

34.3.3.7   Angle/Position Sensing (Goniometry)

The same internal coil that is used to receive the magnetic field to charge the BPB battery may also be programmed as a transmitter in any selected BPB or as a receiver in another selected BPB. The goniometry function is implemented using one BPB as a transmitter and the other BPB as a receiver. The BPB programmed as a receiver detects and measures the signal strength of the received signal (Figure 34.9).

The distance between two BPBs is derived from the intensity of the received magnetic field, which falls off approximately with the cube of the distance between the devices.

There are eight different programmable transmitter–receiver frequencies available for goniometry use. The eight frequencies are clustered around 127 kHz. This permits eight parallel goniometry systems consisting of one transmitter and any number of receivers. There is no limit on the number of BPB receivers that can process the signal strength to give distance measurements (from each of the transmitters). Each BPB receiver is able to send back a measurement 100 times/sec. A goniometry pair (transmitter–receiver) can be used to measure distances between 1 and 20 cm.

34.3.3.8 Temperature Sensing

An internal temperature sensor is incorporated as an additional safety mechanism to guard against overheating of the BPB and to provide temperature data to patients, such as certain quadriplegics, who do not sense temperature. The sensor is accurate to within one-third degree celsius and is operable over the range from 16 to 50°C. In the event a significant temperature rise is detected, the BPB can be shut down or communication with the MCU can be made to initiate appropriate external action (such as shutting down the charging field, if present). Readings are taken once per second and can be read by the MCU.

34.3.4 Recharging Subsystem (Charger and External Coil)

The charger produces a 127-kHz signal that generates a magnetic field in the charging coil. The MCU communicates with the charger to indicate when to turn on a charging field. The MCU interrogates each BPB to determine which BPB is going to be charged and when the BPB is fully charged. The MCU determines which BPBs are not being charged and indicates to the patient where the coil has to be moved to charge those BPBs. If the charger is coupled to several coils but can only power one coil at a time, the MCU can then cause the charger to switch coils so uncharged BPBs can be charged. The MCU can also determine the state of the charge in each BPB and can initially select the most discharged devices to be charged first.

The recharging subsystem includes a temperature sensor that stops the recharging process if the external coil temperature adjacent to the patient skin rises over 41°C.

34.3.5 Magnet

The patient can stop stimulation by placing an external magnet near the location of the implanted device(s). A Neodymium magnet is being used because it is small, lightweight and because it produces a very strong magnetic signal. The default mode of this magnet is to hold the stimulation off when the magnet is positioned on the patient's body, over the area where the BPB is implanted. When the magnet is removed, the stimulation turns back on. Other magnet control modes are available.

34.3.6 FES–BPB System Specifications

TABLE 34.1   Battery-Powered BION Device Specifications

1. Physical	
Implant weight	0.6 g
Implant length with eyelet[++] and diameter	25 mm$_{max}$ length/3.15 mm$_{max}$ diameter
Electrodes area	5.2 mm^2 (0.008 in.^{2}) stimulation electrode
	12.8 mm^2 (0.019 in.^{2}) return electrode
Case materials	Yttria stabilized Zirconia; Titanium 6Al4V alloy
Electrodes material	Iridium

Continued

TABLE 34.1   *Continued*

2. Stimulation parameters			
Pulse amplitude	5 μA–20 mA in 3.3% exponential steps (255 levels)		
Pulse width	7.6–1953 μsec in 7.6 or 15.2 μsec steps		
Pulse frequency	1–4096 pps		
Stimulation control response time	10.6 msec maximum		
Capacitor recharge current	10–500 μA		
Compliance voltage	Up to 14 V automatically adjusted		
Stimulation output capacitor	4 μF		
Delay to start from a trigger	0–42.4 h in 15.6 μsec, 125 msec, 2 sec, 1 min, 10 min steps		
Burst on/off time	Min	Max	Step
Range 1	0.031 sec	0.9996 sec	0.0156 sec
Range 2	0.25 sec	8.00 sec	0.125 sec
3. Sensors			
Temperature	16–50°C with 0.3% accuracy		
Magnetic field to trigger shut off	10.0 Gauss threshold		
Goniometry (number of frequency channels)	8		
Range	1–20 cm		
Repeatable accuracy error	Less than 1% for 1–10 cm		
Pressure (range)	Readout = AC coupled. 300–900 mmHg absolute		
Accuracy	±10 mmHg		
Biopotential sensing (amplification)	10, 30, 100, 300, 1000		
Low frequency roll-off	1, 10, 30, 100, 300 Hz		
High frequency roll-off	300, 1 K, 3 K, 10 kHz		
Notch filter	50 or 60 Hz		
Input referred noise	5 μV rms		
4. Communication			
Number of implants per patient	Up to 850 at 10 msec		
ID, MCU/BPB	27/30 bits		
Band width	5 MHz		
Sense-to-stimulate delay	10.6 msec maximum		
Frequency band	100–500 MHz		
MCU to BPB data rate 15 bits/6 μsec	(15 bits data + 16 bits FEC[a])/6 μsec		
BPB to MCU data rate 8 bits/5 μsec	(8 bits data + 8 bits FEC[a])/5 μsec		
Data streaming (oscilloscope mode)	39.8 K samples/sec X 3 channels (8 bit resolution)		
5. Charging			
Frequency of charging field	127 kHz		
Excessive magnetic field permissible	20 times nominal		
6. Battery: Lithium ion rechargeable, hermetically sealed			
Battery length and diameter	13 mm length, 2.5 mm diameter		
Battery weight	0.21 g		
Battery capacity	3.0 mA h, 10 mW h		
Cell voltage range	3.0–4.0 V (3.6 V nom.)		
Battery life	Nominally 10 year (usage dependent)		

[a] FEC, forward error correction.

34.3.7 Minimally Invasive Procedure to Implant BPBs

To implant a BPB, a minimally invasive procedure is followed. The implantation procedure can be done in a clean Procedure Room, where the patient's implant sites can be surgically cleansed and draped with sterile towels and covered with adherent sterile plastic drapes. The implant physician scrubs his/her forearms and hands, is gowned and gloved, and wears a cap and mask.

The implantation (insertion) tools are shown in Figure 34.10. Under local anesthesia, a 5-mm skin incision is made. A sterile probe electrode (0.71 mm OD; insulated except at the tips, Figure 34.10)

A: Probe electrode

B: Dilator

C: Sheath, with holes

D: Ejection tool (2 marks)

E: 3 ml syringe, with normal saline
FIGURE 34.10   (See color insert following page 32-14.) BPB implantation tools.
FIGURE 34.11   BPB implantation technique.

connected to an external stimulator is directed into the tissues to excite and find the target nerve/motor-point. With adjustments to the probe electrode, the optimal target muscle contraction is located. A customized introducer (dilator plus sheath) is then slid over the probe electrode. Stimulation with the probe electrode is repeated to ensure a similar optimal response and correct location. The probe electrode and dilator are then withdrawn, leaving the sheath in position.

The BPB has a dissolvable suture attached to the return electrode. The BPBs stimulation electrode end is inserted into the sheath and gently pushed by the ejection tool to the sheath tip, so that only the BPB stimulation electrode end protrudes. From the ejection tool tip, saline is infused into the sheath to allow the anodal end of the BPB to have electrical connection to the tissues through small holes in the distal sheath. The BPB is activated to test and confirm its optimal position relative to the target nerve/motor-point. By withdrawing the sheath over the ejection tool, the BPB is deposited into the tissues (Figure 34.11). The sheath and the ejection tool are then removed.

The BPB is retested to confirm that the optimal response is achieved. If this position is not satisfactory in regard to the responses to stimulation or recording, then the BPB can be retrieved by pulling on the suture attached to the BPB (Figure 34.12) and then reinserted. The emerging sutures are cut at the subcutaneous tissue level, and the wound is then closed.

The implanted BPB is tested one week after implantation to confirm that the responses are still adequate. If an inadequate response is observed, the wound could be reopened and the BPB retrieved by pulling on the sutures. A new BPB could then be reinserted to obtain proper response.
FIGURE 34.12   Retrieval of BPB.
FIGURE 34.13   (See color insert following page 32-14.) BPBs measuring pressure in fingers.

34.4   Applications

The different functions of the BPB (as a stimulator, biopotential signal sensor, goniometry sensor, and pressure or temperature sensor) and the availability of multiple BPBs in one patient (up to 850 BPBs) gives the clinician many opportunities to restore neurological function, especially in poststroke syndrome, spinal cord injury, cerebral palsy, multiple sclerosis, traumatic brain injury, and for limb sensing in amputees to control fitted prostheses.

Take, for example, the case where a paralyzed upper extremity is implanted with multiple BPBs placed near motor-points or nerves of muscles in the arm, fore-arm, and hand. It will be possible to trigger sequential functional muscle actions to extend the arm and fore-arm, and open the hand to grasp an object. The limits of each functional action can be controlled from implanted BPBs working as goniometry sensors, measuring the angles of the elbow (see Figure 34.9) and wrist and implanted BPBs working as pressure sensors, measuring the pressure at the finger tip (Figure 34.13).

The reverse of this extension can be similarly achieved using this stimulating and sensing system to bring the grasped object, for example, to the mouth. Similar closed-loop controls of stimulation could be used in the lower extremities for standing and ambulation. For partially paralyzed extremities, sensing of the muscle activities using BPBs would act as triggers to other BPBs to stimulate the motor-points of these muscles, thus augmenting the total action. Goniometry sensors would add the closed-loop controls to reduce or stop the actions. This approach could be used to augment swallowing, bladder control, and respiration.

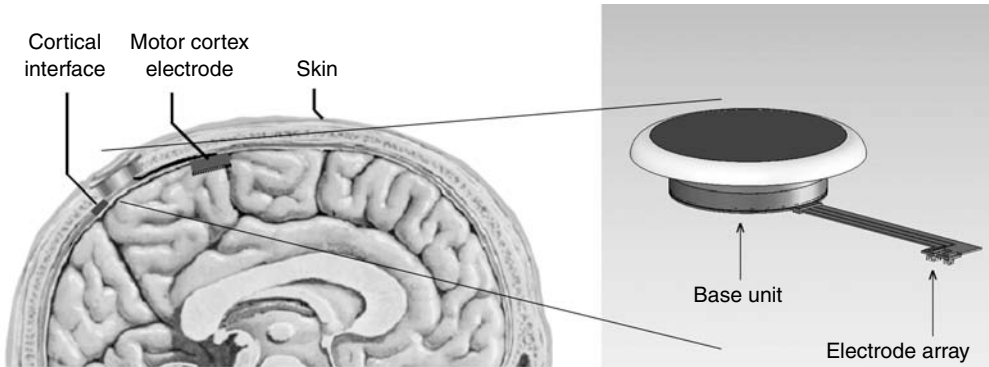
Where pressure points need to be monitored, for example, at the heel (as a trigger for improving walking on stroke patients) or buttock (to avoid pressure sores) or hand (to detect the grasping of an object), BPB
FIGURE 34.14 (See color insert following page 32-14.) Use of BPBs in amputee patients.


FIGURE 34.15 (See color insert following page 32-14.) Cortical interface device.

devices placed in these sites can measure the pressure and either trigger motor-point functional stimulation to activate muscles or stop a functional stimulation sequence.

34.4.1 FES–BPB System in Amputee Patients: Controlling Artificial Limbs

For Amputee Patients (Figure 34.14) BPBs, working as biopotential sensors, would be inserted in the "stump to pick up motor nerve signals, which can be used to control movement of the artificial limb flexible components".

34.4.2 Cortical Interface Device: A Cortical Stimulator and Sensor Using the BPB System Technology

Individuals with spinal cord injury or disease that limits control over voluntary motion or sensing may be able to regain some of the ability of voluntary motion by monitoring the motor cortex and feeding back sensed response signals to the sensory cortex. Voluntary motion is expressed as neural activity in the motor cortex. The sensory cortex depends on muscle spindles and other sensors to help control the limb movement. By feeding back signals to the sensory cortex, the psychological use of the limb would be given back to the patient. The motor cortex signals can also be used to control wheel chairs and other assistive devices.

The miniaturized components developed for the BPB are used to create a cortical interface device (CID) with multiple stimulation and sensing electrodes within a single implantable package (Figure 34.15). The CID has the capability of monitoring up to several hundred electrodes that can be implanted or positioned
FIGURE 34.16   (See color insert following page 32-14.) Cortical interface device (left) dimensions, (right) cross section.

in the motor cortex, sensory cortex, or a combination of both. The CID system consists of a base unit implanted in the skull, underneath the scalp and one or several electrode arrays placed on the sensory or motor cortices.

The CID is equivalent to a group of 64 BPBs in its communication ability. It also includes an additional switching matrix that allows any amplifier to sense voltages either unipolar or bipolar from any two electrodes. The CID base unit dimensions and internal components are shown in Figure 34.16. The CID is constructed with the same technology developed for the BPB. It contains the same electronics as those used in the BPB as far as the communication, charging, power management, biopotential sensing, and stimulation modules are concerned. A CID base unit contains 64 biopotential sensing modules attached to one or more electrode arrays. The battery used in the CID provides 50-mA-h at 3.6 V.

The electrode arrays could be configured for sensing or stimulating purposes. The sensing electrode array includes signal processing capabilities by using the same electronics as those in the biopotential sensing module in the BPB. The stimulating electrode array contains the same stimulation electronics as those in the BPB stimulation module. The CID contains a powerful microprocessor to analyze the signals from the motor cortex and to reduce the data to 64 eight-bit messages that the MCU can use to control up to 64 muscles.

Visual Prostheses

Robert J. Greenberg
Second Sight

The possibility of restoring vision to blind patients using electricity began with the discovery that an electric charge delivered to a blind eye produces a sensation of light. This discovery was made by LeRoy in 1755 [1]. However, it was not until 1966 that the first human experiments in this field began with Giles Brindley's experiments with electrical stimulation of the visual cortex [2]. He used 180 cortical surface electrodes on patients, who were then able to perceive spots of light called "phosphenes," but they were ill defined and could not be combined to make an image. This did fail to produce useful vision in these patients. Similar experiments by William Dobelle in 1974 produced essentially the same results [3,4].

Since these early experiments, efforts have been underway to produce penetrating arrays of electrodes that offer the possibility of more closely spaced electrodes and therefore higher resolution cortical devices [5–8]. Richard Normann (University of Utah) has micromachined 100 electrodes out of silicon, which was primarily used for recording in the sensory cortex of animals [5]. Another group at the University of Michigan led by Ken Wise has also produced micromachined penetrating electrodes for recording [6]. In the 1990s an effort at the NIH headed by Terry Hambrecht made an array of 38 penetrating microelectrodes, which were implanted in a patient and yielded separable phosphenes at electrode placements closer than had been produced with surface electrodes [7,8]. Electronics for an implantable cortical prosthesis are being developed (with 1024 channels) at the Illinois Institute of Technology by Philip Troyk (personal communication).

While the cortical stimulation approaches have made progress, it has been hampered by the physiology. The processing that has occurred by the time the neural signals have reached the cortex is greater than at the more distal sites such as the retina. This results in more complex phosphenes being perceived by the patient. The surgery and the implanted prosthesis do provide risks such as intracranial hemorrhage to a blind patient who has an otherwise normal brain. These factors and the lack of availability of implantable electronics have limited the clinical application of these devices.

The limitations of the cortical approach encouraged several groups in United States over the past 10 years to explore the possibility of producing vision in patients with an intact optic nerve with damaged photoreceptors by stimulating the retina [9–15]. Likely candidate diseases are retinitis pigmentosa (RP) or age-related macular degeneration (AMD). It is difficult to determine exactly how many patients are blinded by these diseases since patients often stop seeing their ophthalmologist after being told there is nothing that can be done. However, estimates of legal blindness in the West (developed world) run as high as 300,000 people with RP and 3,000,000 people with AMD. 1.2 million people are afflicted

35-1

(but not yet blind) with retinitis pigmentosa worldwide and 10 million people are afflicted with AMD in the United States alone [16].

There have emerged two major approaches to retinal stimulation — epiretinal and subretinal. In the epiretinal approach, electrodes are placed on top of the retina to produce phosphenes. In the subretinal approach, photodiodes are implanted underneath the retina and used to generate currents, which stimulate the retina. The epiretinal approach has been pursued by a team at the Johns Hopkins University led by Eugene de Juan and Mark Humayun [9,15] and another at Harvard/MIT Centers led by Joseph Rizzo and John Wyatt [10]. Recently Rizzo and Wyatt have decided to pursue the subretinal approach. Second Sight, a privately held company in Sylmar, CA, is developing a permanently implantable epiretinal prosthesis. Six patients have been implanted with a first generation device containing 16 electrodes and a 60 electrode second generation device should be in patients soon. Patients with the first device have shown the ability to read large letters, locate objects and detect the direction of motion of objects and light. They have also shown the ability to discriminate multiple levels of gray. The second generation device is expected to work even better. The subretinal approach has been pursued by the Chow brothers in Chicago — one an ophthalmologist and the other an engineer — who have formed a company called Optobionics (Chicago, IL) [14]. They implanted ten patients in an initial feasibility study, which showed some temporary subjective improvements in vision that Optobionics believes was caused by a secondary neurotrophic effect and not direct stimulation by the implant. They have recently implanted 20 more patients at 3 centers with better vision than the first group in an attempt to demonstrate improvement in more than one center and to explore the effect in patients with better vision. Subretinal and epiretinal implants are also being pursued in Germany by large groups led by Eberhart Zrenner [11] and Rolf Eckmiller [12] respectively. Two companies have been formed in Germany by these individuals as well. There is also a group in Japan at Nagoya University led by Tohru Yagi. This group is focused primarily on cultured neuron preparations (personal communication).

Finally, there is a group at the Neural Rehabilitation Engineering Laboratory in Brussels, Belgium, led by Claude Veraart which has implanted a nerve cuff electrode with four electrodes around the optic nerve of a blind patient. That patient is able to identify in which quadrant she sees a phosphene [17]. Recently a second patient has been implanted with an eight-channel device. The new device was implanted inside the ocular orbit and has not performed as well as the first implant.

On February 19, 2000, the inaugural symposium of the Alfred Mann Institute-University of Southern California (AMI-USC) titled, "Can We Make the Blind See? — Prospects for Restoring Vision to the Blind" was held. The list of lecturers included Dean Baker Director of the AMI-USC; Gerald Loeb, a FES researcher at the AMI-USC; Dean Bok, a retinal physiologist from UCLA; Retinal prosthesis researchers — Robert Greenberg, Mark Humayun, Joseph Rizzo, John Wyatt, and Alan Chow; Cortical prosthesis researchers —Richard Normann and Philip Troyk; and Dana Ballard, a visual psychophysicist from the University of Rochester.

Dr. Baker provided the welcome and Dr. Loeb gave a brief history of neural prosthetics. Dr. Bok's talk highlighted biological approaches to inherited retinal degenerations, which result in photoreceptor loss. He chose to talk about two genes (rhodopsin and RDS) whose mutations cause a form of autosomal dominant inherited blindness — retinitis pigmentosa [18]. He discussed biological approaches to these diseases. Specifically, he described work by Matthew LaVail, William Hauswirth, and Al Lewin Laboratories where subretinal injections were performed in transgenic rats carrying one of the rhodopsin mutations (P23H). By injecting viral vectored ribozymes for the selective destruction of mutant mRNA produced by the P23H mutation, there was a dramatic arrest in the photoreceptor degeneration. Dr. Bok also spoke about his own work with Matthew LaVail and William Hauswirth laboratories where viral vectored secreted form of ciliary neurotrophic factor (CNTF) was injected subretinally (see Figure 35.1). When tested with transgenic rats containing an RDS mutation (peripherin P216L), the photoreceptor loss was again slowed.

After Dr. Greenberg gave a brief introduction to retinal prosthetics, Mark Humayun spoke about the epiretinal prosthesis efforts at the Johns Hopkins University [9,15]. He spoke about recent experiments of intraocular electrical stimulation in RP and AMD patients. Under local anesthesia, different stimulating
FIGURE 35.1 Experimental protocol for intraocular patient testing at the Johns Hopkins Medical Center.

electrodes were inserted through the eye-wall and positioned over the surface of the retina. Data from the ten most recently tested patients were reported. These awake patients reported simple forms in response to pattern electrical stimulation of the retina. A nonflickering perception was created with stimulating frequencies between 40 and 50 Hz. The stimulation threshold was also dependent on the targeted retinal area (higher in the extramacular region).

Next, Joseph Rizzo and John Wyatt spoke about the work at The Massachusetts Eye and Ear Infirmary and the Massachusetts Institute of Technology (MEEI-MIT) [10]. They reported tests on six humans tested intraocularly similar to the tests performed at the Johns Hopkins Medical Center. Using micro-fabricated electrode arrays placed in contact with the retina, five patients blind from retinitis pigmentosa and one volunteer with normal vision were tested. The normal volunteer was having their eye enucleated because of a cancer. Their most significant results included (1) safe contact of the retina with a microfabricated array (2) determination of strength-duration curves in two volunteers; and (3) creation of visual percepts with crude form. In the best cases, volunteers were able to distinguish two spots of light when two electrodes separated by roughly 2° of visual angle were driven. Thresholds reported exceed the accepted charge-density limits for chronic neural stimulation for the electrodes used. It was suggested that the quality of these results would improve with a chronically implantable prosthesis.

Alan Chow from Optobionics spoke about his Artificial Silicon Retina™ (ASR) [14]. ASRs are semiconductor-based silicon chip microphotodiode arrays (microscopic solar cells) designed to be surgically implanted into the subretinal space. The arrays are approximately 2 to 3 mm in diameter, 50 to 75 μm thick. Dr. Chow reported successful electrical stimulation of normal animal retinas.

Robert Greenberg spoke about "Second Sight" and its mission of producing a chronically implantable retinal prosthesis. "Second Sight" has chosen a retinal prosthesis approach over the cortical approach because of concerns of patient safety even though the cortical approach has the potential to treat the largest number of blind patients (since it does not require the patients to have an intact retina or optic nerve). Second Sight has also chosen the epiretinal approach (see Figure 35.2) over the subretinal approach because of the belief that the photodiodes used by Dr. Chow and Dr. Zrenner will not be able to produce enough electrical energy to stimulate abnormal human retinas.

