Foreword

The present volume is an innovative resource on aging in the nervous system that reflects the considerable maturation of this new field. The authors are leading researchers of the many topics selected. The scope of the topics is broad, but while the editors have sought to be comprehensive, they did not sacrifice depth in the choice of some focused topics about which a great deal is known. This is altogether a commendable effort that should find wide use in academic courses and by the many researchers who have begun to recognize the importance of aging processes in many age-related conditions, conditions that have tended to be studied as specific disease entities but without considering the interactions of the disease with the changes of "usual" aging being taken into account.

Some historical perspectives seem pertinent here. One precursor of this book is James Birren's landmark monograph *Psychology of Aging* (1964), which synthesized the small but serious literature on cognitive and behavioral changes of normal aging in humans in relation to anatomical findings. Birren emphasized the general slowing of mental processes that was progressive across middle-age to later ages during normal aging, as distinct from pathological changes of senility. This slowing, which was observed in rodents and humans, might be attributed to the integrative level of complex circuits, because the conduction properties of axons did not show much change, for example, in the sciatic nerve of old rats (Birren and Wall, 1956). Neuron loss, which was generally assumed to be a major factor in brain aging, is now thought to be largely due to cerebrovascular disease or Alzheimer's disease.

Two other scholarly achievements in the biology of aging that interacted with Birren's book were Alex Comfort's *The Biology of Senescence*, which progressed through three editions (1957, 1964, and 1979), and the two editions of Bernard Strehler's *Time, Cells, and Aging* in 1962 and 1977. These three books are properly regarded as landmarks, and required heroic efforts to synthesize diverse sets of scattered and difficult information. We must mourn the recent death of Alex Comfort and praise the continued vitality of Jim Birren and Bernie Strehler. These books are part of the deep foundation upon which the present volume may be seen to rest. The books also had major importance for me when I was trying to design a Ph.D. project on aging under Alfred Mirsky at the Rockefeller University. Thesis projects were then often discussed with the august faculty of Rockefeller. I recall Peyton Rous saying something like "Why are you wasting your time on a subject like that? Everyone knows that aging is mainly about cancer and vascular disease." Perhaps Rous was thinking of Cazali's aphorism, "A man is as old as his arteries" (Critchley, 1931). But, by ferreting out the strongest papers cited by Birren, Comfort, and Strehler, I did convince Mirsky of biological mechanisms at work in aging that could not be accounted for by vascular disease or cancer, and so he supported my thesis project on the molecular endocrinology of responses to cold stress in aging mice (Finch *et al.*, 1969).

Thus began my own career in the neurobiology of aging, which led to the great pleasure of my working with Charles Mobbs, Giulio Pasinetti, and many other of the present authors who have built this field into its present thriving state. Of course, we must still keep in mind Peyton Rous's concerns about vascular contributions to brain aging!

Preface

This book has been developed to meet our own needs, but is based on our perception that many others have also found these needs unmet by available resources. First, teaching our course on the neurobiology of aging, as well as tutorials, laboratory rotations, and similar exercises, was made much more difficult without a central source for the material contained in this book. Those teaching courses in neurology, neuropathology, and gerontology often face a similar problem. Second, like other researchers studying the neurobiology of aging, as well as physicians treating patients with age-related diseases, we have often needed to obtain an overview of areas outside our immediate area of expertise, but there has been no comprehensive source for such overviews. The present book was thus designed to address each of these needs and to be suitable as both a textbook for advanced students and a reference book for professionals.

Until recently the best general reference for those studying the neurobiology of aging would have been a text on neuropathology or neurology. Although there is obviously some overlap between the present book and such sources, these are not fully adequate for the purposes discussed above. Many neuropathological processes occur early in life and thus relevance to the aging brain is often unclear. Perhaps more important, a key concern in understanding the aging of any system is appreciating the difference between pathological and nonpathological processes. While this difference was formerly the subject of some controversy, there is now general agreement that the distinction between pathological and nonpathological processes is central to understanding and treating age-related impairments of any system, including neuronal systems. Therefore, the editors have worked closely with the contributors to clarify which age-related impairments are pathological and which are not. The nature of this distinction is made clear in many of the chapters, but often lies in the observation that pathological processes are not universal. Thus, as described in several chapters, the incidence of diseases peaks at some age, but the development of nonpathological processes continues to increase with age. This distinction has been particularly troublesome for Alzheimer's disease, the incidence of which peaks very late in life. Most investigators now feel that even for this disease, the incidence declines in extremely old populations.

To enhance the utility of the book, the chapters have been organized into four large sections, based on neurobiological functions that are most vulnerable during aging, a scheme that also provides the basis of the title of the book. Although clearly the information in the present book could be organized many different ways, we have chosen the functional approach to emphasize the relationship between observed age-related changes in neuronal properties and functional decline; thus we hope to avoid a mere cataloging of age-correlated changes. While perhaps other functional schemes could be proposed, our aim was to produce the most comprehensive resource on the neurobiology of aging available, and the scheme chosen was sufficiently broad to comfortably embrace this wealth of material. An additional introductory section was included to develop certain concepts particularly pertinent to aging in the specific context of age-related impairments in neurobiological function.

We acknowledge the role of Dr. James Roberts, whose vision instigated the process that led to this book; Dr. John Morrison, who was a constant source of encouragement and support; and the terrific staff of Academic Press, especially Craig Panner, Hilary Rowe, and Lori Asbury for their patience with the vagaries of academics and for actually crystallizing a process into a book. Finally, we take this opportunity to express our deepest gratitude to the superb scientists who have actually written this book. We have been fortunate to have had the cooperation of many of the leading investigators in the neurobiology of aging, and the quality of the present volume clearly attests to the conscientious efforts of these writers in producing a major resource for the field. We are all too aware that the effort of writing these chapters has necessarily distracted these scientists from their main job of creating new knowledge and deeply appreciate that despite this circumstance they made the time to impart their knowledge and wisdom to the rest of us.

Age-Specific Rates of Neurological Disease

I. Introduction

Is aging "normal" or "pathological?" The emerging answers to this simple question are so complex that the question has essentially been rendered semantic. Additionally, training biases profoundly affect the perspective from which this question is viewed and investigated. For example, clinicians typically view disease as a pathological process amenable to therapeutic intervention, but perceive aging (or more appropriately, senescence) as an inevitable process with limited prospects for significant manipulation. Clouding the question even further is the observation that many diseases are inseparably linked to aging.

Taking advantage of the varied perspectives, clues regarding the nature of aging can, should, and are being sought using a multitude of approaches. Epidemiological studies of aging and disease traditionally give descriptive measures of disease burden and attempt to identify risk factors associated with aging-related disorders. Analysis and interpretation of age-specific disease rates, however, are relatively underappreciated vantage points from which to view aging. A preliminary note of caution is warranted. Age-specific rates deal with populations. Consequently, conclusions derived from the analysis of age-specific rate dynamics are applicable to populations, not to individuals, and especially not to the molecular processes involved in aging. This limitation, however, may have some powerful practical advantages. This chapter focuses on age-specific rates of neurological disease. The major neurological disorders associated with aging are Alzheimer's disease, amyotrophic lateral sclerosis, Parkinson's disease, primary malignant brain tumors, and stroke.

II. Age-Specific Rates

An age-specific rate (R_x) is defined as the number of occurrences of a certain event at a specific age (N_x) divided by the total number of individuals (P_x) alive at that age. This relationship can be expressed as

$$R_x = \frac{N_x}{P_x}. \quad (1)$$

The two commonly measured age-specific rates, incidence and mortality rates, are often used to measure and compare disease burden over time as they are assumed to be independent of changes in the age structure of a population (Hennekens and Buring, 1987), i.e., an age-specific mortality rate should be independent of the relevant age group population size (Fig. 1.1). For example, the mortality rate from primary malignant brain tumor among U.S. men aged 85 years and older should not be dependent on whether there are 1000 or 1,000,000 individuals in that age group.

III. Age-Specific Rates of Neurological Disease

Epidemiological studies in the elderly of developed nations over recent decades have documented an increasing frequency of Alzheimer's disease (Plum, 1979; Katzman, 1986; Fox, 1989; Centers for Disease Control, 1991), amyotrophic lateral sclerosis (Durrleman and Alpérovitch, 1989; Lilienfeld *et al.*, 1989; Chancellor and Warlow, 1992), Parkinson's disease (Duvoisin and Schweitzer, 1966; Kurtzke and Murphy, 1990; Lilienfeld *et al.*, 1990; Chio *et al.*, 1993c; Clarke, 1993), and primary malignant brain tumor (Davis and Schwartz, 1988; Helseth *et al.*, 1988; Boyle *et al.*, 1990; Greig *et al.*, 1990; Davis *et al.*, 1991). Unlike these neurodegenerative disorders, the burden of stroke, especially as measured by mortality, has declined significantly in recent decades (Whisnant, 1984; Klag *et al.*, 1989).

A. Alzheimer's Disease

Age-specific incidence rates of Alzheimer's disease increase exponentially with age (Sayetta, 1986; Hebert *et al.*, 1995; Gao *et al.*, 1998; Jorm and Jolley, 1998). This exponential rate of increasing incidence slows down after the eighth or ninth decade of life (Gao *et al.*, 1998), although there is no actual decline in the incidence rate (Fig. 1.2). Age-specific mortality rates from Alzheimer's disease also increase exponentially with increasing age, but fail to maintain that exponential rate of increase at an earlier age than that seen with age-specific

FIG. 1.1. An age-specific mortality rate is generally considered to be independent of the relevant age group population size; i.e., an age-specific mortality rate should not depend on whether the relevant age group population size is 1000 or 1,000,000.

incidence rates (Imaizumi, 1992). A limitation of Alzheimer's disease mortality data is that dementia is not consistently reported on death certificates (Ganguli and Rodriguez, 1999).

B. Amyotrophic Lateral Sclerosis

Age-specific incidence rates of amyotrophic lateral sclerosis also demonstrate approximately exponential increases with age until the seventh or eighth decade of life (Kahana *et al.*, 1976; Kurtzke, 1982; Leone *et al.*, 1987; Lopez-Vega *et al.*, 1988; Durrleman and Alpérovitch, 1989; Tysnes *et al*., 1991; Brooks, 1996). The age-specific incidence pattern of amyotrophic lateral sclerosis is similar to that seen in Alzheimer's disease (Fig. 1.2). Amyotrophic lateral sclerosis age-specific mortality rates also increase exponentially with increasing age and (as with Alzheimer's disease) fail to maintain that exponential rate of increase at an earlier age than that seen with age-specific incidence rates (Leone *et al.*, 1987; Riggs, 1990b; Chio *et al.*, 1993b; Neilson *et al.*, 1994). Unlike the situation with Alzheimer's disease, mortality due to amyotrophic lateral sclerosis is consistently reported on death certificates (Hoffman and Brody, 1971; Chio *et al.*, 1993a).

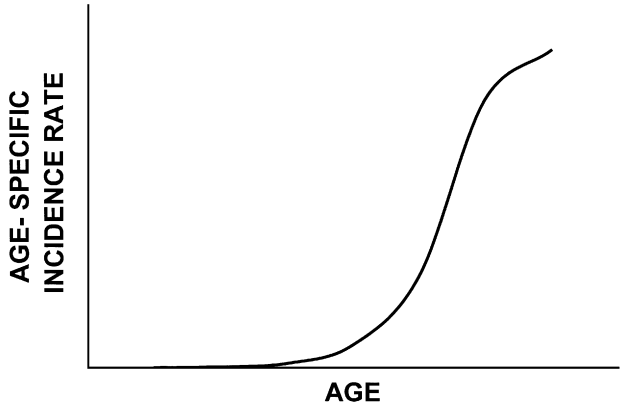

FIG. 1.2. Age-specific mortality rates for most aging-related neurologic disorders demonstrate a similar pattern. Age-specific mortality rates will rise initially at an exponential rate with increasing age. After some age, age-specific mortality rates will increase at a slower rate, plateau, or decline.

C. Parkinson's Disease

Age-specific incidence rates of Parkinson's disease also increase rapidly with increasing age, then decrease after the eighth or ninth decade of life (Morens *et al.*, 1996). This age-specific incidence pattern is also similar to that seen in Alzheimer's disease and amyotrophic lateral sclerosis (Fig. 1.2). Age-specific mortality rates of Parkinson's disease also increase exponentially with increasing age, but again fail to maintain that exponential rate of increase at an earlier age than that seen with age-specific incidence rates (Riggs, 1990c; Bonifati *et al.*, 1993; Imaizumi, 1995). A limitation of Parkinson's disease mortality data is that parkinsonism may not be consistently reported on death certificates as 15 to 25% of patients are only identified in screening survey studies (de Rijk *et al.*, 1995, 1997).

D. Primary Malignant Brain Tumor

Age-specific incidence rates of primary malignant brain tumor also demonstrate rapid increases with age until the seventh or eighth decade of life and then drop off or decline (Sutherland *et al.*, 1987; Helseth *et al.*, 1988; Sant *et al.*, 1988; Ahsan *et al.*, 1995; Polednak and Flannery, 1995; Kuratsu and Ushio, 1997). The age-specific incidence pattern of primary malignant brain tumor is similar to that seen in Alzheimer's disease, amyotrophic lateral sclerosis, and Parkinson's disease (Fig. 1.2). Age-specific mortality rates of primary malignant brain tumor also increase exponentially with increasing age and also fail to maintain that exponential rate of increase after an age that is less than the peak incidence rate (Riggs, 1991a, 1995a).

E. Stroke

Age-specific incidence rates of stroke show a dramatic exponential increase with increasing age (Robins and Baum, 1981). No decline in the exponential rate of increase in stroke incidence occurs before the ninth decade of life. Age-specific mortality rates of stroke also increase exponentially with increasing age (Riggs, 1990d). Unlike neurodegenerative disorders, age-specific stroke mortality does not deviate from increasing exponentially with increasing age before the ninth decade of life (Riggs, 1990d).

IV. Age-Specific Rates and Mortality Dynamics

Age-specific rates of neurological disease can provide more than just a descriptive measure of the societal burden of neurological disorders in an aging population. Age-specific rates are a window of opportunity for understanding mortality dynamics associated with aging at the population level.

A. Deviation from Gompertzian Mortality Dynamics

Gompertz (1825) initially described the exponentially increasing risk of mortality with increasing age. Age-specific mortality, however, is consistently lower than that predicted

by a constant exponential increase at older ages (Juckett and Rosenberg, 1993). This observation is true for both age-specific general mortality and age-specific mortality from many neoplasms and degenerative disorders associated with aging (Riggs, 1993c). The basis for this deviation from a constant exponential increase between age-specific mortality and increasing age may relate to the definition of age-specific mortality rate, which is the number of individuals dying from a particular disease at a specific age divided by the number of individuals alive at that age [Eq. (1)]. The numerator includes individuals susceptible to that particular disease as evidenced by the fact that their death was attributed to that disease. The denominator includes all individuals, both susceptible and nonsusceptible, alive at a specific age. Human populations are quite heterogeneous in their susceptibilities to various diseases. For example, some individuals are inherently more prone to developing Alzheimer's disease, amyotrophic lateral sclerosis, Parkinson's disease, or primary malignant brain tumor than are others.

The rate of exponential increase in age-specific mortality with increasing age in amyotrophic lateral sclerosis (Riggs, 1990b), Parkinson's disease (Riggs, 1990c), and primary malignant brain tumor (Riggs, 1991a) is much greater than the rate of exponential increase in age-specific general mortality with increasing age (Riggs, 1990a). Therefore, individuals susceptible to these neurological disorders in the population are depleted at a faster rate than is the general population. As a mathematical consequence, age-specific mortality rates must deviate from constant exponential (or Gompertzian) dynamics after a certain age (Fig. 1.2). The age at which this deviation occurs varies for different disorders depending on the relative size of the susceptible population subset and the rate at which that population subset is depleted. Thus, deviation of Alzheimer's disease, amyotrophic lateral sclerosis, Parkinson's disease, and primary malignant brain tumor age-specific mortality rates at older ages from that predicted by Gompertzian dynamics is primarily a mathematical phenomenon rather than an indicator of failure to describe the biological relationship between aging and mortality (Riggs, 1993c).

B. The Increasing Burden of Neurodegenerative Disease

The importance of neurological disease in old age is not merely a reflection of the dramatic increase in the number of elderly individuals. The frequency of neurological disorders in the elderly has also increased dramatically. As examples of this rising burden of neurological disease, mortality rates among U.S. men aged 85 years and older increased 328% for amyotrophic lateral sclerosis between 1977 and 1986 (Riggs, 1990b), 411 for Parkinson's disease between 1955 and 1986 (Riggs, 1990c), and 924% for primary malignant brain tumor between 1962 and 1987 (Riggs, 1991a). Does this increasing frequency and burden of neurologic disease in the elderly reflect better case ascertainment from improved diagnostic capabilities, greater interest and knowledge among physicians, and increased environmental pathogenic influences associated with industrialization (Katzman, 1986; Davis and Schwartz, 1988; Durrleman and Alperovitch, 1989; Fox, 1989; Lilienfeld *et al.*, 1989, 1990; Boyle *et al.*, 1990; Davis *et al.*, 1991; Chancellor and Warlow, 1992; Modan *et al.*, 1992; Clarke, 1993)? These factors, although valid, may not entirely account for the increasing frequency of neurological disease in the elderly.

The aging population has had a significant impact on the societal burden from several neurological disorders such as Alzheimer's disease, amyotrophic lateral sclerosis, Parkinson's disease, and primary malignant brain tumor. This increased burden of neurologic disease in the elderly is the result of more than just the dramatically increasing number of elderly individuals. The profound demographic change in the age structure of populations in developed nations is primarily the result of increasing survival. ''Differential survival'' over time, and its effect of less selective culling of the surviving population gene pool, is an additional explanation for the increasing frequency of several neurologic diseases associated with senescence.

From a historical perspective, old age or senescence should be considered an unnatural state. Under primitive conditions, it is quite uncommon to live to old age. Medawar (1952) made this point eloquently in his classic lecture delivered at University College London in 1951 when he stated that senescence ''is in a real and important sense an artefact of domestication; that is, something revealed and made manifest by the most unnatural experiment of prolonging an animal's life.'' In several respects, humankind can be considered the most domesticated member of the animal kingdom. Advancing civilization has been associated with a fivefold increase in human life expectancy since the stone age and a corresponding increase in the burden of disorders of senescence (Riggs, 1993b). Refining this position, a recent *Lancet* editorial (Editorial, 1993) stated that modern ''civilization . . . is not the cause of our chronic diseases . . . it merely unveiled what our genes had lurking in store for us for centuries, if not millennia, as we now live long enough to see these genes massively expressing themselves.''

In the United States in 1900, there were only 3 million people over 65 years old and just 72,000 individuals over 85 years old (Olshansky *et al.*, 1993). By 1996, those corresponding numbers had increased to 33.3 million and 2.2 million (Olshansky *et al.*, 1993). Currently, the oldest old, consisting of those individuals aged 85 years and older, are the fastest growing segment of the population (Suzman *et al.*, 1992). Indeed, between 1951 and 1989, the size of this population subset in the United States grew at a staggering annual rate of 3.14% in men and 4.94% in women (Riggs, 1996a).

Age-specific mortality rates provide an important clue to understanding the increasing burden of neurological disease in the elderly. Because age-specific rates are generally assumed to be independent of the age structure of a population, mortality rates among individuals aged 85 years and older from amyotrophic lateral sclerosis, Parkinson's disease, or primary malignant brain tumor would generally be considered to be independent of the size of that population subset. However, mortality rates among individuals aged 85 years and older (and also other elderly age groups) from amyotrophic lateral sclerosis (Riggs, 1990b), Parkinson's disease (Riggs, 1990c), and primary malignant brain tumor (Riggs, 1991a, 1995a) were directly correlated with the population size of that age group (Riggs, 1996a). Thus, mortality rates from these neurological diseases among ''the oldest old'' were directly

FIG. 1.3. Age-specific mortality rates (per 100,000) from primary malignant brain tumor among U.S. men aged 85 years and over during the years 1962 to 1989 (adapted from data in Riggs, 1995a). Note the direct correlation between the age-specific mortality rate and the relevant age group population size (in 100,000's).

correlated with the size of that age group population subset. Similarly, increasing mortality in the elderly from many other diseases, such as lung cancer (Riggs, 1995b), ovarian cancer (Riggs, 1995c), and multiple myeloma (Riggs, 1995d), demonstrated an increasing dependency with increasing age on increasing age group population size. Thus, in certain aging-related diseases, age-specific mortality rates are a function of age group population size at older ages (Fig. 1.3). This relationship can be expressed as

$$(R_x) = f(P_x). \tag{2}$$

This dependence of age-specific mortality rates on age group population size suggests that something intrinsic about the elderly population is changing, which may account for the observed increasing burden of disease. That intrinsic "something" may be changing genetic susceptibility at the population level. Despite being matched for age and gender, age-specific mortality rate comparisons can be misleading if populations are not also matched genetically (Riggs, 1994). Is it possible that sufficient differences in genetic susceptibility to certain neurological diseases between successive elderly population cohorts could occur over the span of just a few years to have contributed to the substantially increasing burden of those disorders?

Charles Darwin (1859) deduced that in the "struggle for existence, it follows that any being, if it vary however slightly in any manner profitable to itself, under the complex and sometimes varying conditions of life, will have a better chance of survival." Accordingly, survival is not random, and competition for survival will result in "survival of the fittest" (or differential survival). Evolution, by means of differential survival (or, more accurately, differential reproduction), and natural selection occur over a very long time scale. However, the selective culling effect of differential survival on the surviving gene pool of an aging population cohort occurs immediately (Riggs, 1996b). When an individual in a population dies, the remaining population gene pool of that age cohort is immediately altered (Riggs, 1996b). As a result of differential survival, the surviving gene pool, and hence disease susceptibilities, of a population cohort will become progressively altered. The decreasing frequency of the apolipoprotein E $\epsilon 4$ allele with aging (Davignon *et al.*, 1987; Cauley *et al.*, 1993) provides direct evidence that differential survival does alter the surviving gene pool. As adversity to survival in developing nations decreases, individuals survive longer, and the aggregate genetic susceptibility to diseases, including certain neurological disorders, among aging survivors will change. Indeed, if the aggregate gene pool of a surviving elderly cohort did not change as members of that cohort died, this would imply that disease and death occur randomly with respect to genetic influences. The thesis that differential survival in human populations impacts on disease patterns is based on two fundamental principles. First, human populations are genetically heterogeneous. Second, genetic factors influence disease susceptibility. Both of these principles have been verified repeatedly by molecular genetic investigations. Indeed, human populations are genetically heterogeneous in their susceptibility to Alzheimer's disease (Katzman and Saitoh, 1991), amyotrophic lateral sclerosis (Mulder *et al.*, 1986), Parkinson's disease (Kondo and Kurland, 1973), and primary malignant brain tumor (Choi *et al.*, 1970).

The increasing age structure of the world's population primarily reflects enhanced survival due to declining mortality (Olshansky *et al.*, 1993). Enhanced survival has resulted in a several hundred percent increase in the population size of the oldest age groups in the United States over the past four decades (Riggs, 1996a). The magnitude of these demographic changes is sufficient to have contributed significantly to the increasing burden and frequency of neurological disease in the elderly population. As more members of a given cohort survive into old age, there has been less "selection" with respect to the surviving gene pool and a resultant increased genetic propensity to the disorders of senescence (Medawar, 1952; Riggs, 1992a, 1996b).

C. Longitudinal Gompertzian Analysis

Gompertz (1825) described a mathematical relationship between human aging and mortality. Gompertz noted that mortality rose exponentially with increasing age. Because mortality rates are expressed conventionally as deaths per 100,000 population, the Gompertz relationship may be expressed as

$$R_x = R_o(10)^{\alpha x}, \tag{3}$$

where R_x is the mortality rate at age x, R_o is the extrapolated death rate at birth, and α is the slope of the exponential term. The Gompertz equation becomes a linear function when expressed logarithmically:

$$\log R_x = \alpha x + \log R_o. \tag{4}$$

Strehler and Mildvan (1960) introduced the following modification to the Gompertz relationship:

$$B = \frac{\alpha}{\log(K/R_o)}. \tag{5}$$

In this equation, Strehler and Mildvan (1960) defined B as the fractional loss of vitality and K as a proportionality constant that relates the vitality of an organism and the magnitude of

environmental challenges to the mortality rate. Rearranging Eq. (5) yields

$$\alpha = -B(\log R_o) + B\,(\log K). \tag{6}$$

Implicit in the Strehler–Mildvan modification of the Gompertz model of aging and mortality [Eq. (5)], assuming that both B and K are constant, is the prediction of a negative linear relationship between α and log R_o and that annual age-specific mortality rate distributions will intersect at a single, fixed point (Riggs, 1990a). Moreover, this intersect point will occur at the point where age equals $1/B$ and log R_x equals log K. Longitudinal Gompertzian analysis has validated this prediction using mortality data for many aging-related degenerative disorders (Riggs, 1990b,c) and neoplasms (Riggs, 1991a,b,c). Because disease-specific values of B have been constant for every disorder studied, B has been postulated to represent some aggregate measure of genetic influences on age-specific mortality (Riggs, 1991b,c, 1992c). The Strehler–Mildvan modification of the Gompertzian mortality rate distribution conforms to thermodynamic interpretation (Lestienne, 1988). Using a thermodynamic perspective, Atlan (1968) demonstrated that the rate of decline of vitality with age (the quantity B introduced by Strehler and Mildvan) can be conceptualized in terms of entropy. Consequently, longitudinal Gompertzian analysis can be used to determine B, which is an aggregate measure of the rate of increase in genomic entropy for those genetic factors involved in aging-related mortality. Associated with declining mortality, the values of K for cervical cancer (Riggs, 1992b), emphysema (Riggs, 1992c), and stroke (Riggs and Myers, 1994) have declined significantly. Associated with increasing mortality, the value of K for non-Hodgkin's lymphoma has increased significantly (Riggs, 1993a). Consequently, K is not necessarily constant and has been postulated to represent some aggregate measure of environmental influences on age-specific mortality (Riggs, 1992b,c, 1993a). Thus, longitudinal Gompertzian analysis suggests that age-specific mortality rate distributions are determined by the interaction of genetic and environmental influences.

1. Parkinson's Disease Mortality

Parkinson's disease mortality is particularly useful in illustrating the method of longitudinal Gompertzian analysis. Age-specific mortality rates in the United States due to Parkinson's disease from 1955 to 1988 have been determined previously (Riggs, 1990c, 1991d, 1992d) from federal sources (National Center for Health Statistics, 1955–1988). Deaths were recorded for the following age groups (in years); less than 1, 1–4, 5–9, 10–14, 15–19, 20–24, 25–29, 30–34, 35–39, 40–44, 45–49, 50–54, 55–59, 60–64, 65–69, 70–74, 75–79, 80–84, and 85 and over. In the analysis of these data, the mortality rate for each age group was assigned to the mean age of the group. By using the number of deaths in each age group and population size estimates of the corresponding age group, annual age-specific Parkinson's disease mortality rates were determined.

The initial step in longitudinal Gompertzian analysis is to determine if mortality increases exponentially with age (Riggs, 1990a). Parkinson's disease age-specific mortality rates plotted on a logarithmic scale for U.S. men in 1988 are shown in Fig. 1.4. Parkinson's disease log R_x appears to increase linearly between age 45 and 80 years (Fig. 1.4). Using linear regression to analyze the relationship between log R_x and age between age 45 and 80 years yields an r-squared value greater than 0.98 (where r is the correlation coefficient of the linear regression). Therefore, in 1988 the relationship between Parkinson's disease log R_x and age among U.S. men aged 45 to 80 years was highly linear and, thus by definition, Gompertzian. From Eq. (3), the values for α and log R_o are also derived using linear regression. For Parkinson's disease mortality among U.S. men in 1988 between age 45 and 80 years, the following relationship is derived:

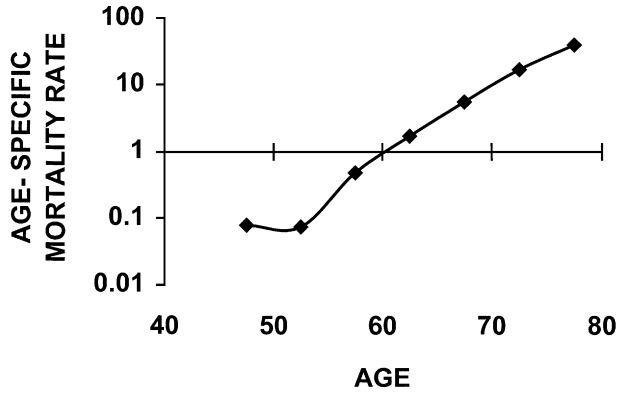

FIG. 1.4. Age-specific Parkinson's disease mortality rates (per 100,000). among U.S. men in 1988 plotted on a logarithmic scale. Note the essentially constant exponential rate of increase in age-specific mortality rates between ages 45 and 80 years.

$$\log R_x = 0.107421x - 6.58931. \tag{7}$$

Values of α and log R_o for Parkinson's disease mortality among U.S. men between 1955 and 1988 have been determined previously (Riggs, 1990c, 1991d, 1992d).

The next step in longitudinal Gompertzian analysis is to determine the relationship between α and log R_o for different years (Riggs, 1990a). The plot of α versus log R_o for Parkinson's disease among U.S. men between 1955 and 1988 (Fig. 1.5) demonstrates the linear negative relationship predicted by the Strehler–Mildvan modification of the Gompertz relationship. Using linear regression to analyze the relationship between α and log R_o (Fig. 1.5), the following equation regarding Parkinson's disease mortality among U.S. men is derived:

$$\alpha = -0.01365 \log R_o + 0.016998. \tag{8}$$

The r-squared value for the linear regression defining Eq. (8) is greater than 0.98. A potential mathematical explanation for this highly linear negative correlation between α and log R_o is that when data from repeated studies that are actually measuring the same phenomenon are analyzed using linear regression, a natural negative linear relationship between the slope and intercept values will emerge spontaneously (Riggs and Hobbs, 1998). However, if this mathematical explanation was the reason for this observed linear negative relationship, the sequence of annual α and log R_o values would be random.

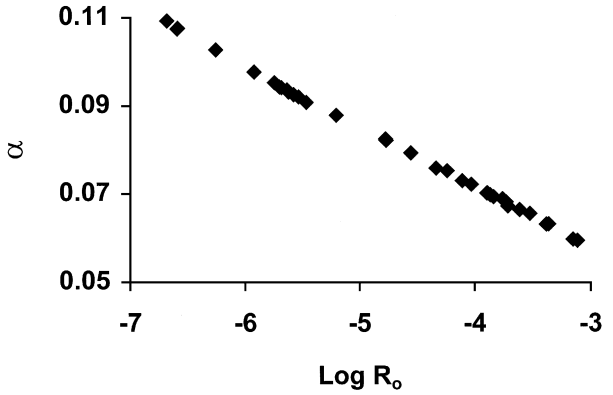

FIG. 1.5. Plot of annual pairs of α and log R_o values for Parkinson's disease mortality among U.S. men aged 45 to 80 years from 1955 to 1988. Note the negative linear relationship between α and log R_o.

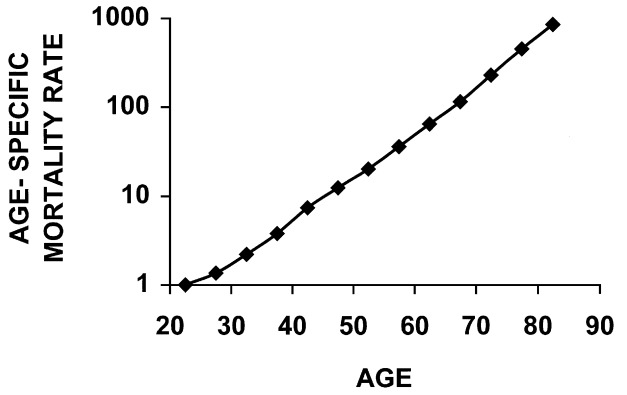

FIG. 1.6. Age-specific stroke mortality rates (per 100,000) among U.S. white men in 1988 plotted on a logarithmic scale. Note the constant exponential rate of increase in age-specific mortality rates between ages 20 and 85 years.

However, the sequence annual α and log R_o data points are not random, but rather are highly ordered (Riggs and Hobbs, 1998).

Because Eq. (8) is in the same format as Eq. (6), the value for B with respect to Parkinson's disease mortality among U.S. men is directly determined. Accordingly, the value of B for Parkinson's disease mortality in U.S. men was 0.01365. Thus, the annual rate of increase in "genomic entropy" between age 45 and 80 years with respect to Parkinson's disease mortality was 1.365% for U.S. men.

2. Stroke Mortality

Longitudinal Gompertzian analysis provides an insightful method of analyzing the trend of declining stroke mortality. Age-specific mortality rates among white men in the United States due to stroke from 1951 to 1988 have been determined previously (Riggs and Myers, 1994) from federal sources (National Center for Health Statistics, 1955–1988). Age-specific stroke mortality rates plotted on a logarithmic scale for U.S. white men in 1988 increase linearly between age 20 and 85 years (Fig. 1.6). Using linear regression to analyze the relationship between log R_x and age between age 20 and 85 years yields an r-squared value greater than 0.99 (where r is the correlation coefficient of the linear regression). Therefore, in 1988 the relationship between log R_x and age for stroke mortality among U.S. white men between age 20 and 85 years was highly linear and, thus by definition, Gompertzian. From Eq. (4), the values for α and log R_o are also derived by linear regression analysis. For example, for stroke mortality among U.S. white men in 1988 between age 20 and 85 years, the following relationship is derived:

$$\log R_x = 0.049429x - 1.23334. \tag{9}$$

Linear regression analysis of the relationship between log R_x from stroke and age between age 20 and 85 years for U.S. white men for the years 1951 through 1988 yields corresponding α and log R_o values for each year (Riggs and Myers, 1994). The corresponding r-squared value for each pair of α and log R_o was greater than 0.99 for every year.

The next step in longitudinal Gompertzian analysis is to determine the relationship between α and log R_o for the different years (Riggs, 1990a). The plot of α versus log R_o for U.S. white men aged 20 to 85 years for the years 1951 through 1988 (Fig. 1.7) does not demonstrate the linear negative relationships seen in many Gompertzian diseases (Fig. 1.5). However, the pattern displayed in Fig. 1.7 is not random. When the annual pairs of α and log R_o values for mortality due to stroke among U.S. white men are connected sequentially (Fig. 1.8), a distinctive pattern is seen. This same pattern was seen when cervical cancer (Riggs, 1992b) and emphysema (Riggs, 1992c) mortalities were analyzed by longitudinal Gompertzian analysis. The pattern in Fig. 1.8 is produced by a function that has a constant slope and a decreasing Y intercept (Riggs, 1992b,c). The slope of the function that relates α and log R_o, from Eq. (6), is equal to $-B$. Because B is always constant, a new value C can be introduced for the term B (log K) in Eq. (6) and be expressed by the equation:

$$C = B(\log K), \tag{10}$$

where C is equal to the varying "Y intercept" in Fig. 1.8. Consequently, Eq. (6) can be written as

$$\alpha = -B(\log R_o) + C. \tag{11}$$

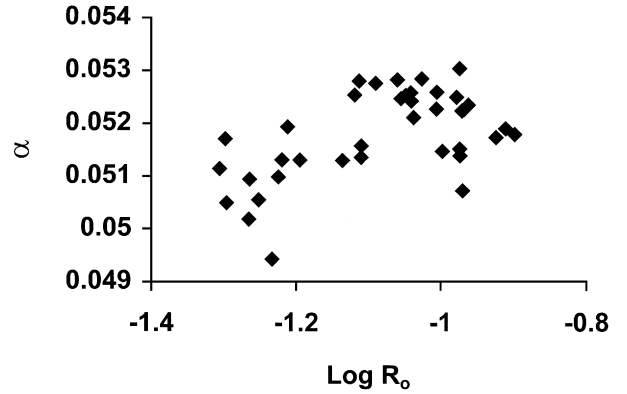

FIG. 1.7. Plot of annual pairs of α and log R_o values for stroke mortality among U.S. white men aged 20 to 85 years from 1951 to 1988. Note the apparent lack of any relationship between α and log R_o.

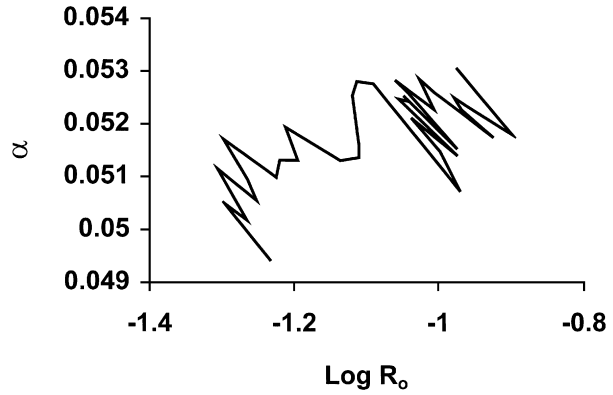

FIG. 1.8. Plot of annual pairs of α versus log R_o for stroke mortality among U.S. white men aged 20 to 85 years from 1951 to 1988 when data pairs (as shown in Fig. 1.7) are connected sequentially. Note that this distinctive nonrandom pattern can be produced by a function interrelating α and log R_o, which has a constant negative linear slope, as shown in Fig. 1.5, and a decreasing Y intercept. The 1951 data point is at the upper right. The 1988 data point is at the lower left.

A method of determining B when C is changing over time was defined in a study using longitudinal Gompertzian analysis of cervical cancer mortality (Riggs, 1992b). The slope [which from Eq. (11) is equal to $-B$] between consecutive pairs of α and log R_o values for stroke mortality in U.S. white men was calculated (Riggs and Myers, 1994). The slope for year N is defined by the following equation (Riggs, 1992b)

$$(-B)_N = \frac{\alpha_{N+1} - \alpha_N}{(\log R_o)_{N+1} - (\log R_o)_N}. \qquad (12)$$

The annual plots of $-B$ for stroke mortality among U.S. white men is shown in Fig. 1.9. As can be seen, there is an underlying dominant or most frequent value of $-B$. From Fig. 1.9, it is also apparent that there are outlier values of $-B$. The basis for these outlier values is inherent in the definition of slope, which is defined as the change in Y (or α) divided by the change in X (or log R_o). As the change in X becomes small, the absolute value of the slope may become large. Thus, the outlier values of $-B$ in Fig. 1.9 occur at points when there were small changes in consecutive values of log

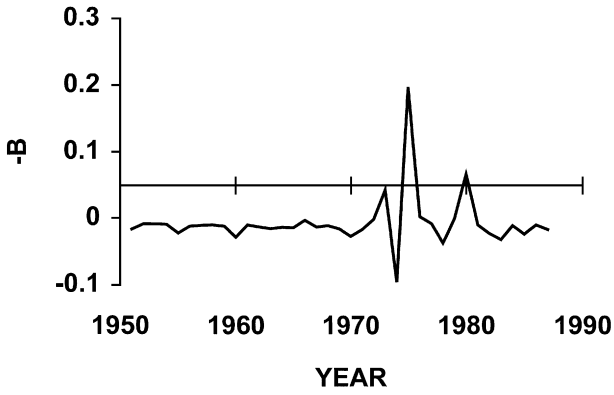

FIG. 1.9. Plot of $-B$ for mortality from stroke among U.S. white men aged 20 to 85 years from 1951 to 1987.

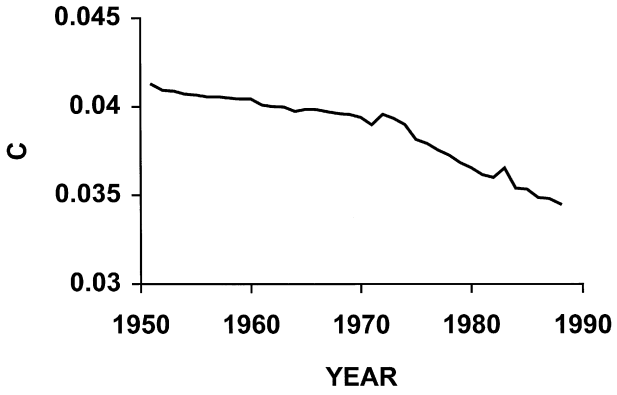

FIG. 1.10. Plot of C for mortality from stroke among U.S. white men aged 20 to 85 years from 1951 to 1988.

R_o. Because the values of $-B$ tend to be small and outlier values of $-B$ can be large, the mean is not a good method of determining the underlying dominant value of $-B$. Instead, the median value of $-B$ is used as the best estimate for the underlying constant value of $-B$ (Riggs, 1992b). The median value of $-B$ for stroke mortality among U.S. white men aged 20 to 85 years was -0.01211 (Riggs and Myers, 1994). Accordingly, the value of B for stroke mortality among U.S. white men was 0.01211. Thus, the annual rate of increase in "genomic entropy" between age 20 and 85 years with respect to stroke mortality was 1.211% for U.S. white men.

Annual values of C for stroke mortality among U.S. white men aged 20 to 85 years between 1951 and 1988 were determined using this median value of $-B$ and Eq. (11). The annual values of C are shown in Fig. 1.10. Thus, age-specific stroke mortality rates among U.S. white men aged 20 to 85 years between 1951 and 1988 conformed to the dynamics predicted by the Strehler–Mildvan model of aging and mortality in which the value of log K (or C) was declining over time. Between 1951 and 1988, etiopathogenic influences (as reflected by C values) among U.S. white men with respect to stroke mortality declined 16.4%.

V. Commentary

Newtonian mechanics was used to assist humankind to successfully navigate to the Moon and back. Newtonian mechanics, however, does not provide insight as to the "true" nature of gravity. Indeed, Newtonian mechanics ignores the heterogeneous atomic composition of large masses and the quantum mechanical interactions between the atoms making up those masses. Newtonian mechanics, nevertheless, is a very functional and practical perspective from which to observe and gain insight into gravitational forces, despite the fact that the "true" nature of the force of gravity remains unknown.

The relationship between age-specific rates and aging may be similar. The molecular interactions involved in aging are so complex that understanding the "true" nature of senescence will be extremely difficult. However, examination and analysis at the macroscopic level of age-specific rates may provide a very functional and practical perspective from which to observe and gain insight into the process of aging.

Finally, is aging ''normal'' or ''pathological?'' Perhaps the ''simple'' correct answer to this complex question is that aging is both ''normal'' and ''pathological''.

Nature versus Nurture in the Aging Brain

The relative contribution of genotype to many phenotypes is not constant, but changes with age. Twin studies have suggested that the contribution of genotype to general health increases until about age 70 and then decreases dramatically thereafter. In families in which age-related neurological diseases occur in a Mendelian autosomal dominant pattern (including Huntington's disease), penetrance of the disease-causing allele increases from 0% in childhood to 100% by about 70 years of age. However, for most diseases such familial cases constitute only a minority of the total; thus the relative contribution of genotype to the total incidence of most diseases decreases after about age 70. Similarly, the contribution of genotype to nonpathological age-related neurobiological impairments also appears to peak at about 70 years of age and then decreases. Thus after age 70, environmental effects increasingly dominate most age-related impairments in neurobiological function.

I. Introduction

A fundamental concern of biological research is to account for variations between individuals. In general this concern is addressed by assessing the relative contributions of genotype and environment to phenotype. However, individual variation of many phenotypes is significantly accounted for by age. It is often assumed that age is essentially a proxy for the cumulative effects of environment and thus that the effect of age on a phenotype is in fact a reflection of environment. In turn, this reasoning would imply that with respect to phenotype during aging, the relative effect of environment should increase and the relative effect of genotype should decrease. To address this hypothesis, it is necessary to assess how stable individual variations are during aging. For example, eye color is completely stable with age, and completely accounted for by genotype at all ages, whereas body weight is unstable with age in two respects: the body weight of each individual changes with age and the variability of body weight increases with age. Although individual differences in body weight are largely due to genotype, it is of interest to assess if age-related changes in body weight (both in average and in variability) are due to genotype or cumulative environmental effects.

Clearly in the case of autosomal dominant age-related genetic diseases, the coupling between genotype and phenotype, e.g., penetrance, increases with age. For example, Huntington's disease is an autosomal dominant disease with complete penetrance, as every individual bearing the disease-causing allele eventually develops the disease (if the individual lives long enough) and no individual without that allele develops the disease. However, at birth there is no phenotypic difference between individuals bearing the mutation for Huntington's disease and normal individuals; the phenotype only develops during aging, and by age 70 there is almost 100% concordance between genotype and phenotype, with the environment playing essentially no role. Thus penetrance of the Huntington's disease allele increases from 0 to 100% during aging. Furthermore, cumulative environmental effects during aging may depend largely on genotype. For example, as described later, practice enhances skill, and a high-fat diet induces obesity, but the effect of these manipulations depends largely on genotype. Thus when individuals share a common environment, the effect of genotype may become more accentuated during aging even for environmentally induced phenotypes. It has therefore become clear that assessing the coupling between genotype and phenotype during aging requires a careful analysis of the effect of age on genetic penetrance. As will be described later, such careful analysis in human twin studies has indicated that the relative contribution of genotype to phenotype often increases with age to a peak at around 70 years of age, after which phenotype is increasingly determined by environment. Interestingly, this pattern applies even to neurobiological functions, including cognitive functions, in which it might be hypothesized that effects of experience would monotonically increase throughout the life span.

These considerations also suggest that the effects of genotype may be revealed by environment. A classic example of this strong interaction between environment and heredity in a neuropathological process is the disease of phenylketonuria, first described by Fölling in 1934. Individuals homozygous

for the disease allele of the phenylalanine hydroxylase gene develop phenylketonuria, a disease leading to severe mental retardation, on a normal diet. However, if maintained on a diet free of phenylalanine, the disease will not develop (discussed in more detail in Rowe & Kahn, 1998, p. 219). As with diet-induced obesity and many other pathological processes, this example indicates that a unitary concept of ''environment'' is of limited value, since the relative contribution of environment and heredity depends profoundly on the specific nature of both environment and heredity. Specifically with respect to the interaction between environment and heredity during aging, a key consideration is that ''environment'' actually changes with age, for example due to profound age-related differences in exposure to drugs. Nevertheless, despite these complications, there has been remarkable agreement concerning the relationship between environment and heredity during aging in typical human (at least Western) environments.

II. Genotype, Environment, and General Health

One way to assess the relative contributions of genotype and environment on phenotype is to analyze the cause of individual variations of the phenotype across a population. Viewed statistically, age-related phenotypes can be analyzed by assessing the amount of variance that is accounted for by genotype, environment, and age, and the shared variance of these factors. A common approach to such an analysis involves examining the shared variance of a phenotype in monozygotic compared to dizygotic twins. In the Swedish Adoption/Twin Study of Aging supported by the MacArthur Foundation Study of Successful Aging, Harris *et al*. (1992) examined individual differences in objectively determined chronic illnesses as well as in self-rated health in monozygotic and dizygotic Swedish twins who were reared together or apart. The burden of chronic illness was assessed by a rating scale that was developed and validated to reflect ''constricted homeostasis'' (Rowe, 1985) as an indicator of general decline of physiological function. Thus this parameter was designed to reflect a broad range of functions, including cardiovascular, respiratory, neurologic, metabolic, and other functions. Individuals were divided into four age groups: less than 50 years old, 50–59 years old, 60–69 years old, and greater than 70.

A key initial observation of this study was that while *average* health scores decreased monotonically with age, *differences* in the health between individuals also increased at least as much with age. The effect of age on health was in contrast to the effect of age on height and weight in this study, as differences in height and weight between individuals were greater in the group aged 50–59 years than in the group aged less than 50 years, but after 60 years of age individual differences actually began to decrease so that the lowest individual variation for both height and weight was found in the oldest group. One interpretation of these observations is that while the health of many individuals deteriorated markedly during aging, other individuals maintained relatively good health as they aged. This interpretation was supported by the observation that the optimum score for objective health was observed in individuals at all age ranges, but the worst reported score for health increased with the age of the group. In contrast, effects of age on height and weight were relatively uniform. Thus a critical question was to determine what accounted for the individual variation in health during aging, which allowed some individuals to age with little impact on health [referred to as ''successful aging'' (Rowe and Kahn, 1997)], whereas other individuals developed severe health problems. Specifically, a key question was to assess the relative contribution of genotype and environment on health during aging.