Richard Normann from the University of Utah spoke about his electrode arrays, which have been used to record both acute and chronic electrophysiological recordings from various brain structures in monkeys, cats, and rats [5]. The standard array is a 4.2-mm square grid with 100 silicon microelectrodes, 1.0 mm long, and a spacing of 0.4 mm (see Figure 35.3). Dr. Normann also spoke about his new Utah Slant Array (USA) electrodes, which have been used to record signals from peripheral nerve.

Philip Troyk from the Illinois Institute of Technology spoke about the issues of implantable hardware. One issue raised was that the next-generation neuroprostheses would be five to ten times denser, electrically and physically than current neuroprosthetic devices. Dr. Troyk discussed the need for heat dissipation by
FIGURE 35.2   Concept for an epiretinal prosthesis.
FIGURE 35.3   Penetrating cortical electrode array designed by Richard Normann's lab.

implanted prosthetics, particularly eye-mounted devices. Data was presented where a suspended-carrier closed-loop Class-E transcutaneous magnetic link was used to generate data transmission rates of over 1 M bit per second with a 5 MHz carrier [19]. Dr. Troyk also pointed out that the stimulation strategies to produce usable sight are still unknown. When reliable implantable hardware systems become available, testing can begin to devise efficacious image-to-stimulation transformations. It is important that the implantable hardware developed at this phase not restrict the nature of the stimulation sequences from the standpoint of amplitude, pulse width, frequency, and temporal modulation.

Then, Dana Ballard from the University of Rochester discussed the visual representations that affect sensory-motor task performance [20]. Volunteers were shown videos of a simulated driving environment and their eye movements, monitored. By tracking saccadic eye movements inferences can be drawn describing the underlying cortical processing [21].

Finally, a panel discussion was convened where the relative merits of the different approaches to visual prosthetics were debated. The session ended with a general consensus that visual prostheses are technically feasible and that chronically implanted devices and clinical testing are a necessary next step to assess efficacy.

Interfering with the Genesis and Propagation of Epileptic Seizures by Neuromodulation

Ana Luisa Velasco
Francisco Velasco
Fiacro Jiménez
Marcos Velasco
Mexico City General Hospital

36.1 Introduction

Epilepsy is a medical condition that is very frequent around the world. It is estimated that 1% of the population suffers epilepsy. From these patients, only 70% are controlled with antiepileptic medication. The other 30% of patients may benefit from surgical intervention. The use of chronic stimulation of the brain, so called neuromodulation, has shown to be a reliable procedure in the control of epileptic seizures. In 1970, the first totally implantable stimulating systems were available [Rise, 2000]. Based on the work of Cooke and Snider [1955], Cooper et al. [1978] used cerebellar stimulation to control different varieties of epileptic seizures.

Our group has worked on two deep brain stimulation procedures according to the type of epileptic seizures (1) stimulation of the centromedian nucleus (CM) of the thalamus in the control of intractable generalized seizures and atypical absences of the Lennox–Gastaut syndrome (LGS) [Velasco et al., 1987,

36-1

1989, 1993a, b, 1995, 2000a, b, 2002] and (2) stimulation of the hippocampus for the control of mesial temporal lobe seizures [Velasco et al., 2000, 2001].

36.2   Electrical Stimulation of the Centromedian Thalamic Nuclei

Although electrical stimulation of the centromedian thalamic nuclei (ESCM) has been used in cases of difficult-to-control seizures with multifocal onset in the frontal and temporal lobes, as well as in cases of seizures with no evidence of focal onset such as LGS, it has proven to have its best result in the latter.

The role of midline and intralaminar thalamic nuclei in the genesis and propagation of epileptic attacks was proposed long ago on the basis of clinical observations [Penfield and Jasper, 1954]. Although the controversy on the anatomical initiation of the epileptic attacks remains, there seems to be an agreement that the thalamocortical interactions are essential in the development of most of them [Pollen et al., 1963; Gloor et al., 1977; Quesney et al., 1977; Avoli et al., 1983; Steriade, 1990; Velasco et al., 1991].

The decision to stimulate the CM was based on the idea to interfere with the thalamocortical interactions and thus stop either the genesis or propagation of the seizures. In 1984, our group performed the first ESCM trial on a 12-year-old male who had severe atypical absences refractory to high levels of antiepileptic medication. The CM was chosen as a target because of its relatively large size and close relationship to the conventional stereotaxic landmarks and because the CM is an intralaminar nucleus that forms part of the nonspecific reticular-thalamocortical system, which transmits and integrates the cerebral inputs of the generalized seizures [Jasper and Droogleever-Fortuyn, 1947; Hunter and Jasper, 1949; Gloor et al., 1979]. Since then, several types of seizures were included in the protocol of ESCM [Velasco et al., 1993a]. The best results were obtained in patients with generalized seizures of the LGS (associated with 2-Hz spike wave complexes and mental deterioration). Other forms of seizures particularly those with focal origins (as in temporal lobe seizures), are not significantly improved by ESCM to a lesser extent [Velasco et al., 2000b]. However secondary tonic–clonic generalization is relieved suggesting that ESCM interferes with the propagation mechanisms of focally initiated epileptic activity.

The ESCM procedure has been refined progressively by increasing the number of treated patients and lengthening the follow-up period. Our group has also better defined a number of predictor factors that must be taken into account to achieve a good outcome. There are three such main predictor factors (1) selection of responding patients, (2) verifying correct DBS implantation based on definition of the stereotaxic coordinates of the CM optimal effective areas and neurophysiologic characterization of the targeted area, and (3) performing periodic monitoring of the reliability of ESCM on a long-term follow-up [Velasco et al., 2000b, 2001].

36.2.1   Patient's Selection

In this chapter we analyze the last 13 patients with LGS selected from patients of the Epilepsy Surgery Clinic of the General Hospital of Mexico on the basis of having generalized difficult-to-control seizures of the LGS. They underwent ESCM with the idea to correlate seizure type, stereotaxic targeting, and neurophysiologic responses with the final outcome of the patient. The LGS is one of the most severe forms of childhood epilepsy. It is characterized by drug-resistant generalized seizures, the most characteristic being the tonic and atonic seizures, atypical absences, myoclonic attacks, episodes of nonconvulsive, and tonic *status epilepticus*. The peak onset is known to be between 1 and 7 years of age. It is usually preceded by other types of seizure disorders, especially infantile spasms. LGS is accompanied by severe mental deterioration as it progresses. From the electroencephalographic (EEG) standpoint, the diagnosis is based upon the presence of slow spike–wave complexes (<2.5 cps) and bursts of rapid (10 Hz) rhythms during slow sleep. The overall prognosis is very severe, 90% of the patients are mentally retarded and 80% continue to have seizures through adulthood [Aicardi, 1994]. The selected patients had either secondary LGS with stable or nonprogressive diseases (birth trauma, postencephalitic sequelae, cortical dysplasia,

and stable tuberous sclerosis) or primary LGS with no demonstrable lesion in the magnetic resonance imaging (MRI).

36.2.2 Correct Targeting

To have the optimal results with ESCM, it is of extreme importance to have good patient selection combined with adequate target localization. The latter should be obtained from two points of view: stereotaxic (defined with ventriculography and MRI) and neurophysiologic definition.

36.2.2.1 Ventriculographic Definition of CM Target

Surgical technique: under general anesthesia, electrodes (Medtronic Model 3387 DBS lead Medtronic, Inc., Minneapolis, MN) are stereotactically placed in both left and right CM nuclei through a coronal incision and bifrontal burr holes made at a distance of 10 to 15 mm at each side of the midline at the level of the coronal suture. The CM localization is accomplished by air ventriculography. This method allows us to demonstrate the anterior commissure (AC) and posterior commissure (PC) of the third ventricle with remarkable precision. Two lines are drawn, the AC–PC line and the vertical line perpendicular to the PC (VPC). The target point for the electrode tip was a distance 10 mm from the midline and the intersection of the AC–PC line with the VPC [Velasco et al., 1989, 2000b].

Electrodes are fixed to burr holes using a plastic ring and silastic ring caps (Medtronic). The position of the contacts along the trajectory of the electrode is plotted on the sagittal and frontal sections of the Schaltenbrand and Bailey atlas [1959] according to the standardization technique described elsewhere [Velasco et al., 1975].

The optimal targets for seizure arrest are located in the basolateral portion of the CM, which corresponds to the parvocellular portion; this is an area of maximal neuronal population [Mehler, 1996] Figure 36.1. The best antiepileptic results are located as follows: LAT = 10.0 ± 2.0 mm from the midline, H = from 2.0 to 7.0 mm above the AC–PC line, and AP = from 3.0 to 5.0 mm in front or PC–VPC intersection. Since
FIGURE 36.1 Optimal targets for seizure arrest located in the basolateral portion of the CM.

the CM is a large nucleus with several subdivisions, it is important to point out that the electrode contacts used for stimulation in patients with good outcome are positioned in the ventrolateral or parvocellular part of the CM considered by anatomists as the core of the CM nucleus of Luys, which is surrounded by denser fiber connections ascending from the brainstem to terminate in other nuclei of the thalamus [Mehler, 1996].

36.2.2.2 MRI Confirmation of the CM Target

Electrodes are left externalized to confirm their position by MRI. Scans are performed using 1.5 T Edge equipment software version 9.3 (Marconi Medical Systems, Cleveland, Ohio), using T2 weighted fast spin echo sequence (echo time 11 ms; repetition time 4070 msec; field of view 16.0 cm; 256×256 matrix). Sections are oriented parallel and perpendicular to the AC–PC line for axial and frontal views, and parallel to the midsagittal plane for sagittal sections [Velasco et al., 2000b, 2002].

36.2.2.3 Neurophysiologic Confirmation of the CM Target

Stimuli are delivered by a Grass S8 stimulator and isolation unit attached to the patient by means of a Tektronix CRU and a comparative 10 kΩ resistor in order to monitor the voltage (V), current flow (μA), and impedance (kΩ) of the stimulated contacts within the brain tissue [Velasco et al., 1993a].

The electrical incremental and desynchronizing responses are elicited by unilateral electrical stimulation through adjacent electrode contacts (where the cathode was always the lower contact). Stimuli consist of 5 to 30 sec trains of monophasic square pulses of 1.0 msec duration and 6- to 60-Hz frequency. Analysis of the scalp distribution of the incremental spike–wave and desynchronizing electrocortical responses is made from EEG recordings taken from frontopolar (FP2, FP1), frontal (F4, F3), central (C4, C3), parietal (P4, P3), occipital (O2, O1), frontotemporal (F8, F7), and anterior temporal (T4, T3) referred to ipsilateral ears (A2, A1) (Sensitivity = 10 μA/cm; time constant = 0.35 sec; paper speed = 15 mm/sec).

Low-frequency (6/sec), threshold (4–5 V = 320–400 μA) unilateral stimulation of CM elicits incremental responses with the typical waxing and waning profile. The incremental responses produced by this stimulation procedure along the CM or other structures are described elsewhere [Velasco et al., 1996]. Although there are three types of incremental responses that may be elicited, the Type A one points the best place to obtain the optimum antiepileptic effect. They are recruiting-like responses elicited by the stimulation of the caudal-basal portions of CM (parvocellular CM close to the nonspecific mesencephalic structures, such as the mesencephalic *tegmentum* tract). They consist of monophasic negative potentials with a latency of 20 msec and peak latency of 30–35 msec, see Figure 36.2a. Suprathreshold Type A responses show a bilateral regional scalp distribution with maximal amplitude at the frontal region ipsilateral to the stimulated side, see Figure 36.2b [Velasco et al., 1996].

Unilateral high-frequency (60/sec) threshold and suprathreshold stimulation of the caudal-basal and central CM elicits a regional EEG desynchronization consisting of an increased frequency of the EEG activity superimposed on a slow negative shift. It also shows a bilateral regional scalp distribution with maximal amplitude at the frontal region ipsilateral to the stimulated side, see Figure 36.2(c) [Velasco et al., 1996].

36.2.3 Periodic Monitoring of the Reliability of ESCM on a Long-Term Follow-Up

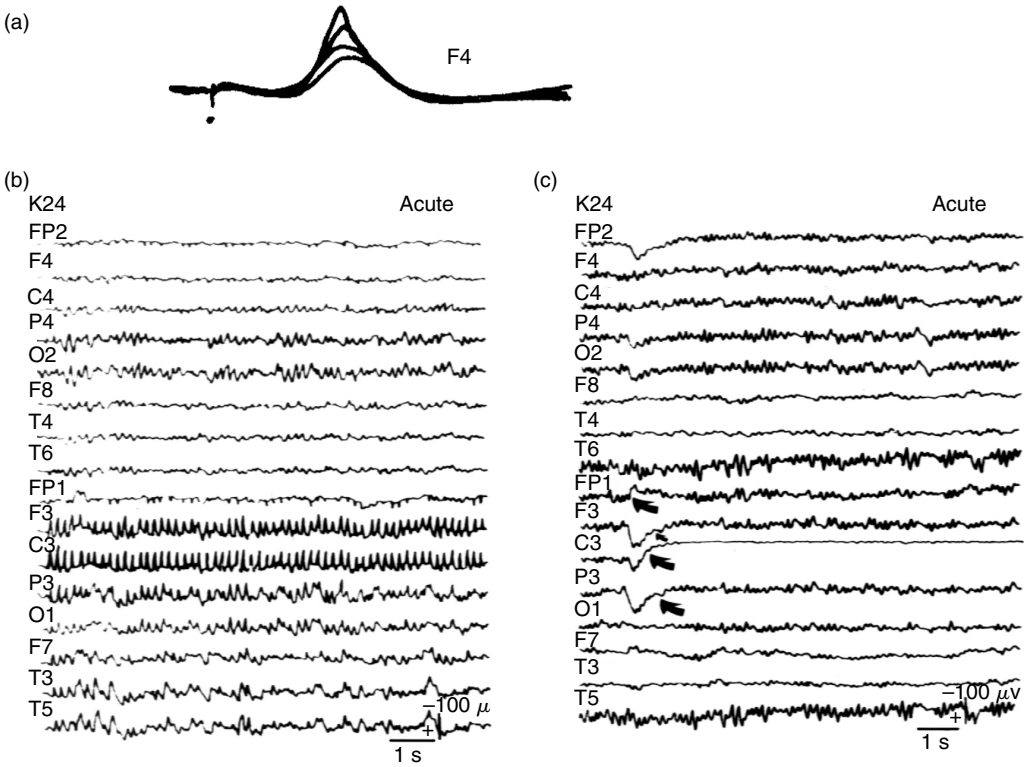
Incremental responses, EEG desynchronization, and slow negative shifts may be useful as biological responses for monitoring the efficiency of the ESCM, particularly when the stimulating electrodes are internalized subcutaneously and the physical characteristics of the electrical stimuli cannot be monitored any longer [Velasco et al., 1995]. In view of the patient's lack of subjective sensations and the long latency of the antiepileptic effects of ESCM, the reliability of ESCM is questionable. The use of 10 or 60/sec and 6 V (800 μA) transcutaneous activation of CM with the internalized pulse generator (IPG) by Medtronic, Inc., Minneapolis and the recording of scalp incremental responses, EEG desynchronization and slow negative shifts are advisable.


FIGURE 36.2 Neurophysiologic confirmation of the CM target. (a) Type A recruiting-like responses elicited by the stimulation of the caudal-basal portions of CM. They consist of monophasic negative potentials with a latency of 20 msec and peak latency of 30 to 35 msec. (b) Low-frequency (6/sec) stimulation elicits suprathreshold Type A responses showing a bilateral regional scalp distribution with maximal amplitude at the frontal region ipsilateral to the stimulated side. (c) Unilateral high-frequency (60/sec) threshold and suprathreshold stimulation of the caudal-basal and central CM elicits a regional EEG desynchronization consisting of an increased frequency of the EEG activity superimposed on a slow negative shift with a bilateral regional scalp distribution with maximal amplitude at the frontal region ipsilateral to the stimulated side.

36.2.3.1 Chronic Stimulation Parameters

The parameters recommended for ESCM are as follows: 2 h of daily stimulation sessions. Stimulus consists of 1-min trains of Lilly pulses with an interstimulus interval of 4 min, alternating right and left CM. Such trains consist in a 130-Hz frequency, with individual pulses of 450 μs in duration and amplitude of 400 to 600 μA.

36.2.4 Results

Electrical stimulation of the centromedian thalamic nuclei produces a significant reduction in the number of primary and secondary generalized tonic–clonic seizures (GTC) and atypical absences of the LGS, and also the number of interictal generalized slow spike–wave complexes.

As said above, the results depend on both the seizure type and correct target selection. Note that the patients with excellent result (i.e., 100% improvement) had generalized seizures and correct stereotaxic placement and electrophysiological responses. All patients who had less than 80% seizure improvement had either other seizure type (i.e., LC who had residual complex partial seizures [CXP]), or incorrect target selection according to either anatomic (stereotaxic) or physiologic parameters (Table 36.1).

TABLE 36.1   The Predictors of Seizure Relief Obtained after ESCM Are Shown

Initials	Seizure type			Stereotactic placement		Electro physiological		Final improvement (%)
	GTC	AA	CXP	RCM	LCM	RCM	LCM	
GA	Y	Y	N	C	C	C	C	100
MAM	Y	Y	N	C	C	C	C	100
AMP	Y	Y	N	C	I	C	C	95
MS	Y	Y	N	C	C	C	C	95
MAPR	Y	Y	N	C	I	C	C	95
JM	Y	Y	N	C	C	C	C	91
JS	Y	Y	N	C	C	C	C	89
IM	Y	Y	N	C	C	C	C	87
LC	Y	Y	Y	C	C	I	I	80
EGV	Y	Y	N	C	C	C	I	70
DC	N	Y	N	C	I	C	C	58
JR	Y	Y	N	C	I	I	I	53
LVAP	N	Y	N	C	C	I	I	30

Note all patients had generalized tonic–clonic seizures (GTC), atypical absences (AA) and only LC also had complex partial seizures (CXP). Correct (C) and Incorrect (I) stereotaxic and electrophysiological parameters are shown. Note that all patients with a seizure improvement 100% had generalized seizures and correct target localization parameters. (From Velasco et al., submitted for publication)

36.3   Electrical Stimulation of the Hippocampus (ESHC)

In the Epilepsy Surgery Clinic of the General Hospital of Mexico, 70% of patients referred for surgery have CXP arising from the hippocampal formation; other series have reported a similar referral number [Wieser et al., 1993; Williamson, 1993]. Resective surgery of the epileptic focus yields very good results [Engel, 1987; Velasco et al., 2000c], nevertheless there are cases that escape this surgical possibility, that is, patients with bilateral hippocampal foci or patients with epileptic foci located nearby eloquent areas for speech and memory (usually the left side). These latter patients cannot be operated on because it would mean having severe neurological impairment particularly related to short-term memory. These patients are candidates for neuromodulating procedures. Unfortunately, our experience with ESCM pointed out that CM is not the place to stimulate in patients with CXP originating in the temporal lobe. On the other hand, animal experiments showed that the application of an electrical stimulus to the amygdala or hippocampus following the kindling stimulus produces a significant and long-lasting suppressive effect on seizures [Weiss et al., 1995]. For these reasons we decided to perform a preliminary study in 10 patients with nonlesional temporal lobe epilepsy in whom intracranial electrodes were implanted (either subdural basotemporal grid or hippocampal electrodes) for the detection of the epileptic foci [Velasco et al., 2000c]. The study consisted in performing subacute hippocampal stimulation (SAHCS) trial for a duration of 2–3 weeks once the epileptic focus was located and before performing the temporal lobectomy. Two patients had bilateral hippocampal depth electrodes implanted to determine the lateralization of the epileptic focus and eight had unilateral subdural electrode grids on the pial surface of the basotemporal cortex to determine the precise site and extent of the focus (see Figure 36.3). In all patients, antiepileptic drugs were discontinued for 72 h before SAHCS initiation. Thereafter, SAHCS was applied for a minimum of 16 days. SAHCS was bipolar and between continuous electrode contacts (cathode attached to the most anterior contact) and consisted of continuous stimulation with biphasic Lilly pulses, 130-Hz frequency, 450 μsec in duration, and amplitude of 200–400 μA). The reliability of SAHCS was determined by daily measurement of voltage, impedance, and current flow at the intracerebral contacts by means of externalized electrode systems [Velasco et al., 1993a].