This question was addressed by comparing the health during aging of monozygotic twins reared together or reared apart with the health of dizygotic twins reared together or reared apart, using standard statistical methods. For example, objective health in monozygotic twins reared apart was highly correlated at ages below 50, between 50 and 59, and between 60 and 69, but was not significantly correlated over the age of 70 years. Essentially similar results were obtained in twins reared together. Detailed analysis indicated that the relative contribution of genotype to objective health roughly doubled from the youngest group to the group aged 60–69, but after the age of 70 there was no longer a significant effect of genotype on objective health. These data suggest that objective health is significantly influenced by genotype (not surprisingly) and that the effect of genotype increases with age up until the age of about 70 years (surprisingly), after which the effects of environment become more important and the relative contribution of genotype to phenotype decreases dramatically.

Because effects of environment, unique to each individual, must surely accumulate with age, it may seem counterintuitive that effects of genotype could increase with age at all. This apparent conundrum can be resolved in the context of the following considerations. First, the effect of genes for age-related genetic diseases must, by definition, increase with age. Furthermore, because some effects of genes involve exacerbating effects of environment, cumulative environmental effects may be exaggerated as a function of genotype. Finally, the incidence rate of familial forms of diseases peaks earlier than the incidence rate of sporadic or nonfamilial forms. As described later, the net effect of these phenomena is that the concordance between genotype and phenotype increases with age, as the phenotype of genetic diseases develops, but then the relative contribution of genotype to phenotype decreases with age with increased incidence rates of sporadic forms of diseases and nondisease impairments. Nevertheless, these observations regarding general health may not apply to specific diseases. For example, the relative influence of genotype to death from coronary heart disease increases monotonically with age (Marenberg *et al*., 1994).

III. Motor Systems

As described in detail in later chapters of this book, motor system functionality decreases monotonically with age. In humans, this decline includes the development of several age-related diseases of motor systems (including Huntington's disease and Parkinson's disease) superimposed on universal but gradual impairments in neuromuscular functions. The incidence of each disease peaks at a characteristic age (for Huntington's disease around age 40, for Parkinson's disease

around age 70) and then begins to decline, whereas after this age the universal age-related impairments constitute an increasingly important component of the total variance in motor function. As the incidence of disease increases, the contribution of disease to individual variation in motor function also increases, and to the extent that risk of disease is primarily genetic, the genotype contributes substantially to phenotype during this time. However, as the incidence of motor diseases decreases (after about age 70), there is also a decline in the relative contribution of motor disease genes to age-related impairments in motor function.

A. Huntington's Disease

The age-specific incidence rate of Huntington's disease peaks at around age 40 (Greenamyre and Shoulson, 1994), whereas the overall prevalence in most populations is about 10 per 100,000 population (Conneally, 1984). (For mechanistic analysis, the incidence the rate, reflecting the rate of new cases, is more informative than prevalence, the total number of cases, as incidence specifically reflects age-specific vulnerability to developing the disease, whereas prevalance reflects a complex set of factors, including integrated incidence rate and longevity after development of the disease.) Monozygotic twins are essentially 100% concordant in the development of Huntington's disease, demonstrating the primary contribution of genotype to the risk of developing Huntington's disease (Sudarsky *et al*., 1983). More recent work has demonstrated that Huntington's disease is caused by a variable expansion of a CAG repeat producing a polyglutamine stretch in the gene product, huntingtin (Lunkes *et al*., 1998). Characterization of the allele for Huntington's disease has made it possible to definitively test for the relationship between genotype and Huntington's phenotype. Thus Kremer *et al*. (1994) studied 1007 late middle-aged patients who were clinically diagnosed with Huntington's disease from 565 families and 113 controls with other age-related neurological diseases. Of the 1007 diagnosed patients, 995 were found to bear from 36 to 121 CAG repeats, whereas none of the patients with other neurological diseases were found to bear these repeats. Thus by late middle age the concordance between genotype and Huntington's phenotype is essentially 100%.

Nevertheless, at relatively young ages (under age 20 years), there is little concordance between genotype and Huntington's phenotype, as at these young ages only about 10% of individuals who express CAG repeats in the huntingtin gene exhibit Huntington's phenotype. Therefore, with respect to incidence, Huntington's disease represents an extreme form of the coupling between genotype and age-related phenotype, in which the coupling increases from very low below the age of 20 years (at which age the great majority of individuals bearing the CAG repeat do not exhibit the Huntington's phenotype) to essentially 100% concordance by age 70 years (at which age almost every individual who bears the CAG repeat would have developed the disease). By the same token, however, the relative contribution of the CAG repeat to phenotypic variation in the whole population increases with age as the incidence of the disease peaks at about 40 years of age, but then begins to decline as the incidence of Huntington's disease decreases.

However, other aspects of the phenotype exhibit a more subtle relationship to genotype. For example, the number of CAG repeats can vary widely, from fewer than 30 to more than 100; the number of CAG repeats is highly (inversely) correlated with age of onset of Huntington's disease early in life, but the strength of this correlation decreases with age (Crauford and Dodge, 1993; Kremer *et al*., 1993). Therefore the coupling between genotype and the age of onset of Huntington's disease decreases with age.

B. Parkinson's Disease

Parkinson's disease is about 10-fold more prevalent than Huntington's disease, and the incident rate of Parkinson's disease peaks later than that of Huntington's disease, at about 75 years of age, after which incidence rate begins to decline (Martilla, 1987). In marked contrast to the perfect concordance for Huntington's disease in identical twins, several studies have failed to observe any concordance for Parkinson's disease in identical twins (Lilienfeld, 1994). At a minimum, this observation clearly indicates a much lower overall contribution of genotype to Parkinson's phenotype than for Huntington's phenotype. However, several families have been studied in which the Parkinson's disease follows a dominant Mendelian pattern of inheritance (Golbe *et al*., 1996), and in several different families this led to the identification of an allele of α-synuclein as the genetic basis of the disease in these families. (Polymeropoulos *et al*., 1997). In another group of families in which Parkinson's disease is inherited in an autosomal recessive Mendelian pattern, mutations in the gene coding for a novel protein, named parkin, account for the appearance of the Parkinson's phenotype (Hattori *et al*., 1998; Kitada *et al*., 1998). Nevertheless, mutations in α-synuclein and parkin only account for a very small subset of all cases of familial Parkinson's disease (Vaughan *et al*., 1998), and thus of an even smaller subset of all cases of Parkinson's disease.

Clearly the coupling of genotype to phenotype is much lower, and the genetic basis much more complex, in Parkinson's disease than in Huntington's disease. However, Parkinson's disease is not only much more common than Huntington's disease, it is a much more heterogeneous syndrome, and thus plausibly involves a more heterogeneous set of pathophysiological processes. For those forms of Parkinson's disease for which a single gene defect has been defined, the coupling between genotype and phenotype behaves as it does in Huntington's. Thus within kindreds in which α-synuclein mutations are common, at young ages there is no concordance between mutations in α-synuclein and Parkinson's phenotype, whereas by age 70 there is a very high concordance between genotype and phenotype. However, in the population as a whole, this relationship is less evident (and indeed not detected at all in twin studies), as α-synuclein mutations only account for a small proportion of all cases of Parkinson's disease (in contrast to Huntington's disease, all of whose cases are accounted for by mutations in a single gene).

A key phenomenon for interpreting these data is that the incidence rate of familial forms of Parkinson's disease peaks earlier than in sporadic or nonfamilial forms. Thus mutations in parkin lead to juvenile onset Parkinson's disease, whose incidence peaks at around 20 years of age, and the incidence

of Parkinson's disease due to mutations in α-synuclein peaks at around 50 years of age. In contrast, the incidence rate of Parkinson's disease in the population as a whole peaks around 70 years. Because twin studies indicated that genotype makes little contribution to the late-onset (and most common) form of the disease, taken together these data imply that the contribution of genotype to Parkinson's phenotype increases with age up until about age 50 and then begins to decline such that by age 70, there is little contribution of genotype to phenotype (Langston, 1998). Thus a major question is the extent to which genotype accounts for nondisease phenotype during aging. Twin studies have indicated that although psychomotor speed declines with age, the effect of genotype and possibly early environment continues to dominate this phenotype during aging, at least up until age 67, whereas in contrast, effects of exercise were minimal (Simonen *et al*., 1998). Nevertheless, the effect of age on the penetrance of genotype on psychomotor function has not been elucidated in detail after the age of 70 years.

IV. Cognitive Function

Although genetic effects on motor diseases increase with age before they decrease, it might be hypothesized that cognitive functions are more likely to reflect cumulative experience during aging, and thus the contribution of genotype might be less for cognitive functions. However, as described later, effects of genotype are probably at least as great on cognitive functions during aging as for motor functions.

A. Alzheimer's Disease

In contrast to Parkinson's disease, twin studies have demonstrated a significant genetic contribution to the risk of developing Alzheimer's disease (Breitner *et al*., 1993, 1995; Bergem, 1994; Gallo and Breitner, 1995; Raiha *et al*., 1996, 1997; Bergem *et al*., 1997; Gatz *et al*., 1997; Plassman and Breitner, 1997; Rubinsztein, 1997). For example, in a study of Swedish twins, concordance between monozygotic twins was 67%, compared to only 22% for dizygotic twins (Gatz *et al*., 1997). Conclusions from twin studies have been corroborated in family studies. For example, offspring whose parents had both been diagnosed with Alzheimer's disease had a 47% chance of developing Alzheimer's disease by age 65, far higher than the risk of the general population at that age (Bird *et al*., 1993). Similarly, analysis of 70 kindreds with evidence of hereditary forms of Alzheimer's disease indicated that offspring whose parents had Alzheimer's disease had a lifetime risk of developing the disease by age 87 of 64%, again, far higher than the risk in age-matched controls (Farrer *et al*., 1990). Interestingly, the risk for offspring in families with early-onset Alzheimer's disease was only 53%, compared to a remarkable 86% for offspring in families with late-onset Alzheimer's disease (Farrer *et al*., 1990). Thus at least within these kindreds, there is evidence of increased penetrance of genotype during aging. However, the incidence rate of Alzheimer's disease appears to decrease after age 90 (Lautenschlager *et al*., 1996). Because of the relatively small number of individuals alive at these very advanced ages, it is not yet known if the effect of genotype on the risk of Alzheimer's disease may decline after age 90.

As with Parkinson's disease, allelic variations in several specific genes (presenilin 1, presenilin 2, β-amyloid precursor, and apolipoprotein E) have been implicated in the etiology of Alzheimer's disease (Cruts and Van Broeckhoven, 1998; see the review by O'Malley and Tanzi in the present volume). Thus how aging influences the penetrance of these genes is of great interest. Campion *et al*. (1999) addressed this question in a particularly interesting recent study that examined the genetic basis of early-onset autosomal dominant Alzheimer's disease in the entire population of the city of Rouen. In this study, early-onset autosomal dominant Alzheimer's disease was defined by the occurrence of Alzheimer's disease before the age of 61 years in three generations of a given family. Thirty-four such families were observed in Rouen, with a population of about 500,000. In 56% of such families, allelic variations in presenilin 1 were observed, and in 15% of such families, allelic variations of the β-amyloid precursor were observed. In contrast, in nine families that did not exhibit an early-onset form of the Alzheimer's disease, such allelic variations were not observed. These data suggest that the penetrance of presenilin 1 and β-amyloid precursor mutations reaches 100% at relatively young ages (around age 60). However, because the incidence of Alzheimer's disease before the age of 60 is less than 1% of the incidence at age 80–90, this clearly demonstrates that the coupling between presenilin 1 (or β *N*-amyloid precursor) and Alzheimer's disease phenotype peaks at around age 60 and then returns to negligible by age 80. In contrast to the (eventual) complete penetrance of the presenilin and β-amyloid alleles, alleles of the apolipoprotein E gene are never completely penetrant, but nevertheless account for a much larger proportion (possibly 20%) of cases of Alzheimer's disease (Slooter *et al*., 1998). Nevertheless, the effect of apolipoprotein E genotype peaks at around age 70 and then declines (but is significant even at 90 years of age) (Farrer *et al*., 1997; Slooter *et al*., 1998). Thus, taken together, evidence suggests that the coupling between genotype and Alzheimer's disease phenotype peaks by 70 years of age and then, as with other age-related diseases, the role of genotype begins to decline.

B. Nonpathological Age-Related Changes in Cognitive Functions

Although Alzheimer's disease causes devastating loss of cognitive function in affected individuals, far more individuals experience much milder cognitive impairments that are apparently not associated with disease (Botwinick, 1978). Because the effects of genotype on performance in standardized intelligence tests have been examined in great detail in young populations, several studies have used similar methodologies to assess effects of aging on the contribution of genotype to performance on these tests (Plomin *et al*., 1994; Finkel *et al*., 1995, 1998; McClearn *et al*., 1997; Emery *et al*., 1998). For example, Plomin et al. (1994), as part of the Swedish Adoption/Twin Study of Aging, examined cognitive functions in 112 pairs of twins (both monozygotic and dizygotic) reared apart and in 111 matched pairs of twins reared together. The age of the twins was 64.1 ± 7.5 (mean $\pm$ SD) years. At this age, the average heritability of general cognitive function (a

composite of spatial, verbal, memory, and speed of processing performances, after removal of effects of age and gender) was 80%. In a detailed review of studies from both the Swedish Adoption/Twin Study of Aging and the Minnesota Twin Study of Adult Development and Aging, Finkel *et al*. (1995) concluded that both sets of studies suggested that the heritability of general cognitive function is about 80% throughout adulthood, compared to estimates of about 50% during childhood and adolescence, but evidence suggested a possible decrease in heritability after age 70 years. A further analysis of the Swedish twin study appeared to corroborate this result, as in Swedish twins over the age of 80, the heritability of general cognitive function was estimated to be about 62% (McClearn *et al*., 1997). Other studies have also suggested that the heritability of general cognitive function increases from about 50% in childhood and adolescence to about 80% in adulthood (McCartney *et al*., 1990; McGue *et al*., 1993). It should be noted that although aging influences the heritability of general cognitive function, the effect of age on cognitive function itself is more specific to specific subsystems. In general, functions reflecting knowledge improve with age, whereas functions reflecting speed of processing and memory are impaired with age. Thus aspects of cognition reflected by the Wechsler subscales of information, vocabulary, and comprehension are relatively unimpaired or even improve with age in nondemented individuals, whereas cognitive functions reflected by the subscales of block design, picture arrangement, and digit symbol tend to deteriorate robustly with age (Botwinick, 1978). Interestingly, the heritability of general cognitive function during aging is greater than the heritability of any of the functions reflected by subscales, which has been interpreted to indicate that the ''nature of the genetic influence in the cognitive domain appears to be more general than specific'' (Plomin *et al*., 1994). Thus, in contrast to the effect of age on the heritability of general cognitive function, the heritability of memory function alone is reported to be stable with age (Finkel and McGue, 1998).

V. Genotype Influences Cumulative Effect of Environment

Because cognitive function is defined by experience, it may seem surprising that the heritability of cognitive function can increase with age at all (although decreasing after the age of 70). One resolution of this apparent paradox is that the influence of experience may be enhanced by genotype. For example, in a twin study examining the effect of genotype on the acquisition of a motor skill, Fox *et al*. (1996) reported that while genotype influenced the initial performance of the skill, the effect of genotype on the enhancement of the skill by practice was even greater. These investigators concluded that ''the effect of practice is to decrease the effect of environmental variation (previous learning) and increase the relative strength of genetic influences on motor performance.'' Similarly, it seems plausible that genotype may influence the cumulative effect of experience on general cognitive functions. However, after the age of 70 it appears that these genetic effects have reached their peak, and the effects of unique experiences come to dominate.

A similar phenomenon may influence neuroendocrine functions during aging. For example, it has been reported in males that the heritability of body mass index is about 46% in males aged 46–59 years old and 61% in males 60–76 years old (Herskind *et al*., 1996). As with other phenotypes, the mechanism of this increasing penetrance on body mass index is unclear. However, work in rodents suggests a possible mechanism. Two strains of mice, C57BL/6J and A/J, have similar body weights throughout life if fed a standard laboratory chow, which is very low in fat. In contrast, when fed a diet high in fat, C57BL/6J gain a substantial amount of body weight and, after several months, develop diabetes, whereas A/J mice, while consuming the same amount of the diet, stay relatively thin and normoglycemic (Surwit *et al*., 1988). Thus in the presence of one environment (characterized by a low-fat diet), there is little effect of genotype on body weight or blood glucose, whereas in a different environment (characterized by a high-fat diet), the effect of genotype (which initially is very small) increases substantially as body weight and blood glucose increase over time in C57BL/6J mice, but not A/J mice. Furthermore, the increase of heritability of body weight over time on a high-fat diet appears to be mediated through a neuroendocrine mechanism, as the high-fat diet induces weight-reducing responses in the hypothalamus of A/J mice, but not in C57BL/6J mice (Bergen *et al*., 1999).

Age-related impairments in sensory functions may also involve genetic exacerbation of environmental insults. For example, C57BL/6J mice exhibit gradual age-related impairments in auditory function, leading to essentially complete loss of hearing by old age, whereas CBA and other strains of mice retain largely normal auditory function until old age; this effect of genotype is now known to be due to a recessive gene whose penetrance increases with age (see Willott, this volume). Of particular interest, however, is that this recessive gene also greatly potentiates noise-induced hearing loss (Erway *et al*., 1996). Thus, while the effect of genotype on hearing function clearly increases with age in mice, part of the mechanism by which this occurs may involve exacerbation of environment, as is the case in diet-induced obesity. Similarly, the concordance of age-related macular degeneration is 100% in monozygotic twins but only 42% in dizygotic twins (Meyers *et al*., 1995); thus again the effects of genotype on macular degeneration increase with age. Numerous environmental effects of macular degeneration have been observed (including smoking and diabetes), so it will be of interest to assess if the genetic effects involve exacerbation of these deleterious effects.

VI. Summary

Although genotype in humans contributes increasingly to many age-related impairments up until about age 70, it is important to emphasize that the contribution of genotype to phenotype begins to decline after age 70, and for many phenotypes the effect of environment is at least as great as the effect of genotype. Furthermore, it is now appreciated that simple changes in lifestyle, such as moderate exercise, can have a profound beneficial effect, especially on impairments that occur after the age of 70 (Rowe and Kahn, 1997). In addition,

as described earlier, age-related increases in the heritability of genetic diseases may involve a genetic mechanism that exacerbates deleterious environmental effects. Thus, burgeoning advances in genomics should not only stimulate further analysis of the genetic basis of age-related impairments, they should equally inform further analysis of (potentially more tractable) environmental influences. While initially the interaction between heredity and environment will be most easily determined in analyzing age-related diseases, ultimately the effects of these interactions on nonpathological age-related impairments may be of even greater general significance.

Neurochemistry of Receptor Dynamics in the Aging Brain

I. Introduction

Alterations in central nervous system (CNS) function are intrinsic to aging processes in many species. Numerous investigations have been conducted to identify changes in synaptic processes that are associated with specific age-related disorders. Various neurotransmitter systems have been shown to undergo changes as a function of aging. For example, there is a loss of dopaminergic cells and a corresponding increase in neurotransmitter synthesis with aging (Greenwood *et al*., 1991). Other researchers have shown that declines in striatal noradrenaline, dopamine, and serotonin concentrations occur with age and suggest that these changes correspond to alterations in cognitive function (Tanila *et al*., 1994). Additional studies using aged nonhuman primates have demonstrated reductions in a variety of neurotransmitters, including acetylcholine, norepinephrine, and serotonin (Beal *et al*., 1991).

This chapter focuses on the neurochemistry of changes that occur in various receptor systems in the aging brain. The serotonin (5-hydroxytryptamine; 5-HT) neurotransmitter system, in particular, has been shown to be differentially regulated as a function of age (Steinbusch *et al*., 1990; Johnson *et al*., 1993). Because numerous age-related changes are observed in the serotonergic system, a neurochemical system with diffuse neuronal connections in the CNS, we will specifically refer to this neurotransmitter system throughout the chapter to exemplify various facets of receptor-related changes in the aging brain. For example, the serotonergic system has been implicated in several neurobehavioral processes, including anxiety (Jolas *et al*., 1995), depression (Delgado *et al*., 1990; Cowen, 1993; Stockmeier *et al*., 1998), pain transmission (Yaksh and Wilson, 1979; Crisp and Smith, 1989), and mood and cognition (Altman *et al*., 1990; Bliss and Collingridge, 1993). In fact, the quality of these behaviors is often disrupted with advanced age (Timiras, 1994) and is associated with a decline in serotonergic neuronal function. Additionally, several reports of increased 5-HT turnover (Petkov *et al*., 1987; Steinbusch *et al*., 1990) and decreased 5-HT levels or release (Schlicker *et al*., 1989; Ko *et al*., 1997) in the CNS with aging indicate the emergence of age-induced changes in the neurochemical balance of the 5-HT neurotransmitter system.

In a broader context, this chapter highlights fundamental issues and approaches used to address the neurochemical aspects of receptor expression and function. Whether assessment is made of receptor structure, localization, or distribution, these indices are regulated in a dynamic fashion. Indeed, neurochemical analysis of receptor expression is linked to continual processes of receptor-specific turnover, up- and down-regulation, and kinetics of receptor recovery, as well as modulation by paracrine and autocrine factors, which include a variety of hormone and cytokines. We will endeavor to provide insight into the numerous issues and research strategies that link the neurochemistry of receptors to normal and pathological processes in the aging CNS. This snapshot of the dynamics of receptors in the aging brain can serve as a model for similar issues to be examined in peripheral tissues.

The following sections describe various findings of alterations in receptor turnover, signal transduction, neuromodulatory regulation, and the relevance of these changes to the aging brain. We will first, however, explore the age-related changes that occur in receptor density for several specific neurotransmitter receptor systems (i.e., serotonin, dopamine, adrenaline, and acetylcholine).

II. Receptor Density and Function

The density of receptors in a given membrane and their ability to recover from insult (e.g., hypoxic injury or neurotoxic exposure) are critical factors in the ability of the aging brain to adapt to and subsequently respond to pharmaceutical agents that interact specifically with these receptors. For example, we have found that the density of hippocampal 5-HT_{1A} receptors is decreased with aging (Keck and Lakoski, 2000). It is important to recognize that changes in receptor number may reflect alterations in the rates of receptor synthesis and turnover. Thus, it is also vital to consider the importance of modifications in

other indices, such as receptor recovery, when treating disorders such as depression and anxiety, which are associated with altered 5-HT_{1A} receptor function (Charney *et al*., 1990; Meltzer, 1990).

The serotonin receptor subtype 5-HT_{1A}, in particular, is significant due to its implication in disorders of mood; the functional importance of this receptor has been validated by the effectiveness of 5-HT_{1A} receptor agonists/antagonists in the treatment of anxiety and depression, respectively (Fernández-Guasti and López-Rubalcava, 1990; Martin *et al*., 1990). Changes in 5-HT_{1A} receptor density with age are variable; human studies report a decline in 5-HT_{1A} receptor density (Dillon *et al*., 1991) and mRNA abundance (Burnet *et al*., 1994), whereas investigations using the rat do not consistently demonstrate losses in 5-HT_{1A} receptor number. Yamaguchi and Yamagata (1991) showed no significant change in the number of cortical 5-HT_{1A} receptors with age, yet observations in our own laboratory indicate a slight decrease in receptor density in the hippocampus associated with aging (Keck and Lakoski, 2000). Interestingly, deficiencies of 5-HT_{1A} receptors have been observed in cortical tissue from patients diagnosed with the age-related disorder Alzheimer's disease (Middlemiss *et al*., 1986). This diversity in age-specific changes in basal 5-HT_{1A} receptor number may reflect neuroanatomical differences, between rats and humans, in radioligand binding using the agonist 8-hydroxy-2(di-*n*-propylamino)-tetralin ([^{3}H]8-OH-DPAT), which selectively binds to 5-HT_{1A} receptor sites (Duncan *et al*., 1998).

Despite conflicting binding data, age-dependent changes in 5-HT_{1A} receptor function are well documented and include the attenuation of 5-HT_{1A} receptor agonist-induced reduction of 5-hydroxyindoleacetic acid (Robson *et al*., 1993), declines in 5-HT_{1A} receptor-mediated circadian rhythmicity (Penev *et al*., 1995), decreases in the functional adaptation of the 5-HT_{1A} receptor following exposure to a subchronic stressor (de Castro *et al*., 1996), and a loss of responsiveness to an irreversible inactivating agent, *N*-ethoxycarbonyl-2-ethoxy-1,2-dihydroquinoline (EEDQ; Keck and Lakoski, 1996a). Correspondingly, 5-HT_{1A} receptors from old animals display distinct patterns of recovery and turnover following irreversible inactivation compared to their young counterparts (Keck and Lakoski, 2000; see later). Moreover, studies of corticosteroid hormone modulation of the 5-HT_{1A} receptor in the aging hippocampus demonstrated an age-dependent loss in the ability of high and low levels of corticosterone pretreatment to down- and upregulate the density of 5-HT_{1A} receptor agonist binding, respectively (Maines *et al*., 1998). Similar observations have been noted for the serotonin transporter in which there was an age-related loss in the ability of corticosterone treatment to induce a decline in binding density in hippocampal tissue (Maines *et al*., 1999). Thus, in the hippocampus, an age-dependent change in 5-HT_{1A} receptor/ corticosteroid interaction was revealed.

Another 5-HT receptor subtype, the 5-HT_{2A} receptor, has become increasingly important since the discovery and use of therapeutically effective atypical antipsychotic medications for the treatment of mood disorders and psychosis. Several *in vitro*, *in vivo*, postmortem, and positron emission tomography (PET) findings confirm a decline in 5-HT_{2A} receptor binding with advancing age (Druse *et al*., 1997; Baeken *et al*., 1998; Meltzer *et al*., 1998). For example, a study utilized PET scans in young and elderly individuals to test for cortical alterations in 5-HT_{2A} receptor-binding density. Even after correcting for effects of cerebral atrophy, a significant loss (57%) in specific binding was demonstrated in the elderly group for this binding site relative to the young control group (Meltzer *et al*., 1998). These findings underscore the role of 5-HT_{2A} receptors in the etiology of mood changes in the elderly and may have important therapeutic implications for the treatment of disorders such as geriatric depression.

As a consequence of aging, there are a variety of anatomical and physiological changes in brain dopamine (DA)-binding proteins. Araki *et al*. (1997) demonstrated a decrease in radioligand binding (using [^{3}H]mazindol) to the DA transporter. The clinical importance of age-related changes in the classical DA receptors (D_1 and D_2) is exemplified by the resultant motor disturbances associated with altered receptor number/function. It has been suggested that the decreased motor abilities associated with normal aging or neurodegenerative diseases, such as Parkinson's disease, result from alterations in striatal D_1 and D_2 receptors (Cross and Rossor, 1983; Joseph *et al*., 1983; Rinne *et al*., 1991; Roth and Joseph, 1994; Turjanski *et al*., 1995). In fact, a large body of evidence supporting this theory reveals substantial declines in D_2 receptor densities in both humans (D. F. Wong *et al*., 1984, 1997; W. F. Wong *et al*., 1997) and rodents (O'Boyle and Waddingron, 1984; Tajuddin and Druse, 1996) and demonstrates a loss of D_2 receptor-containing neurons (Han *et al*., 1989) with aging. Additionally, researchers have uncovered a variety of age-related changes in D_2 receptor mRNA, including a reduction in receptor mRNA levels (Mesco *et al*., 1991; Della Vedova *et al*., 1992), and a decrease in the rate of D_2 receptor mRNA synthesis (Mesco *et al*., 1993). Together, these findings strengthen the implied relationship among aging, DA receptor modification, and disease-related motor dysfunction.

Like the dopaminergic and serotonergic receptor systems, acetylcholine (ACh) receptors undergo age-related alterations. Studies of muscarinic (M) cholinergic receptor subtypes M_1 and M_2 have shown an age-specific pattern of binding density (Biegon *et al*., 1989). Declines in nicotinic ACh receptors have also been shown in aged humans (Marutle *et al*., 1998), and postmortem investigations of cortical and hippocampal tissues revealed age-related decreases in mRNA expression for nicotinic receptor subunits α_4 and β_2 (Tohgi *et al*., 1998). These findings, exhibiting decreases in nicotinic acetylcholine receptor transcription during aging, suggest that such changes may be important contributors to the cognitive decline seen in the elderly (Tohgi *et al*., 1998). Additionally, Buyukuysal and associates (1998) reported a reduction in the stimulated release of ACh as well as a decline in muscarinic ACh receptor density with advancing age. A corroborating report by Vannuchi *et al*. (1997) showed a decline in ACh neurotransmitter release in aged rats and an associated decline in cognitive performance. These reports lend further support for a relationship between cholinergic decline and cognitive dysfunction and point to the muscarinic receptor as a possible target for medications used to treat memory problems associated with aging (Vannuchi *et al*., 1997).

Similar to cholinergic receptors, adrenergic receptors are also described to decline in number with aging. Using quanti-

tative autoradiographic analyses and ^{125}I-labeled pindolol binding as an indicator of β-adrenergic receptor density, a significant region-specific loss was demonstrated in the aging rat brain (Miller and Zahniser, 1988). A report by Gould and Bickford (1997) supports an age-related loss in the adrenergic receptor system function. More specifically, these investigators showed that in aged rats there is a deficiency in β-adrenergic signal transduction. Together, these data indicate that with aging there is a significant decline in β-adrenergic receptor number and function.

It is clear that with aging there is a myriad of alterations in receptor numbers that occur in the mammalian CNS. As changes in receptor density are critical aspects to the changing neurochemistry of neurotransmitter system functioning, these age-induced alterations in receptors will likely extend into physiological, behavioral, and cognitive ramifications.

III. Receptor Turnover

The practical importance of analysis of changes in receptor turnover with aging has already been introduced briefly in terms of older individuals' abilities to adapt to neurological damage. The capability to recover quickly, or at all, from receptor loss/cellular injury could impact the overall progression of and recovery from an illness. A fast rate of receptor turnover might enhance the recuperation process, especially if the illness had an associated loss of receptor number or receptor function. Similarly, a slow turnover of receptors following insult might decrease the likelihood of recovery. Furthermore, the development or discovery of agents that enhance receptor turnover (e.g., neurotrophic factors, estrogen) might prove very useful for the treatment of trauma-related processes in young individuals, as well as progressive neurodegenerative disease processes in the elderly.

A. Approaches to Investigate Receptor Inactivation and Turnover

In investigations using animal models, various neurotoxins and drug agents have been used to examine (1) the sensitivity of ''aged'' receptors to the damaging effects of a toxin and (2) the recovery of various receptors (Riekkinen *et al*., 1992; Zawia *et al*., 1992). In general, these studies have shown a loss in receptor plasticity with aging and a low rate of receptor regeneration (Greenberg and Weiss, 1979; Pitha *et al*., 1982; Zhou *et al*., 1984). The alkylating agent EEDQ (Battaglia *et al*., 1987; Cox *et al*., 1993; Gozlan *et al*., 1994; Pinto and Battaglia, 1994; Raghupathi *et al*., 1996), which acts to irreversibly block specific receptors, is one such agent that has been used frequently to investigate age-related changes in receptor turnover. The EEDQ molecule noncompetitively inactivates several G-protein-coupled receptor sites, including serotonergic (Pinto and Battaglia, 1993; Gozlan *et al*., 1994; Keck and Lakoski, 1996b; Ni *et al*., 1997; Kettle *et al*., 1999), dopaminergic (Henry and Roth, 1984), α-adrenergic (Adler *et al*., 1985), β-adrenergic (Neve and Molinoff, 1986), and muscarinic (Norman and Creese, 1986) receptors. This neurotoxicant irreversibly inactivates receptors by producing a receptor-linked mixed carbonic anhydride, which, in turn, forms an irreversible bond with nucleophilic groups in the ligand-binding pocket of the binding site (Belleau *et al*., 1969). Subsequently, the kinetics of receptor recovery can be established and compared in young adult and old animal models. Results of these types of experiments contribute much needed information regarding the effects of aging on the functional capacity of neurotransmitter systems following a neurotoxic insult.

Of the serotonergic receptor subtypes, the 5-HT$_{1A}$ receptor is the most sensitive to inactivation by EEDQ (Gozlan *et al*., 1983, 1994). This receptor subtype has been shown to be negatively coupled to adenylate cyclase via pertussis toxin-sensitive guanine nucleotide-binding proteins (Zgombick *et al*., 1989). Pretreatment with WAY 100,635, a selective 5-HT$_{1A}$ receptor antagonist, protects these binding sites (over 70%) from inactivation by EEDQ (Gozlan *et al*., 1994) and confirms that the irreversible inactivator interacts directly at the ligand recognition site of the 5-HT$_{1A}$ receptor. Therefore, EEDQ administration has been a very appropriate pharmacological tool to examine 5-HT$_{1A}$ receptor recovery with aging (Keck and Lakoski, 1997).

In our own work, we have investigated the kinetics of receptor recovery for the aging 5-HT$_{1A}$ receptor (Keck and Lakoski, 1996b, 1997, 2000). Our findings have provided an interesting framework in which to characterize age-associated changes in the recovery profile of the 5-HT$_{1A}$-binding site in the CNS. We examined the kinetics of 5-HT$_{1A}$ receptor recovery with aging and discovered that, unlike D_2 receptors or α_1- and α_2-adrenoceptors, hippocampal 5-HT$_{1A}$ receptors demonstrate a faster rate of recovery in old rats compared to young adult rats. Dopaminergic and α-adrenergic receptors, however, have been shown to undergo a delayed rate of recovery in aged animals (see later; Henry and Roth, 1984; Leff *et al*., 1984; Zhou *et al*., 1984; Henry *et al*., 1987). In our studies, 5-HT$_{1A}$ receptor density in the hippocampus returned to vehicle control levels at an earlier time point in old, 22-month rats compared to young, 3-month rats. The turnover of hippocampal 5-HT$_{1A}$ receptors was nearly three times faster in old rats versus young adult rats (Keck and Lakoski, 2000). From these findings, we surmise that a cooperative relationship exists between age-dependent increases in 5-HT$_{1A}$ receptor turnover and increases in the turnover of the 5-HT neurotransmitter itself (Petkov *et al*., 1987; Steinbusch *et al*., 1990).

Numerous studies of toxin-induced degradation of the dopaminergic receptor system have demonstrated age-related differences in the rate of recovery of dopamine receptors, especially the D_2 receptor. Typically, senescent rats have been shown to exhibit lower rates of dopamine receptor turnover, production, and degradation compared to mature rats (Henry and Roth, 1984; Leff *et al*., 1984; Norman *et al*., 1987; Battaglia *et al*., 1988) following treatment with EEDQ. An age-related decline in receptor synthesis following EEDQ treatment also correlated with a reduced recovery in motor function (Henry *et al*., 1987). Results from other investigations showing that the rates of recovery for both D_1 and D_2 receptor proteins were higher in young rats than in older age groups (Kula *et al*., 1992; Crawford *et al*., 1994) lend additional support for an age-related alteration in the recovery pattern of dopaminergic receptors.

For adrenergic receptors, the recovery of [^{3}H]prazocin and [^{3}H]rauwolscine binding, which labels α_1- and α_2-adreno-

ceptors, respectively, was delayed significantly in aged compared to young rats (Zhou *et al*., 1984). Similar to the β-adrenoreceptor, the *de novo* synthesis of new receptor proteins was demonstrated to be low in senescent animals (Pitha *et al*., 1982).

Hence, a general theme has unfolded that indicates an overall decline in the ability of aged receptors to recover from neurotoxic injury, with an exception being 5-HT_{1A} receptors in senescent rats which have been shown to recover at a faster rate compared to the same receptor populations in young rats.

IV. Receptor/Effector Coupling Processes

The topic of age-related changes in receptor-linked signal transduction mechanisms requires an entire book of its own. However, we have included here a short description of some of the relevant findings in the serotonergic system with aging to serve as a cursory introduction to the large realm of alterations that can occur in receptor/effector coupling mechanisms. In the serotonergic system, age-induced changes in receptor/effector coupling mechanisms and metabolism suggest that the 5-HT receptor function is altered with aging (Robson *et al*., 1993).

From our early studies with EEDQ, we discovered an age-related decrease in 5-HT_{1A} receptor affinity following EEDQ treatment. Using EEDQ, we hypothesized that a subpopulation of low-affinity 5-HT_{1A} receptors, perhaps G-protein-uncoupled, was unmasked. Previous work by other researchers indicated that [^{3}H]8-OH-DPAT, the agonist radioligand used in our studies, labeled both high and low affinity-binding sites (Mongeau *et al*., 1992; Nénonéné *et al*., 1994). The high affinity site was perceived to be G-protein coupled, as the addition of the nonhydrolyzable GTP analog GppNHp converted this binding site to a low affinity state (Mongeau *et al*., 1992; Nénonéné *et al*., 1994). Nénonéné *et al*. (1994) also demonstrated that the low affinity [^{3}H]8-OH-DPAT-binding site was insensitive to GppNHp, implying that this binding site was uncoupled from its G-protein.

Our own research findings showing age- and brain-region specific changes following treatment with EEDQ (Keck and Lakoski, 2000) may reflect similar alterations in the affinity of the radioligand [^{3}H]8-OH-DPAT for 5-HT_{1A} receptors and/or in the ability of these receptors to interact with their corresponding G-proteins. Because EEDQ evidently interacts specifically with receptors that are coupled to G-proteins and because subpopulations of 5-HT_{1A} receptors in specific brain tissues are insensitive to EEDQ blockade in aged rats, our findings demonstrating an age-dependent decrease in affinity for the same pool of receptors following EEDQ treatment imply that an increase in the proportion of low affinity/G-protein-uncoupled sites (unaffected by EEDQ administration) emerges with aging (see also Keck and Lakoski, 1996a). The density of [^{3}H]8-OH-DPAT binding is not affected by EEDQ in these brain regions in old rats, yet treatment with the irreversible inactivator produces concomitant decreases in affinity. Future binding studies using a radiolabeled antagonist selective for the 5-HT_{1A} receptor (such as [^{3}H]p-MPPF; Kung *et al*., 1996) would be useful to confirm these observations.

Age-associated changes in the affinity for 5-HT_{1A} receptors in the hippocampus, frontal cortex, and amygdala following EEDQ may be especially important, as it is well known that these brain areas play a role in memory (Eichenbaum *et al*., 1992) and general cognitive function, two related abilities that are often compromised with aging. Likewise, deficiencies of 5-HT_{1A} receptors have been observed in the cortices of patients with age-related diseases such as Alzheimer's disease (Middlemiss *et al*., 1986). One explanation for the age-related decline in 5-HT_{1A} receptor affinity following EEDQ treatment may be that age-dependent changes in the conformation of these receptors account for difficult interactions among receptor proteins, G-protein-coupled effectors, and EEDQ. For example, it has been shown that sulfhydryl groups are needed to assure efficient coupling between the receptor and its G-protein (Kitamura and Nomura, 1987). These nucleophilic groups may also be crucial for the alkylation process induced by EEDQ at the target receptor. An age-related decrease in the number or accessibility of sulfhydryl groups (Reader *et al*., 1995) or EEDQ-sensitive carboxylic groups at the receptor site, perhaps coupled with an increase in the number of receptors that are dissociated from the G-protein, could affect the affinity of this agent for the 5-HT_{1A} receptor. These mechanisms may also contribute to the limited effect of EEDQ treatment on 5-HT_{1A} receptor binding observed in the frontal cortex and amygdala of old rats.

Multiple signal transduction processes are also coupled to the expression and function of other 5-HT receptor subtypes as well as a plethora of dopaminergic, adrenergic, and cholinergic receptors. In addition to the classical role of coupling to G-proteins commonly found with metabotropic receptors, it is important to acknowledge that age-dependent changes in other signal transduction components, ranging from expression of adenylate cyclase to calcium-mediated sequestering processes, will also impact the ability of the aged receptor to effectively and efficiently transduce signaling information.

V. Neuromodulatory Regulation of Receptors

Age-related changes in the hormonal regulation of receptor number and function are vital forces in the changing responsiveness of CNS tissues to neurotransmitter effects. For example, the loss of estrogen in the aged female has been recognized to alter the effects of the neurotransmitter 5-HT in a variety of ways. Estrogen replacement therapy increases the efficacy of fluoxetine (a selective serotonin reuptake inhibitor) in the treatment of depression in geriatric females (Schneider *et al*., 1997; McCusker *et al*., 1998; Rubinow *et al*., 1998). This gonadal hormone has been shown to produce increases in tryptophan hydroxylase mRNA expression (Pecins-Thompson *et al*., 1996), 5-HT levels in the plasma, blood and platelets (Malyszko *et al*., 1995; Blum *et al*., 1996), and excretion of the serotonin metabolite 5-hydroxyindole acetic acid (5-HIAA; Lippert *et al*., 1996; Mueck *et al*., 1997). These data support a general role for estrogen in the enhancement of serotonergic activity.

The contribution of estrogen to 5-HT_{1A} receptor expression has also been investigated by several research groups. For instance, the hyperphagic response elicited by the selective

5-HT_{1A} receptor agonist 8-OH-DPAT was less prominent in the presence of estrogen (Salamanca and Uphouse, 1992; Uphouse *et al*., 1994; Maswood and Uphouse, 1997). In another study, Maswood *et al*. (1995) suggested that 8-OH-DPAT was less effective in reducing tissue concentrations of the serotonin metabolite 5-HIAA due to the presence of estrogen. Furthermore, Lakoski (1988, 1989) reported that the ability of 8-OH-DPAT to reduce the firing of dorsal raphe neurons was reduced by estrogen. All of these studies suggest an inhibitory role of estrogen on the function of 5-HT_{1A} receptors. Still others have reported an enhanced activity of the 5-HT_{1A} receptor following estrogen. Chronic estradiol increased the functional response to 8-OH-DPAT by enhancing the ability of the agonist to increase serum corticosterone levels *in vivo* (Matsuda *et al*., 1991). Also, estradiol treatment has been shown to selectively potentiate the ability of centrally administered 8-OH-DPAT to decrease heart rate (Alper and Schmitz, 1996), enhance the inhibition of adenylyl cyclase activity by 5-HT (Clarke and Maayani, 1990), and increase the hypothermic response to 8-OH-DPAT in ovariectomized rats (Young *et al*., 1993). While the density of 5-HT receptor-binding sites varies with estrous cycle (Biegon *et al*., 1980; Al-Dahan *et al*., 1994), data describing changes in 5-HT_{1A} receptor binding or mRNA concentration following treatment with estrogen remain inconsistent (Biegon *et al*., 1982, 1983; Biegon and McEwen, 1982; Clarke and Maayani, 1990; Sumner and Fink, 1993; Frankfurt *et al*., 1994). Although the effects of estrogen on 5-HT_{1A} receptor density and/or function is uncertain (i.e., increased versus decreased), an interaction among this ovarian hormone and 5-HT_{1A} receptors is well documented (Maswood *et al*., 1995; Cologer-Clifford *et al*., 1996; McKittrick and McEwen, 1996).

Evidence shows that estrogen is capable of producing neurotrophic effects on neurons and receptors. Estrogen treatment increases the growth and arborization of neuronal processes (neurites) on dendrites and axons of developing neurons (Nichizuka and Arai, 1981; Hammer and Jacobson, 1984; Stanley *et al*., 1986). Moreover, while estrogen promotes the expansion of neurites primarily during development, following injury to adult brain regions (e.g., deafferentation or axotomy), the growth-promoting attributes of estrogen are expressed anew and estrogen is again capable of influencing dendritic differentiation and synapse development (Matsumoto and Arai, 1981). Similarly, treating cultured neurons damaged by glutamate with estrogen protects against cell death and free-radical buildup (Behl *et al*., 1997). Ultimately, estrogen-induced enhancement of receptor function will be beneficial in treating disorders of the CNS involving receptor dysfunction.

The findings just described lead to the intriguing hypothesis that estrogen supplementation may prevent or improve degenerative symptoms associated with a loss of serotonergic cells, receptors, or function observed in disorders such as Alzheimer's disease (Aletrino *et al*., 1992; Palmer and DeKosky, 1993; Storga *et al*., 1996; Baldereschi *et al*., 1998). Indeed, estrogen therapy has been shown to augment cognitive functioning in the postmenopausal woman (Jacobs *et al*., 1998), protect against the development of dementia in Parkinson's disease (Marder *et al*., 1998), improve attention, orientation, mood, and social interaction in females with senile dementia of the Alzheimer's type (Fillit *et al*., 1986), and enhance verbal memory in women with Alzheimer's disease (Asthana *et al*., 1996). In the future, consistent data illustrating a change in the degree of 5-HT_{1A} receptor mRNA expression following estrogen administration would be useful in the development of new treatments for aging female populations undergoing degenerative processes (e.g., Alzheimer's disease). In essence, estrogen and other growth factors, such as nerve growth factor, may work together to decrease the vulnerability of adult serotonergic neurons to disease processes or aging and may increase their compensatory responses following neurodegenerative injury.

VI. Future Directions

Future studies that examine age-induced changes in neurotransmitters and the corresponding onset of neurodegenerative diseases will provide information about the relationship between aging receptors and age-related declines in cognition, anxiety, depression, and Alzheimer's disease. A practical goal of current researchers should be to investigate the age-dependent role of molecular changes in the expression of neurotransmitter receptors and their subtypes in the etiology of these behavioral processes. Indeed, there is a great need for additional information regarding the molecular substrates of neurotransmitter-related behaviors in the aging animal. As the involvement of multiple neurotransmitter systems in aging processes becomes more fully understood, particularly at the level of gene regulation, new approaches for the treatment of cognitive and mood disorders in aged populations will ensue.

Tremendous advances have been made in our understanding of the fundamental biological processes that govern the dynamics of receptor expression and function. However, the future will be even brighter as image analysis techniques are developed to visualize receptor dynamics across the life span. The enhancements in image resolution that can be obtained *in vivo* are providing the first steps toward monitoring receptors in an organism on a continual basis throughout the health span. Thus, the temporal limitation of our current approaches, which often make it cumbersome and difficult to correlate the neurochemical profile of a given receptor subtype with a behavioral and/or genetic trait, holds great promise for resolution in the coming years.

Demography and Epidemiology of Age-Associated Neuronal Impairment

With the increasing longevity of the United States population, the clinical challenge is shifting from preventing premature death to improving function and quality of life. Some of the major neurological impairments—stroke, Alzheimer's disease, and Parkinson's disease, to name a few—are strongly associated with age. Thus, increasing longevity means many elderly persons must cope with cognitive, sensory, or motor impairments, some of which may result in fundamental and often permanent declines in quality of life. Although the elderly belong to the fastest growing segment of the population and the numbers of people afflicted with these impairments will likely keep pace, many of the diseases remain poorly defined in epidemiological terms. This chapter reviews what is known of the demography and epidemiological risk factors of the major age-related neurological impairments. © 2001 Academic Press.

I. Introduction

The average 65-year-old person in the United States today can expect another 18 years of life, due to mortality declines over the last 100 years. Some 13 out of every 100 Americans are 65 years old or older, and the numbers of elderly are projected to grow. By 2030, according to Census Bureau estimates, the group will make up 20% of the nation's population. Of the 34 million people 65 years or over today, 4 million of them are in the ''oldest old'' category, 85 years and older. The oldest old comprise the fastest-growing segment of the United States population, and their numbers are expected to more than double in the next few decades, as Fig. 4.1 shows [U.S. Department of Health and Human Services (USDHHS), 1999].

Explanations for the gains in life expectancy are a source of controversy among demographers. In the first half of the 20th century, approximately 20 years were added to the average life expectancy (USDHHS, 1999). Gains made over this time period and prior to it were mainly attributed to public health measures, among them control of infectious diseases through water, food, and sanitation improvements, workplace and motor-vehicle safety improvements, and greater access to family planning (Ten Great Public Health Achievements—United States, 1900–1999). Since 1950, another 8 years have been added to the average life expectancy, which as of 1997 stood at 79.4 years for women and 73.6 years for men. Explanations offered for the increasing longevity of the population have shifted since the 1960s away from public health advances toward a debate over whether improvements in lifestyle or advances in medicine should receive the most credit. On the lifestyle side of the debate, better education, better nutrition, diet, and less tobacco use are factors commonly cited for declines in mortality. However, advances in medicine have turned what were once inevitably fatal diseases—diseases of the heart, malignant neoplasms, and cerebrovascular disease—into survivable ones, by either delaying their onset or transforming them into chronic diseases. Thus the clinical challenge has shifted from preventing premature death to improving function and quality of life.

Better survival of these diseases also means the opportunity for other chronic, nonfatal ailments to cause disability in the population as it ages. Many of the major neurological impairments, such as stroke, Alzheimer's disease, and Parkinson's disease, are age associated. The age of onset of many of these impairments has unfortunately not changed and will therefore affect a larger number of people for a longer amount of time as life expectancy increases. In addition, a distinction should be made wherever possible between neuronal changes that are normal with aging and age associated degenerative neuronal diseases.