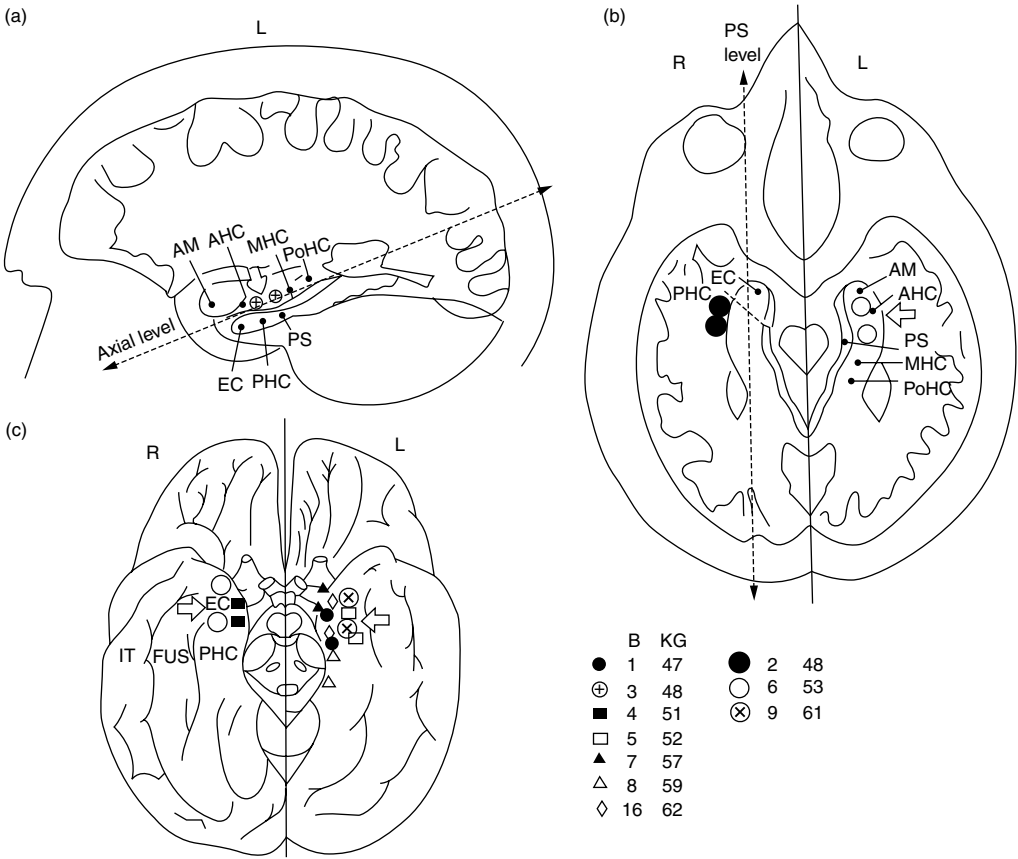
To evaluate the antiepileptic effects of SAHCS on temporal lobe epileptogenesis, the number and type of clinical seizures/day and the number of interictal negative EEG spikes at the epileptic focus/10 sec was


FIGURE 36.3 Diagrams showing the position of the depth and subdural electrode contacts for SAHCS. (a and b) show parasagittal and axial sections and (c) basotemporal cortex all of them showing the position of the stimulation contacts in different patients (indicated by different symbols at the right bottom corner). Arrows indicate sites where SAHCS produced evident and fast antiepileptic responses. Abbreviations: AHC, MHC, and PoHC: anterior, middle, and posterior hippocampus. AM: amygdala, PS presubiculum, PHC, EC, FUS, and IT: parahippocampal, entorhinal, fusiform, and inferior temporal gyri. (Reproduced from Velasco et al. *Arch. Med. Res.* 2000d, 31:316–328. With permission.)

evaluated. At completion of the clinical and EEG studies, SAHCS was discontinued, the electrodes were removed, and an anterior temporal lobectomy was performed ipsilateral to the epileptic focus and SAHCS. Biopsies of mesial and lateral temporal lobe were fixed in 10% formaldehyde buffer solution, embedded in paraffin, and cut in serial coronal sections of 10-μm thickness and perpendicular to the fascia dentata, taken every 1000 μm and stained with hematoxilin-eosin for perikarion and with Gomori's technique used for the collagen. Histopathological analysis of the temporal lobe tissue was performed under light microscope by comparing the contiguous hippocampal tissue at the stimulated vs. nonstimulated tissues.

In seven patients in whom stimulation sites were located within the hippocampal formation and gyrus, there was an evident antiepileptic response. Both CXP and secondary GTC seizures were abolished after 6 days of continuous stimulation and interictal EEG spikes were significantly reduced from days 4 to 11 of SAHCS. The most evident and fastest antiepileptic responses were found in five patients in whom the stimulation contacts were located at either the anterior pes hippocampus near the amygdala or at the anterior parahippocampal gyrus near the entorhinal cortex. Three patients did not respond, two of them when SAHCS was accidentally interrupted and the other patient when the stimulated contacts were located at the white matter lateral to the hippocampus.

Histopathological analysis of the hippocampal tissues revealed abnormalities due to depth electrode penetration or lesion due to the foreign body electrodes. However, no histopathological differences were found between stimulated and nonstimulated hippocampal tissues. Therefore, the SAHCS effect does not appear to depend on a lesional process but rather to a functional blockage of the hippocampus.

During this preliminary study we took advantage of this ethically permissible situation and studied some basic mechanisms underlying the beneficial therapeutic effect on seizures due to hippocampal stimulation [Velasco et al., 2000d, e, 2001a, b]. Such studies suggest that the antiepileptic effect of hippocampal stimulation is due to an inhibition mechanism, that is, increased threshold and decreased duration of the afterdischarges induced by acute hippocampal stimulation; depression of the paired pulse hippocampal recovery cycles; and single photon emission computed tomography (SPECT) hypoperfusion and autoradiographic increase of the benzodiazepine receptor binding in the stimulated hippocampal tissue [Cuéllar et al., 1994].

Based upon these results we decided to proceed with a long-term hippocampal stimulation protocol to demonstrate that chronic hippocampal stimulation (CHCS) may produce a sustained antiepileptic effect without undesirable effects on language and memory. So far, we have stimulated 8 patients on a long-term basis, but we will only take into consideration those 6 patients who have a follow-up period of at least 1 year (1 to 4 years).

36.3.1   Study Design

Candidates were selected from patients of the Epilepsy Surgery Clinic of the General Hospital of Mexico on the basis of having difficult-to-control temporal lobe seizures. All of them underwent a careful clinical history with special emphasis on the seizure type (CXP), adequate antiepileptic medication with adequate blood levels, four serial EEGs, magnetic resonance, SPECT, neuropsychological exam, and psychiatric evaluation. All of them had bilateral hippocampal transitory eight contact depth electrodes (SD 8P, Ad Tech Medical Instrument Co., Racine, WI, USA) implanted to be able to assess the epileptic foci. Two of them had bilateral independent hippocampal foci and the other four patients were selected on the basis of having their hippocampal focus on the dominant hemisphere, with neuropsychological evidence of verbal memory situated here.

Once the precise epileptic focus was defined, the transitory electrodes were replaced by four contact depth brain stimulation electrodes (3789 DBS and IPG by Medtronic, Inc., Minneapolis, MN) (Figure 36.4) and connected to an independent IPG system that were placed in a subcutaneous subclavicular pocket on each side. The target of the electrode contacts was the site of maximal interictal and ictal activities. All antiepileptic drugs were withdrawn to avoid any possible interference with the neuromodulation procedure [Velasco et al., 2000e] and were replaced with phenytoin.

36.3.1.1   Chronic Stimulation Parameters

The parameters recommended for ESHC are as follows: daily stimulation sessions with 1-min trains of Lilly pulses with an interstimulus interval of 4 min. Such trains consist in a 130-Hz frequency, with individual pulses of 450 μsec in duration and amplitude of 400 to 600 μA. In those patients with bilateral electrodes, the stimulation has the same characteristics but the stimulation alternates right and left hippocampus.

36.3.2   Results

In analyzing the antiepileptic effect of ESHC, the six patients were divided into two distinct groups: three patients had normal MRIs and the other three had ipsilateral hippocampal sclerosis. The best results were obtained in the first group with normal MRIs. The antiepileptic effect was evident since the stimulation started and the patients were seizure free after the first three to six months of stimulation. Our longest follow-up period is on patient KG67 who had bilateral hippocampal stimulation and has now been 4 years seizure free. Patient KG101 is under left hippocampal stimulation and has been seizure free for 15 months and the most recent patient KG109 also has left hippocampal stimulation and has been seizure
FIGURE 36.4 Illustrates the replacement of transitory electrodes by four contact depth brain stimulation electrodes.

free for a year. The neuropsychological tests in all of them became normal after 6 months of stimulation (Figure 36.5a).

The patients that constitute the second group have unilateral left mesial temporal sclerosis. Patient KG71 had bilateral epileptic foci. Even though he had a 75% seizure reduction, he persisted with auras during the 10-months follow-up. Unfortunately he had to undergo explantation because of skin erosion. Patient KG102 had 60% seizure improvement, which could be observed very slowly and took 9 months to reach its actual seizure number (follow-up of 20 months). KG106 has had only 50% seizure improvement after one year of stimulation (Figure 36.5b). In all the patients of this group there has only been a slight improvement in the neuropsychological tests. The three patients in this group improved only slightly in their memory tests after more than 6 months stimulation.

Even though these are preliminary results, we may say that stimulating the hippocampal epileptic focus is effective in the control of mesial temporal lobe seizures. The best cases are those who have normal MRI, in whom seizure control can be achieved up to 100%. This result is of extreme importance because these patients with intractable seizures and normal MRI are the ones that are excluded as candidates for temporal lobectomy and are left with no other alternative. Patients with mesial temporal lobe sclerosis do not do so well and their follow-up shows only 50 to 75% seizure reduction. If the patient has temporal sclerosis and the seizures are starting within the sclerotic hippocampus, lobectomy could be risked. Patients with bilateral hippocampal foci and unilateral sclerosis though should be considered for neuromodulation, since they could have better results and the risk of having residual seizures after unilateral lobectomy is high.

36.4 Conclusion

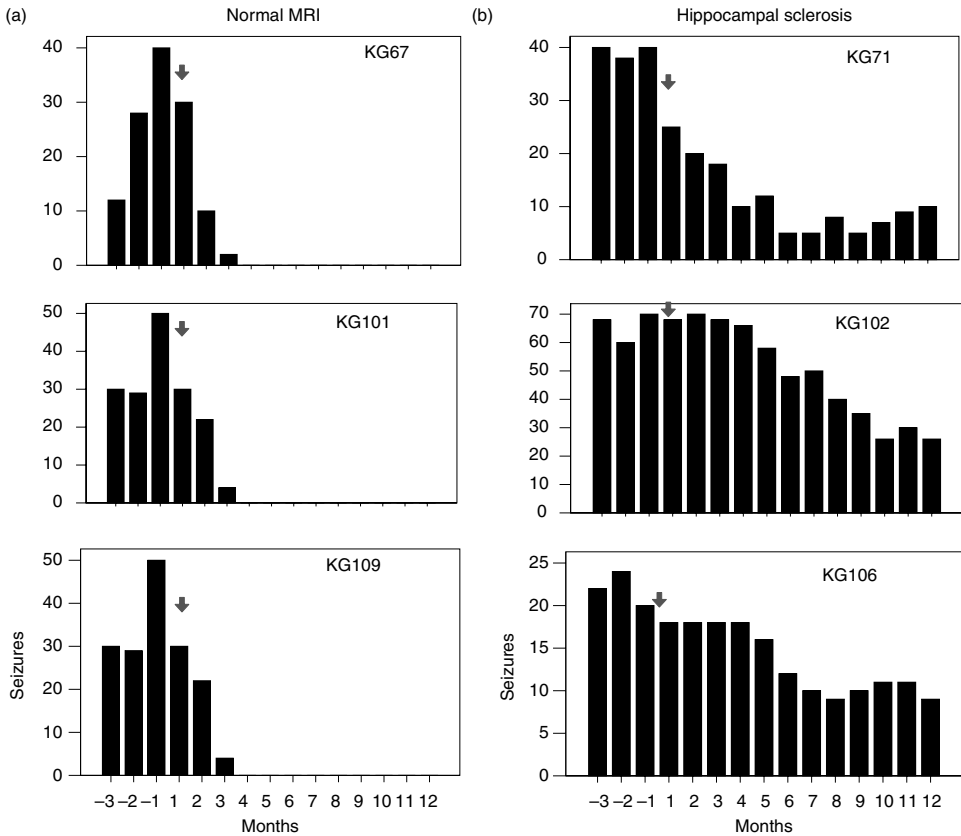
Neuromodulation constitutes an innovative neurosurgical technique in the treatment of difficult-to-control seizures. Stimulation should be targeted according to the seizure type: ESCM for generalized seizures and ESHC for mesial temporal lobe epilepsy. Neuromodulation is a method that has several


FIGURE 36.5   Seizure reduction per month in 6 patients with ESHC, graphs show 3-month baseline period, stimulation started at the fourth month (arrow) after that, 12-month stimulation follow-up. (a) Three patients with normal MRI. (b) Three patients with left hippocampal sclerosis.

advantages: it is nonlesional, with reversible effect when turned off, does not interfere with the functioning eloquent areas, and even improves neuropsychological performance. Unfortunately it has some disadvantages: neurostimulating systems are expensive, it needs periodic follow-up visits to verify whether it is functioning adequately, and the stimulators have to be exchanged when the batteries wear off, which implies a surgical procedure. Probably the most important disadvantage is the skin erosion due to the stimulating system that often leads to explantation mainly in young children.

Challenges remain. For the epileptologists there are a number of variables that are influencing the antiepileptic effect of neurostimulation that we are probably missing and there are as well other seizure types that are subject to be studied to know the antiepileptic effects of neuromodulation, that is, supplementary motor cortex epilepsy. For the engineers the need to improve neuromodulation systems so that they are less invasive (so that they are not rejected by the patients and can be implanted in small children), include rechargeable batteries, may even be remote controlled so the use of extension cables is discontinued. The systems have to be low cost so that they can be accessed by a larger number of epileptic patients. They also need to be more reliable and include user-friendly software so that the patient can check it by himself to avoid so many follow-up visits to guarantee reliable functioning.

Transcranial Magnetic Stimulation of Deep Brain Regions

Yiftach Roth
Sheba Medical Center

Abraham Zangen
Weizmann Institute of Science

37.1 Introduction

Transcranial magnetic stimulation (TMS) is a noninvasive technique used to apply brief magnetic pulses to the brain. The pulses are administered by passing high currents through an electromagnetic coil placed upon the scalp that can induce electrical currents in the underlying cortical tissue, thereby producing a localized axonal depolarization. Neuronal stimulation by TMS was first demonstrated in 1985 [Barker et al., 1985], when a circular coil was placed over a normal subject vertex and evoked action potentials from the abductor digiti minimi. Since then this technique has been applied to studying nerve conduction, excitability, and conductivity in the brain and peripheral nerves, and to studying and treating various neurobehavioral disorders, primarily mood disorders [Kircaldie et al., 1997; Wassermann and Lisanby, 2001].

The ability of TMS technique to elicit neuronal response has until recently been limited to brain cortex. The coils used for TMS (such as round or a figure-of-eight coils) induce stimulation in cortical regions mainly just superficially under the windings of the coil. The intensity of the electric field drops dramatically deeper in the brain as a function of the distance from the coil [Maccabee et al., 1990; Tofts, 1990; Tofts et al., 1991; Eaton, 1992]. Therefore, to stimulate deep brain regions, a very high intensity

37-1

would be needed. Such intensity cannot be reached by standard magnetic stimulators, using the regular figure-of-eight or circular coils. Stimulation of regions at depth of 3 to 4 cm, such as the leg motor area, may be achieved using coils such as the double cone coil [Terao et al., 1994, 2000; Stokic et al., 1997], which is a larger figure-of-eight with an angle of about 95° between the two wings. However, the intensity needed to stimulate deeper brain regions effectively would stimulate cortical regions and facial nerves over the level that might lead to facial pain, facial and cervical muscle contractions, and may cause epileptic seizures and other undesirable side effects.

This chapter describes principles and design of TMS coils for deep brain stimulation. The construction of such coils should meet simultaneously several goals:

1. High enough electric field intensity in the desired deep brain region that will surpass the threshold for neuronal activation
2. High percentage of electric field in the desired deep brain region relative to the maximal intensity in the cortex
3. Minimal aversive side effects during stimulation such as pain and activation of facial muscles

37.2   Basic Principles of TMS

The TMS stimulation circuit consists of a high-voltage power supply which charges a bank of capacitors, which are then rapidly discharged via an electronic switch into the TMS coil, to create the briefly changing magnetic field pulse. A typical circuit is shown in Figure 37.1, where low-voltage AC is transformed into high-voltage DC, which charges the capacitors. A crucial component is the thyristor switch, which has to traverse very high current at a very short time of 50 to 250 μsec. The cycle time depends on the capacitance (typically 10 to 250 μF) and on the coil inductance (typically 10 to 30 μH). Typical peak currents and voltages are 5000 A and 1500 V, respectively.

Most TMS stimulators produce a biphasic pulse of electric current. During the discharge cycle, the TMS circuit behaves like a RCL circuit, and the current I is given by:

$$I(t) = \frac{V}{wL} \exp(-\alpha t) \sin(wt) \tag{37.1}$$

where $\alpha = R/2L$, $w = \sqrt{((LC)^{-1} - \alpha^2)}$, and R, C, and L are the total values of the resistance, capacitance, and inductance, respectively, in the circuit. The inductance is mainly the coil inductance, but there is additional contribution from the cables, and the resistance includes contributions from the thyristor and the coil.

Biologically, the most relevant parameter for neuronal activation is the induced electric field, which is proportional to the rate of change of the current (dI/dt). The brief strong current generates a time-varying magnetic field B. An electric field E is generated in every point in space with direction perpendicular to the magnetic field, with amplitude proportional to the time-rate of change of the vector potential $A(r)$.
FIGURE 37.1   Typical magnetic stimulation circuit, including high-voltage transformer, capacitor, resistor, thyristor trigger, and stimulating coil.

The vector potential $A(r)$ in position r is related to the current in the coil I by the expression:

$$A(r) = \frac{\mu_0 I}{4\pi} \int \frac{dl'}{|r - r'|} \tag{37.2}$$

where $\mu_0 = 4\pi \times 10^{-7}$ Tm/A is the permeability of free space, the integral of dl' is over the wire path, and r' is a vector indicating the position of the wire element. The magnetic and electric fields are related to the vector potential through the expressions:

$$B_A = \nabla \times A \tag{37.3}$$

$$E_A = \frac{-\partial A}{\partial t} \tag{37.4}$$

The only quantity which is changing with time is the current I. Hence the electric field E_A can be written as:

$$E_A = \frac{-\mu_0}{4\pi} \frac{\partial I}{\partial t} \int \frac{dl'}{|r - r'|} \tag{37.5}$$

Since brain tissue has conducting properties, while the air and skull are almost complete insulators, the vector potential will induce accumulation of electric charge at the brain surface. This charge is another source for electric field, which can be expressed as:

$$E_\Phi = -\nabla \Phi \tag{37.6}$$

where Φ is the scalar potential produced by the surface electrostatic charge. The total field in the brain tissue E is the vectorial sum of these two fields:

$$E = E_A + E_\Phi \tag{37.7}$$

The influence of the electrostatic field E_Φ is in general to oppose the induced field E_A and consequently to reduce the total field E. The amount of surface charge produced and hence the magnitude of E_Φ depends strongly on coil configuration and orientation. This issue will be elaborated in the following sections.

Figure 37.2 demonstrates the electric field pulse produced by a figure-of-eight coil, as measured by a two-wire probe in a brain phantom filled with saline solution at physiologic concentration. In repetitive TMS (rTMS), several such pulses are administered in a train of between 1 and 20 Hz.

This electric field produces action potential in excitable neuronal cells, which might result in activation of neuronal circuits when applied above certain threshold. The neuronal response depends not only on the electric field strength, but also on the pulse duration through a strength–duration curve of the form:

$$E_{th} = b(1 + c/\tau) \tag{37.8}$$

where E_{th} is the threshold electric field required to induce neuronal response and τ is the duration the field was above this threshold. The biological parameters determining neural response are the threshold at infinite duration, termed the rheobase (b, measured in V/m), and the duration at which the threshold is twice the rheobase, termed the chronaxie (c, in μsec). Motor and sensory curves as reported by Bourland et al. [1996] are shown in Figure 37.3. These curves should be treated as illustrative only since the chronaxie and rheobase depend on many biological and experimental factors such as whether the nerves are myelinated or not (hence peripheral and cortical parameters should be different) and on train frequency in rTMS, which in general reduces the threshold for stimulation.

As shown by Heller and Van Hulstein [1992], the three-dimensional maximum of the electric field intensity will always be located at the brain surface for any configuration or superposition of TMS coils.
FIGURE 37.2 The induced electric field of a figure-of-eight coil vs. time over a TMS pulse cycle. The timescale is 100 μs.
FIGURE 37.3 Neural strength–duration curve depicting stimulation threshold vs. duration.

It is possible, however, to increase considerably the depth penetration and the percentage of electric field intensity in deep brain regions, relative to the maximal field at the cortex. The next section outlines the construction principles for efficient deep brain stimulation, and the following sections demonstrates several examples of TMS coils designed to accomplish this goal.

37.3   Deep TMS Coils: Design Principles

While the activation of peripheral nerves depends mainly on the derivative of the electric field along the nerve fiber [Maccabee et al., 1993], the most relevant parameter for activation of brain structures seems to be the electric field intensity [Amassian et al., 1992; Thielscher and Kammer, 2002]. In both cases, however, Physiological studies indicate that optimal activation occurs when the field is oriented in the same direction as the nerve fiber [Durand et al., 1989; Roth and Basser 1990; Basser and Roth 1991, Brasil-Neto et al., 1992, Mills et al., 1992, Pascual-Leone et al., 1994, Niehaus et al., 2000, Kammer et al., 2001]. Hence, in order to stimulate deep brain regions, it is necessary to use coils in such an orientation

that they will produce a significant field in the preferable direction to activate the neuronal structures or axons under consideration.

In light of these findings, the geometrical features of each specific design are mainly dependent on two goals:

1. The location and size of the deep brain region or regions intended to be activated
2. The preferred direction or directions we want to stimulate

The design of a specific coil is dictated by these goals. Nevertheless, all deep TMS coils have to share the following important features:

1. *Base complementary to the human head*: The part of the coil close to the head (the base) must be optimally complementary to the human skull at the desired region. In some coils the base may be flexible and be able to receive the shape of an individual patient, and in other coils it may be more robust, namely arcuated in a shape that fits the average human skull at the desired region. In the latter case there may be few similar models designed to fit smaller and larger heads.

2. *Proper orientation of stimulating coil elements*: Coils must be oriented such that they will produce a considerable field in a direction tangential to the surface, which should also be the preferable direction to activate the neurons under consideration. That is, wires of the coils are directed in one or more directions, which results in a preferred activation of neuronal structures orientated in these particular directions. In some cases, there is one preferred direction along the length or width axis, and in other cases, there are two preferred directions along both the length and width axes.

3. *Summation of electric impulses*: The induced electric field in the desired deep brain regions is obtained by optimal summation of electric fields, induced by several coil elements with common direction, located in different locations around the skull. The principle of summation may be applied either in time or in space or in a combination of both. The main kinds of summation are listed below:

   (a) *One-point spatial summation*: In this kind of summation coil elements, carrying current in the desired direction, are placed in various locations around the head in such a configuration to create high electric field intensity in a specific deep brain region, which is simultaneously a high percent of the maximal electric field at the brain cortex.