A. Epidemiological Caveats

Estimates of the incidence of neurological impairments, i.e., the rate of new cases occurring in a given population over a specific time period, are given to uncertainty by the very nature of the diseases themselves. Because these diseases typically begin and progress slowly, the age of onset may be difficult to pinpoint. For a variety of cultural or socioeconomic reasons, patients may not seek out medical care even when symptoms

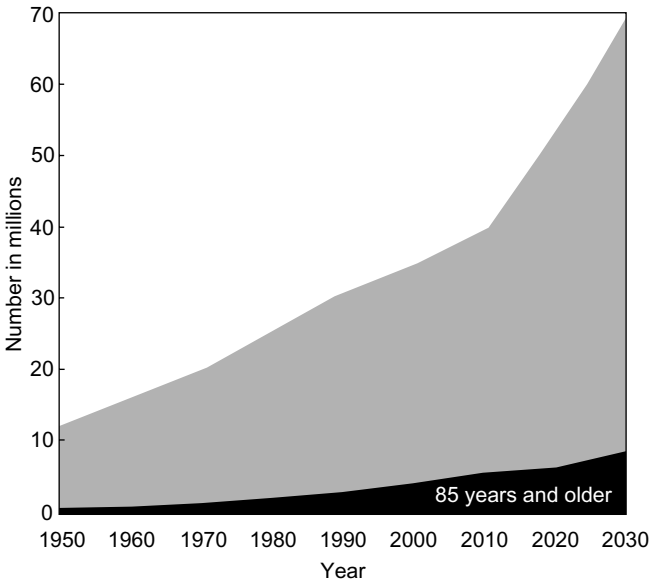

FIG. 4.1. Population 65 years of age and older: United States, 1950–2030. The population 65 years and older is expected to swell in the next few decades, particularly the segment 85 years and older. From U.S. Department of Health and Human Services (1999) (available online: *http://www.cdc.gov/nchs/products/pubs/pubd/hus/charts/hus99f01.pdf*).

do become apparent or may mistake symptoms for changes due to normal aging. Data derived from door-to-door surveys may therefore differ from results of clinic-based studies. When diagnostic criteria also differ between studies, comparisons of incidence data yield little more than a range of estimates.

Estimates of prevalence—the number of cases present in a population at one particular time—are also hampered by these difficulties, as prevalence is a function of incidence as well as of survival. Underreporting of conditions on death certificates adds to the uncertainty of prevalence figures for neurological impairments associated with aging. As few as a quarter of dementia cases may actually be reported on death certificates—typically, pneumonia, or cerebrovascular disease is listed and mention of dementia is neglected as an underlying cause (Ganguli and Rodriguez, 1999). In 1979 the Centers for Disease Control added a classification for Alzheimer's disease in its record keeping. Between 1994 and 1995, Alzheimer's disease was the only one of the 15 leading causes of death the center tracks to show statistically significant increases in age-adjusted death rate, increasing by 8% (Monthly Vital Statistics Report, 1997). Better reporting is probably responsible for this trend rather than true increases in prevalence, and this may be the case for other age-associated neurological impairments as well.

Several other general caveats should be considered when assessing the national scope of a particular type of neurological impairment. Dementia statistics, for example, are often lumped together under the general category of dementia rather than separating out cases by Alzheimer's disease, vascular dementia, Lewy body disease, dementia in Parkinson's disease, or other types. Mixed-type cases of neurological disorders further complicate attempts at classification. Studies also differ on the degree of disease included in data. Some look only at cases of dementia diagnosed as moderate to severe, for example, whereas others also include mild and even questionable cases in their data.

Differential use of medical services among sectors of the population affects the overall quality of data collected in clinic-based studies, whereas changing lifestyles and diets may cause temporal variation in data. Exposure to risk factors is similarly difficult to determine, particularly in retrospectively collected data such as case-controlled studies.

II. Stroke

Stroke is defined as "rapidly developing clinical signs of focal (or global) disturbances of cerebral function, with symptoms lasting 24 hours or longer or leading to death, with no apparent cause other than of vascular origin" (World Health Organization, 1989). The term cerebral vascular accident (CVA) also refers to stroke, but has fallen out of favor in recent years as various public health organizations began a push for increased awareness of the more preventable causes of stroke. The phrase "brain attack" was introduced in the mid-1990s to make health professionals and the public more aware of the need to recognize stroke symptoms and begin therapeutic intervention immediately. A 1996 NSA/Gallup poll on stroke revealed that the majority of persons surveyed could not recognize even basic symptoms of stroke. Even as recently as the late 1980s, only 37% of victims presented for treatment within the first 24 hr after a stroke, and emergency rooms often gave possible stroke patients low triage priority, believing that post-stroke rehabilitation was the most that could be offered (Heros *et al*., 1997). Introduction of the term "brain attack" reflects changing attitudes toward strokes with the recognition that the window of opportunity for treatment is extremely short and that prompt intervention must begin within that time in order to lessen the burden of the disease in terms of both mortality and disability.

A. Mortality

Approximately 20% of all first-time strokes result in death within a month (Warlow, 1998). Stroke is the third leading cause of death in the United States after coronary heart disease and cancer, and has been since 1938. Although age-adjusted death rates from stroke have declined 70% over the past 50 years in the United States, about 160,000 deaths per year are still directly attributable to strokes (Morbidity and Mortality, 1999). Decreases in stroke death rates are considered a major public health achievement and parallel the decrease in death rates from cardiovascular disease over the last half-century. The early 1990s saw a slight trend toward increasing death rates from stroke, but this trend appears to have reversed: in 1997 the age-adjusted death rate per 100,000 was 25.9, down 1.9% from 1996 (Hoyert *et al*., 1999).

B. Stroke-Related Disability

As the most common source of neurological impairment as well as a primary source of severe long-term disability, the consequences of stroke in the United States are enormous.

Because one of the two main risk factors for stroke is age, the elderly bear most of the burden of resulting disability. Of people who survive 6 months after a first-time stroke, one-third are dependent on others for care. Some four million people are stroke survivors in the United States, according to the National Stroke Association. Of those, one-third are left with moderate poststroke disability, whereas another third live with severe disability after stroke (American Heart Association, 1999). Stroke-related disabilities disproportionately affect the elderly, however. Three quarters of older stroke victims are left with permanent impairments, whereas only one-third of younger stroke victims are (Malmagren *et al*., 1989). Medicare reimbursement costs for inpatient rehabilitation are higher for stroke than for any other condition (Steiner and Neu, 1993).

Cognitive, language, and emotional deficits are common after stroke. Motor impairments, including paralysis, muscle weakness, and difficulties eating and swallowing, may also result. Risk of dementia rises markedly after stroke. Case-control and retrospective studies have found dementia risk at least nine times higher in stroke survivors than in the stroke-free population (Prencipe *et al*., 1997). Chances for a repeat stroke are high, particularly in the days immediately following the first stroke. Cumulative risk of a second stroke rises from 10–18% 1 year after the initial stroke to 20–34% 3 years after (Viitanen *et al*., 1988). In addition, stroke survivors are more prone to other vascular events outside of the cerebrum, including a 3% per annum rate of serious coronary events (Warlow, 1998).

C. Types of Stroke

Most available epidemiological data lump the different types of brain events together under the umbrella term stroke, without differentiating between even the two broadest subtypes: ischemic stroke and hemorrhagic stroke. Some 80% of all strokes are of the ischemic or cerebral infarct type, within which there are four subcategories: lacunes of small arteries, artherostenosis of larger intracranial and extracranial arteries, hypoperfusion, and cerebroembolism of cardiac origin. The elderly are disproportionately affected by strokes of the cerebroembolitic and lacunar type when compared to younger populations (Caplan, 1997). Approximately 70% of people who suffer a severe stroke of the cerebral infarct type require nursing home care, and more than half remain in nursing homes 1 year after the stroke (Brown *et al*., 1999).

The majority of the remaining 20% of strokes are of the hemorrhagic type, of which the two main subcategories are intracerebral hemorrhage and subarachnoid hemorrhage type (Thompson and Furlan, 1997). Subarachnoid hemorrhage accounts for 8 to 10% of all strokes. Intracerebral hemorrhage accounts for 8% of strokes but has been declining in frequency (Caplan, 1997).

D. Incidence

Although there are important regional and temporal variations, the incidence of stroke in the United States is comparable to that in other Western countries. From the early 1950s to the latter half of the 1970s, the average annual age- and sex-adjusted stroke incidence rate for the residents of Rochester, Minnesota declined from 213 per 100,000 people to 115, a 46% decline (Broderick *et al*., 1989). By the early 1980s, however, annual incidence rates rose back up to 145 per 100,000, with increases seen for both sexes and all age groups (Brown *et al*., 1996). Imaging techniques and better diagnosis may play a role in the trend toward increases through better detection of even mild cases of stroke. Because strokes are closely linked to aging, incidence rates for older populations are higher: ischemic strokes resulting in hospitalization among people over 40 in Manhattan occurred at an annual rate of 327 per 100,000 (Sacco *et al*., 1991). This figure is in line with results of a large-scale comparison of incidence rates in Western countries for populations 45 and older, where age-standardized incidence rates ranged from 300 to 500 per 100,000 (Sudlow and Warlow, 1997).

E. Prevalence

The National Stroke Association estimates that four out of five families will be affected by stroke. The most recent estimates for the United States are 730,000 strokes per year, up from previous estimates of half a million strokes per year (Broderick *et al*., 1998). Three-quarters of all strokes occurring are first-time strokes. Second-time strokes make up about 20% of all strokes (Thompson and Furlan, 1997). A number of population-based studies have shown overall prevalence rates for those over the age of 55 to be between 1 and 8% (Prencipe *et al*., 1997).

F. Age

Two-thirds of all strokes occur past the age of 65 (National Institutes of Health, 1998). Stroke mortality rates nearly double with each 5-year age increment (Sacco, 1994). Both incidence and prevalence rates also rise exponentially with age. The Framingham study showed incidence doubling with each decade of life, whereas the Rochester study saw 10% increases in incidence rates per year of life (Sacco, 1994). The Rotterdam study, based on self-reported cases of stroke, found prevalence to be 2.5% for men and 1.6% for women in the 55- to 64-year-old age group. This rose to 5.0 and 3.3% for men and women in the 65–74 group and to 8.9 and 6.7% in the 75–84 age group. For men and women 85 and older, rates were even higher: 11.6 and 10.5%, respectively (Bots *et al*., 1996).

G. Gender

Men are at greater risk for stroke incidence than women. The International Stroke Incidence Collaboration, which analyzed 11 incidence studies from Western countries, found consistently higher incidence rates in men for all age groups (Sudlow and Warlow, 1997). A male:female ratio of 1.3:1 is typical for incidence studies of most types of stroke, although women appear to be at greater risk than men for subarachnoid hemorrhage-type strokes (Sacco, 1994). Despite the fact that women have a lower overall incidence of stroke than men, they account for over 60% of deaths from strokes, most likely due to women's longer life expectancies and higher age at time of stroke (Hoyert *et al*., 1999). The Cardiovascular Health

study noted that stroke prevalence rates, while higher overall for men, are actually higher for women than for men in the very oldest age ranges, above 85 years of age (Mittelmark *et al*., 1993). Other studies, however, including the Rotterdam study, have found that men have higher prevalence rates than women in all age ranges (Bots *et al*., 1996).

H. Race

Major studies on stroke in the United States, such as the Framingham and Rochester studies, are not representative of the racial diversity of the nation. Only 1% of the population in Rochester is black, and most of the population is relatively affluent. A more recent large-scale population-based study, the Greater Cincinnati/Northern Kentucky Stroke Study, covered a diverse community and revealed significantly higher incidence rates for blacks than for whites. The overall incidence of first-time strokes among blacks during the first 6 months of 1993 was 288 per 100,000, far exceeding the first-time stroke rate among the white population of the Rochester study (Broderick *et al*., 1998).

Stroke mortality for blacks is nearly twice that for whites (Gillum, 1999). In 1997, age-adjusted death rates per 100,000 were 48.6 for black men and 37.9 for black women vs 25.7 for white men and 22.5 for white women (Hoyert *et al*., 1999). However, the excess stroke mortality in blacks appears to occur mainly in younger persons; at ages greater than 75 years, whites are more likely than blacks to have strokes (Howard *et al*., 1994). Blacks are more likely to suffer cerebrovascular events of greater severity, have a greater level of disability following a stroke, and require longer stays hospital stays following acute stroke than are members of other racial groups. Blacks are also more likely than whites to die during hospitalization for acute stroke (Horner, 1991; Kuhlemeier and Stiens, 1994). A number of risk factors for stroke, including hypertension, diabetes, obesity, and smoking, are present in undue proportion among the black population and may account at least partially for these trends (National Institutes of Health, 1999).

A multiracial comparison in Manhattan of annual stroke incidence resulting in hospitalization also yielded wide rate discrepancies between race, as Fig. 4.2 shows. For people 85 and over, for example, the average annual age-specific stroke incidence rate per 100,000 was 651 for whites, 1461 for blacks, and 1778 for Hispanics. Stroke rates among Asian Americans are generally similar to those of whites in the United States, although stroke rates among Asians living in the Far East are much higher, suggesting a role for environmental factors (National Institutes of Health, 1999; Sacco *et al*., 1999).

I. Geography

Within the United States, there are marked regional variations in stroke rates. For the past 6 decades the southeastern area of the country has had a higher incidence rate of stroke and a stroke mortality rate 10% higher than the rest of the country. The area has been dubbed the "stroke belt," with the population born in these states, especially South Carolina, North Carolina, and Georgia, at much higher risk of stroke (Lackland *et al*., 1999; National Institutes of Health, 1999). Blacks living in the stroke belt are at greater risk for stroke than whites. In addition to race, suggested factors for the greater stroke risk in the southeast are diet and a proportionally greater number of elderly people living in the region.

The International Stroke Incidence Collaboration revealed wide variation in age-standardized annual incidence rates in Western countries for the age group 45–84. The high was 627 per 100,000 in Novosibirsk, Russia; the low was 238 per

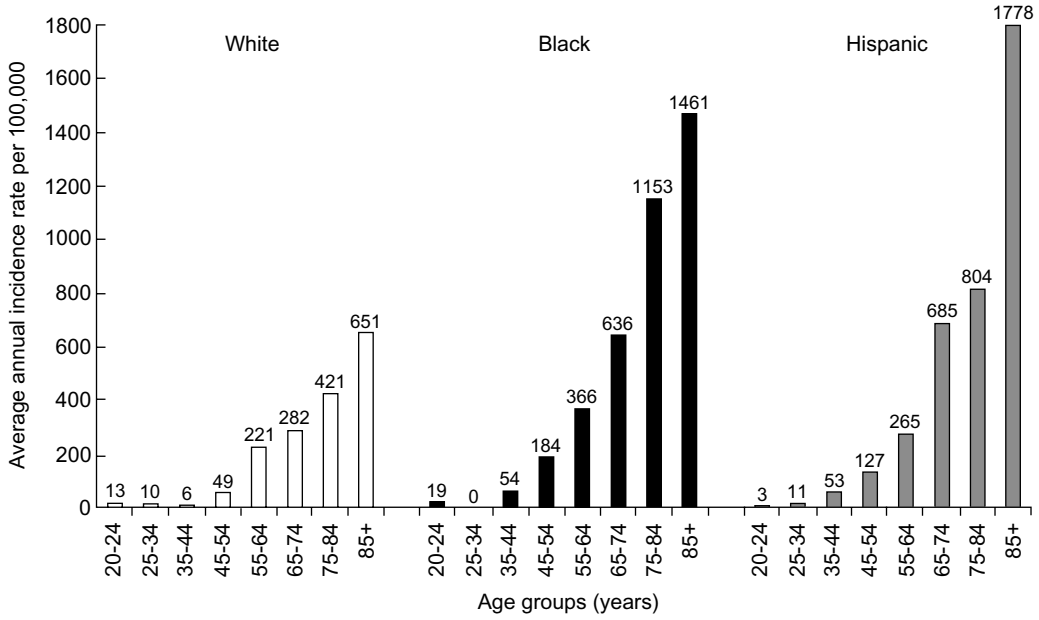

FIG. 4.2. Stroke population at risk: Average annual age-specific incidence rates of stroke (per 100,000 Population) among whites, blacks, and Hispanics aged $\geq$ 20 years in northern Manhattan (1993 to 1996). Risk of stroke increases sharply with age, but also varies widely by race. From Sacco *et al.* (1998).

100,000 in Dijon, France (Sudlow and Warlow, 1997). Prevalence rates also vary widely between countries: prevalence ranges from 500 to 600 per 100,000 in most Western countries to 900 in Eastern countries (Sacco, 1994). Data from less developed nations often suffer from underreporting on death certificates, whereas methodologies and diagnostic criteria for incidence and prevalence studies are not consistent in these nations.

J. Risk Factors: Hypertension

The single greatest modifiable risk factor for stroke is hypertension. Along with age, it is the biggest predictor of stroke. In the Framingham study, even borderline hypertension increased relative risk by as much as 1.5; for definite hypertensives, the relative risk of stroke was 3.1 for men and 2.9 for women compared to those with normal blood pressure. The Rochester study found a 4.0 relative risk for definite hypertensives (Sacco, 1994). Forty to 90% of all stroke victims have hypertension prior to the stroke (National Institutes of Health, 1999). For every 7.5 mm Hg increase in diastolic pressure, the incidence of stroke increases by 46%, according to one meta-analysis of hypertensive drug treatments (Wolf, 1998). The likelihood of hypertension increases with age. Isolated systolic hypertension affects 18% of men and 30% of women over the age of 75, dramatically increasing the risk of stroke in this population [Systolic Hypertension on the Elderly Program (SHEP), Cooperative Research Group, 1991].

K. Other Risk Factors

Atrial fibrillation is present in as many as 15% of all stroke victims, and in those over the age of 80, one in four strokes is directly caused by the condition (National Institutes of Health, 1999). Other forms of cardiac disease, including coronary artery disease, congestive heart failure, and left ventricular hypertrophy, are linked to higher stroke rates, as are vascular malformations. Diabetes mellitus is often accompanied by atherosclerosis and other vascular complications. Estimates of the relative risk for stroke in diabetics range from 1.5 to 3.0 (Sacco, 1994). High plasma cholesterol, fibrinogen, and homocysteine are other suspected risk factors (Warlow, 1998; Bostom *et al*., 1999).

Roughly 15% of strokes are preceded by transient ischemic attacks (TIAs) (Poungvarin, 1998). TIAs are often the first warning of subsequent major stroke. Some 50,000 people per year in the United States have a TIA; of these victims, one-third have an acute stroke at a later time (National Institutes of Health, 1999). The subsequent stroke typically strikes in the same vascular area (Sacco, 1994).

Lifestyle choices strongly influence stroke risk. The major offender is cigarette smoking. A meta-analysis of 32 studies found that tobacco use increased risk by 50% (Wolf, 1998). According to the Framingham study, the relationship was also dose dependent: those who smoked 40 or more cigarettes per day had double the risk of those who smoked 10 cigarettes a day or fewer (Wolf *et al*., 1988). Heavy alcohol consumption and physical inactivity also appear to be offenders. Eating fruit and vegetables—other than legumes and potatoes—may be protective for ischemic stroke risk (Joshipura *et al*., 1999).

III. Dementias: Age-Associated Cognitive Impairment

A. Alzheimer's Disease

1. Prevalence

Prevalence estimates and projections on Alzheimer's disease vary according to study. The General Accounting Office completed a recent report on prevalence to the Secretary of Health and Human Services based on a meta-analysis of 18 studies both in the United States and abroad (U.S. General Accounting Office, 1998). According to the report, at least 1.9 million Americans 65 years and older in 1995 had Alzheimer's disease when all levels of severity of the disease were included, and 1.1 million were afflicted when only moderate and severe forms were included. Overall numbers are probably underestimated, with figures closer to 2.1 million due to the likelihood of missed cases and cases of mixed-type dementia excluded from the count. By 1997, there were an estimated 2.32 million people with Alzheimer's disease, although this figure ranges from 1.09 million at the low end to 4.58 million at the high end (Brookmeyer *et al*., 1998). The Centers for Disease Control National Center for Health Statistics reported 22,475 deaths from Alzheimer's listed on death certificates that year, and an age-adjusted mortality rate of 2.7 (Hoyert *et al*., 1999).

If U.S. Census Bureau projections for the aging of the nation are taken into account, the General Accounting Office report predicts that between 2.9 million and 3.2 million Americans will have some degree of Alzheimer's disease by 2015 (U.S. General Accounting Office, 1998). Other similarly derived projections suggest that 1 in 45 older Americans can expect to have the disease by 2050, a near quadrupling in prevalence from today's figures. A high-end projection shows 14 million patients with the disease by 2040 (Evans, 1990).

2. Incidence

Four studies in the United States establish current incidence rates for Alzheimer's disease, each using standard criteria for diagnosis (Shock *et al*., 1984; Kokmen *et al*., 1988; Bachman *et al*., 1993; Hebert *et al*., 1995). From these studies (Framingham, East Boston, Rochester, MN, and Baltimore) the age-specific incidence rate was found to increase exponentially after the age of 65, doubling every 5 years at least through the age of 90 (Brookmeyer *et al*., 1998). Fig. 4.3 shows age-specific incidence rates derived from these studies on a log scale.

The number of new Alzheimer's cases likely to be diagnosed over the first five decades of the 21st century is determined by multiplying U.S. Census Bureau projections of the U.S. elderly population for that time period by known age-specific incidence rates of the disease. One such estimate predicts a growth in new cases from 360,000 in 1997 to 1.14 million in 2047, even in the absence of new diagnostic tools (Brookmeyer *et al*., 1998). These projections also assume no new treatments or preventions.

3. Age

The largest risk factor for Alzheimer's disease is age. Table 4.1 shows estimates of prevalence derived from 18 major

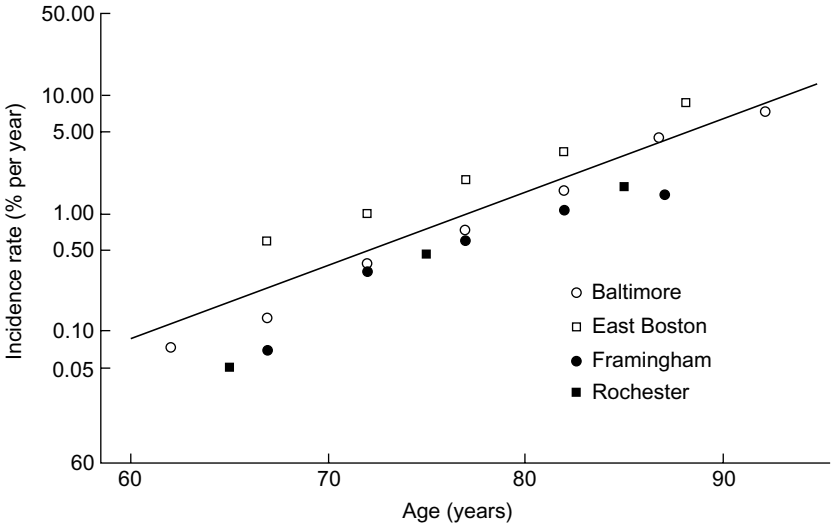

FIG. 4.3. Age-specific incidence rates of Alzheimer's disease on a log scale from 4 U.S. studies: Framingham, East Boston, Rochester, and Baltimore. Incidence of Alzheimer's disease rises exponentially after age 65, doubling every 5 years. From Brookmeyer *et al.* (1998).

studies. When the U.S. elderly population is broken down into 5-year incremental age groups beginning at age 65, the majority of Alzheimer's cases occur within the three groups encompassing ages 75 to 89. These combined age groups claim 1.1 million out of the 1.9 million total Alzheimer's patients among the elderly and create a crucible for the elderly: out of the 13.5 million people alive between the ages of 75 and 89 in 1995, Alzheimer's disease afflicted 8.4% of them (U.S. General Accounting Office, 1998; U.S. Census Bureau). Taking the number of cases among a particular age group as a percentage of the total population alive of that same age, the age group with the smallest percentage of cases—1.1%—is the youngest group beginning at age 65. Unsurprisingly for a disease whose major risk factor is age, the percentages increase steadily by higher age group until a full 50% of the population aged 95 and over are afflicted.

TABLE 4.1 Estimates of Alzheimer's Disease (AD) Prevalence by Age[a]

	Any AD		Moderate or severe AD	
Age	Number	Percent	Number	Percent
65–69	104,785	1.1	61,815	0.6
70–74	194,716	2.2	111,111	1.3
75–79	304,399	4.6	169,549	2.5
80–84	411,363	9.2	227,757	5.1
85–89	412,764	17.8	232,726	10.0
90–94	312,509	31.5	185,516	18.7
95+	166,287	52.5	110,595	34.9
Total	**1,906,822**	**5.7**	**1,099,069**	**3.3**

[a]The integration of 18 major studies shows Alzheimer's disease prevalence also increases by age, with at least 1.1 million people between the ages of 75 to 89 years old afflicted. Alzheimer's disease: estimates of prevalence in the United States. Report to the Secretary of Health and Human Services. United States General Accounting Office, January 1998. GAO/HEHS-98-16 (available online: http://frwebgate.access.gpo.gov/cgi-bin/useftp.cgi? IP address=162.140.64.88; filename: he98016.pdf; directory: /diskb/wais/data/gao).

Unfortunately, both prevalence and incidence estimates for this oldest population are sketchier than for other age ranges due to small sample size in all of the studies analyzed. Some literature suggests that the incidence rate may level off or decline past the age of 95, but recent studies have found the opposite trend. A very high rate of incidence for this group is shown from extrapolations of the four main U.S. studies and a Swedish study (Fratiglioni *et al*., 1997). In a recent study of nonagenarians, the prevalence of general dementia appeared to increase from 13% among 77 to 84 year olds to 48% in those 95 years old and over, and to as high as 61% when questionable cases of dementia were included (von Strauss *et al*., 1999). The Canadian Study of Health and Aging found similar results (Ebly *et al*., 1994). The prevalence of general dementia rose from 23% in the 85- to 89-year old population to 40% in the 90- to 94-year old group. For those 95 years and over, the prevalence of dementia reached 58%, with three-quarters of the cases of dementia thought to be due to Alzheimer's disease.

Even less data exist on the prevalence and incidence of Alzheimer's disease among centenarians. A 1991 study of all Finnish centenarians revealed that 26.8% of the 179 subjects had clinically diagnosed Alzheimer's (Sobel *et al*., 1995). Of a smaller Japanese study of 49 centenarians, 70.2% had some form of dementia, with three-quarters of the dementia attributed to Alzheimer's disease (Asada *et al*., 1996). Ebly *et al.* (1994) of the Canadian Study on Health and Aging suggested that dementia is nearly unavoidable in those living past 100, finding that 84.6% of those people 100 years or older are affected, the majority by Alzheimer's disease. In contrast, early findings of the New England Centenarian Study show fewer than expected cases of Alzheimer's disease at that age, with at least one-third of the subjects free of all types of dementia (Perls *et al*., 1999).

4. Family History

Another confirmed risk factor for Alzheimer's disease is family history. Specific genetic risk factors will be discussed in a subsequent chapter; however, a general association exists between positive family history of Alzheimer's disease and incidence risk in first-degree relatives. The association is statistically significant for a family history of early-onset Alzheimer's disease. The association for late-onset disease, while still positive, is thought to be nonsignificant (Thal *et al*., 1988).

A family history of Down syndrome may be a risk factor for Alzheimer's disease, although the low incidence of Down syndrome in the general population affects the reliability of data (Jorm, 1990). One study showed an increased risk of dementia in mothers, not fathers, of Down patients (Schupf *et al*., 1994). Alzheimer's neuropathology is known to be nearly ubiquitous in elderly Down syndrome patients at autopsy; however, actual symptoms of Alzheimer's disease are expressed in only a minority of them (Wisniewski *et al*., 1985).

Less clear-cut than age and family history risks are risks with gender, ethnicity or cultural differences, and education level. For these topics, what data do exist are often conflicting, and sample sizes are often less than adequate.

5. Gender

There is mounting evidence that Alzheimer's disease prevalence rates are higher in women than in men (U.S. General Accounting Office, 1998). Neuropathological studies consistently confirm this (Nishihara and Ishii, 1986; Ojeda *et al*., 1986; Wade *et al*., 1987). Among nonagenerians in particular, women are at significantly greater risk of having Alzheimer's disease than men (von Strauss *et al*., 1999). Higher prevalence rates among women may in part reflect better survival with the disease, as one study showed significantly worse survival for males than females (Beard *et al*., 1994).

Women also appear to be at greater incidence risk for Alzheimer's disease than men, although the evidence is not conclusive. A meta-analysis by Gao *et al*. (1998) of eight studies revealed a higher incidence rate in women than in men without respect to age, but at least five other studies did not (Nilsson, 1984; Copeland *et al*., 1992; Bachman *et al*., 1993; Kokmen *et al*., 1993; Letenneur *et al*., 1994). A greater incidence risk for women may be seen only in those over the age of 80; below that age incidence risk may actually be greater in men (Letenneur *et al*., 1999).

6. Race/Ethnicity

A major criticism leveled at national prevalence and incidence data on Alzheimer's disease is the largely Caucasian populations the data are derived from, calling into question the relevance of the results to the diverse population of the United States. The 18 studies from the United States and Europe that were integrated for the General Accounting Office analysis include very few nonwhite elderly subjects. The racial and ethnic composition of the United States elderly is expected to change dramatically in the next 50 years, and lack of data on Alzheimer's disease among minority groups renders national projections of the disease for this time period less reliable.

Although a 3-year comparison of general dementia prevalence rates and incidence in elderly blacks and whites showed no statistically significant differences in risk for race (Fillenbaum *et al*., 1998), other evidence shows a higher prevalence of dementia among certain ethnic groups, particularly among blacks (Schoenberg *et al*., 1985; Heyman *et al*., 1991). However, studies specifically comparing Alzheimer's disease prevalence among various racial groups, rather than that of general dementia, are scarce. Tang *et al*. (1998) suggested that blacks and Hispanics of a certain genotype may be at higher risk of developing Alzheimer's disease than whites. When members of all three groups who lacked the susceptibility allele APOE $\epsilon 4$ were compared, blacks had a four times higher cumulative risk for developing late-onset Alzheimer's disease than whites, and Caribbean Hispanics had a risk two times as great as whites. For those subjects who do possess the APOE $\epsilon 4$ allele, risk appears elevated for Caucasians but not other ethnic groups.

There is also some evidence that Alzheimer's disease patients of different racial backgrounds may experience differences in disease progression. One study shows a racial difference in neuropsychiatric symptoms without separating by type of dementing illness: blacks have a significantly greater likelihood of psychotic symptoms with dementia whereas whites have a greater likelihood of depression with the disease (Cohen and Magai, 1999).

Cultural or environmental factors may influence risk. Japanese males who emmigrate to the island of Hawaii are more likely to have Alzheimer's disease than Japanese men of the same age living in Japan, suggesting influences other than race. The prevalence rate of Alzheimer's disease among Hawaiian Japanese-American men approaches that seen for North Americans in general, while far exceeding rates typically seen in Japan (White *et al*., 1996). African Americans living in Indianapolis have a significantly higher age-adjusted prevalence rate of Alzheimer's disease, as well as other types of dementia, than members of a Nigerian African population living in Ibadan, Nigeria, despite similar racial origins (Hendrie *et al*., 1995). In a study based on hospital discharge records, Israeli Jews of American or European origin had double the Alzheimer's disease incidence rates of Israeli Jews of Asian or African origin. This study did not rule out cultural differences in hospital service use, however (Treves *et al*., 1986). One other example of possible environmental or cultural effect is a study showing higher prevalence rates of Alzheimer's disease in New York than in London (Copeland *et al*., 1987).

7. Other Risk Factors

A positive history of head trauma became a suspected risk factor in Alzheimer's disease after the discovery of Alzheimer's-like neuropathology in boxers afflicted with dementia pugilistica, as well as in 30% of nonboxers dying after one severe head injury (Graham *et al*., 1996). While there is consensus that a history of head injury in subjects with the apolipoprotein E-$\epsilon 4$ genotype increases risk for Alzheimer's disease, studies looking for a more general relationship with head injury without respect to genetic factors are not in agreement. Head injury with loss of consciousness has been shown to be a significant predisposing factor in Alzheimer's disease in

several recent case-control studies but not in others (van Duijin, 1996). Recall bias is one possible flaw in case-controlled studies: retrospectively collected information on head injury reveals a positive association with Alzheimer's disease, whereas prospectively collected information does not support such a link (Chandra *et al*., 1989). One longitudinal incidence study did show an increased risk for Alzheimer's disease in subjects with a history of head injuries involving loss of consciousness greater than 5 min and also for subjects whose injuries occurred within the past 30 years (Schofield *et al*., 1997).

Lack of education may be a risk factor. Studies showing lower education as a risk factor of developing Alzheimer's disease slightly outweigh in number those studies that fail to find any link between education and risk (Beard *et al*., 1992). The possibility that people with more education or higher premorbid intelligence may better mask evidence of decline on cognitive function tests cannot be excluded. Other confounding factors, such as occupational or early life exposures, are also difficult to rule out.

The presence of aluminum in neuritic plaques of Alzheimer's disease patients at autopsy spurred investigation into a link between exposure to the metal and development of the disease. Aluminum in drinking water and in mines has been linked to increased risk for Alzheimer's disease (Rifat *et al*., 1990; Doll, 1993; Jacquim *et al*., 1994). Risk from other sources of aluminum, such as medications and antiperspirants, has not been established conclusively (van Duijin, 1996). Interestingly, no difference has been found in serum and bone aluminum levels between control patients and Alzheimer's disease patients (O'Mahony *et al*., 1995; Zapatero *et al*., 1995). Other possible risk factors for Alzheimer's disease, such as depression, smoking, and exposure to glues, fertilizers, and pesticides, have been investigated. Here again, conclusive results are lacking.

8. Possible Protective Factors

Estrogen replacement therapy is a possible but not conclusively proven protective factor against developing Alzheimer's disease. Women in one study who took estrogen for longer than 1 year after menopause had an 80% lower incidence risk for Alzheimer's disease when compared to women who did not take the therapy, whereas the Baltimore Longitudinal Study on Aging found Alzheimer's risk reduced by half in women who had a postmenopausal history of estrogen replacement therapy (National Institute on Aging, 1998). A review of 10 randomized studies and 9 observational studies on estrogen use and Alzheimer's disease found some support for use of the therapy, but not enough to conclusively endorse it for the prevention of Alzheimer's disease (Haskell *et al*., 1997).

Arthritis sufferers appear to be at lower risk of Alzheimer's disease. This has been linked to regular use of nonsteroidal inflammatory drugs other than aspirin (Breitner *et al*., 1994). Regular use of nonsteroidal inflammatory such as ibuprofen, naproxen sodium, and indomethacin for 2 years led to a 60% reduction in the risk of developing Alzheimer's disease among subjects in the Baltimore Longitudinal Study on Aging (National Institute on Aging, 1998). Use of aspirin lowered risk only slightly, whereas acetominophen use was not associated with any risk reduction.

B. Vascular Dementia

Vascular dementia is thought to be the second leading cause of dementia after Alzheimer's disease in the United States and Europe (Jorm, 1990). Whereas Alzheimer's disease accounts for two-thirds or more of all cases of dementia, vascular dementia is believed to cause between 10 and 20% of the cases (Small *et al*., 1997; Nyenhuis and Gorelick, 1998). There is debate as to whether the category vascular dementia is a clinically useful one at all, however. The term encompasses several subtypes of pathology, including multi-infarct dementia, Binswanger-type dementia, and dementia of the hemodynamic type. Prevalence and incidence data on vascular dementia typically do not discriminate between subtype.

Estimates on the prevalence and incidence of the disease may be influenced by bias in diagnostic criteria. Diagnosis requires the presence of both cerebrovascular disease and dementia, even though a direct causal relationship remains to be found; thus areas with a high prevalence of cerebrovascular disease may be prone to overestimation of vascular dementia rates at the expense of other diagnoses (van Duijin, 1996; Brust, 1988). Nolan *et al*. (1998) found at autopsy that cerebrovascular disease alone was the cause of none of 87 cases of dementia, although cerebrovascular disease was seen to coexist with Alzheimer's disease pathology.

In Japan, China, and Russia, where stroke rates are high, estimates of vascular dementia rates range from moderately high to very high. Some studies show it to be as common or more common than Alzheimer's disease (Jorm, 1991; Li *et al*., 1991; Udea *et al*., 1992; Yoshitake *et al*., 1995). At least three studies suggest that vascular dementia is overdiagnosed in these regions and that rates are in fact much more similar to those seen in the United States, i.e., trailing Alzheimer's disease as the underlying cause of most dementia (Lin *et al*., 1998; Nolan *et al*., 1998; Yamada *et al*., 1999).

Age, gender, and race are risk factors for vascular dementia. Like Alzheimer's disease, rates increase exponentially with age, although the rise appears to be steeper for vascular dementia than for Alzheimer's disease (Jorm *et al*., 1987). The balance of both prevalence and incidence evidence shows males more likely to have vascular dementia (Jorm, 1990; van Duijin, 1996). Blacks appear to suffer from the disease in greater proportion than members of other races (Gorelick, 1997; Lindsay *et al*., 1997). Stroke risk factors are closely linked to, but not necessarily identical to, vascular dementia risk factors (Leys *et al*., 1998). Age, gender, and race are also risk factors for stroke. Other factors include arterial hypertension, diabetes mellitus, and low HDL cholesterol levels.

C. Dementia with Lewy Body Disease

Pathological studies suggest that Lewy body disease may vie with vascular dementia—or even exceed it—as the second leading cause of dementia. Seventeen to 36% of all cases of dementia appear to be caused by the disease (Gomez-Tortosa *et al*., 1998). An autopsy series found that the disease accounted for 25% of dementia cases (McKeith *et al*., 1996).

When mixed-type dementia cases are included, Lewy body disease may be far more widespread than was first believed. As many as 30% of elderly patients diagnosed clinically and

pathologically with Alzheimer's disease also showed significant Lewy body pathology at autopsy. In addition, at least some Lewy body pathology is nearly ubiquitous at autopsy of Parkinson's disease patients (Hughes, 1997). Because clinical and pathological aspects of the disease overlap with both Alzheimer's disease and Parkinson's disease, prevalence and incidence rates of dementia with Lewy body disease are not yet established (Holmes *et al*., 1999).

As with Alzheimer's disease and vascular dementia, the largest risk factor for incidence of the disease is age in that above the age of 50, incidence rates rise steadily. Family history is also implicated. Alzheimer's disease in a first-degree relative increases the risk of developing dementia with Lewy body disease greatly. Presence of the apolipoprotein E ϵ4 allele is a risk factor, but somewhat less so for Lewy body disease than for Alzheimer's disease. Gender appears to be a risk factor as well: men are twice as likely as women to have dementia with Lewy body disease (Papka *et al*., 1998). Data on other demographic and epidemiological aspects of the disease are lacking.

IV. Age-Associated Sensory–Motor Impairments

A. Visual Impairment

Visual function changes and ocular disease often accompany the aging process. Decreases in acuity, accommodation, and dark adaptation are common among the elderly. Among Americans 65 and older, 7 million people (or 21%) have some degree of visual impairment. Of those, 3.5 million people report severe vision loss. Based on these estimates, visual impairments will affect 15 million elderly people, 7.6 million of them severely, by the year 2030 (Lighthouse, Inc., 1995). Figure 4.4 shows U.S. Department of Health estimates of visual impairment among the noninstitutionalized elderly. Age-related macular degeneration, primary glaucoma, and diabetic retinopathy are the main neurological impairments affecting vision in the elderly.

1. Age-Related Macular Degeneration

Retinal degeneration affects the elderly in two forms, one of which, peripheral retinal degeneration, occurs in as much as half of the elderly population but results in little change in vision and is not treated (Ernest, 1997). The other form, age-related macular degeneration (AMD), is far more serious. Also referred to as age-related maculopathy, it is the leading cause of new cases of legal blindness in the United States as well as the leading cause of visual impairment among those 70 years and older.

AMD itself has two types, the ''dry'' or nonexudative type, also called the atrophic form, and the ''wet'' or neovascular/exudative type. The latter form results in more severe vision loss. The dry type affects more people, however, accounting for 80% of all AMD patients, some of whose condition may then deteriorate into the wet form (Ferris *et al*., 1984).

An estimated 4.5 million people had AMD in the United States in 1992 (Hyman, 1992). When longer life expectancies and current prevalence data are taken into account, as many as 7.5 million people are likely to have AMD by the year 2020. Incidence data on the disease are lacking, however. This affects the accuracy of projections, particularly since several studies have reported an increase in the rate of AMD-related blindness registrations in the past few decades. It is not known if the increases are genuine or an artifact of better diagnosis and reporting (Hyman, 1992).

Prevalence rate estimates for AMD vary from study to study, particularly since no uniform diagnostic criteria have been established for the disease. In the United States, two major population-based prevalence studies, one national in scope and one in Framingham, Massachusetts, showed overall prevalence rates of 5.8 and 8.8%, respectively (Kahn *et al*., 1977a; Klein and Klein, 1982). A more recent study suggests that 15% of Caucasians 40 years and older (13.2 million people) show some signs of the disease (Prevent Blindness America, 1994).

The disease is strongly age related. Prevalence rates among people under the age of 55 approach zero (O'Shea, 1998). The Framingham study found that prevalence more than doubled

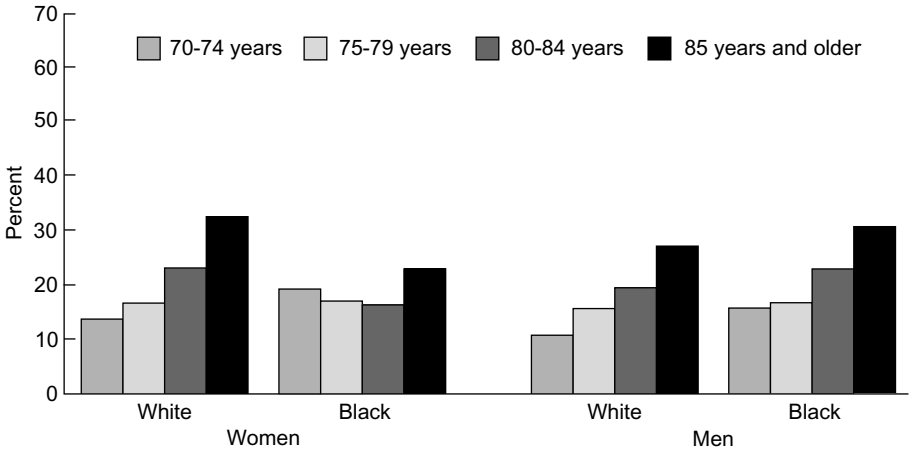

FIG. 4.4. Prevalence of vision impairment by age, sex, and race in 1995. Visual impairment becomes more common with age, although there are underlying gender and racial differences in prevalence. From U.S. Department of Health and Human Services (1999) (available online: *http://www.cdc.gov/nchs/products/pubs/pubd/hus/charts/hus99f12.pdf*).

between the age groups 65–74 and 75–85, rising from 11 to 28% (Kahn *et al*., 1977a,b; Klein and Klein, 1982). Other research indicates that more than one-third of the population 75 and over in the United States is affected by AMD, 3% of them severely so (Prevent Blindness America, 1994).

Whether there is an association between gender and AMD remains under debate. Some studies show a slight female preponderance among AMD sufferers. In one Scandinavian study on the incidence of blindness caused by AMD, female cases outnumbered male cases by as much as 2.8:1 (Rosenberg and Klie, 1996). In that study, the age-specific incidence of AMD blindness was 140:100,000 for females and 66:100,000 for males in the age group 60 and over. A national study in the United States, however, found no clear-cut gender differences in prevalence rates, but did not assess incidence rates (Klein and Klein, 1982).

Race may be a risk factor in AMD, although this also has not been determined conclusively. It should be noted first that African Americans have a greater proportion of visual impairments overall than do whites, which may be due to diminished access to eye care (Schmeidler and Halfmann, 1998). For AMD, however, blacks are thought to have a lower risk of the disease than whites. Theories on this topic focus on the possible protective effects of darker pigmentation. Signs of the disease are common in both groups, but more severe, late-stage forms of the disease appear more commonly in elderly whites than blacks in the United States (Friedman *et al*., 1999). At least four studies have shown higher overall rates of AMD among whites than blacks (Hyman, 1992), and another study has shown whites to have a higher frequency of early stage, age-related macular degeneration than blacks (Schachat *et al*., 1995). Rates among whites may exceed those found among Asians as well. The National Health and Nutrition Examination Survey, however, showed no significant differences by race in prevalence of AMD (Goldberg *et al.*, 1988).

Other factors that have been examined for positive risk association with AMD include high blood pressure, cardiovascular disease, exposure to sunlight, altitude, light-colored iris pigmentation, smoking, heredity, and lack of dietary antioxidants. Some evidence suggesting elevated risk for these factors has been demonstrated but all remain under debate. Income and education are not risk factors for AMD (Klein *et al*., 1994).

2. Primary Glaucoma

Of existing, not incident, cases of legal blindness in the United States, glaucoma is the leading cause (National Society to Prevent Blindness, 1980). There are several forms of glaucoma, all involving optic nerve atrophy and defects of the visual field (Ernest, 1997). Two of the forms, open angle and angle closure, are together known as primary glaucoma. They are most closely associated with aging and cause visual impairment in as many as 6% of Americans over the age of 65 (Glaucoma Foundation, Inc., 1997). Worldwide, an estimated 67 million people live with glaucoma (Flanagan, 1998).

Angle closure glaucoma is the rarer of the two forms. It is an acute disease, with onset late in life. Open angle glaucoma occurs five times as commonly and is a chronic, slow-progressing form of the disease (Ernest, 1997). Unlike acute angle closure glaucoma, which typically causes pain at onset and causes patients to seek medical care, open angle glaucoma may go undetected for years. Incidence and prevalence estimates may thus be too low. Researchers in Sweden themselves uncovered nearly half of the cases of open angle glaucoma in one population-based survey (Ekström, 1996). Among an Australian population 49 and older, 3.0% were affected, and half of the cases had remained undetected until the study (Mitchell *et al*., 1996).

Estimates for 1997 showed four million Americans overall with open angle glaucoma, more than half of whom are middle-aged or older (Glaucoma Foundation, Inc., 1997). The Beaver Dam Eye Study found an overall prevalence of open angle glaucoma of 2.1%. It also found a strong association with age: prevalence was 0.9% among 43 to 54 year olds, but increased to 4.7% among those 75 years and older (Klein *et al*., 1992). Among those aged 80 to 89 years, the disease affects as many as 9.7% of the population (Wensor *et al*., 1998). Incidence of this form is thought to rise from 0.2% among 50 year olds to 2% among 70 year olds (Ernest, 1997).

Older African Americans are at as much as three times higher risk of having primary glaucoma than whites. Approximately half a million, or 6%, of older African Americans have the disease compared to 2%, or nearly 1.5 million, of older Caucasians (Prevent Blindness America, 1994). The likelihood of visual impairment due to the disease is even greater among older African Americans. Risk of impairment may be as much as 6% greater among blacks than whites (Tielsch *et al*., 1990). The major accepted risk factor for the disease is abnormally high intraocular pressure (Flanagan, 1998). Sleep apnea may also increase risk (Mojon *et al*., 1999).

3. Diabetic Retinopathy

The risk of diabetic retinopathy increases as the length of time living with diabetes increases. Risk, therefore, is also strongly linked to aging, as the majority of diabetes cases are diagnosed after the age of 40. The incidence of diabetic retinopathy is greatest during the years 45 to 75. Nearly 2% of people living 15 years with diabetes are blind, and 10% have some form of visual impairment from the disease. In a Rochester, Minnesota study, a cumulative blindness incidence of 8.2% was demonstrated in patients living 20 years with diabetes (Sanchez-Thorin, 1998). Diabetic retinopathy caused 14.4% of legal blindness among 65 to 74 year olds in the United States in 1978, the only data inclusive of all races and types of blindness (National Society to Prevent Blindness, 1980).

Race is a risk factor. African Americans and Hispanic Americans are more likely to have diabetes and diabetic retinopathy than Caucasian Americans (Prevent Blindness America, 1994). Black women have the greatest risk of blindness with the disease, although a study has shown slower disease progression in African Americans than in whites (Kahn and Hiller, 1974; Arkfen *et al*., 1994). Native Americans also have a greater risk of diabetic retinopathy compared to whites (Lee *et al*., 1992a,b). White men appear to have the lowest overall incidence of the disease (Kahn and Hiller, 1974).

Risk for diabetic retinopathy is also elevated with hyperglycemia. High blood pressure and gross proteinuria are other predisposing factors for diabetic retinopathy among type I

diabetics. Type I diabetics have a greater risk for blindness with the disease than type II diabetics.