   (b) *Morphological line spatial summation*: The goal of this summation is to induce electric field at several points along a certain neuronal structure. This line should not be straight and may have a complex bent path. The application of diffusion tensor imaging (DTI) in magnetic resonance imaging (MRI) for fiber tracking is an evolving field, which may improve significantly the efficacy of TMS treatment. If, for example, we know the path of a certain axonal bundle, a coil shall be designed in a configuration that will produce significant electric field at several points along the bundle. This configuration may enable induction of an action potential in this bundle, while minimizing the activation of other brain regions. For example, the TMS coil may be activated in an intensity that will induce subthreshold electric field at most brain regions, which will not induce an action potential, while the induction of subthreshold field along the desired path may induce an action potential in this bundle, thus increasing the specificity of the TMS treatment.

   (c) *Temporal summation*: The various coil elements may be stimulated consecutively and not simultaneously. As shown in Figure 37.3, the neuronal activation threshold depends on both electric field intensity and the stimulation duration. The TMS coil may be designed in such configuration that the various elements are scattered around the desired region or path, so that passing a current in each element will produce a significant field at the desired deep brain region. In such a case, the coil may be stimulated consecutively, so that at each time period only a certain element or a group of elements are activated. This way, in the desired deep brain region will be induced a significant electric field at all time periods while in more cortical regions a significant field will be induced mainly at certain periods when proximate coil elements are activated. This will enable stimulation of the deep brain structure while minimizing stimulation of other brain regions and specifically of cortical regions. A detailed study into the neural response to trains with inter-pulse

intervals of milliseconds (instead of hundreds if milliseconds as in rTMS) will aid in refining this technique.

4. *Minimization of radial components*: Coil construction is meant to minimize wire elements carrying current components which are nontangential to the skull. Electrical field intensity in the tissue to be stimulated and the rate of decrease of electrical field as a function of distance from the coil depend on the orientation of the coil elements relative to the tissue surface. It has been shown that coil elements which are nontangential to the surface induce accumulation of surface charge, which leads to cancellation of the perpendicular component of the induced field at all points within the tissue, and reduction of the electrical field in all other directions. At each specific point, the produced electric field is affected by the lengths of the nontangential components, and their distances from this point. Thus, the length of coil elements which are not tangential to the brain tissue surface should be minimized. Furthermore, the nontangential coil elements should be as small as possible and placed as far as possible from the deep region to be activated.

5. *Remote location of return paths*: The wires leading currents in a direction opposite to the preferred direction (the return paths) should be located far from the base and the desired brain region. This enables higher absolute electric field in the desired brain region. In some cases the return paths may be in the air, namely, far from the head. In other cases part of the return paths may be adjacent to a different region in the head which is distant from the desired brain region.

6. *Shielding*: Feature 5 enables the possibility of screening. Since the return paths are far from the main base, it is possible to screen all, or part of their field, by inserting a shield around them or between them and the base. The shield is comprised of a material with high magnetic permeability, capable of inhibiting or diverting a magnetic field, such as mu metal, iron, or steel core. Alternatively the shield is comprised of a metal with high conductivity which can cause electric currents or charge accumulation that may oppose the effect produced by the return portions.

Specific deep TMS coils for stimulating different deep brain regions are described in the next sections.

37.4 A Coil for Stimulation of Deep Brain Regions Related to Mood Disorders: Simulations and Phantom Measurements

Accumulating evidence suggests that the nucleus accumbens plays a major role in mediating reward and motivation [Self and Nestler, 1995; Schultz et al., 1997; Breiter and Rosen, 1999; Ikemoto and Panksepp, 1999; Kalivas and Nakamura, 1999]. Functional MRI and positron emission tomographic studies showed that the nucleus accumbens is activated in cocaine addicts in response to cocaine administration [Lyons et al., 1996; Breiter et al., 1997]. Other brain regions are also associated with reward circuits, such as the ventral tegmental area, amygdala, and medial prefrontal, cingulate, and orbitofrontal cortices [Breiter and Rosen, 1999; Kalivas and Nakamura, 1999]. Moreover, neuronal fibers connecting the medial prefrontal, cingulate, or orbitofrontal cortex with the nucleus accumbens may have an important role in reward and motivation [Jentsch and Taylor, 1999; Volkow and Fowler, 2000]. The nucleus accumbens is also connected to the amygdala and the ventral tegmental area. Therefore, activation of these brain regions may affect neuronal circuits mediating reward and motivation. In rats and monkeys and even in humans, electrical stimulation of the median forebrain bundle is rewarding, and when a stimulating electrode is inserted into various parts of that bundle (including the ventral tegmental area, the median prefrontal cortex and the nucleus accumbens septi), compulsive self-stimulation can be obtained [Milner, 1991; Jacques, 1999]. The new coil (termed the *Hesed coil*) is designed to stimulate effectively deeper brain regions without increasing the electrical field intensity in the superficial cortical regions. Numeric simulations and phantom measurements of the total electrical field produced by the Hesed coil inside a homogeneous spherical volume conductor are presented and compared with results from a circular coil in different orientations and from the double-cone coil. The drop of the electrical field in the brain as a function of the distance from the new coil is much slower compared with previous coils. It is hoped that such a coil can

stimulate deeper regions such as the nucleus accumbens and the fibers connecting the medial prefrontal or cingulate cortex with the nucleus accumbens. Activation of these fibers may induce reward, and chronic treatment may have antidepressant properties or serve as a new strategy against drug addiction.

37.4.1 Methods

37.4.1.1 Numerical Simulations

The simulations were conducted using a Mathematical program [Wolfram, 1999]. The head was modeled as a spherical homogeneous volume conductor with a radius of 7 cm. The induced and electrostatic field at a specific point inside the spherical volume were computed for several coil configurations, using the method presented by Eaton [1992], and the total electric fields in the x, y, and z directions were calculated.

The vector potential A and scalar potential Φ can be expanded in terms of spherical harmonic functions up to N order. After enforcing the boundary conditions at the sphere boundary, the final expressions for the total electric field in the three Cartesian directions are:

$$E_j = E_{Aj} + E_{\Phi j}, \quad j = x, y, z \tag{37.9}$$

where the induced field in each direction is given by:

$$E_{Aj} = -\mu_0 \frac{\partial I}{\partial t} \sum_{l=0}^{N} \sum_{m=-l}^{l} Y_{lm}(\theta, \varphi) C_{lm}^{j}, \quad j = x, y, z \tag{37.10}$$

where $Y_{lm}(\theta, \varphi)$ are spherical harmonic functions, r, θ, and φ are spherical coordinates of the point inside the conductive sphere where the electric field is calculated (see Figure 37.4), and C_{lm}^{j} are jth component of the integration over the coil path:

$$C_{lm}^{j} = \int_{\text{coil}} \frac{Y_{lm}^{*}(\theta', \varphi') \mathrm{d}lj}{(2l+1) r'^{l+1}}, \quad j = x, y, z \tag{37.11}$$

where $*$ means complex conjugate, r', θ', and φ' are spherical coordinates of the coil element (Figure 37.4), and $\mathrm{d}lj$ is the jth component of the differential element of the coil.
FIGURE 37.4 The relation between the spherical coordinate system and the Cartesian coordinate system in which the field components in every point were calculated. R is the radius vector to the point inside the sphere where the field is computed, and r' is the vector to the differential coil element on which the integration is performed.

The electrostatic fields in x, y, and z directions are given by:

$$E_{\Phi x} = -\sin(\theta)\cos(\varphi)\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}lr^{l-1}Y_{lm}(\theta,\varphi)$$

$$+\cos(\varphi)\cos(\varphi)\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}r^{l-1}\tfrac{1}{2}[\exp(i\varphi)\sqrt{((l-m+1)(l+m))}Y_{l,m-1}(\theta,\varphi)$$

$$-\exp(-i\varphi)\sqrt{((l+m+1)(l-m))}Y_{l,m+1}(\theta,\varphi)]$$

$$+\frac{\sin(\varphi)}{\sin(\theta)}\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}r^{l-1}imY_{lm}(\theta,\varphi) \tag{37.12}$$

$$E_{\Phi y} = -\sin(\theta)\sin(\varphi)\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}lr^{l-1}Y_{lm}(\theta,\varphi)$$

$$+\cos(\theta)\sin(\varphi)\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}r^{l-1}\tfrac{1}{2}[\exp(i\varphi)\sqrt{((l-m+1)(l+m))}Y_{l,m-1}(\theta,\varphi)$$

$$-\exp(-i\varphi)\sqrt{((l+m+1)(l-m))}Y_{l,m+1}(\theta,\varphi)]$$

$$+\frac{\cos(\varphi)}{\sin(\theta)}\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}r^{l-1}imY_{lm}(\theta,\varphi) \tag{37.13}$$

$$E_{\Phi z} = -\cos(\theta)\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}lr^{l-1}Y_{lm}(\theta,\varphi)$$

$$-\sin(\theta)\sum_{l=1}^{N+1}\sum_{m=-l}^{l}V_{lm}r^{l-1}\tfrac{1}{2}[\exp(i\varphi)\sqrt{((l-m+1)(l+m))}Y_{l,m-1}(\theta,\varphi)$$

$$-\exp(-i\varphi)\sqrt{((l+m+1)(l-m))}Y_{l,m+1}(\theta,\varphi)] \tag{37.14}$$

where $i = \sqrt{-1}$, and V_{lm} is a complex function of the integrals over coil path C_{lm}^{j}:

$$V_{lm} = -\frac{\mu_0}{l}\frac{\partial I}{\partial t}(\sqrt{[(l+m-1)(l+m)/(2l+1)(2l-1)]}0.5(C_{l-1,m-1}^{y}i - C_{l-1,m-1}^{x})$$

$$+\sqrt{[(l-m-1)(l-m)/(2l+1)(2l-1)]}0.5(C_{l-1,m+1}^{y}i + C_{l-1,m+1}^{x})$$

$$+\sqrt{[(l-m)(l+m)/(2l+1)(2l-1)]}C_{l-1,m}^{z}) \tag{37.15}$$

The simulations were performed using 10th order approximation. The summations in Equation 37.10 to Equation 37.15 were computed up to $N = 10$. The convergence rate depends on the distance from coil elements and on coil configuration, and in general, is faster for more remote points. For the new coil design, the convergence rate was faster than for the circular coil. For points close to the coils (up to 1.5 cm), the induced field was corrected by the exact formula (Equation 37.5). For more remote points the error was less than 1%. In all the calculations, the rate of current change was taken as 10,000 A/100 μsec. The field is given in volts per meter.

37.4.1.2 Measurements of the Electrical Field Induced in a Phantom Brain

The electrical field induced by the new coil and the double-cone coil (Magstim; Whitland, UK) was measured in a saline solution placed in a hollow glass model of the human head ($15 \times 17 \times 20$ cm^3; Cardinal

Industries, Inc., Milwaukee, WI, USA), using a two-wire probe. The distance between the noninsulated edges of the two wires of the probe was 14 mm. Voltage measured divided by the distance between the wire edges gives the induced electrical field figure. Stimulation was delivered using the Magstim Model 200 stimulator at 100% power level. The coils were placed on the glass surface and the electrical field was measured in numerous points within the saline solution.

37.4.2 Results

The simulations revealed that, in general, the presence of accumulating surface charge induced by coil configurations having a radial current component changes the total field in a nontrivial way. The presence of an electrostatic field not only reduces the total field at any point, but also leads to significant reduction in the percentage of the total field in depth, relative to total field at the surface. Moreover, both the total field and the percentage relative to the surface at any specific point depend on its distance from the nontangential coil elements.

The basic concept of the new coil design is to generate summation of the electrical field in depth by inducing electrical fields at different locations around the surface of the head, all of which have a common direction. Such an approach increased the percentage of electrical field induced in depth, relative to the field in the surface regions. In addition, because a radial component had a dramatic effect on the percentage of the electrical field in depth, an effort was made to minimize the overall length of nontangential coil elements, and to locate them as distant as possible from the deep region to be activated. This region simulated the location of the nucleus accumbens. Calculations for several coil configurations were made and the optimal configuration (termed the *Hesed coil*) was compared with standard circular coils and with the double-cone coil. We compare simulation results of field distribution of the Hesed coil design (Figure 37.5), of a double-cone coil, and of a circular coil oriented perpendicular (Figure 37.6[a]) and parallel (Figure 37.6b) to the head. Figure 37.5 shows the coil design when applied on the human head. The coil contains several strips (26 in the example of Figure 37.5) attached to the head, all connected serially, and having wires that induce stimulation in the desired direction. This desired direction is the anteroposterior direction in the example shown in Figure 37.5 (z direction). For each strip there is a return path wire having current component at the opposite direction (z direction), located 5 cm above the head. These return paths are located at the top edges of four fans to remove the currents flowing through them away from the deep regions of the head. The specific design of the fans is meant to reduce the inductance of the coil. The fans are connected to the frame near strips 7, 9, 18, and 20 (see Figure 37.5). These loci were chosen to remove the return paths as much as possible from the deep brain region to be activated most effectively. The only wires with currents that have radial components are those connecting the strips that are attached to the head with their return paths, along the sides of the fans. An optimized coil would have a flexible frame allowing all elements of the coil that are touching the head to be tangential to the head surface (see Figure 37.5).

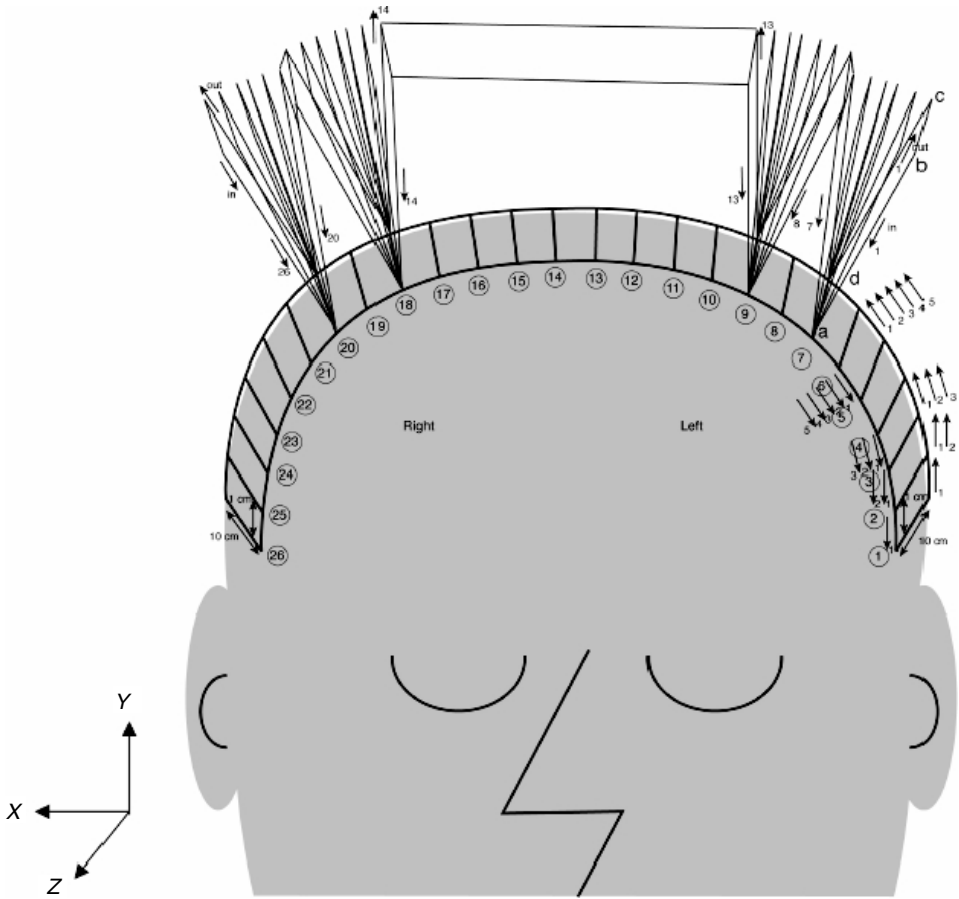
In the calculations of the field produced by the Hesed coil design, we assumed that the only coil elements carrying current components that are not tangential to the surface are the wires connecting the return paths with the strips that are attached to the head (along the fans). This is a plausible assumption in the realistic case, where the coil is attached to the skull. In the human head, the cerebral spinal fluid is approximately parallel to the skull everywhere and it can be assumed that the conductive properties of the cerebral spinal fluid are similar to those of the brain. The electrostatic field resulting from the contribution of the nontangential elements was calculated for each point and subtracted from the induced field of the coil. To obtain maximal efficacy, given the limitations of the stimulator and the need for a specific range of the coil inductance (15 to 25 μH), the average lengths of the strips were taken as 8 cm. The simulations were made for strips of length of 9 cm over one hemisphere and of 7 cm over the other (to obtain a slight preference for one hemisphere stimulation and to have the opportunity to reach stimulation threshold in one hemisphere only). The wires connecting the head strips to their return paths (the nontangential elements) were taken as 5 cm long. The locations of the strips were determined to fit the human head, as in Figure 37.5. Hence, the distances of strips 13 and 14 from the sphere center were taken as approximately


FIGURE 37.5 The Hesed coil shape when applied over the human head. The same coil can be placed around the forehead to stimulate nerve fibers in the superoinferior direction. The only elements that produce an electrical field in the z-direction are the 26 strips attached to the head (numbered 1 to 26), where the current is in the $+z$ direction, and the 26 return paths at the edges of the fans where the current is in the $-z$ direction.

6 cm; strips 3 and 24 were located approximately 7 cm from the sphere center. For the orientation shown in Figure 37.5, the maximal total field in the anteroposterior direction (z direction) was produced at the cortex near the center of strips 1 and 26 at the sides. The field at the top of the head was reduced considerably because of the influence of the return paths and of the nontangential wires along the sides of the fans.

Figure 37.7 shows the induced (Figure 37.7a) and total (Figure 37.7b) field in the z-direction (Ez, defined in Figure 37.6) of a one-turn 5.5-cm-diameter circular coil placed perpendicular and parallel to a 7-cm-radius spherical volume conductor, as a function of distance from the coil edge. The fields were calculated along the line connecting the sphere center to the coil point closest to the surface (line o–p in Figure 37.6). It is clear that the reduction in total field resulting from charge accumulation is much larger when the coil is oriented perpendicular to surface (Figure 37.7). In addition, a comparison was made with the induced and total fields of one winding from the new Hesed coil, including strip 1 with its connection to the return path and its return path itself (and taking strips length of 5.5 cm). The simulations show that although the induced field of the strip is slightly larger than that of a circular coil with similar dimensions (see Figure 37.7), the difference in the total field is much larger (see Figure 37.7). This results from the fact that the field reduction due to electrostatic charge accumulation in the case of the winding of strip 1 is very small, because the only elements carrying radial current components are the wires along paths
FIGURE 37.6 (a) A circular coil with diameter D placed perpendicular to the head surface. The head is modeled as a sphere with a radius $R = 7$ cm. The coil has current component in the y-direction, which is perpendicular to the head, and a component in the z-direction, which is completely parallel to the head surface only at the attachment point p. (b) A circular coil with diameter D placed tangential to the head surface. The coil has current components in the x- and z-directions, which are completely parallel to the head surface only at the attachment point p.

a–b and c–d (see Figure 37.5), which are a relatively small fraction of the winding length, and are distant from the points under consideration. The induced and total field in z-direction (Ez) resulting from the entire Hesed coil compared with the double-cone coil is shown in Figure 37.8. The field of the Hesed coil is computed along the line from strip 26 (where it is maximal) to the sphere center. The field of the double-cone coil is computed along the line from the junction at the coil center (where it is maximal) to the sphere center. Although the double-cone coil produces a much larger-induced field than the Hesed coil (see Figure 37.8a), the rate of decay of the effective total field with distance is much smaller for the Hesed coil (see Figure 37.8b). Hence, at depth of 6 cm, the total electrical field of the Hesed coil is already a little larger than that of the double-cone coil (see Figure 37.8b).

Figure 37.9 shows the z-component of the electrical field as a function of distance, relative to the field at a distance of 1 cm, for the Hesed coil, a double-cone coil with 14-cm diameter for each wing, and the 5.5-cm-diameter circular coil oriented tangential and perpendicular to the head surface. The field produced by the Hesed coil at a depth of 6 cm is approximately 35% of the field at a depth of 1 cm near the middle of strip 26 (where the field induced by the Hesed coil is highest throughout the brain). The field produced by the double-cone coil at a depth of 6 cm is only about 8% of the field 1 cm from the coil. The field produced by the 5.5-cm-diameter circular coil at this depth is less than 2% of the field 1 cm from the coil. For a larger circular coil, the percentage of field in depth is somewhat higher, but still smaller than that of the double-cone coil (data not shown).

Actual measurements of the electrical fields in a phantom brain using the first manufactured version of the Hesed coil and a double-cone coil basically confirmed our theoretical calculations. Both coils produced slightly lower fields at any point in the phantom brain compared with the theoretical calculations. However, this was more evident in the case of the Hesed coil, and the percentage of field in depth relative to the surface was slightly lower compared with our calculations. The results for the total field and the percentage in depth are presented in Figure 37.10.

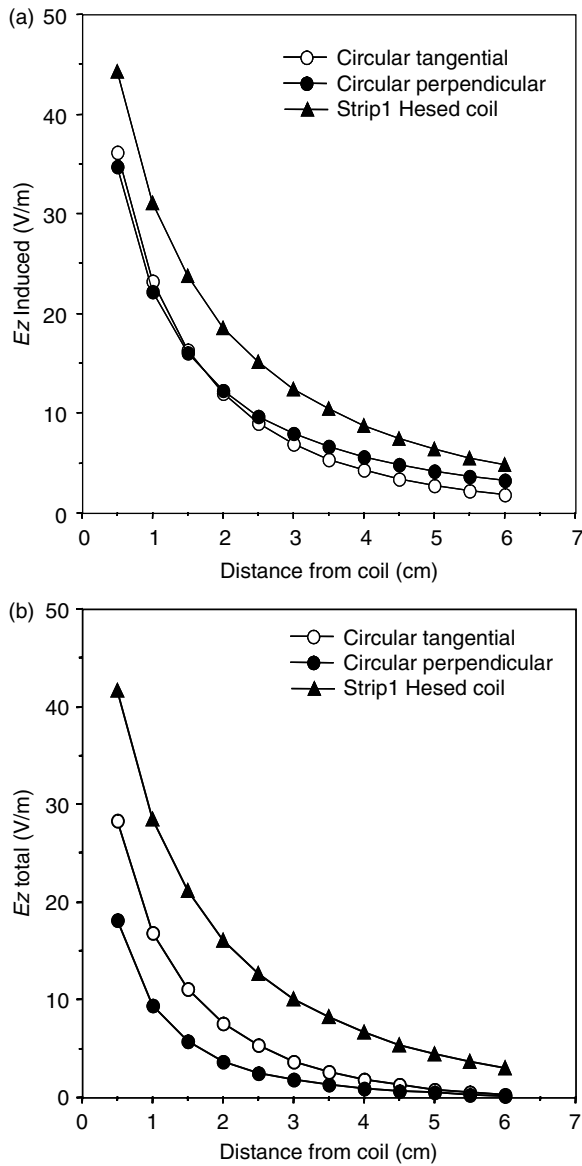
It is clear that the total field induced by the double-cone coil, using the maximal output of the stimulator (10,000 A/100 μsec) produces a markedly greater electrical field up to 6-cm depth, compared with the


FIGURE 37.7 (a,b) Induced (a) and total (b) electrical field in the z-direction plotted as a function of distance from a one-turn circular coil of 5.5-cm diameter placed tangential or perpendicular to the head surface. In addition the induced and total fields of the winding of the Hesed coil connected to strip 1 (see Figure 37.2) is shown for the case of strip length of 5.5 cm.

Hesed coil (see Figure 37.10a), but the percentage in depth is markedly greater when the Hesed coil is used (see Figure 37.10b).

37.5 Transcranial Magnetic Stimulation of Deep Brain Regions: Evidence for Efficacy of the H-Coil

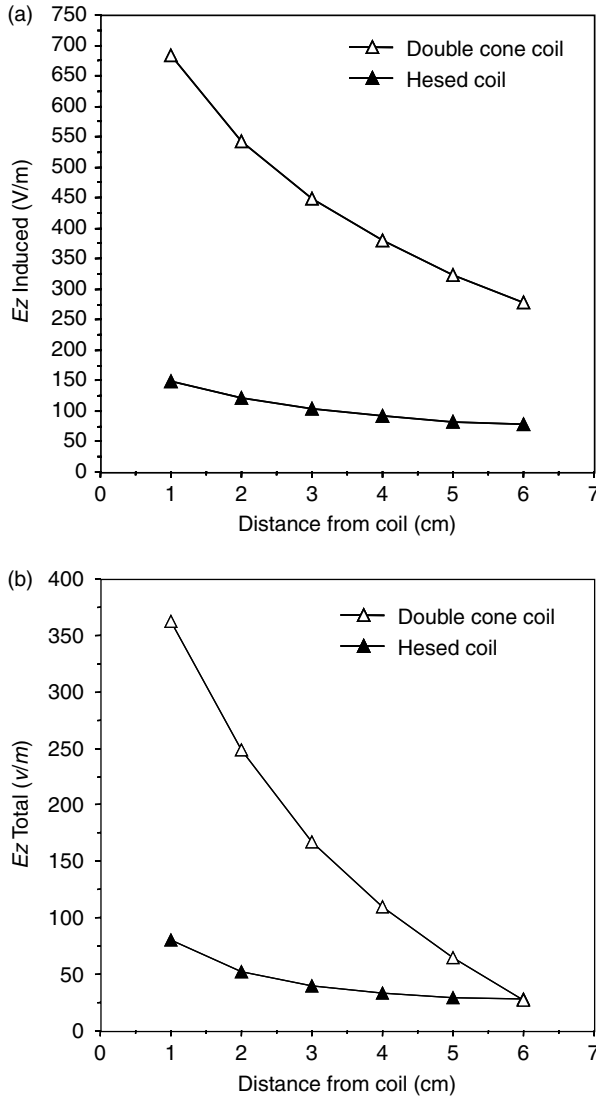
The biological efficacy of the H-coil was tested [Zangen et al., 2005] using the motor threshold as a measure of a biological effect. The rate of decrease of the electric field as a function of distance from the


FIGURE 37.8   (a,b) Induced (a) and total (b) electrical field in the *z*-direction plotted as a function of distance for the double-cone coil and the Hesed coil. The electrical fields were calculated for a six-turn double-cone coil with a diameter of 14 cm for each wing, an opening angle of 95°, and a central linear section of 3 cm, and for the Hesed coil with strip lengths of 9 cm over the right hemisphere and 7 cm over the left hemisphere. The field of the Hesed coil is computed along the line from strip 26 (where *Ez* is maximal) to the sphere center. The field of the double-cone coil is computed along the line from the central linear section (where *Ez* is maximal) to the sphere center.

coil was measured by gradually increasing the distance of the coil from the skull and measuring the motor threshold at each distance. A comparison was made to the figure-8 coil.

37.5.1 Methods

37.5.1.1 Subject

Six healthy, right-handed volunteers (4 men and 2 women, mean age 36 yr, range 25 to 45 yr) gave written informed consent for the study, which was approved by the National Institute of Neurological Disorders
FIGURE 37.9 Electrical field in the z-direction relative to the field 1 cm from the coil as a function of distance. Data are presented for the Hesed coil, the double-cone coil, and the 5.5-cm-diameter circular coil oriented tangential and perpendicular to the head surface. The total electrical field in each point along the line from the point of maximal Ez to the sphere center was divided by the Ez value calculated at a 1-cm distance.

and Stroke Institutional Review Board. Subjects were interviewed and examined by a neurologist and found to be free of any significant medical illness or medications known to affect the CNS.

37.5.2 TMS Coils

The TMS coils used in this study were a specific version of the H-coil and a figure-of-eight coil. The H-coil version used in this study allows a comfortable placement above the hand motor cortex. The theoretical considerations and design principles of the H-coils are explained in our previous study [Roth et al., 2002]. In short, the coil is designed to generate summation of the electric field in a specific brain region by locating coil elements at different locations around this region, all of which have a common current component which induce electric field in the desired direction (termed $+z$ direction). In addition, since a radial component has a dramatic effect on electric field magnitude and on the rate of decay of the electric field with distance, the overall length of coil elements which are nontangential to the skull should be minimized, and these elements as well as coil elements having current component in the opposite direction ($-z$ direction) should be located as distant as possible from the brain region to be activated.

The H-coil version used in the present study is shown in Figure 37.11. The coil has 10 strips carrying a current in a common direction ($+z$ direction) and located around the desired motor cortex site (segments A–B and G–H in Figure 37.11). The average length of the strips is 11 cm. The only coil elements having radial current components are those connected to the return paths of five of the strips (segments C–I and J–F in Figure 37.1). The length of these wires is 8 cm. The return paths of the other five strips are placed on the head at the contralateral hemisphere (segment D–E in Figure 37.11). The wires connecting between the strips and the return paths (segments B–C and F–A in Figure 37.11) are on average 9-cm long. The H-coil was compared to a standard commercial Magstim figure-of-eight coil with internal loop diameters of 7 cm.

37.5.2.1 Experimental Setup

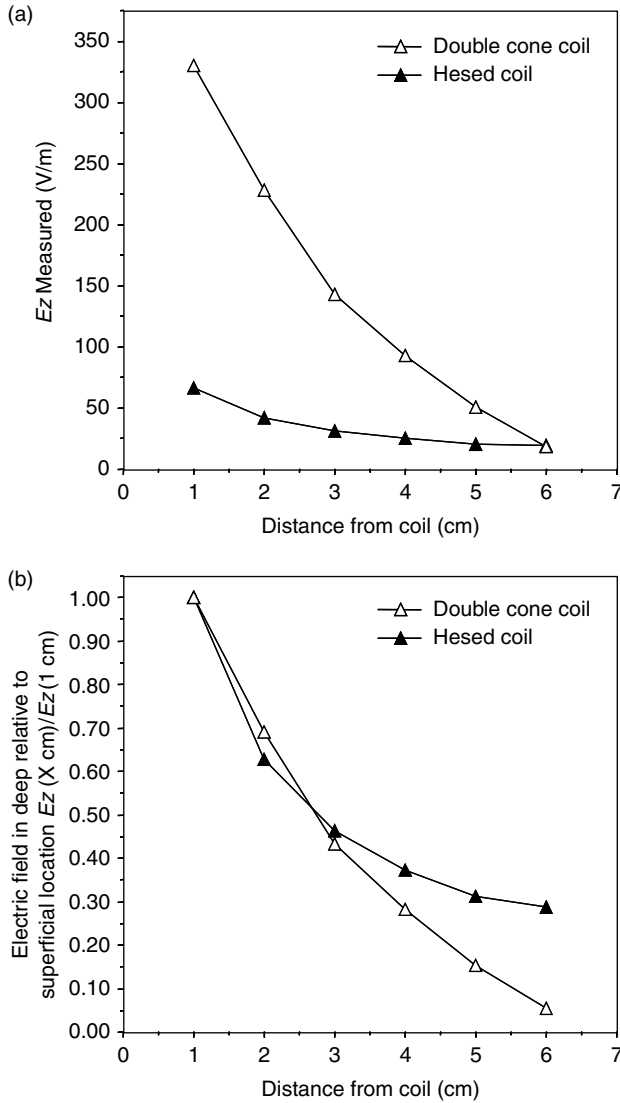
Subjects were seated with the right forearm and hand supported. Motor evoked potentials (MEPs) of the right APB muscle were recorded using silver–silver chloride surface electrodes. Subjects were instructed to maintain muscle relaxation throughout the study. Electromyogram (EMG) amplitude was amplified using a conventional EMG machine (Counterpoint, Dantec Electronics, Skovlunde, Denmark) with band-pass


FIGURE 37.10 Measurements of the electrical field induced by the Hesed coil and the double-cone coil in a phantom brain. (a,b) The electrical field induced in the z-direction (a) and the electrical field in the z-direction *relative* to the field 1 cm from the coil (b) is plotted as a function of distance from the coil. For both coils, the data show the measurements along the line from the point where maximal Ez value is obtained (as described earlier) to the sphere center.

between 10 and 2,000 Hz. The signal was digitized at a frequency of 5 kHz and fed into a laboratory computer.

A magstim super rapid stimulator (The Magstim Company New York, NY), which produces a biphasic pulse, coupled with either the figure-8 coil or the H-coil, was used. Preliminary studies showed the H-coil to have a loudness when activated of 122 dB, similar to other coils used in our laboratory. As a standard laboratory practice, subjects were fitted with foam ear plugs to attenuate the sound.

The coil was placed on the scalp over the left motor cortex. The intersection of the figure-8 coil was placed tangentially to the scalp with the handle pointing backward and laterally at a 45° angle away from the midline. Thus the current induced in the neural tissue was directed approximately perpendicular to the line of the central sulcus and therefore optimal for activating the corticospinal pathways transsynaptically [Brasil-Neto et al. 1992; Kaneko et al. 1996]. Similarly, the H-coil was placed on the scalp with the handle
FIGURE 37.11   Sketch of the H-coil version used in this study placed on a human head. The coil orientation shown in the figure is designated for optimal stimulation of the left abductor pollicis brevis (APB) (indicated by a black spot).

pointing backward in such a way that the center of the strips cover the motor cortex and in such a direction that the current induced in the neural tissue would be perpendicular to the line of the central sulcus. With a slightly suprathreshold stimulus intensity, the stimulating coil was moved over the left hemisphere to determine the optimal position for eliciting MEPs of maximal amplitudes (the "hot spot"). The optimal position of the coil was then marked on the scalp to ensure coil placement throughout the experiment. Resting motor threshold was determined to the nearest 1% of the maximum stimulator output and was defined as the minimal stimulus intensity required to produce MEPs of >50 μV in document ≥ 5 of 10 consecutive trials at least 5 sec apart.

The coils were held in a stable coil holder, which could be adjusted at different heights above the "hot spot" on the scalp. The resting motor threshold was determined at different distances above the scalp, using increments of 0.5 cm.

37.5.2.2   Safety Measurements

Since the H-coil was not used in previous clinical TMS studies, we asked the subjects to report any side effects including pain, anxiety, or dizziness and we performed cognitive and hearing tests before and after the TMS session. For the cognitive testing we used the CalCap computer program to test immediate and delayed memory as described previously [Wassermann et al., 1996].

37.5.3   Results

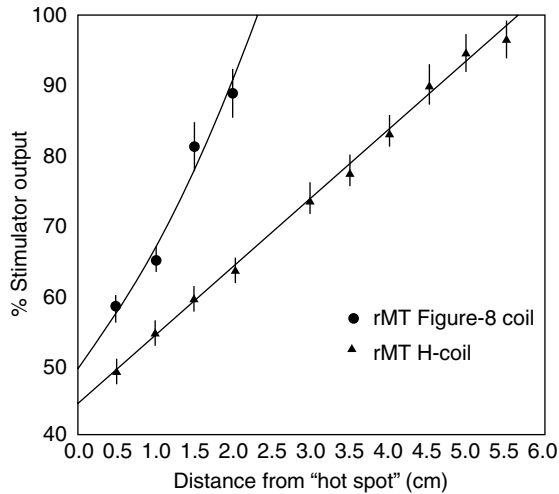
None of the six subjects who participated in the study reported any significant side effects after the TMS session. We did not find any change in cognitive or hearing abilities in these six subjects. A slight and short-lasting headache was reported by one out of the six subjects. In a different experiment done subsequently, not reported in this book, we used the H-coil to deliver single or paired pulses at 1 Hz during 20 sec over five different locations on the scalp in three additional subjects. The third of these subjects experienced some hearing loss in his left ear, a 30-dB loss at 4000 Hz which has been stable for 10 months and appears permanent. The ear protection had fallen out transiently during the study.


FIGURE 37.12 Intensity needed for APB stimulation at different heights above the scalp. Resting motor threshold of the APB was measured at different distances above the "hot spot" when using either the H-coil or the figure-8 coil. The percentage of stimulator power needed to reach the resting motor threshold vs. the distance of the coil from the "hot spot" on the skull is plotted. The points represent means and SDs of six healthy volunteers.

The percentage of stimulator output required for APB activation by each coil is plotted in Figure 37.12 as a function of distance from the "hot spot" on the scalp. It can be seen that the efficacy of the H-coil at large distances from the scalp was significantly greater as compared to the figure-8 coil. When using the maximal stimulation power output, the figure-8 coil can be effective (reach stimulation threshold) up to 2 cm away from the coil, while the H-coil can be effective at 5.5 cm away from the coil. Moreover, the rate of decay of effectiveness as a function of the distance from the coil is much slower in the H-coil relative to the figure-8 coil (Figure 37.12).

37.5.4 Discussion

The findings confirm our theoretical calculations and phantom brain measurements [Roth et al., 2002] indicating the ability of the H-coil to stimulate brain structures at a large distance from the coil. The comparison between the TMS coils demonstrated a significantly improved depth penetration, and a much slower rate of decay of effectiveness as a function of the distance from the coil, when using the H-coil relative to the regular figure-8 coil. This indicates that when stimulating deep brain regions by using the H-coil, the cortical stimulation is not much higher for the same activation in depth.

The H-coil produces a summation of the electric field from several coil elements carrying current in the same direction. In contrast, the electric field of the figure-8 coil is produced by a concentrated region in the center of the coil. In addition, the relative fraction of the figure-8 field that is produced by coil elements which are nontangential to skull surface is much larger then in the H-coil. These two reasons lead to the fact that although the figure 8 field is more focal, it has more significant reduction both in absolute field magnitude at any point and in the percentage of the deep region field relative to field at the surface.

According to our calculations and phantom brain measurements [Roth et al., 2002], the field induced in cortical regions by the H-coil is much lower than that of the double-cone coil. Therefore, it is likely that excitation threshold can be reached at 4 to 6 cm using the H-coil without inducing pain and other side effects.

It should be emphasized that although the structure stimulated in this study was in the motor cortex, and the medium between the coils and the "hot spot" was mainly air, the rate of decay within the brain itself should be very similar. This is a delicate point that should be elaborated. The electric conductivity

of the brain is much greater then that of air. In conductive materials such as the brain, radial current components of the coil would lead to charge accumulation on the surface of the brain, which would cause a decrease of the field in any point inside the brain. Hence, the rate of decay of electric field with distance would be faster in the brain then that measured in air. Nevertheless, the field distribution inside the brain is *independent* of the location of the interface between the conductive and insulating media [Branston and Tofts 1990; Tofts 1990; Eaton 1992]. As a result, the rate of decay within the brain when attaching the coil to the skull would be similar to that measured in this study, where the coil was raised above the skull. Small changes are expected due to the fact that coil configuration relative to the skull is somewhat different when it is raised. The H-coil is designed to minimize radial current components when attached to the scalp; hence the amount of radial components may be slightly different and probably larger when the H-coil is raised above the scalp. Therefore, the advantage of the H-coil as compared to the figure-8 coil, in terms of the rate of decay of the field as a function of distance, may be even greater when the coils are attached to the scalp.

Although the H-coil has a remarkable ability to penetrate into deeper brain regions, due to the slower decay of the electric field as a function of distance, none of the subjects in the present study reported any side effects and cognitive or hearing abilities were not affected. Nevertheless, it should be emphasized that subjects in the present study experienced only 20 to 30 single pulses at intensities greater then those needed for minimal APB activation (when looking for the hot spot for APB activation) and that the rest of the pulses were given just at the minimal level for APB activation when the coil was placed either on the scalp or at different heights above the scalp. Future studies will address the safety and efficacy of the H-coil when used in higher doses. As we have reported, one subject has experienced some hearing loss in a subsequent experiment. Our past safety studies have not demonstrated that hearing loss is to be expected [Pascual-Leone et al., 1992]. As the loudness of the H-coil does not appear different from other coils, this result may be due in part to particularly sensitive hearing in this subject and lapse in the hearing protection. However, as we did caution before, the event does emphasize need in all TMS studies to take care to protect hearing.

37.6 Transcranial Magnetic Stimulation of Deep Prefrontal Regions

Medial prefrontal and orbitofrontal regions are known to be associated with reward circuits. The H1 and H2 coils are designed to stimulated deep prefrontal structures, with minimal undesired side effects such as pain, motor stimulation, and facial muscles activation. The coils are wounded with a double 14 AWG (American Wire Gauge) insulated cupper wire winded into several windings, connected in series. Detailed illustration of the wiring pattern of H1 is shown in Figure 37.13, and of H2 is shown in Figure 37.14.

The effective part of the H1 coil in contact with the patient scalp has a shape of half a donut, with 14 strips of 7–12-cm length (Figure 37.13). These strips produce the most effective field of the coil, and are oriented in an anterior–posterior axis. The 14 strips are distributed above the prefrontal cortex of the left hemisphere, with a separation of 1 cm between them. Three strips (8–10 in Figure 37.13) are elongated toward the forehead, and their continuations pass in the left–right direction along the orbitofrontal cortex (segments I–J 8–10 in Figure 37.13), with a separation of 1 cm between them. The return paths of strips 1–7 are attached to the head in the right hemisphere (segments D–E 1–7 in Figure 37.13), with a separation of 0.8 cm between them. The return paths of strips 8–14 are remote 7 cm from the head (segments M–G 8–14 in Figure 37.13), with a separation of 0.3 cm between them.

The frame of the inner rim of the half donut is flexible in order to fit the variability in human skull shape.

The paths of the 14 windings of the H1 coil are shown in Figure 37.13. The windings of strips 1–7 traverse the path A–B–C–D–E–F–G–H–A. The winding of strips 8–10 traverse the path A–I–J–K–L–M–G–H–A. The windings of strip 11–14 traverse the path A–N–L–M–G–H–A.

H1-Coil Specifications

Number of Windings	14 wire loops, including strips and return paths
Strips length	Strips 1–7, 11–14: 7 cm
	Strips 8–10: 10–12 cm
Main induced field direction	Anterior–posterior axis
Strips separation	1 cm (typical)
Connecting cable	2 ± 0.5 m
Coil inductance (including cable)	$30 \pm 1 \,\mu$H
Max. magnetic field strength	3.2 T
Max. electric field strength 0.5 cm from coil	200 V/m
Wire size (circular section copper)	Two 14 AWG Insulated Wires in Parallel
Wire length	750 cm

Figure 37.14 shows a diagram of the H2 coil, which is designed to stimulate deep brain regions and fit the human head. The effective part of the coil in contact with the patient scalp has a shape of half a donut, with 10 strips of 14–22 cm length (Figure 37.14). These strips produce the most effective field of the coil, and are oriented in a right–left direction (lateral–medial axis). Three strips pass in front of the forehead along the orbitofrontal cortex (1–3 in Figure 37.14), with a separation of 1 cm between them. Seven strips pass above the forehead along the prefrontal cortex (4–10 in Figure 37.14), with 0.8-cm separation.

The paths of the ten windings are shown in Figure 37.3. The windings of strips 1–3 traverse the path A–B–C–D–E–F–G–H–I–J–Q–R–S–T–K–L–A. The winding of strip four traverses the path A–B–G–H–I–J–Q–R–S–T–K–L–A. The winding of strip five traverses the path A–M–N–B–G–O–P–H–I–J–Q–R–S–T–K–L–A. The windings of strips 6–7 traverse the path A–M–N–B–G–O–P–H–I–J–K–L–A. The windings of strips 8–9 traverse the path A–B–G–H–I–J–K–L–A. The winding of strip ten traverses the path A–H–I–J–K–L–A.