B. Hearing Impairment

Hearing loss associated with aging has numerous causes and is regarded as the most common medical problem affecting the elderly (Mhoon, 1997). Figure 4.5 shows the prevalence of hearing impairment among the noninstitutionalized elderly. Most studies on hearing loss show prevalence rates ranging from 27 and 47% among the elderly (Moscicki *et al*., 1985; Ries, 1985; Adams and Benson, 1990). A recent population-based study of 4541 people aged 48 to 92 found prevalence of all degrees of hearing loss to be 45.9% among those 65 and older, with moderate and severe hearing loss accounting for 41.9% of the cases (Cruickshanks *et al*., 1998). In an audiologic survey of people 70 years and older living at home, 60% were affected by significant losses in the speech frequency range (Herbst and Humphrey, 1980). Even after adjusting for noise exposure, occupation, and education, a statistically significant preponderance of hearing loss was seen in males (Cruickshanks *et al*., 1998). Among nursing home residents, hearing losses affect as much as 80 to 90% of the population (Hull, 1995).

Otologic changes may occur with aging in all parts of the ear, but those involving sensorineural impairment are the most common. Sensorineural loss can be divided into sensory loss, involving the cochlea or organ of Corti, and neural loss, involving peripheral nerves, ganglion cells, the auditory nerve, or central auditory pathways.

Forms of sensorineural impairment, in addition to traumas and hereditary or congenital defects, include ototoxicity, Ménière's disease, and hearing loss due to metabolic, autoimmune, and demyelinating disorders. Infection, neoplasms, and brain stem ischemias also cause sensorineural hearing deficits. These disorders are not necessarily age related, but they do commonly affect the elderly. Noise, smoking, cardiovascular disease, hyperlipoproteinemia, and low dietary antioxidant intake are all thought to be factors contributing to sensory impairment in hearing. Exposure to these factors increases with age. Tinnitus is an example of this—increases in prevalence rates are associated with both age and level of noise exposure (Coles, *et al*., 1987).

1. Presbycusis

By far, however, the hearing loss associated most commonly with aging is a progressive, bilaterally symmetric hearing impairment of unknown cause, affecting primarily the ability to hear high tones. Onset rarely occurs before middle age. The general term presbycusis is used to describe this disease.

Four types of presbycusis have been described: sensory, neural, strial, and cochlear conductive types (Kennedy and Clemis, 1990). The four types are discriminated by area of sensorineural degeneration and atrophy in the inner ear. The elderly are often affected by more than one type. However, one-quarter of the cases of presbycusis fit into none of the four categories (Mhoon, 1997).

Because presbycusis is used as an umbrella term for a variety of underlying pathologies, demographic and epidemiological studies on it are not readily available. However, prevalence and incidence data are available for general hearing losses among the elderly and, as mentioned earlier, presbycusis accounts for the vast majority of all hearing loss in this population. Although the disease is accepted to be strongly age related, conflicting evidence exists on whether presbycusis incidence and prevalence rates continue to rise steadily among the oldest old segment of the population. A recent longitudinal study of presbycusis in a Swedish population suggests that annual declines in hearing threshold level off in the ninth decade of life (Jonsson and Rosenhall, 1998).

2. Ototoxicity

Medication effects can also cause sensorineural impairment in the inner ear. Known as ototoxicity, this form of hearing loss affects the elderly in greater proportion than other segments of the population because of the greater likelihood of polyphar-

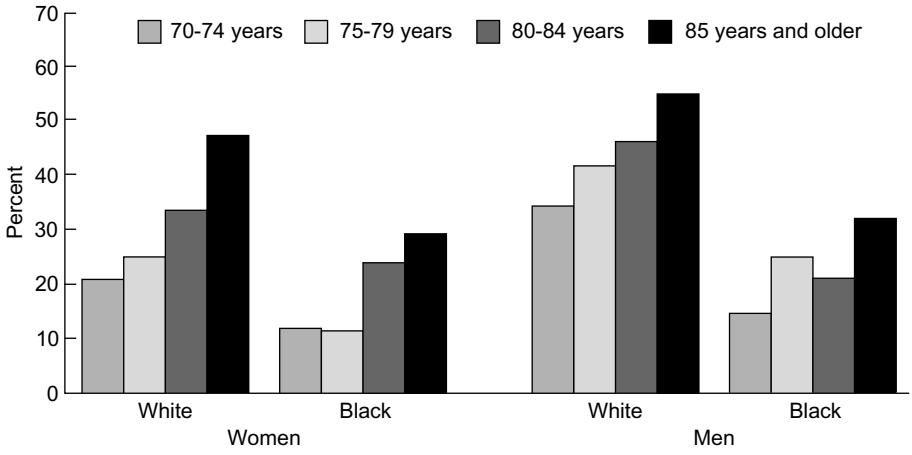

FIG. 4.5. Prevalence of hearing impairment by age, sex, and race in 1995. Hearing impairments may affect as many as half the population 85 years and older, although overall prevalence rates vary significantly by race and gender. From U.S. Department of Health and Human Services (1999). (available online: *http://www.cdc.gov/nchs/products/pubs/pubd/hus/charts/hus99f13.pdf*)

macy among the elderly and the greater sensitivity of the elderly to side effects. Temporary ototoxicity can be caused by ibuprofen and aspirin, drugs commonly used by older patients with arthritis. Other drugs with ototoxic effects are aminoglycoside antibiotics, quinine, ethacrynic acid, and furosemide (Mhoon, 1997).

C. Gait Impairment and Postural Instability

Postural stability and gait depend on the integration of a host of sensory, neural, and musculoskeletal factors, all of which are susceptible to changes with aging. Nutt (1997) classifies balance and gait disorders by a broad area of dysfunction: afferent or sensory disturbances, central or integrative disturbances, and efferent or motor disturbances.

Afferent dysfunctions, such as age-related vestibular and proprioceptive changes and the aforementioned age-related vision losses, contribute to spatial disorientation and distortion of environmental signals. Because these senses normally provide redundant and overlapping information, loss of one is not in itself enough to cause significant instability. In the elderly, however, more than one of the senses are often compromised or provide conflicting information, affecting balance and gait. Central nervous system disorders affect stability in the elderly, especially through diseases that affect the frontal lobes, basal ganglia, and brain stem. Cognition-related judgement decline is a common cause of gait impairment and falls. Efferent declines with age typically include changes in muscle strength and tone, but may also involve motor neuropathies, corticospinal pathways, and diseases of the cerebellum. These declines are accompanied by an inability to coordinate motor function and also result in gait disturbances.

Gait disorders affect as many as 57% of women and 42% of men over the age of 75 (Waite *et al*., 1997). Spastic gait and ataxic gait are examples commonly afflicting the elderly. These disorders are caused by a specific area of decline (afferent, central, or efferent) discussed in detail later. However, the most common gait disturbance in the elderly, ''cautious'' gait, is not described by a particular area of decline. Cautious gait, also known as senile gait, is a general term for unsteadiness with aging. One theory as to cause is normal-pressure hydrocephalus; another is the cumulative effects of many minor neurologic defects and progressive losses that can accompany neuronal aging in the elderly (Jenkyn and Reeves, 1981; Fisher, 1982; Horak *et al*., 1989).

1. Afferent Impairment

Dysfunction of the peripheral vestibular system most commonly causes a weaving or ''drunken'' gait, whereas central disorders of the vestibular system may produce an ataxic gait or weaving. Prioprioceptive declines, either of the peripheral system or of spinal pathways, cause ataxic gait disorders and loss of position sense.

a. Vestibular Changes. Disorders of the vestibular system, manifest chiefly as complaints of dizziness and/or vertigo, are extremely common in the elderly. At least half of home-dwelling subjects over the age of 62 had some form of vertigo, and the numbers are thought to be significantly higher among nursing home and hospital residents (Babin and Harker 1982). Sloane *et al*. (1989) found that dizziness or loss of balance affected 65% of community-dwelling individuals over the age of 60, many of them on a daily basis. As many as 69% of elderly individuals demonstrate impairment on vestibular function tests (Lord *et al*., 1991).

Age-related changes in vestibular function can be due to peripheral, central, or systemic disorders. Neural involvement is limited to the former two, although causes other than neural degeneration, such as motion sickness, tumors, and vascular anomalies, can also account for peripheral and central vestibular dysfunction. Peripheral vestibular disorders typically cause severe symptoms of vertigo (the sensation of individual or environment rotating), whereas central disorders more often result in milder symptoms of dizziness (general sensations of dysequilibrium and spatial disorientation including light-headedness, swaying, and unsteadiness) (Nutt, 1997).

Disorders of the peripheral vestibular system are not well classified. Degenerative losses with aging may be seen in the sensory epithelium, otoconia of the saccule, hair cells, or peripheral nerve. Belal and Glorig (1986) used the general term presbyastasis to describe disequilibrium due to peripheral vestibular changes with aging and found the condition prevalent in 79% of elderly patients presenting with dizziness. Histopathologic evidence in the vestibular labyrinth necessary to consider presbyastasis a distinct disease entity is not well established, however.

Another general term for peripheral vestibular dysfunction, this one associated with vertigo when the head is placed in certain positions, is benign paroxysmal positional vertigo. Whereas symptoms of this condition are well established, etiology is not. General degenerative processes in the labyrinth are thought to cause the majority of cases, but vestibular neuronitis, surgical trauma, head injury, and medication effects can also be predisposing factors. Benign paroxysmal positional vertigo was the most prevalent diagnosis of 1194 patients in a Montreal dizziness clinic, affecting nearly 40% of patients (Katsarkas, 1994).

b. Proprioceptive Changes. Proprioceptive changes with aging can result from losses in the sensory nerve terminals of muscles, tendons, and joints or in the multiple central nervous system connections. Peripheral sensation is vital to postural stability, walking on uneven ground, and spatial orientation during position changes, particularly when other senses are compromised. It accounts for roughly 56% of the maintenance of static posture, whereas vestibular and visual senses are secondary, accounting for roughly 22 and 21%, respectively (Lord *et al*., 1991).

Loss of sensory input from lower limbs is particularly prevalent among the elderly. Among nursing home residents in Australia, nearly 36% of elderly subjects received abnormal ratings on static balance tests, whereas on dynamic balance tests, over 73% of subjects demonstrated impairment (Lord *et al*., 1991). Poor scores on both types of tests were significantly associated with reduced tactile sense as well as reduced joint and vibration sense.

Proprioceptive losses are nearly unavoidable with age. In a comparison of healthy 80 year olds with healthy 20 year olds, ankle vibration sense declined 86% with age. One-leg standing

with eyes open declined 32%, whereas with eyes closed it declined 100% (Potvin *et al*., 1980). Bohannon *et al*. (1984) found that no subjects in their eighth decade of life were able to balance on one leg with eyes closed for 30 sec, whereas three-quarters of subjects in their third decade of life were able to do so.

2. Central Nervous System Impairment

Impairments of higher-level central integrative functions in the elderly affect postural stability and gait in a number of ways. Input from sensory systems can be compromised by neurological losses in central pathways. In the vestibular system, for example, central vestibular nuclei and pathways are vulnerable to atherosclerosis and chronic hypertension (Belal and Glorig, 1986). Ischemias and infarcts, neuromas, and demyelinating diseases in the brain stem, basal ganglia, cerebellum, and thalamus compromise central pathways of all types of sensory functions. Walking may become impossible due to the resulting severity of disequilibrium (Nutt, 1997).

The elderly are at greater risk for a number of diseases affecting cerebral blood flow, such as postural hypotension, stroke, cardiac dysrhythmias, and systemic diseases such as diabetes. These may cause central neurologic deficits in deep white or gray matter as well as in the frontal lobes. These types of dysfunction are associated with loss of balance, freezing, or shortened steps, although central gait disorders are still somewhat controversial and not generally well classified.

Loss of cognitive function due to dementing illnesses affects stability through impaired judgement and gait. Medications commonly taken by the elderly, particularly certain psychotropic, cardiac, and analgesic drugs, are known to compromise central functioning and thus stability through a variety of mechanisms.

3. Efferent Impairment

Diminished effector component function of the motor system affects the ability of the elderly to maintain postural stability, producing a wide variety of gait disturbances. Distal and proximal nerve declines such as motor neuropathy result in a waddling or slapping gait. Corticospinal pathway dysfunction commonly causes ''spastic'' gait. Parkinsonism or dysfunction in the basal ganglia results in tremor, rigidity, and bradykinesia, whereas choreic diseases produce distinctly irregular movements. Cerebellar changes cause ataxic gait and balance incoordination (Nutt, 1997).

4. Falls

Postural instability is of primary importance in day-to-day function in the elderly in that its presence is the major predictor of falls. Among those over the age of 65, the sixth leading cause of death is unintentional injury, mainly from complications of falls (Sattin, 1992). Falls affect at least a third of community dwellers over the age of 65 (Tinetti *et al*., 1988). Risk of not being able to get up after a fall is as high as 50% in the elderly. Falling increases the likelihood of nursing home placement; unfortunately, however, falls in nursing homes are even more prevalent, affecting half of all residents annually and directly accounting for 1800 fatalities each year (Tinetti, 1997). The incidence rate of falls among residents of nursing homes is as high as 1.5 falls per bed per year (Rubenstein *et al*., 1994).

The model that best describes falls is a multifactorial one, taking into account environmental, activity, and host factors. Because postural stability in the host requires sensory, central integrative, and effector contributions, impairments in any of these systems can compromise balance and equilibrium. The age-related visual, vestibular, proprioceptive, and central nervous system losses described earlier therefore strongly predispose the elderly to falling. Nonneuronal host factors such as arthritis, joint and muscle weakness, systemic diseases such as electrolyte and sugar imbalances, postural hypotension, and acute illnesses also contribute to the high rate of falls among the elderly. The heightened sensitivity to the effects of medications among the elderly is another very common factor in falls.

D. Parkinson's Disease and Parkinsonism

Parkinson's disease in the most common disease of the cluster of chronic, progressive, and age-related motor system disorders. Also known as idiopathic Parkinson's disease or primary parkinsonism, it predominates this group of movement disorders by as much as 68% and is of still unknown etiology (de Rijk *et al*., 1997). The term parkinsonism is a general one, covering related disorders with most, but not necessarily all, of the same symptoms as Parkinson's disease, and may also include symptoms distinct from those of Parkinson's disease. In some literature the term includes idiopathic Parkinson's disease.

Non-Parkinson's disease forms of parkinsonism are relatively uncommon and are of both known and unknown cause. The second most common form of parkinsonism after Parkinson's disease is progressive supranuclear palsy (Litvan and Hutton, 1998). Mayeux *et al*. (1995) found the disease to be 12 times less frequent than Parkinson's disease in terms of crude annual incidence. Progressive supranuclear palsy increases in incidence rate with age, rising from 1.7 for 50- to 59-year olds to 14.7 for 80- to 99-year olds (Bower *et al*., 1997). Other non-Parkinson's forms of parkinsonism include postencephalitic parkinsonism, drug-induced parkinsonism, striatonigral parkinsonism, arteriosclerotic parkinsonism, toxin-induced parkinsonism, the parkinsonism–dementia complex of Guam, and parkinsonism accompanying distinct neurological disorders (National Institutes of Health, 1994). The Europarkinson collaborative study separated the various forms of parkinsonism by frequency of occurrence and found that after Parkinson's disease, unspecified parkinsonism accounted for 14% of all types in Europe (de Rijk *et al*., 1997).

1. Prevalence

Prevalence estimates range widely by study and are subject to the usual caveats: differing diagnostic criteria and methodology by study, underestimates caused by delays in diagnosis due to the progressive nature of the disease, and overestimates

caused by symptom overlap with other neurological diseases. In five community studies in Europe, the survey investigators themselves uncovered 24% of the total cases of Parkinson's disease in the population, suggesting that many patients do not seek medical attention for symptoms and thus go undiagnosed (de Rijk *et al*., 1997). However, as many as 25% of expertly diagnosed cases of Parkinson's disease were found at postmortem to be otherwise, according to data from the Parkinson's Disease Society Brain Bank of the United Kingdom (Hughes *et al*., 1992). Up to 40% of false-positive diagnoses may be due to essential tremor (Tanner and Goldman, 1996).

Parkinson's disease affects some 500,000 Americans at this time (National Institutes of Health, 1994.). It accounted for 4.6% of all visits to neurologists in the United States in 1991–1992, but among those 65 and older, it accounted for 16.9% of visits to neurologists (Schappert, 1995). The prevalence in North America is thought to be 150 per 100,000 people (Checkoway and Nelson, 1999). For a disease with possible environmental causes, however, regional variations in prevalence are important and are masked by large-scale national estimates.

Within America there are notable geographic variations in Parkinson's disease mortality, suggesting the possibility of an accompanying uneven distribution by region and perhaps also by race in prevalence. Lanska (1997) found a decreasing gradient from north to south for underlying cause and all-cause mortality rates among whites, but a weaker gradient and lower overall mortality rates for blacks. A twofold increased risk of death is associated with parkinsonism (Bennett *et al*., 1996).

Variations in prevalence estimates have been found at the international level. In an analysis of age-adjusted prevalence rates from 27 regions of the world, there was a 13-fold difference between the highest and the lowest end rates (234 per 100,000 in Uruguay and 18 per 100,000 in China, respectively) (Zhang and Roman, 1993). If data from Chinese provinces are excluded, however, only a fourfold difference is detected worldwide (Wang, 1990). Low prevalence rates in China have been reported consistently. Other data from door-to-door surveys conducted by WHO investigators found the lowest worldwide age-adjusted prevalence rates among blacks in Nigeria, followed by China (Zhang and Roman, 1993). High-end estimates include a crude prevalence of 244.4 per 100,000 in a door-to-door survey in Alberta, Canada (Svenson *et al*., 1993).

2. Incidence

The latency period between the beginning of dopaminergic neurodegeneration and the actual onset of symptoms has yet to be determined, nor are there definitive antemortem diagnostic tests. Approximately 50,000 new cases of Parkinson's disease are diagnosed each year in the United States (National Institutes of Health, 1994). A population-based longitudinal study in Olmsted County, Minnesota revealed an increase in annual incidence rates over the period from 1935 to 1984 of 9.2 per 100,000 to 16.3 per 100,000 (Tanner *et al*., 1992). Other studies have shown no changes in incidence in the past half century, suggesting little temporal variation (Tanner and Goldman, 1996).

Internationally, annual incidence figures as low as 4.5 per 100,000 were determined in Libya and as high as 16.1 per 100,000 in Iceland (Tanner and Goldman, 1996). Incidence rates by region and nation vary widely and include discrepancies as to what forms of parkinsonism are included in data. Overall rates for the United States typically fall at the high end of international incidence comparisons.

3. Age

As with dementia, Parkinson's disease is strongly related to aging. Young-onset forms (defined as below the age of 40) are known and thought to be increasing in prevalence, but the typical age of onset is 60 years of age. Both incidence and prevalence of the disease rise steeply above the age of 50 worldwide, regardless of overall prevalence variations by geographic region. Older literature reported that prevalence and incidence rates drop among the oldest-old. More recent data suggest this trend is most likely due to missed diagnoses and predict a continued exponential rise with age (Ben-Shlomo, 1996).

Advancing age brings with it an increase in prevalence of nearly all types of parkinsonian clinical signs. The exception appears to be resting tremor, which shows a decrease in prevalence with age (see Table 4.2). Bennett *et al* (1996) assessed the prevalence of parkinsonian signs: bradykinesia, gait disturbance, rigidity, and tremor. With Parkinson's disease patients included, 52.4% of those 85 and older had at least two signs. For elderly aged 65–74 and 75–84, 14.9 and 29.5% had at least two parkinsonian signs, respectively.

4. Gender

Men outnumber women in Parkinson's disease. Most of the evidence collected shows age-adjusted prevalence rates slightly higher in men than in women, and male cases appear to outnumber female cases by 20 to 30% (Checkoway and Nelson, 1999). Mayeux *et al.* (1995) found a lower cumulative incidence rate among women regardless of racial background.

5. Race/Ethnicity

The wide discrepancies in prevalence and incidence rates between different regions of the world may reflect underlying differences in racial susceptibility to the disease, or may be due to other factors entirely. Zhang and Roman (1993) found that regardless of region, door-to-door surveys yielded consistently higher rates than other methods and suggested that regional variations may be due to case-ascertainment differences rather than true variation in Parkinson's disease between populations. Several studies report reduced rates of Parkinson's disease among black Africans and also among blacks in other regions of the world in clinic-based studies (Richards and Chaudhuri, 1996). In Copiah County, Mississippi, lower age-adjusted rates were determined among blacks than whites in door-to-door surveys; identical survey methods in Nigeria, however, revealed a fivefold lower prevalence among Nigerian blacks than American blacks (Osuntokum *et al*., 1987; Schoenberg *et al*., 1998).

Mayeux *et al*. (1995) found lower age-adjusted prevalence rates of Parkinson's disease among blacks than other racial groups in a Manhattan community registry study, but impor-

TABLE 4.2 Age-Specific Estimates of the Prevalence of Parkinsonian Signs[a]

Parkinsonian sign	No. in sample	Prevalence according to age %			*P* value for trend (age)
		65–74 years	75–84 years	≥85 years	
Bradykinesia

[a]Parkinsonian signs are increasingly prevalent with age. From Bennett *et al.* (1996).

tantly, highest incidence rates and mortality rates from the disease among black men. Richards and Chaudhuri (1996) proposed the explanation that blacks, with higher stroke and cardiovascular disease risk, may be more susceptible to vascular parkinsonism, poorer survival, and therefore appear to have lower prevalence rates of Parkinson's disease than whites.

6. Risk Factors

Symptoms of Parkinson's disease have been described as long ago as 1000 B.C. but the disorder continues to be an etiological enigma. Theories as to cause shifted dramatically over the course of the 20th century. In the first half of the century the major risk factor was thought to be exposure to infectious agents, after a form of parkinsonism was linked to pandemic encephalitis lethargica in the early decades of the 20th century. The disease caused by this agent is now recognized as postencephalitic parkinsonism and is considered distinct from Parkinson's disease. Research for other infectious agents led to the discovery of rare forms of parkinsonism caused by Western and Eastern equine encephalomyelitis and Japanese B encephalitis (National Institutes of Health, 1994).

Toward the latter part of the 20th century research shifted from viral agents toward environmental toxins after the identification of drug-induced and other chemical injury forms of parkinsonism. Research intensified following the discovery in the mid-1980s of parkinsonism among heroin users who had been exposed to the street drug contaminant 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine (MPTP). Although onset of this form of parkinsonism was sudden rather than progressive, it otherwise closely mimicked pathologically and clinically Parkinson's disease, whereas other known chemical toxins caused more general neurological injury with some parkinsonian signs. The finding that the common herbicide paraquat is structurally similar to MPTP led to speculation on exposure to agricultural chemicals as major risk factors for Parkinson's disease.

Results from numerous studies on pesticide and herbicide exposure have yielded contradictory results as to risk. A high prevalence of Parkinson's disease has been found in rural areas, in areas with vegetable farming, and in areas with steel and wood pulp mills, according to data extracted from sales of antiparkinsonian drugs (Aquilonius and Hartvig., 1986; Barbeau *et al*., 1987; Rybicki *et al*., 1993). Studies of varying population size and methodology have shown rural living, well water, and farming associated with an increased risk of Parkinson's disease. When these associations were examined by Hubble *et al.* (1993) using multiple logistic regression, they were each found to be a function of pesticide exposure. Increasing years of exposure to organophosphates and certain herbicides are linked to increasing risk of Parkinson's disease in two studies (Seidler *et al*., 1996; Gorell *et al*., 1998). However, many other case-controlled studies have found no significant risk from exposure to pesticides or rural living, and chemical toxins remain far from being conclusively established risk factors (Checkoway and Nelson, 1999). Metals such as mercury and manganese have also been examined for their role in Parkinson's disease, with similarly inconclusive results.

Family studies in the 1990s have produced evidence for genetic explanations (Payami and Zareparsi, 1998). A positive family history of parkinsonian signs is associated with increased risk of Parkinson's disease, but it is still unclear

whether this is due to genetic or environmental influences (Tanner, 1994; Elbaz *et al*., 1999). Although nearly one-third of Parkinson's disease cases are familial, no clear inheritance patterns have been found other than in a very small subset of the population (Payami and Zareparsi, 1998). Autosomal dominant inheritance of Parkinson's disease appears to be rare and is particularly associated with young-onset disease. Twin studies also have not shown strict Mendelian inheritance.