H2-Coil Specifications

Number of windings	10 wire loops, including strips and return paths
Strips length	14–22 cm
Main induced field direction	Lateral–medial axis
Strips separation	0.8 cm (typical)
Connecting cable	2 ± 0.5 m
Coil inductance (including cable)	$25 \pm 1 \,\mu$H
Max. magnetic field strength	3.0 T
Max. electric field strength 0.5 cm from coil	190 V/m
Wire size (circular section copper)	Two 14 AWG insulated wires in parallel
Wire length	800 cm

37.6.1 Comparison of Electric Field Distributions

The electric field distribution produced by H1 and H2 coils, were measured in a brain phantom with general dimensions of $23 \times 19 \times 15$ cm^3, which was filled with 0.9% weight/volume saline. In order to determine output of the coil at depth, the induced electric field was measured using a two-wire probe. The distance between the ends of the two-wire of the probe was measured to be 12.7 ± 0.2 mm. Voltage measured divided by the distance between the wires gives the induced electric field value. The two coils were compared to a standard Magstim Figure-8 coil with internal loop diameter of 7 cm, and a Magstim double-cone coil. The double-cone coil is considered to be able to stimulate deeper brain regions compared to other coils [Terao et al., 1994, 2000; Stokic et al., 1997].

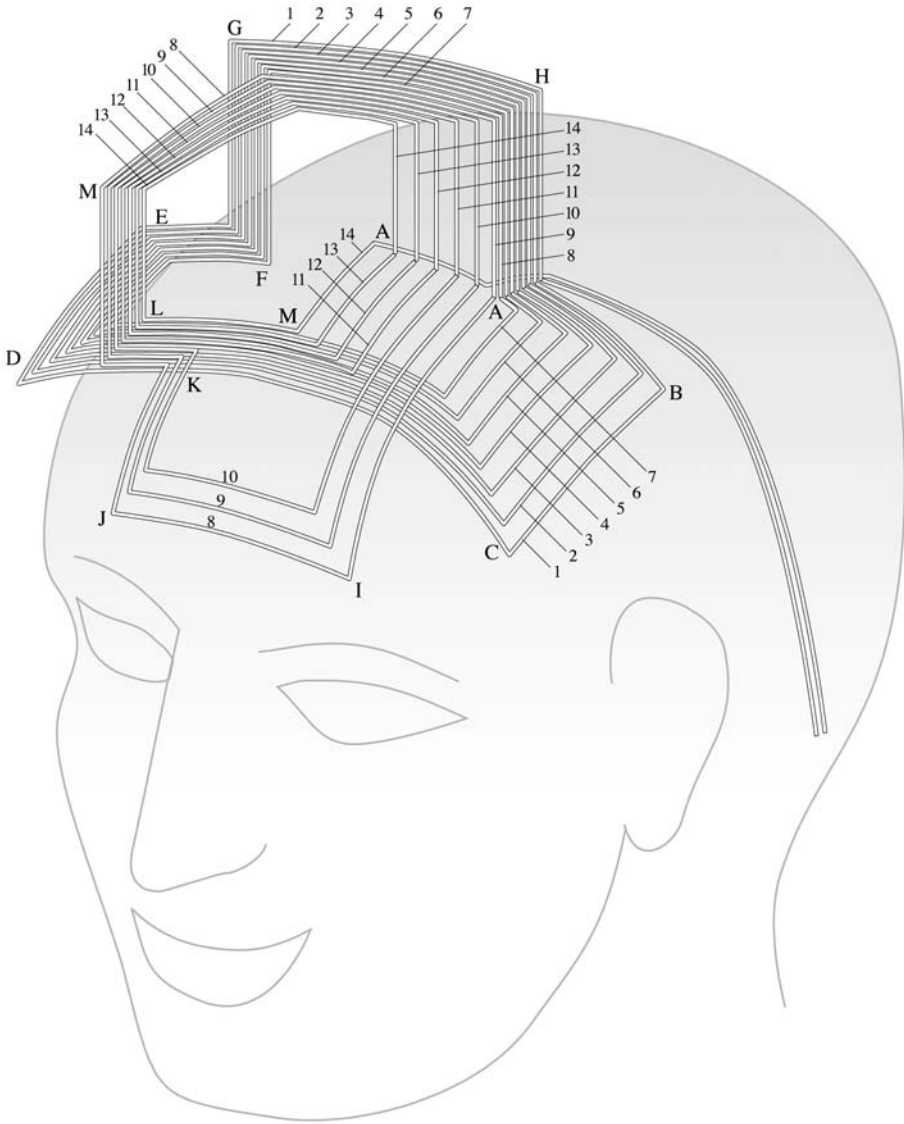
The depth penetration of the coils was tested by measuring the electric field along the up–down line (Z-axis) beneath the center of the most effective part of the coil, at 100% output of Magstim Rapid stimulator. In H1 the most effective part was under strip 8 (under third of A–I 8 segment in Figure 37.13 above), where the probe is oriented in an anterior–posterior direction (Y-axis). In H2 the most effective


FIGURE 37.13 Sketch of the H1 coil near a human head. The coil orientation shown in the figure is designated for activation of structures in the prefrontal cortex, in the anterior–posterior direction.

part was the center of strip 5 (center of C–F 5 segment in Figure 37.14 above), where the probe is oriented in a lateral–medial direction (X-axis). In the double cone coil and the figure-8 coil, the most effective part was the junction at coil center, where the probe is oriented in an anterior–posterior direction (Y-axis). Plots of total electric field as a function of distance are shown in Figure 37.15.

Figure 37.16 shows the electric field as a function of distance, relative to the field at a distance of 1 cm, for the four coils.

It can be seen that the total electric field induced by the double-cone coil, and by the figure-8 coil, using the maximal output of the stimulator, is markedly greater than the field produced by the H1 and H2 at short distances of 1 to 2 cm. Yet, at distances of above 5 cm the fields of the H1 and H2 coils become greater, due to their much slower rate of decay. From Figure 37.16 it can be seen that the percentage in depth for the H coils is greater then the two other coils already at 2 cm distance, and this advantage of the
FIGURE 37.14 Sketch of the H2-coil near a human head. The coil orientation shown in the figure is designated for activation of structures in the prefrontal cortex, in the lateral–medial direction.

H coils becomes more prominent with increasing distance. Comparing between the two H coils it can be seen that H1 produces slightly smaller absolute field magnitude, but larger percentage in depth, relative to H2. The fields produced by the H1 and H2 at 6-cm depth are about 63 and 57% of the field 1 cm from the coil, respectively, while the fields of the double-cone coil and the figure-8 coil attenuate to 8 to 10% at this distance.

Stimulation of brain structures at 3–4 cm depth with the double-cone coil is painful since a much higher field is induced at superficial cortical areas and at the facial muscles. In order to reach stimulation
FIGURE 37.15 Phantom measurements of the electric field in the *z*-direction (up–down direction), plotted as a function of distance, for H1 and H2 coils, the double-cone coil, and the figure-8 coil.
FIGURE 37.16 Electric field relative to the field 1 cm from coil, as a function of distance, for the H1 and H2 coils, the double-cone coil, and the figure-8 coil, according to the phantom brain measurements.

threshold at 5–8-cm depth, a much higher intensity would be needed which would increase pain and the risk for other side effects such as convulsions. The total field induced by the H1 and H2 coils, even at maximal power output, will be three to four times lower than the double cone in cortical regions. The H1 and H2 fields at 5–6-cm depth are not much smaller than their fields in the cortex and greater than the double-cone coil field at that depth. Therefore, it is likely that excitation threshold can be reached at 6–7 cm using the H coils, without the induction of pain and other side effects. The percentage of the electric field in depth produced by the standard figure-8 coils is similar to the double-cone coil, but the absolute field magnitude is much smaller. Therefore the figure-8 coil would not only cause greater side effects, but could not reach stimulation threshold in depth, even at maximal power output.

Boston University

V.1   A Brief Note Regarding This Edition

Due to unforeseen circumstances, the bulk of this section is largely identical to the previous edition with the notable exception of the addition of a chapter relating to micro- and nanotechnologies in advanced **biomaterials**. The content remains current, and the following introduction is taken from the previous edition with minor changes describing the content of this Section. In addition, a number of relevant biomaterials journals have been added to the list.

Biomaterial is used to make devices to replace a part or a function of the body in a safe, reliable, economic, and physiologically acceptable manner [Hench and Erthridge, 1982]. A variety of devices and materials are used in the treatment of disease or injury. Commonplace examples include sutures, needles, catheters, plates, tooth fillings, etc. A biomaterial is a synthetic material used to replace part of a living system or to function in intimate contact with living tissue. The Clemson University Advisory Board for Biomaterials has formally defined a biomaterial to be "a systemically and pharmacologically inert substance designed for implantation within or incorporation with living systems." Black defined biomaterials as "a nonviable material used in a medical device, intended to interact with biological systems" [Black, 1992]. Others include "materials of synthetic as well as of natural origin in contact with tissue, blood, and biological fluids, and intended for use for prosthetic, diagnostic, therapeutic, and storage applications without adversely affecting the living organism and its components" [Bruck, 1980]. Still another definition of biomaterials is stated as "any substance (other than drugs) or combination of substances, synthetic or natural in origin, which can be used for any period of time, as a whole or as a part of a system which treats, augments, or replaces any tissue, organ, or function of the body" [Williams, 1987] and adds to the many ways of looking the same but expressing in different ways. By contrast, a **biological material** is a material such as skin or artery, produced by a biological system. Artificial materials that simply are in contact with the skin, such as hearing aids and wearable artificial limbs are not included in our definition of biomaterials since the skin acts as a barrier with the external world.

According to these definitions, one must have a vast field of knowledge or collaborate with different specialties in order to develop and use biomaterials in medicine and dentistry as Table V.1 indicates. The uses of biomaterials, as indicated in Table V.2, include replacement of a body part which has lost function due to disease or trauma, to assist in healing, to improve function, and to correct abnormalities. The role of biomaterials has been influenced considerably by advances in many areas of biotechnology and science. For example, with the advent of antibiotics, infectious disease is less of a threat than in former times so that degenerative disease assumes a greater importance. Moreover, advances in surgical technique and instruments have permitted materials to be used in ways which were not possible previously. This section of the handbook is intended to develop in the reader a familiarity with the uses of materials in medicine and dentistry and with some rational basis for these applications.

The performance of materials in the body can be classified in many ways. First, biomaterials may be considered from the point of view of the problem area which is to be solved, as in Table V.2. Second,

TABLE V.1   Fields of Knowledge to Develop Biomaterials

Discipline	Examples
Science and engineering	Materials sciences: structure–property relationship of synthetic and biological materials including metals, ceramics, polymers, composites, tissues (blood and connective tissues), etc.
Biology and physiology	Cell and molecular biology, anatomy, animal and human physiology, histopathology, experimental surgery, immunology, etc.
Clinical sciences	All the clinical specialties: dentistry, maxillofacial, neurosurgery, obstetrics and gynecology, ophthalmology, orthopedics, otolaryngology, plastic and reconstructive surgery, thoracic and cardiovascular surgery, veterinary medicine, and surgery, etc.

TABLE V.2   Uses of Biomaterials

Problem area	Examples
Replacement of diseased or damaged part	Artificial hip joint, kidney dialysis machine
Assist in healing	Sutures, bone plates, and screws
Improve function	Cardiac pacemaker, intraocular lens
Correct functional abnormality	Cardiac pacemaker
Correct cosmetic problem	Augmentation mammoplasty, chin augmentation
Aid to diagnosis	Probes and catheters
Aid to treatment	Catheters, drains

TABLE V.3   Biomaterials in Organs

Organ	Examples
Heart	Cardiac pacemaker, artificial heart valve, total artificial heart
Lung	Oxygenator machine
Eye	Contact lens, intraocular lens
Ear	Artificial stapes, cochlea implant
Bone	Bone plate, intramedullary rod
Kidney	Kidney dialysis machine
Bladder	Catheter and stent

TABLE V.4   Biomaterials in Body Systems

System	Examples
Skeletal	Bone plate, total joint replacements
Muscular	Sutures, muscle stimulator
Circulatory	Artificial heart valves, blood vessels
Respiratory	Oxygenator machine
Integumentary	Sutures, burn dressings, artificial skin
Urinary	Catheters, stent, kidney dialysis machine
Nervous	Hydrocephalus drain, cardiac pacemaker, nerve stimulator
Endocrine	Microencapsulated pancreatic islet cells
Reproductive	Augmentation mammoplasty, other cosmetic replacements

we may consider the body on a tissue level, an organ level (Table V.3), or a system level (Table V.4). Third, we may consider the classification of materials as polymers, metals, ceramics, and composites as is done in Table V.5. In that vein, the role of such materials as biomaterials is governed by the interaction between the material and the body; specifically, the effect of the body environment on the material and the effect of the material on the body [Williams and Roaf, 1973; Bruck, 1980; Hench and Erthridge, 1982; von Recum, 1986; Black, 1992; Park and Lakes, 1992; and Greco, 1994].

It should be evident from any of these perspectives that most current applications of biomaterials involve structural functions, even in those organs and systems which are not primarily structural in their nature, or very simple chemical or electrical functions. Complex chemical functions such as those of the liver and complex electrical or electrochemical functions such as those of the brain and sense organs cannot be carried out by biomaterials at this time.

V.2   Historical Background

The use of biomaterials did not become practical until the advent of an aseptic surgical technique developed by Dr. J. Lister in the 1860s. Earlier surgical procedures, whether they involved biomaterials or not, were generally unsuccessful as a result of infection. Problems of infection tend to be exacerbated in the

TABLE V.5   Materials for Use in the Body

Materials	Advantages	Disadvantages	Examples
Polymers (nylon, silicone rubber, polyester, polytetrafuoroethylene, etc.)	Resilient Easy to fabricate	Not strong Deforms with time May degrade	Sutures, blood vessels, hip socket, ear, nose, other soft tissues, sutures
Metals (Ti and its alloys, Co–Cr alloys, stainless steels, Au, Ag, Pt, etc.)	Strong, tough, ductile	May corrode Dense Difficult to make	Joint replacements, bone plates and screws, dental root implants, pacer and suture wires
Ceramics (aluminum oxide, calcium phosphates including hydroxyapatite, carbon)	Very biocompatible, Inert Strong in compression	Brittle Not resilient Difficult to make	Dental; femoral head of hip replacement, coating of dental and orthopedic implants
Composites (carbon–carbon, wire or fiber reinforced bone cement)	Strong, tailor-made	Difficult to make	Joint implants, heart valves

presence of biomaterials, since the implant can provide a region inaccessible to the body's immunologically competent cells. The earliest successful implants, as well as a large fraction of modern ones, were in the skeletal system. Bone plates were introduced in the early 1900s to aid in the fixation of long-bone fractures. Many of these early plates broke as a result of unsophisticated mechanical design; they were too thin and had stress-concentrating corners. Also, materials such as vanadium steel that was chosen for its good mechanical properties corroded rapidly in the body and caused adverse effects on the healing processes. Better designs and materials soon followed. Following the introduction of stainless steels and cobalt chromium alloys in the 1930s, greater success was achieved in fracture fixation, and the first joint-replacement surgeries were performed. As for polymers, it was found that warplane pilots in World War II who were injured by fragments of plastic PMMA (polymethyl methacrylate) aircraft canopy, did not suffer adverse chronic reactions from the presence of the fragments in the body. PMMA became widely used after that time for corneal replacement and for replacements of sections of damaged skull bones. Following further advances in materials and in surgical technique, blood vessel replacements were tried in the 1950s and heart valve replacements and cemented joint replacements in the 1960s. Table V.6 lists notable developments relating to implants. Recent years have seen many further advances.

V.3   Performance of Biomaterials

The success of biomaterials in the body depends on factors such as the material properties, design, and **biocompatibility** of the material used, as well as other factors not under the control of the engineer, including the technique used by the surgeon, the health and condition of the patient, and the activities of the patient. If we can assign a numerical value f to the probability of failure of an implant, then the reliability can be expressed as

$$r = 1 - f \tag{V.1}$$

If, as is usually the case, there are multiple modes of failure, the total reliability r_t is given by the product of the individual reliabilities $r_1 = (1 - f_1)$, etc.

$$r_t = r_1 \cdot r_2 \cdots r_n \tag{V.2}$$

Consequently, even if one failure mode such as implant fracture is perfectly controlled so that the corresponding reliability is unity, other failure modes such as infection could severely limit the utility represented by the total reliability of the implant. One mode of failure which can occur in a biomaterial, but not in

TABLE V.6 Notable Developments Relating to Implants

Year	Investigators	Development
Late 18-19th century		Various metal devices to fix bone fractures; wires and pins from Fe, Au, Ag, and Pt
1860–1870	J. Lister	Aseptic surgical techniques
1886	H. Hansmann	Ni-plated steel bone fracture plate
1893–1912	W.A. Lane	Steel screws and plates (Lane fracture plate)
1912	W.D. Sherman	Vanadium steel plates, first developed for medical use; lesser stress concentration and corrosion (Sherman plate)
1924	A.A. Zierold	Introduced Stellites® (CoCrMo alloy)
1926	M.Z. Lange	Introduced 18-8sMo stainless steel, better than 18-8 stainless steel
1926	E.W. Hey-Groves	Used carpenter's screw for femoral neck fracture
1931	M.N. Smith-Petersen	First femoral neck fracture fixation device made of stainless steel
1936	C.S. Venable, W.G. Stuck	Introduced Vitallium® (19-9 stainless steel), later changed the material to CoCr alloys
1938	P. Wiles	First total hip replacement prosthesis
1939	J.C. Burch, H.M Carney	Introduced tantalum (Ta)
1946	J. and R. Judet	First biomechanically designed femoral head replacement prosthesis. First plastics (PMMA) used in joint replacements
1940s	M.J. Dorzee, A. Franceschetti	First used acrylics (PMMA) for corneal replacement
1947	J. Cotton	Introduced Ti and its alloys
1952	A.B. Voorhees, A. Jaretzta, A.B. Blackmore	First successful blood vessel replacement made of cloth for tissue ingrowth
1958	S. Furman, G. Robinson	First successful direct heart stimulation
1958	J. Charnley	First use of acrylic bone cement in total hip replacement on the advice of Dr. D. Smith
1960	A. Starr, M.L. Edwards	First commercial heart valves
1970s	W.J. Kolff	Total heart replacement

Source: Park, J.B. [1984] New York: Plenum Publishing Co.

engineering materials used in other contexts, is an attack by the body's immune system on the implant. Another such failure mode is an unwanted effect of the implant upon the body; for example, toxicity, inducing allergic reactions, or causing cancer. Consequently, biocompatibility is included as a material requirement in addition to those requirements associated directly with the function of the implant.

Biocompatibility involves the acceptance of an artificial implant by the surrounding tissues and by the body as a whole. Biocompatible materials do not irritate the surrounding structures, do not provoke an abnormal inflammatory response, do not incite allergic or immunologic reactions, and do not cause cancer. Other compatibility characteristics that may be important in the function of an implant device made of biomaterials include (1) adequate mechanical properties such as strength, stiffness, and fatigue properties; (2) appropriate optical properties if the material is to be used in the eye, skin, or tooth; and (3) appropriate density. Sterilizability, manufacturability, long-term storage, and appropriate engineering design are also to be considered.

The failure modes may differ in importance as time passes following the implant surgery. For example, consider the case of a total joint replacement in which infection is most likely soon after surgery, while loosening and implant fracture become progressively more important as time goes on. Failure modes also depend on the type of implant and its location and function in the body. For example, an artificial blood vessel is more likely to cause problems by inducing a clot or becoming clogged with thrombus than by breaking or tearing mechanically.

With these basic concepts in mind, the chapters in this book focus on biomaterials consisting of different materials such as metallic, ceramic, polymeric, and composite. The impact of recent advances in the area of nano- and microtechnology on biomaterial design is highlighted in Chapter 46.

Defining Terms

Biocompatibility: Acceptance of an artificial implant by the surrounding tissues and by the body as a whole.

Biological material: A material produced by a biological system.

Biomaterial: A synthetic material used to make devices to replace part of a living system or to function in intimate contact with living tissue.

38.1 Introduction

Metals are used as biomaterials due to their excellent electrical and thermal conductivity and mechanical properties. Since some electrons are independent in metals, they can quickly transfer an electric charge and thermal energy. The mobile free electrons act as the binding force to hold the positive metal ions together. This attraction is strong, as evidenced by the closely packed atomic arrangement resulting in high specific gravity and high melting points of most metals. Since the metallic bond is essentially nondirectional, the position of the metal ions can be altered without destroying the crystal structure resulting in a plastically deformable solid.

Some metals are used as passive substitutes for hard tissue replacement such as total hip and knee joints, for fracture healing aids as bone plates and screws, spinal fixation devices, and dental implants because of their excellent mechanical properties and **corrosion** resistance. Some metallic alloys are used for more active roles in devices such as vascular stents, catheter guide wires, orthodontic archwires, and cochlea implants.

The first metal alloy developed specifically for human use was the "vanadium steel" which was used to manufacture bone fracture plates (Sherman plates) and screws. Most metals such as iron (Fe), chromium (Cr), cobalt (Co), nickel (Ni), titanium (Ti), tantalum (Ta), niobium (Nb), molybdenum (Mo), and tungsten (W), that were used to make alloys for manufacturing implants can only be tolerated by the body

38-1

in minute amounts. Sometimes those metallic elements, in naturally occurring forms, are essential in red blood cell functions (Fe) or synthesis of a vitamin B_{12} (Co), but cannot be tolerated in large amounts in the body [Black, 1992]. The biocompatibility of the metallic implant is of considerable concern because these implants can corrode in an *in vivo* environment [Williams, 1982]. The consequences of corrosion are the disintegration of the implant material per se, which will weaken the implant, and the harmful effect of corrosion products on the surrounding tissues and organs.

38.2   Stainless Steels

The first stainless steel utilized for implant fabrication was the 18-8 (type 302 in modern classification), which is stronger and more resistant to corrosion than the vanadium steel. Vanadium steel is no longer used in implants since its corrosion resistance is inadequate *in vivo*. Later 18-8sMo stainless steel was introduced which contains a small percentage of molybdenum to improve the corrosion resistance in chloride solution (salt water). This alloy became known as *type 316 stainless steel*. In the 1950s the carbon content of 316 stainless steel was reduced from 0.08 to a maximum amount of 0.03% (all are weight percent unless specified) for better corrosion resistance to chloride solution and to minimize the sensitization and hence, became known as type *316L stainless steel*. The minimum effective concentration of chromium is 11% to impart corrosion resistance in stainless steels. The chromium is a reactive element, but it and its alloys can be *passivated* by 30% nitric acid to give excellent corrosion resistance.

The *austenitic stainless steels*, especially type 316 and 316L, are most widely used for implant fabrication. These cannot be hardened by heat treatment but can be hardened by cold-working. This group of stainless steels is nonmagnetic and possesses better corrosion resistance than any others. The inclusion of molybdenum enhances resistance to *pitting corrosion* in salt water. The American Society of Testing and Materials (ASTM) recommends type 316L rather than 316 for implant fabrication. The specifications for 316L stainless steel are given in Table 38.1. The only difference in composition between the 316L and 316 stainless steel is the maximum content of carbon, that is, 0.03 and 0.08%, respectively, as noted earlier.

The nickel stabilizes the austenitic phase [γ, face centered cubic crystal (fcc) structure], at room temperature and enhances corrosion resistance. The austenitic phase formation can be influenced by both the Ni and Cr contents as shown in Figure 38.1 for 0.10% carbon stainless steels. The minimum amount of Ni for maintaining austenitic phase is approximately 10%.

Table 38.2 gives the mechanical properties of 316L stainless steel. A wide range of properties exists depending on the heat treatment (annealing to obtain softer materials) or cold working (for greater strength and hardness). Figure 38.2 shows the effect of cold working on the yield and ultimate tensile strength of 18-8 stainless steels. The engineer must consequently be careful when selecting materials of this type. Even the 316L stainless steels may corrode inside the body under certain circumstances in a highly stressed and oxygen depleted region, such as the contacts under the screws of the bone fracture

plate. Thus, these stainless steels are suitable to use only in temporary implant devices such as fracture plates, screws, and hip nails. Surface modification methods such as anodization, **passivation**, and glow-discharge nitrogen-implantation, are widely used in order to improve corrosion resistance, wear resistance, and fatigue strength of 316L stainless steel [Bordiji et al., 1996].

38.3 CoCr Alloys

There are basically two types of cobalt–chromium alloys (1) the castable CoCrMo alloy and (2) the CoNiCrMo alloy which is usually *wrought* by (hot) *forging*. The castable CoCrMo alloy has been used for many decades in dentistry and, relatively recently, in making artificial joints. The wrought CoNiCrMo alloy is relatively new, now used for making the stems of prostheses for heavily loaded joints such as the knee and hip.

The ASTM lists four types of CoCr alloys which are recommended for surgical implant applications (1) cast CoCrMo alloy (F75), (2) wrought CoCrWNi alloy (F90), (3) wrought CoNiCrMo alloy (F562), and (4) wrought CoNiCrMoWFe alloy (F563). The chemical compositions of each are summarized in Table 38.3. At the present time only two of the four alloys are used extensively in implant fabrications, the castable CoCrMo and the wrought CoNiCrMo alloy. As can be noticed from Table 38.3, the compositions are quite different from each other.

The two basic elements of the CoCr alloys form a solid solution of up to 65% Co. The molybdenum is added to produce finer grains which results in higher strengths after casting or forging. The chromium enhances corrosion resistance as well as solid solution strengthening of the alloy.

The CoNiCrMo alloy originally called MP35N (Standard Pressed Steel Co.) contains approximately 35% Co and Ni each. The alloy is highly corrosion resistant to seawater (containing chloride ions) under stress. Cold working can increase the strength of the alloy considerably as shown in Figure 38.3. However, there is a considerable difficulty of cold working on this alloy, especially when making large devices such as hip joint stems. Only hot-forging can be used to fabricate a large implant with the alloy.

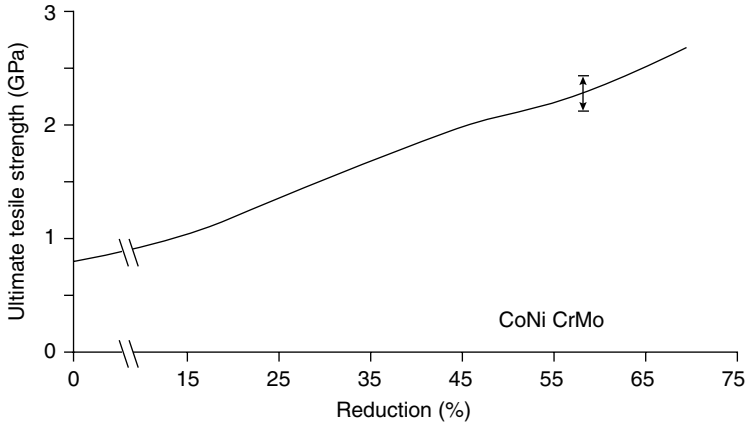
The abrasive wear properties of the wrought CoNiCrMo alloy are similar to the cast CoCrMo alloy (about 0.14 mm/yr in joint simulation tests with ultra high molecular weight polyethylene acetabular cup); however, the former is not recommended for the bearing surfaces of joint prosthesis because of its poor frictional properties with itself or other materials. The superior fatigue and ultimate tensile strength of the wrought CoNiCrMo alloy make it suitable for the applications which require long service life without fracture or stress fatigue. Such is the case for the stems of the hip joint prostheses. This advantage is better appreciated when the implant has to be replaced, since it is quite difficult to remove the failed


FIGURE 38.3 Relationship between ultimate tensile and the amount of cold-work for CoNiCrMo alloy [Devine and Wulff, 1975].

TABLE 38.4 Mechanical Property Requirements of Co-Cr Alloys (ASTM F76, F90, F562) (American Society for Testing and Materials, F75–87, p. 42; F90–87, p. 47; F562–84, p. 150, 1992)

	Cast CoCrMo	Wrought CoCrWNi	Wrought CoNiCrMo (F562)	
Property	(F75)	(F90)	Solution annealed	Cold-worked and aged
Tensile strength (MPa)	655	860	793–1000	1793 min.
Yield strength (0.2% offset) (MPa)	450	310	240–655	1585
Elongation (%)	8	10	50.0	8.0
Reduction of area (%)	8	—	65.0	35.0
Fatigue strength (MPa)[a]	310	—	—	—

[a] From Semlitch, M. (1980). *Eng. Med.* 9, 201–207.

piece of implant embedded deep in the femoral medullary canal. Furthermore, the revision arthroplasty is usually inferior to the primary surgery in terms of its function due to poorer fixation of the implant.

The mechanical properties required for CoCr alloys are given in Table 38.4. As with the other alloys, the increased strength is accompanied by decreased ductility. Both the cast and wrought alloys have excellent corrosion resistance.

Experimental determination of the rate of nickel release from the CoNiCrMo alloy and 316L stainless steel in 37°C Ringer's solution showed an interesting result. Although the cobalt alloy has more initial release of nickel ions into the solution, the rate of release was about the same (3×10^{-10} g/cm^2/day) for both alloys [Richards-Mfg-Company, 1980]. This is rather surprising since the nickel content of the CoNiCrMo alloy is about three times that of 316L stainless steel.

The metallic products released from the prosthesis because of wear, corrosion, and fretting may impair organs and local tissues. *In vitro* studies have indicated that particulate Co is toxic to human osteoblast-like cell lines and inhibits synthesis of type-I collagen, osteocalcin and alkaline phosphatase in the culture medium. However, particulate Cr and CoCr alloy are well tolerated by cell lines with no significant toxicity. The toxicity of metal extracts *in vitro* have indicated that Co and Ni extracts at 50% concentration appear to be highly toxic since all viability parameters were altered after 24 h. However, Cr extract seems to be less toxic than Ni and Co [Granchi et al., 1996].

The modulus of elasticity for the CoCr alloys does not change with the changes in their ultimate tensile strength. The values range from 220 to 234 GPa which are higher than other materials such as stainless

steels. This may have some implications of different load transfer modes to the bone in artificial joint replacements, although the effect of the increased modulus on the fixation and longevity of implants is not clear. Low wear (average linear wear on the MeKee-Farrar component was 4.2 μm/yr) has been recognized as an advantage of metal-on-metal hip articulations because of its hardness and toughness [Schmalzried et al., 1996].

38.4   Ti Alloys

38.4.1   Pure Ti and Ti6Al4V

Attempts to use titanium for implant fabrication dates to the late 1930s. It was found that titanium was tolerated in cat femurs, as was stainless steel and Vitallium® (CoCrMo alloy). Titanium's lightness (4.5 g/cm^3, see Table 38.5) and good mechanochemical properties are salient features for implant application.

There are four grades of unalloyed commercially pure (cp) titanium for surgical implant applications as given in Table 38.6. The impurity contents separate them; oxygen, iron, and nitrogen should be controlled carefully. Oxygen in particular has a great influence on the ductility and strength.

One titanium alloy (Ti6Al4V) is widely used to manufacture implants and its chemical requirements are given in Table 38.7. The main alloying elements of the alloy are aluminum (5.5–6.5%) and vanadium

TABLE 38.5   Specific Gravities of Some Metallic Implant Alloys

Alloys	Density (g/cm^3)
Ti and its allloys	4.5
316 Stainless steel	7.9
CoCrMo	8.3
CoNiCrMo	9.2
NiTi	6.7

TABLE 38.6   Chemical Compositions of Titanium and its Alloy (American Society for Testing and Materials, F67–89, p. 39; F136–84, p. 55, 1992)

Element	Grade 1	Grade 2	Grade 3	Grade 4	Ti6Al4V[a]
Nitrogen	0.03	0.03	0.05	0.05	0.05
Carbon	0.10	0.10	0.10	0.10	0.08
Hydrogen	0.015	0.015	0.015	0.015	0.0125
Iron	0.20	0.30	0.30	0.50	0.25
Oxygen	0.18	0.25	0.35	0.40	0.13
Titanium			Balance		

[a] Aluminum 6.00% (5.50–6.50), vanadium 4.00% (3.50–4.50), and other elements 0.1% maximum or 0.4% total.
All are maximum allowable weight percent.

TABLE 38.7   Mechanical Properties of Ti and its Alloys (ASTM F136) (American Society for Testing and Materials, F67–89, p. 39; F136–84, p. 55, 1992 and Davidson et al., 1994)

Properties	Grade 1	Grade 2	Grade 3	Grade 4	Ti6Al4V	Ti13Nb13Zr
Tensile strength (MPa)	240	345	450	550	860	1030
Yield strength (0.2% offset) (MPa)	170	275	380	485	795	900
Elongation (%)	24	20	18	15	10	15
Reduction of area (%)	30	30	30	25	25	45

(3.5~4.5%). The Ti6Al4V alloy has approximately the same fatigue strength (550 MPa) of CoCr alloy after rotary bending fatigue tests [Imam et al., 1983]. Titanium is an allotropic material, which exists as a hexagonal close packed structure (hcp, α-Ti) up to 882°C and body-centered cubic structure (bcc, β-Ti) above that temperature. Titanium alloys can be strengthened and mechanical properties varied by controlled composition and thermomechanical processing techniques. The addition of alloying elements to titanium enables it to have a wide range of properties: (1) Aluminum tends to stabilize the α-phase, that is increase the transformation temperature from α- to β-phase (Figure 38.4). (2) Vanadium stabilizes the β-phase by lowering the temperature of the transformation from α to β.

The α-alloy has a single-phase microstructure (Figure 38.5a) which promotes good weldability. The stabilizing effect of the high aluminum content of these groups of alloys makes excellent strength
FIGURE 38.4 Part of Phase-diagram of Ti–Al–V at 4 w/o V [Smith and Hughes, 1966].
FIGURE 38.5 Microstructure of Ti alloys (all are 500X) [Hille, 1966]. (a) Annealed α-alloy. (b) Ti6Al4V, α–β alloy, annealed. (c) β-alloy, annealed. (d) Ti6Al4V, heat-treated at 1650°C and quenched [Imam et al., 1983].

characteristics and oxidation resistance at high temperature (300 to 600°C). These alloys cannot be heat-treated for precipitation hardening since they are single-phased.

The addition of controlled amounts of β-stabilizers causes the higher strength β-phase to persist below the transformation temperature which results in the two-phase system. The precipitates of β-phase will appear by heat treatment in the solid solution temperature and subsequent quenching, followed by aging at a somewhat lower temperature. The aging cycle causes the coherent precipitation of some fine α particles from the metastable β, imparting α structure may produce local strain field capable of absorbing deformation energy. Cracks are stopped or deterred at the α particles, so that the hardness is higher than for the solid solution (Figure 38.5b).

The higher percentage of β-stabilizing elements (13%V in Ti13V11Cr3Al alloy) results in a microstructure that is substantially β which can be strengthened by heat-treatment (Figure 38.5c). Another Ti alloy (Ti13Nb13Zr) with13%Nb and 13%Zr showed **martensite** structure after water quenched and aged, which showed high corrosion resistant with low modulus ($E = 79$ MPa) [Davidson et al., 1994]. Formation of plates of martensite induces considerable elastic distortion in the parent crystal structure and increases strength (Figure 38.5d).

The mechanical properties of the commercially pure titanium and its alloys are given in Table 38.7. The modulus of elasticity of these materials is about 110 GPa except 13Nb13Zr alloy. From Table 38.7 one can see that the higher impurity content of the cp-Ti leads to higher strength and reduced ductility. The strength of the material varies from a value much lower than that of 316 stainless steel or the CoCr alloys to a value about equal to that of annealed 316 stainless steel of the cast CoCrMo alloy. However, when compared by the specific strength (strength per density) the titanium alloys exceed any other implant materials as shown in Figure 38.6. Titanium, nevertheless, has poor shear strength making it less desirable for bone screws, plates, and similar applications. It also tends to gall or seize when in sliding contact with itself or another metal.

Titanium derives its resistance to corrosion by the formation of a solid oxide layer to a depth of 10 nm. Under *in vivo* conditions the oxide (TiO_2) is the only stable reaction product. However, micromotion at the cement-prosthesis and cement-bone are inevitable and consequently, titanium oxide and titanium
FIGURE 38.6   Yield strength to density ratio of some implant materials [Hille, 1966].

alloy particles are released in cemented joint prosthesis. Sometimes this wear debris accumulates as periprosthetic fluid collections and triggers giant cell response around the implants. This cystic collection continued to enlarge and aspiration revealed "dark" heavily stained fluid containing titanium wear particles and histiocytic cells. Histological examination of the stained soft tissue showed "fibrin necrotic debris" and collagenous, fibrous tissue containing a histiocytic and foreign body giant cell infiltrate. The metallosis, black staining of the periprosthetic tissues, has been implicated in knee implant [Breen and Stoker, 1993].

The titanium implant surface consists of a thin oxide layer and the biological fluid of water molecules, dissolved ions, and biomolecules (proteins with surrounding water shell) as shown in Figure 38.7. The microarchitecture (microgeometry, roughness, etc.) of the surface and its chemical compositions are important due to the following reasons:

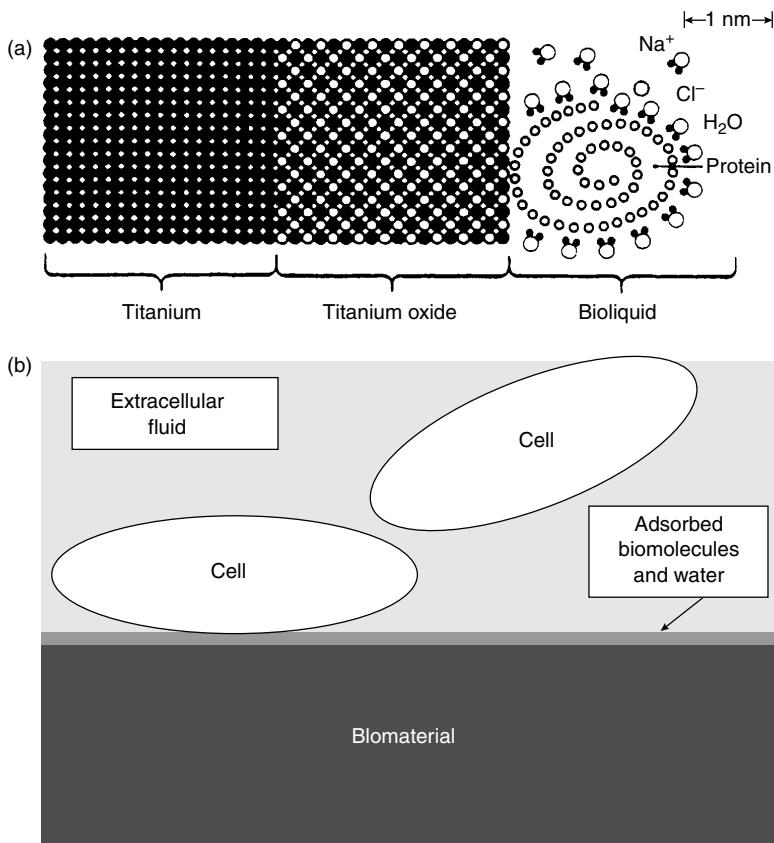
1. Physical nature of the surface either at the atomic, molecular, or higher level relative to the dimensions of the biological units may cause different contact areas with biomolecules, cells, etc. The different contact areas, in turn, may produce different perturbations and types of bonding of the biological units, which may influence their conformation and function.
2. Chemical composition of the surface may produce different types of bonding to the biomolecules, which may then also affect their properties and function. Metals undergo chemical reactions at the surface depending on the environment which cause the difficulties of understanding the exact nature of the interactions.


FIGURE 38.7 (a) Interface between a titanium implant and bioliquid and (b) the cell surface interaction [Kasemo and Lausma, 1988].
FIGURE 38.8   Chemical change of titanium implant surface of alkali following heat treatment [Kim et al., 1996].

The surface-tissue interaction is dynamic rather than static, i.e., it will develop into new stages as time passes, especially during the initial period after implantation. During the initial few seconds after implantation, there will be only water, dissolved ions, and free biomolecules in the closest proximity of the surface but no cells. The composition of biofluid will then change continuously as inflammatory and healing processes proceed, which in turn also probably causes changes in the composition of the adsorbed layer of biomolecules on the implant surface until quasiequilibrium sets in. Eventually, cells and tissues will approach the surface and, depending on the nature of the adsorbed layer, they will respond in specific ways that may further modify the adsorbed biomolecules. The type of cells closest to the surface and their activities will change with time. For example, depending on the type of initial interaction, the final results may be fibrous capsule formation or tissue integration [Kasemo and Lausma, 1988; Hazan et al., 1993; Takatsuka et al., 1995; Takeshita et al., 1997; Yan et al., 1997].

Osseointegration is defined as direct contact without intervening soft tissue between viable remodeled bone and an implant. Surface roughness of titanium alloys have a significant effect on the bone apposition to the implant and on the bone implant interfacial pull out strength. The average roughness increased from 0.5 to 5.9 μm and the interfacial shear strength increased from 0.48 to 3.5 MPa [Feighan et al., 1995]. Highest levels of osteoblast cell attachment are obtained with rough sand blast surfaces where cells differentiated more than those on the smooth surfaces [Keller et al., 1994]. Chemical changes of the titanium surface following heat treatment is thought to form a TiO_2 hydrogel layer on top of the TiO_2 layer as shown in Figure 38.8. The TiO_2 hydrogel layer may induce the apatite crystal formation [Kim et al., 1996].

In general, on the rougher surfaces there are lower cell numbers, decreased rate of cellular proliferation, and increased matrix production compared to smooth surface. Bone formation appears to be strongly related to the presence of transforming growth factor β_1 in the bone matrix [Kieswetter et al., 1996].

38.4.2   TiNi Alloys

The *titanium–nickel* alloys show unusual properties, that is, after it is deformed the material can snap back to its previous shape following heating of the material. This phenomenon is called **shape memory effect (SME)**. The SME of TiNi alloy was first observed by Buehler and Wiley at the U.S. Naval Ordnance Laboratory [Buehler et al., 1963]. The equiatomic TiNi or NiTi alloy (Nitinol) exhibits an exceptional SME near room temperature: if it is plastically deformed below the transformation temperature, it reverts back to its original shape as the temperature is raised. The SME can be generally related to a diffusionless martensitic phase transformation which is also thermoelastic in nature, the thermoelasticity being attributed to the ordering in the parent and martensitic phases [Wayman and Shimizu, 1972]. Another unusual
FIGURE 38.9 Schematic illustration of the stainless steel wire and TiNi SMA wire springs for orthodontic archwire behavior. (Modified from Wayman, C.M. and Duerig, T.W. (1990). London: Butterworth-Heinemann, pp. 3–20.)

property is the **superelasticity**, which is shown schematically in Figure 38.9. As can be seen, the stress does not increase with increased strain after the initial elastic stress region and upon release of the stress or strain the metal springs back to its original shape in contrast to other metals such as stainless steel. The superlastic property is utilized in orthodontic archwires since the conventional stainless steel wires are too stiff and harsh for the tooth. In addition, the shape memory effect can also be utilized.

Some possible applications of shape memory alloys are orthodontic dental archwire, intracranial aneurysm clip, *vena cava* filter, contractile artificial muscles for an artificial heart, vascular stent, catheter guide wire, and orthopedic staple [Duerig et al., 1990].

In order to develop such devices, it is necessary to understand fully the mechanical and thermal behavior associated with the martensitic phase transformation. A widely known NiTi alloy is 55-Nitinol (55 weight% or 50 atomic % Ni), which has a single phase and the mechanical memory plus other properties, for example, high acoustic damping, direct conversion of heat energy into mechanical energy, good fatigue properties, and low temperature ductility. Deviation from the 55-Nitinol (near stoichiometric NiTi) in the Ni-rich direction yields a second group of alloys which are also completely nonmagnetic but differ from 55-Nitinol in their ability to be thermally hardened to higher hardness levels. Shape recovery capability decreases and heat treatability increases rapidly as the Ni content approaches 60%. Both 55 and 60-Nitinols have relatively low modulus of elasticity and can be tougher and more resilient than stainless steel, NiCr, or CoCr alloys.

Efficiency of 55-Nitinol shape recovery can be controlled by changing the final annealing temperatures during preparation of the alloy device [Lee et al., 1988]. For the most efficient recovery, the shape is fixed by constraining the specimen in a desired configuration and heating to 482 to 510°C. If the annealed wire is deformed at a temperature below the shape recovery temperature, shape recovery will occur upon heating, provided the deformation has not exceeded crystallographic strain limits ($\sim$8% strain in tension). The NiTi alloys also exhibit good biocompatibility and corrosion resistance *in vivo*.

There is no significant difference between titanium and NiTi in the inhibition of mitosis in human fibroblasts. NiTi showed lower percentage bone and bone contact area than titanium and the Ti6Al4V alloy [Takeshita et al., 1997].

The mechanical properties of NiTi alloys are especially sensitive to the stoichiometry of composition (typical composition is given in Table 38.8) and the individual thermal and mechanical history. Although much is known about the processing, mechanical behavior, and properties relating to the shape memory effect, considerably less is known about the thermomechanical and physical metallurgy of the alloy.

TABLE 38.8 Chemical
Composition of Ni–Ti Alloy Wire

Element	Composition (%)
Ni	54.01
Co	0.64
Cr	0.76
Mn	0.64
Fe	0.66
Ti	Balance

38.5 Dental Metals

Dental **amalgam** is an alloy made of liquid mercury and other solid metal particulate alloys made of silver, tin, copper, etc. The solid alloy is mixed with (liquid) mercury in a mechanical vibrating mixer and the resulting material is packed into the prepared cavity. One of the solid alloys is composed of at least 65% silver, and not more than 29% tin, 6% copper, 2% zinc, and 3% mercury. The reaction during setting is thought to be

$$\gamma + Hg \rightarrow \gamma + \gamma_1 + \gamma_2 \tag{38.1}$$

in which the γ phase is Ag_3Sn, the γ_1 phase is Ag_2Hg_3, and the γ_2 phase is Sn_7Hg. The phase diagram for the Ag-Sn-Hg system shows that over a wide compositional range all three phases are present. The final composition of dental amalgams typically contain 45% to 55% mercury, 35% to 45% silver, and about 15% tin after fully set in about one day.

 Gold and gold alloys are useful metals in dentistry as a result of their durability, stability, and corrosion resistance [Nielsen, 1986]. Gold fillings are introduced by two methods: casting and malleting. *Cast* restorations are made by taking a wax impression of the prepared cavity, making a mold from this impression in a material such as gypsum silica, which tolerates high temperature, and casting molten gold in the mold. The patient is given a temporary filling for the intervening time. Gold *alloys* are used for cast restorations, since they have mechanical properties which are superior to those of pure gold. Corrosion resistance is retained in these alloys provided they contain 75% or more of gold and other **noble** metals. Copper, alloyed with gold, significantly increases its strength. Platinum also improves the strength, but no more than about 4% can be added, or the melting point of the alloy is elevated excessively. Silver compensates for the color of copper. A small amount of zinc may be added to lower the melting point and to scavenge oxides formed during melting. Gold alloys of different composition are available. Softer alloys containing more than 83% gold are used for inlays which are not subjected to much stress. Harder alloys containing less gold are chosen for crowns and cusps which are more heavily stressed.

 Malleted restorations are built up in the cavity from layers of *pure* gold foil. The foils are welded together by pressure at ambient temperature. In this type of welding, the metal layers are joined by thermal diffusion of atoms from one layer to the other. Since intimate contact is required in this procedure, it is particularly important to avoid contamination. The pure gold is relatively soft, so this type of restoration is limited to areas not subjected to much stress.

38.6 Other Metals

Several other metals have been used for a variety of specialized implant applications. *Tantalum* has been subjected to animal implant studies and has been shown very biocompatible. Due to its poor mechanical properties (Table 38.9) and its high density (16.6 g/cm^3) it is restricted to few applications such as wire sutures for plastic surgeons and neurosurgeons and a radioisotope for bladder tumors.

TABLE 38.9 Mechanical Properties of Tantalum (American Society for Testing and Materials, F560–86, p. 143, 1992)

Properties	Annealed	Cold-worked
Tensile strength (MPa)	207	517
Yield strength (0.2% offset) (MPa)	138	345
Elongation (%)	20–30	2
Young's modulus (GPa)	—	190

Platinum group metals (PGM) such as Pt, Pd, Rh, Ir, Ru, and Os are extremely corrosion resistant but have poor mechanical properties [Wynblatt, 1986]. They are mainly used as alloys for electrodes such as pacemaker tips because of their high resistance to corrosion and low threshold potentials for electrical conductivity.

Thermoseeds made of 70% Ni and 30% Cu have been produced which possess Curie points in the therapeutic **hyperthermia** range, approximately 40 to 50°C [Ferguson et al., 1992]. Upon the application of an alternating magnetic field, eddy currents are induced, which will provide a continuous heat source through resistive heating of the material. As the temperature of a ferromagnetic substance nears its Curie point, however, there is a loss of ferromagnetic properties and a resulting loss of heat output. Thus, self-regulation of temperature is achieved and can be used to deliver a constant hyperthermic temperature extracorporeally at any time and duration.

Surface modifications of metal alloys such as coatings by plasma spray, physical or chemical vapor deposition, ion implantaion, and fluidized bed deposition have been used in industry [Smith, 1993]. Coating implants with tissue compatible materials such as hydroxyapatite, oxide ceramics, Bioglass®, and pyrolytic carbon are typical applications in implants. Such efforts have been largely ineffective if the implants are permanent and particularly if the implants are subjected to a large loading. The main problem is the delamination of the coating or eventual wear of the coating. The added cost of coating or ion implanting hinders the use of such techniques unless the technique shows unequivocal superiority compared to the non-treated implants.

38.7 Corrosion of Metallic Implants

Corrosion is the unwanted chemical reaction of a metal with its environment, resulting in its continued degradation to oxides, hydroxides, or other compounds. Tissue fluid in the human body contains water, dissolved oxygen, proteins, and various ions such as chloride and hydroxide. As a result, the human body presents a very aggressive environment for metals used for implantation. Corrosion resistance of a metallic implant material is consequently an important aspect of its biocompatibility.

38.7.1 Electrochemical Aspects

The lowest free energy state of many metals in an oxygenated and hydrated environment is that of the oxide. Corrosion occurs when metal atoms become ionized and go into solution, or combine with oxygen or other species in solution to form a compound which flakes off or dissolves. The body environment is very aggressive in terms of corrosion since it is not only aqueous but also contains chloride ions and proteins. A variety of chemical reactions occur when a metal is exposed to an aqueous environment, as shown in Figure 38.10. The electrolyte, which contains ions in solution, serves to complete the electric circuit. In the human body, the required ions are plentiful in the body fluids. Anions are negative ions which migrate toward the **anode**, and cations are positive ions which migrate toward the **cathode**. At the anode, or positive electrode, the metal oxidizes by losing valence electrons as in the following:

$$M \rightarrow M^{+n} + ne^- \tag{38.2}$$
FIGURE 38.10   Electrochemical cell.

TABLE 38.10   Standard Electrochemical Series

Reaction	ΔE_0 [volts]
$Li \leftrightarrow Li^+$	-3.05
$Na \leftrightarrow Na^+$	-2.71
$Al \leftrightarrow Al^{+++}$	-1.66
$Ti \leftrightarrow Ti^{+++}$	-1.63
$Cr \leftrightarrow Cr^{++}$	-0.56
$Fe \leftrightarrow Fe^{++}$	-0.44
$Cu \leftrightarrow Cu^{++}$	-0.34
$Co \leftrightarrow Co^{++}$	-0.28
$Ni \leftrightarrow Ni^{++}$	-0.23
$H_2 \leftrightarrow 2H^+$	-0.00
$Ag \leftrightarrow Ag^+$	$+0.80$
$Au \leftrightarrow Au^+$	$+1.68$

At the cathode, or negative electrode, the following reduction reactions are important:

$$M^{+n} + ne^- \rightarrow M \tag{38.3}$$

$$M^{++} + OH^- + 2e^- \rightarrow MOH \tag{38.4}$$

$$2H_3O^+ + 2e^- \rightarrow H_2 \uparrow + 2H_2O \tag{38.5}$$

$$1/2O_2 + H_2O + 2e^- \rightarrow 2OH^- \tag{38.6}$$

The tendency of metals to corrode is expressed most simply in the standard electrochemical series of **Nernst potentials**, shown in Table 38.10. These potentials are obtained in electrochemical measurements in which one electrode is a standard hydrogen electrode formed by bubbling hydrogen through a layer of finely divided platinum black. The potential of this reference electrode is defined to be zero. Noble metals are those which have a potential higher than that of a standard hydrogen electrode; base metals have lower potentials.

If two dissimilar metals are present in the same environment, the one which is most negative in the **galvanic series** will become the anode, and bimetallic (or galvanic) corrosion will occur. **Galvanic corrosion** can be much more rapid than the corrosion of a single metal. Consequently, implantation of dissimilar metals (mixed metals) is to be avoided. Galvanic action can also result in corrosion within a single metal, if there is inhomogeneity in the metal or in its environment, as shown in Figure 38.11.
FIGURE 38.11 Micro-corrosion cells. (a) Grain boundaries are anodic with respect to the grain interior. (b) Crevice corrosion due to oxygen-deficient zone in metal's environment.

The potential difference, E, actually observed depends on the concentration of the metal ions in solution according to the Nernst equation,

$$E = E_o + (RT/nF) \ln[M^{+n}] \tag{38.7}$$

in which R is the gas constant, E_o is the standard electrochemical potential, T is the absolute temperature, F is Faraday's constant (96,487 C/mol), and n is the number of moles of ions.

The order of nobility observed in actual practice may differ from that predicted thermodynamically. The reasons are that some metals become covered with a *passivating* film of reaction products which protects the metal from further attack. The dissolution reaction may be strongly irreversible so that a potential barrier must be overcome. In this case, corrosion may be inhibited even though it remains energetically favorable. The kinetics of corrosion reactions are not determined by the thermodynamics alone.

38.7.2 Pourbaix Diagrams in Corrosion

The **Pourbaix diagram** is a plot of regions of *corrosion*, **passivity**, and **immunity** as they depend on electrode potential and pH [Pourbaix, 1974]. The Pourbaix diagrams are derived from the Nernst equation and from the solubility of the degradation products and the equilibrium constants of the reaction. For the sake of definition, the *corrosion region* is set arbitrarily at a concentration of greater than 10^{-6} g atom/l (molar) or more of metal in the solution at equilibrium. This corresponds to about 0.06 mg/l for metals such as iron and copper, and 0.03 mg/l for aluminum. *Immunity* is defined as equilibrium between metal and its ions at less than 10^{-6} M. In the region of immunity, the corrosion is energetically impossible. Immunity is also referred to as cathodic protection. In the passivation domain, the stable solid constituent is an oxide, hydroxide, hydride, or a salt of the metal. *Passivity* is defined as equilibrium between a metal and its reaction products (oxides, hydroxides, etc.) at a concentration of 10^{-6} M or less. This situation is useful if reaction products are adherent. In the biomaterials setting, passivity may or may not be adequate; disruption of a passive layer may cause an increase in corrosion. The equilibrium state may not occur if reaction products are removed by the tissue fluid. Materials differ in their propensity to re-establish a passive layer which has been damaged. This layer of material may protect the underlying metal if it is firmly adherent and nonporous; in that case further corrosion is prevented. Passivation can also result from a concentration polarization due to a buildup of ions near the electrodes. This is not likely to occur in the body since the ions are continually replenished. Cathodic depolarization reactions can aid in the passivation of a metal by virtue of an energy barrier which hinders the kinetics. Equation 38.5 and Equation 38.6 are examples.

There are two diagonal lines in the diagrams shown in Figure 38.12. The top oxygen line represents the upper limit of the stability of water and is associated with oxygen rich solutions or electrolytes near
FIGURE 38.12 Pourbaix diagram for chromium, showing regions associated with various body fluids. (Modified from Black, J. (1992). *Biological Performance of Materials, 2nd ed.* New York: M. Dekker, Inc.)

oxidizing materials. In the region above this line, oxygen is evolved according to $2H_2O \rightarrow O_2 \uparrow + 4H^+ + 4e^-$. In the human body, saliva, intracellular fluid, and interstitial fluid occupy regions near the oxygen line, since they are saturated with oxygen. The lower hydrogen diagonal line represents the lower limit of the stability of water. Hydrogen gas is evolved according to Equation 38.5. Aqueous corrosion occurs in the region between these diagonal lines on the Pourbaix diagram. In the human body, urine, bile, the lower gastrointestinal tract, and secretions of ductless glands, occupy a region somewhat above the hydrogen line.

The significance of the Pourbaix diagram is as follows. Different parts of the body have different pH values and oxygen concentrations. Consequently, a metal which performs well (is immune or passive) in one part of the body may suffer an unacceptable amount of corrosion in another part. Moreover, pH can change dramatically in tissue that has been injured or infected. In particular, normal tissue fluid has a pH of about 7.4, but in a wound it can be as low as 3.5, and in an infected wound the pH can increase to 9.0.

Pourbaix diagrams are useful, but do not tell the whole story; there are some limitations. Diagrams are made considering equilibrium among metal, water, and reaction products. The presence of other ions, for example, chloride, may result in very much different behavior and large molecules in the body may also change the situation. Prediction of passivity may in some cases be optimistic, since reaction rates are not considered.

38.7.3 Rate of Corrosion and Polarization Curves

The regions in the Pourbaix diagram specify whether corrosion will take place, but they do not determine the rate. The rate, expressed as an electric current density (current per unit area), depends upon electrode potential as shown in the polarization curves shown in Figure 38.13. From such curves, it is possible to calculate the number of ions per unit time liberated into the tissue, as well as the depth of metal removed by corrosion in a given time. An alternative experiment is one in which the weight loss of a specimen of metal due to corrosion is measured as a function of time.

The rate of corrosion also depends on the presence of synergistic factors, such as those of mechanical origin (uneven distribution of mechanical stress). The stressed alloy failures occur due to the propagation of cracks in corrosive environments. For example, in corrosion fatigue (stress corrosion cracking), repetitive deformation of a metal in a corrosive environment results in acceleration of both the corrosion and the fatigue microdamage. Since the body environment involves both repeated mechanical loading and a chemically aggressive environment, fatigue testing of implant materials should always be performed under physiological environmental conditions; under Ringer's solution at body temperature. In *fretting corrosion*, rubbing of one part on another disrupts the passivation layer, resulting in accelerated corrosion. In
FIGURE 38.13 Potential-current density curves for some biomaterials [Greener et al., 1972].

pitting, the corrosion rate is accelerated in a local region. Stainless steel is vulnerable to pitting. Localized corrosion can occur if there is inhomogeneity in the metal or in the environment. *Grain boundaries* in the metal may be susceptible to the initiation of corrosion, as a result of their higher energy level. *Crevices* are also vulnerable to corrosion, since the chemical environment in the crevice may differ from that in the surrounding medium. The area of contact between a screw and a bone plate, for example, can suffer **crevice corrosion**.

38.7.4 Corrosion of Available Metals

Choosing a metal for implantation should take into account the corrosion properties discussed above. Metals which are in current use as biomaterials include gold, cobalt chromium alloys, type 316 stainless steel, cp-titanium, titanium alloys, nickel–titanium alloys, and silver-tin-mercury amalgam.

The noble metals are immune to corrosion and would be ideal materials if corrosion resistance were the only concern. Gold is widely used in dental restorations and in that setting it offers superior performance and longevity. Gold is not, however, used in orthopaedic applications as a result of its high density, insufficient strength, and high cost.

Titanium is a base metal in the context of the electrochemical series, however, it forms a robust passivating layer and remains passive under physiological conditions. Corrosion currents in normal saline are very low: 10^{-8} A/cm^2. Titanium implants remain virtually unchanged in appearance. Ti offers superior corrosion resistance but is not as stiff or strong as steel or Co–Cr alloys.

Cobalt–chromium alloys, like titanium, are passive in the human body. They are widely in use in orthopedic applications. They do not exhibit pitting corrosion.

Stainless steels contain enough chromium to confer corrosion resistance by passivity. The passive layer is not as robust as in the case of titanium or the cobalt chrome alloys. Only the most corrosion resistant of the stainless steels are suitable for implants. These are the austenitic types — 316, 316L, and 317, which contain molybdenum. Even these types of stainless steel are vulnerable to pitting and to crevice corrosion around screws.

The phases of dental amalgam are passive at neutral pH, the transpassive potential for the γ_2 phase is easily exceeded, due to interphase galvanic couples or potentials due to differential aeration under dental plaque. Amalgam, therefore, often corrodes and is the most active (corrosion prone) material used in dentistry.

Corrosion of an implant in the clinical setting can result in symptoms such as local pain and swelling in the region of the implant, with no evidence of infection; cracking or flaking of the implant as seen on x-ray films, and excretion of excess metal ions. At surgery, gray or black discoloration of the surrounding tissue may be seen and flakes of metal may be found in the tissue. Corrosion also plays a role in the mechanical failures of orthopaedic implants. Most of these failures are due to fatigue, and the presence of a saline environment certainly exacerbates fatigue. The extent to which corrosion influences fatigue in the body is not precisely known.

38.7.5 Stress Corrosion Cracking

When an implant is subjected to stress, the corrosion process could be accelerated due to the mechanical energy. If the mechanical stress is repeated then fatigue stress corrosion takes place such as in the femoral stem of the hip joint and hip nails made of stainless steels [Dobbs and Scales, 1979; Sloter and Piehler, 1979]. However, other mechanisms of corrosion such as fretting may also be involved at point of contact such as in the counter-sink of the hip nail or bone fracture plate for the screws.

38.8 Manufacturing of Implants

38.8.1 Stainless Steels

The austenitic stainless steels work-harden very rapidly as shown in Figure 38.2 and therefore, cannot be cold-worked without intermediate heat treatments. The heat treatments should not induce, however, the formation of chromium carbide (CCr_4) in the grain boundaries; this may cause corrosion. For the same reason, the austenitic stainless steel implants are not usually welded.

The distortion of components by the heat treatments can occur but this problem can be solved by controlling the uniformity of heating. Another undesirable effect of the heat treatment is the formation of surface oxide scales which have to be removed either chemically (acid) or mechanically (sand-blasting). After the scales are removed the surface of the component is polished to a mirror or mat finish. The surface is then cleaned, degreased, and passivated in nitric acid (ASTM Standard F86). The component is washed and cleaned again before packaging and sterilizing.

38.8.2 Co–Cr Alloys

The CoCrMo alloy is particularly susceptible to work-hardening so that the normal fabrication procedure used with other metals cannot be employed. Instead, the alloy is cast by a lost wax (or investment casting) method which involves making a wax pattern of the desired component. The pattern is coated with a refractory material, first by a thin coating with a slurry (suspension of silica in ethyl silicate solution) followed by complete investing after drying (1) the wax is then melted out in a furnace (100–150°C), (2) the mold is heated to a high temperature burning out any traces of wax or gas forming materials, (3) molten alloy is poured with gravitational or centrifugal force, and (4) the mold is broken after cooled. The mold temperature is about 800–1000°C and the alloy is at 1350–1400°C.

Controlling the mold temperature will have an effect on the grain size of the final cast; coarse ones are formed at higher temperatures which will decrease the strength. However, high processing temperature will result in larger carbide precipitates with greater distances between them resulting in a less brittle material. Again there is a complementary (trade off) relationship between strength and toughness.

38.8.3 Ti and Its Alloys

Titanium is very reactive at high temperature and burns readily in the presence of oxygen. Therefore, it requires an inert atmosphere for high temperature processing or is processed by vacuum melting. Oxygen diffuses readily in titanium and the dissolved oxygen embrittles the metal. As a result, any hot working or forging operation should be carried out below 925°C. Machining at room temperature is not

the solution to all the problems since the material also tends to gall or seize the cutting tools. Very sharp tools with slow speeds and large feeds are used to minimize this effect. Electrochemical machining is an attractive means.

Defining Terms

Amalgam: An alloy obtained by mixing silver tin alloy with mercury.

Anode: Positive electrode in an electrochemical cell.

Cathode: Negative electrode in an electrochemical cell.

Corrosion: Unwanted reaction of metal with environment. In a Pourbaix diagram, it is the region in which the metal ions are present at a concentration of more than 10^{-6} M.

Crevice corrosion: A form of localized corrosion in which concentration gradients around pre-existing crevices in the material drive corrosion processes.

Curie temperature: Transition temperature of a material from ferromagnetic to paramagnetic.

Galvanic corrosion: Dissolution of metal driven by macroscopic differences in electrochemical potential, usually as a result of dissimilar metals in proximity.

Galvanic series: Table of electrochemical potentials (voltage) associated with the ionization of metal atoms. These are called Nernst potentials.

Hyperthermia: Application of high enough thermal energy (heat) to suppress the cancerous cell activities. Above 41.5°C (but below 60°C) is needed to have any effect.

Immunity: Resistance to corrosion by an energetic barrier. In a Pourbaix diagram, it is the region in which the metal is in equilibrium with its ions at a concentration of less than 10^{-6} M. Noble metals resist corrosion by immunity.

Martensite: A metastable structure formed by quenching of austenite (g) structure in alloys such as steel and Ti alloys. They are brittle and hard, and therefore, are further treated with heat to make tougher.

Nernst potential: Standard electrochemical potential measured with respect to a standard hydrogen electrode.

Noble: Type of metal with a positive standard electrochemical potential.

Passivation: Production of corrosion resistance by a surface layer of reaction products (Normally oxide layer which is impervious to gas and water.)

Passivity: Resistance to corrosion by a surface layer of reaction products. In a Pourbaix diagram, it is the region in which the metal is in equilibrium with its reaction products at a concentration of less than 10^{-6} molar.

Pitting: A form of localized corrosion in which pits form on the metal surface.

Pourbaix diagram: Plot of electrical potential vs. pH for a material in which the regions of corrosion, passivity, and immunity are identified.

Shape memory effect (SME):   Thermoelastic behavior of some alloys which can revert back to their original shape when the temperature is greater than the phase transformation temperature of the alloy.

Superelasticity: Minimal stress increase beyond the initial strain region resulting in very low modulus in the region for some shape memory alloys.