More recently, theories on risk factors have centered on multifactorial explanations that include both environmental and endogenous toxins in concert with genetics. Susceptibility is thought to be heightened in individuals with impaired mitochondrial DNA or damaged antioxidative mechanisms, and current research focuses on identifying these genetic polymorphisms.

7. Possible Protective Factors

Both case-controlled and prospectively collected data consistently reveal an inverse association between risk of Parkinson's disease and smoking. Risk may be reduced by as much as 50% in smokers compared to nonsmokers (Checkoway and Nelson, 1999). Antioxidant vitamin use and tocopherol intake have also been examined in case-controlled studies for possible protective effects against Parkinson's disease; early results have shown they may decrease risk, but the studies are small (Tanner and Goldman, 1996).

V. Conclusion

Degenerative neurological disorders affecting cognition, sensory function, and motor ability are more common with advancing age. The resulting functional impairment causes impaired quality of life in older years and dependence, leading to the need for help with basic personal care. These disorders are highly associated with the need for professional long-term care services, either in the home or in an institutional setting. In the goal of making increasing life expectancy a story of successful aging more than increasing disability, research into the causes and treatments of age-related neurological disorders is of paramount importance.

Memory Changes with Aging and Dementia

I. The Concept of Different Memory Functions

Human memory is quite complex, serving many functions and with component processes that have been separated into several different, although related, types. Some of the distinctions made about memory refer to the way that information is initially acquired and others refer to the specific content of the information (i.e., semantic meanings or autobiographical information). Some of the different memory systems that have been identified interact with each other almost constantly and others appear to operate relatively independently. This chapter provides a general overview of the human memory system and describes how the various aspects of memory change during the course of human aging. These changes associated with normal aging are then compared with the much more devastating changes that occur in patients with dementing illness. Themes that run through the entire chapter are that different aspects of human memory are more or less vulnerable to the effects of aging and disease and that these changes must be understood in terms of neurobiologic changes that occur over periods of years.

II. Aging and Cognition

Many aspects of cognitive functioning change with age and, although many cognitive functions decline with age, the extent and pattern of the decline vary by both the individual and the type of function. Some aspects of cognitive functioning are uniformly performed at lower levels in individuals when they are older, relative to their own level of performance at younger ages. Other cognitive functions change very little across the life span, on average, and some functions even appear to be enhanced at later periods of life. There are considerable individual differences in the extent to which cognition changes with aging. Some individuals age ''successfully'' so that many cognitive functions remain unimpaired during aging and some may even improve (Rowe and Kahn, 1987). Other individuals may follow a more typical course of aging where some cognitive functions remain intact, such as memory for material learned in school or complex motor acts such as driving a car, while performance in other cognitive domains declines. Examples of functions that typically show age-related decline are learning new information with practice and the speed of performance of motor acts (Botwinick and Storandt, 1974; West and Crook, 1990). Some individuals manifest general declines in functioning, relative to population-based expectations, with performance in many different aspects of cognitive functioning appearing to be deteriorated relative to their previous levels of functioning. Finally, some individuals develop age-related conditions that grossly deteriorate their cognitive functioning, including the progressive dementia such as Alzheimer's disease. The pattern of age-related change described in this chapter is those that occur in most people.

Many characteristics of individuals are thought to predict cognitive functioning in late life. The potential predictors of late life cognitive functioning include socioeconomic factors, lifelong patterns of activities, educational history, current and previous psychiatric conditions such as depression or substance abuse, and medical factors. Some factors exert a transient influence on performance, such as suppression of attention or memory during episodes of dysphoria, and others, such as educational background, have more lasting effects on performance.

III. Primary and Secondary Memory

Primary memory, also referred to as ''immediate memory,'' has several important features that distinguish it from secondary (i.e., long-term) memory. Primary memory is a limited capacity memory system used to hold small amounts of information for short periods of time, often while various cognitive operations are performed on that information. Because information in primary memory is available to be manipulated,

this entire memory system is also referred to as "working memory." A variety of evidence has been collected to demonstrate that working memory has different characteristics in the visuospatial and verbal modalities (Baddeley, 1986). Working memory is utilized to hold information "on-line" or "in mind" while it used. A well-known example of working memory involves remembering a telephone number long enough to dial it. Furthermore, primary memory involves a component of adaptive forgetting. For example, if a person were unable to forget information needed only for a brief period of time, then the immediate memory buffer would be full to overflowing with old information. Thus, adaptive forgetting, which is thought to occur because new information displaces old in this limited capacity system, is a component of working memory (Baddeley, 1986).

Secondary memory is the system used to hold memory for long periods of time and is thought to be essentially permanent. Information enters the secondary memory system as a result of exposure and practice. Storage of information in secondary memory enables one to retain it over a period of delay even if attention and cognitive effort are directed elsewhere. For instance, learning a long list of words presented over several exposure trials and then recalling it after a period of delay is an example of secondary memory. Storage of information into secondary memory is influenced by a variety of processes, most notably practice or repetition. Access or retrieval of information from secondary memory can be difficult, and successful retrieval often depends on the availability of appropriate retrieval cues.

Aging is associated with several changes in performance on tasks involving primary and secondary memory. Generally, primary memory capacity remains constant with age, as shown through studies measuring immediate memory span. The capacity of immediate memory is measured with a task such as digit span in which a person is required to listen and then repeat back a list of digits that increase in number from trial to trial. Younger subjects usually have a memory span averaging about 6.5 to 6.7 digits, whereas older subjects average 6.0 to 6.5, for a difference of less than 10% (Botwinick and Storandt, 1974). However, when the task is modified from the usual laboratory version of verbally repeating the digits to a more real world task that includes dialing a phone number, a greater age difference is found (Craik, 1977). The difference between these two cognitive tasks is the move from auditory memory that simply requires the subject to repeat back the number to one involving not only verbal memory but the coordination of memory with a more complicated motor response. It is possible that the additional attention demanded by the motor component leads to a loss of digits prior to recall.

Numerous age-related differences are found with both encoding and retrieval of information in secondary memory. Significant differences are found between young and old subjects on free recall tasks that require both storage and retrieval of information. Tasks that minimize the difficulty of correct retrieval such as recognition and cued-recall tasks show considerably smaller age differences (Botwinick and Storandt, 1974; Hultch, 1975). On tasks that tax the ability to store and retrieve information in secondary memory (e.g., immediate and delayed recall of paired associates), there are significant decrements associated with increasing age (Kausler and Lair, 1966). These decrements indicate that older adults are less able to learn quickly information that exceeds short-term memory capacity and even less able to remember this information after a delay of 20 min or more. However, if older subjects were given greater practice time or allowed to pace themselves during learning rather than following the pace of the experimenter, they can perform as well as their younger counterparts (Canestrari, 1963; Cohen and Faulkner, 1983). The fact that self-paced learning or learning at a relatively slow rate does not show much age-related decline suggests that slower processing speed is at least partly responsible for much age-related decline in the learning rate (Cohen and Falkner, 1983). If the degree of initial learning is equated for young and old subjects, then the rate at which forgetting occurs over time is nearly equal for young and older persons (Albert *et al*., 1987). These latter data confirm that much of the memory deficit observed in older adults is due to learning failures (i.e., failures to store information into secondary memory). With aging the process of storing information in long-term memory slows down and this results in more memory failures, particularly for events that occurred recently.

It could be that studies of list learning and paired-associate acquisition are not the most relevant measures to employ with normal elderly. With independent living as the primary goal of most elderly individuals, there have been many studies of practical or everyday memory designed to assess the relationship of cognitive functioning and activities of daily living (ADL) skills (Fillenbaum, 1985). A study of 151 healthy subjects in three age groups (20–39 years; 40–59 years; older than 60 year) assessed practical memory (i.e., shopping lists, telephone numbers) (Cavanaugh *et al*., 1983). The main problem for the older group was remembering names and numbers or what the investigators referred to as arbitrary facts, but the ability to recall meaningful information (i.e., gist of conversations, newspaper articles) remained intact across the age groups. When old and young subjects were asked to keep daily dairies of their memory failures and use of memory aids, older subjects reported more failures (Poon *et al*., 1979). Most of the memory failures reported were forgetting of names, faces, objects, appointments, locations, addresses, and phone numbers. These tasks for which memory failures increase with age appear to depend heavily on the ability to learn new and relatively arbitrary facts, whereas memory tasks that are less subject to age-related decline involve the learning of meaningful information. The range of strategies that can be employed in learning meaningful information is somewhat greater and these tasks allow the learner to utilize information about meaning and relationships that have previously been stored in memory. Memory failures reported by older persons also tended to occur primarily when the older subjects were out of their normal routine or required to remember information that they had not used recently. By way of contrast, younger subjects tended to forget more during times of stress primarily because they experienced more stress than the older subjects.

As might be expected, the functional capacity of memory is correlated significantly both with physical health ($r=0.54$ to 0.55) and with mental health ($r=0.54$ to 0.60) (Fillenbaum, 1985). These correlations are particularly important in an elderly population where deficits in both physical and mental health are more common and hence are more likely to be

important contributors to individual differences in memory performance.

IV. Implicit and Explicit Memory

Implicit and explicit refer to the means by which information is stored and retrieved from the memory system. In explicit memory tasks, the individual stores and retrieves information from memory on a volitional, controlled access basis. An example of explicit memory is when a subject learns a set of paired words in a learning format and then is asked to recall them later. The conscious attempt to recall the information is referred to as ''explicit memory.'' In contrast, in implicit memory, conscious awareness of the attempt to store and/or recall information is not required, but a change in behavior provides evidence that learning has taken place (Graf and Schachter, 1985). An example of an implicit memory task could be that a subject is asked to learn a list of words, including the word ''three.'' Later, they are shown word stems (e.g., thr_ _) and asked to tell the experimenter the first word that comes to mind. Subjects in this situation are more likely to respond ''three'' than are subjects without prior exposure to the word three; this change in behavior is evidence of implicit memory.

As noted earlier, explicit memory functions change with normal aging, although evidence shows that implicit memory functions are less likely to deteriorate with age (Lupien *et al*., 1997). This finding may suggest that the processes of voluntary or conscious storage and retrieval from long-term storage are a major contributor to changes in memory performance with age.

V. Episodic and Semantic Memory

Episodic memory refers to the process of remembering events. The information stored about these events can be verbal, such as the content of conversations, or visuospatial, such as the recollections of faces and locations. In addition, episodic memory content includes activities and current events. Thus, both information regarding content and context are included in episodic memory. Storage of new information into episodic memory does become more difficult with aging, as this information is stored in secondary memory. The total fund of information stored in episodic memory, however, tends to hold up quite well and may actually increase with age.

Semantic memory refers to stored information about language and the meanings of words. Semantic memory is not contextually dated and this information is generally shared with others who have the same cultural background. While acquisition of new semantic knowledge may become more difficult with normal aging, the total amount of stored semantic information appears to decline little or not at all in normally aged persons (Psychological Corporation, 1997). There are many different ways to assess the intactness of semantic memory. As examples, confrontation naming refers to the ability to name objects presented to the subject, whereas fluency tests examine the ability of the subject to produce verbal output when given either a categorical (e.g., animals) or a phonological (e.g., words starting with F) rule for generating instances. One of the most common complaints of older adults is that they cannot remember the names of things, even those that they know very well. In one study, young (age range 17–23 years) and old (age range 65–85 years) healthy subjects were measured on a word retrieval task (Bowles and Poon, 1985). The stimulus was a definition of a word and the subjects were asked to name the word that had been defined. The younger subjects were superior to the older subjects on both word retrieval and response latency. Older individuals, even those who do not suffer from dementia, are often less able to name objects as compared to younger individuals. Older persons generate more circumlocutions and multiword responses than younger subjects when asked to provide a single word for a picture presented (i.e., confrontation naming; Albert *et al*., 1987; Randolph *et al*., 1993). Circumlocutions indicate that the individuals recognize the item but cannot specifically retrieve its name. These same studies demonstrate that the specificity of the age-related change to retrieval by the finding that the ability to correctly choose which of several words is the correct name for an object is unaffected by aging.

There are also age-related differences in the ability to continuously access semantic storage. Semantic access is typicallymeasured through ''verbal fluency'' procedures. In these assessments, subjects are asked to continuously generate words that either start with the same letter (phonological fluency) or are from the same conceptual category (category fluency). It is routinely found that older individuals produce fewer words than younger individuals in discrete time periods (Rosen, 1980). Older individuals do not make more errors than younger ones, indicating that they are not having problems in adhering to the task demands. One possible explanation for the reduced verbal output of older persons on tasks such as this is that it is simply a reflection of a reduction in general speed of cognitive processing. In summary, modest aging-related declines in the ability to spontaneously access semantic information are routinely found. These declines are apparently not due to an actual decrease in the total amount of information available in the semantic storage system at later ages, as recognition procedures and prompting make the performance of older individuals the same as younger ones.

VI. Declarative versus Procedural Memory

A variety of studies involving patients with specific types of brain damage indicate that there are different neurobiologic systems involved in laying down memory for facts vs laying down memory for procedures or rules for accomplishing tasks (Squire and Cohen, 1982). A review of all the evidence supporting this distinction is beyond the scope of this chapter, but the essence of it is that patients with damage to medial temporal regions of the brain have severe impairments in the ability to learn new facts (e.g., a list of words or a person's name) but have only minor impairments in the ability to learn new skills (e.g., how to read words backwards, do tracing of forms presented in a mirror). Because of the evidence that different neurobiologic systems are involved in these two kinds of learning and memory, a number of studies have looked at how these two kinds of memory are affected by aging.

Memory for facts is referred to as declarative memory. These facts can be recently learned or they can be acquired a long time ago. In the case of information learned long ago, this can be referred to as ''remote memory.'' As described previously, the rate at which new facts can be stored in memory clearly slows down with normal aging. However, the total amount of information available in remote memory (sometimes referred to as tertiary) can be relatively intact throughout the life span. Evaluation of remote memory can be conducted through recognition and/or recall of public events throughout history. Older subjects often perform better than their younger counterparts recalling events over a long period and maintain consistent levels of memory across history (Warrington and Sanders, 1971).

In contrast, procedural memory is the system used to learn and retain the ability to perform skills. An example of procedural learning would be learning the skills required to perform a new motor skill, such as tracing in a mirror. An example of procedural memory would be recalling how to ride a bicycle or to swim, if the individual had not performed either of these acts for a period of time. Other types of procedures stored in remote memory include skills learned long ago, such as the ability to read and spell. It is normal for elderly individuals to perform as well as younger individuals on these tests. A further finding of importance in this area is that the performance of elderly individuals on these tests is generally consistent with or higher than their level of previous academic achievement, i.e., older persons usually are able to read and spell at a level that is equal to a younger person with a similar educational background (Jastak, 1984). This finding indicates that some memory skills are stable over time within individuals and may even improve with exposure to new information over the life span.

VII. Other Age-Related Changes in Cognition

A. Language

A superficial assessment of the language performance of older individuals would indicate that language is well preserved throughout the life span, at least until the late 80s, because performance on the vocabulary subtest on the Wechsler Adult Intelligence Scale has been found to be consistent over time (Owen, 1953). However, there are clear findings suggesting notable age-related declines in the spontaneous production of language (Kemper, 1987). There are some additional changes in verbal skills with aging, most of which were described previously in the section on semantic memory. Lexical functioning refers to the structure of meaning and its representation in words. Intact lexical functions include the ability to access and recognize words on demand. A study of subjects in two age groups (17–23 and 65–85 years) measured performance on a ''lexical decision task'' where they were asked to determine if a briefly presented string of letters created a word (Bowles and Poon, 1985). There was no significant difference across age on either accuracy or response latency. Older and younger individuals perform equally well on tasks of word recognition reading (Jastak, 1984).

Phonologic knowledge refers to the sound-based rules of language. This skill appears to be well preserved across age (Bayles and Kazniak, 1987) except in individuals who experience stroke or other identifiable brain changes. The ability to meaningfully combine words using grammatical rules is referred to as the syntactic component of language and it is also preserved across age (Obler *et al*., 1985) unless other factors intervene.

B. Visuospatial Functioning

Visuospatial functioning requires the ability to perceive and subsequently manipulate visual information. This ability is often measured through either the production or the recognition of figures. Some decline occurs as individuals advance in age. A cross-sectional analysis of 1800 community residents age 65 and older found a decrease in visuospatial ability and speed of execution as age increased (Mazaux *et al*., 1995). There was also poorer performance among female subjects and those with lower education. Age-related declines in the ability to reproduce complex figures have been reported in other studies as well (Plude *et al*., 1986). One potential contributor to the age-related decline in performance on these tasks is that they require manipulation of items in a novel way and often with a speeded component.

While there is a decrease in visuospatial performance as an individual ages, the decline is significantly less than with demented older adults. Comparisons between healthy elderly subjects and those with mild cognitive impairment found that objective psychological measurements, such as those testing visuospatial ability, exhibited high sensitivity and specificity in distinguishing between subjects with and without a decline in cognitive functioning (Flicker *et al*., 1991).

C. Psychomotor Functions

Psychomotor functions involve the combination of precise motor responses, attention, and cognitive problem-solving abilities. Reduced motor speed as age increases has been demonstrated both in laboratory tasks and in real world environments. Older commercial drivers were found to have more accidents than younger drivers because of slower reaction times (Barrett *et al*., 1977). Even though the accident rates of pilots ages 40 to 60 are lower than those of younger pilots, the accidents older pilots had were attributable to slower response times (Birren, 1964). Response times can be improved with training in older individuals, ages 60–80, by having them play video games 2 hr a week for 7 weeks (Clark *et al*., 1987). In general, older typists perform more slowly than their younger counterparts. When highly skilled older typists exhibited performance speed that was equal to that of less skilled younger typists, the older typists made more errors. Thus, reaction time can be reduced if the skill is sufficiently practiced, but there is a possible cost of an increase in errors made due to keystroke errors (Bosman, 1993). Greater distractibility among older typists has been offered as a reason for the decline in typing skills. For example, when older and younger typists were compared after removing all distracting stimuli, there were no age-related differences (Salthouse, 1984). However, attention studies have shown that there are few age-related differences in distractibility when perceptual

difficulties such as vision or hearing are controlled (Denney and Palmer, 1981; Rabbitt, 1985). Even those who age successfully exhibit some decline in psychomotor abilities past the seventh decade of life. Those who age normally have a progressive decline on psychomotor tasks from their mid-60s. Like visuospatial abilities, psychomotor abilities decline significantly and sharply among older adults with dementia.

D. Executive Functions

Executive functions involve an individual's capacity to conceptualize, to think independently, and to utilize self-control, self-direction, and flexibility. Studies of patients with specific types of brain injury and studies using brain imaging provide evidence that the prefrontal areas of the neocortex are involved in cognitive activities of this type (Reitan and Wolfson, 1994). Describing executive functions has proved to be difficult, but the essence of these functions appears to be that they involve a sequence of planning and execution. The first step is that individuals must determine what they need or want to do and develop a global plan. The next step is to identify and organize the steps and elements needed to carry out the intention. Another element of executive functioning is the translation of intention or plan into productive activity. During this stage, there is a continuous process of evaluation of the plan, with shifts following errors in execution. Because executive functioning is thought to involve frontal lobe functioning, measures that have been proven sensitive to dysfunction of the frontal lobe are often the types of tests that are referred to as tests of executive functioning. One of the standard measures of executive functioning has been the Wisconsin Card Sorting Test (WCST; Heaton *et al*., 1993). The WCST is a multidimensional problem-solving test, where individuals are required to identify concepts, respond accordingly, and modify their concepts in response to external feedback. Because the concepts in the test change, the test also requires cognitive flexibility for successful completion. One major barrier to effective performance in executive functioning tests could be the inability to adopt a flexible approach to problem solving. Mental inflexibility is difficult to measure and is often assessed through tests of abstraction that emphasize shifts in concept formulation. A study comparing healthy subjects in the 50s, 60s, and 70s found no statistically significant differences among groups on the WCST and three other frontal lobe measures, suggesting that there is little decline on executive functioning with age (Boone *et al*., 1990). In this same domain, one more specific type of performance has been examined closely, the tendency to perseverate when asked to shift concepts. Research in this area has found that the level of perseveration found in elderly individuals was quite dependent on the tests employed (Boone *et al*., 1993). Age effects were found in 45–65-year-old subjects who had more perseveration than younger subjects (20–35 years) in planning tasks (Ardila and Rosselli, 1987; Daigenault *et al*., 1992). There have been indications that normal aging includes an increase of perseverative behaviors prior to age 65 (Nelson, 1976), and other research has suggested that the increase does not occur until after age 70 or 80 (Haaland *et al*., 1987). The more meaningful and concrete the presentation of a conceptual problem, the more older individuals will succeed (Botwinick, 1978). As a result, it appears as though there is more individual variation in executive functioning and hence more variability in age effects than in simpler aspects of cognitive functioning. This may not be surprising because of the fact that executive functioning tests also require intactness of multiple lower-level skills, including perception, attention, memory, and motor skills. Based on the variability in performance across individuals in the area of executive functioning, it is important to make clear distinctions between healthy elderly individuals and those with any early stages of brain disease. Normal aging begins to show some decline in the late 70s to early 80s, and demented individuals have a very sharp decline on executive abilities (Zec, 1993).

VIII. Cognitive Changes in Dementia

Dementia is a major public health problem, with an estimated 6 million cases in America at this time and more cases expected as the population ages. Neuropsychological assessment is a crucial component of any dementia evaluation. Both American (McKhann *et al*., 1984) and European community (CPMP Working Party, 1992) standards require neuropsychological assessment as a component of the diagnostic workup. Virtually all dementing illnesses are progressive, degenerative conditions and neuropsychological assessment is also crucial for the evaluation of progression (Katzman, 1986).

A. Definition of Dementia

Dementia is defined similarly in several different diagnostic systems (e.g., World Health Organization, 1992; American Psychiatric Association, 1994) as a condition marked by the loss of memory functions and at least one other aspect of cognitive function that is sufficiently severe to interfere with the person's ability to perform ordinary activities of daily living. To differentiate dementia from preexisting conditions such as mental retardation, the impairments must represent a decline from the patients previous level of functioning. Additional cognitive deficits, which may indicate a dementing illness include aphasia (loss of language function), apraxia (loss of the ability to perform a previously learned motor activity), agnosia (inability to recognize familiar objects), and loss of executive functions (i.e., conceptual skills, planning, and control over component skill areas). The definition of dementia also differentiates this condition from others where the loss of cognitive function is limited to a single cognitive function, such as amnesia or aphasia where loss of memory or loss of language competence is the principal change in cognitive functioning. Dementia has multiple etiologies and, whenever possible, the etiological factor is coded during the diagnostic process. In this chapter, our discussion of dementia is limited in scope and describes the key aspects of two different overall categories of dementia, cortical dementia and subcortical dementia. In addition, the typical neuropsychological profiles of the most commonly seen examples of the two types of dementia are compared to each other.

B. Cortical versus Subcortical Dementia

The constellation of impairments seen in Parkinson's disease (PD) and Huntington's disease (HD), combined with the

neuropathology of these disorders, which is found primarily in subcortical regions, has lead to an ongoing distinction between cortical and subcortical dementia (Cummings, 1986; Cummings and Benson, 1990; Rebok and Folstein, 1993). In this conception, dementias such as Alzheimer's disease (AD), which affect the cortex and, eventually, all of the cognitive functions dependent on the intact cortex, can be discriminated from dementing conditions, which impact principally on the subcortical regions. Studies have suggested that subcortical (HD) and cortical (AD) dementias can be discriminated even at the later stages of illness (Paulsen *et al*., 1995a). While there is some controversy about this distinction, in line with findings of certain types of language and other ''cortical'' abnormalities in PD (see Rebok and Folstein, 1993, for a discussion), most dementias that affect subcortical regions (e.g., HIV, HD, and PD) have similar features. The question of the validity of this distinction will continue to be debated, but there are some clear differences between the group of ''subcortical dementias'' and AD in the breadth and magnitude of impairments, especially in terms of early impairments in attention in subcortical dementia, global slowing processes in subcortical dementias even in their early stages, very salient signs of depression, and sparing of recognition memory. Accordingly, we organize our discussion of these conditions in line with this distinction.

C. Alzheimer's Disease

This disease, first reported by Alzheimer at the outset of this century, is the most common of the dementing conditions. At least half of all patients with dementia who are over the age of 65 will be found to meet criteria for AD at a postmortem assessment (Arriagada *et al*., 1992), with the proportion of cases with AD compared to other dementias increasing as the age of the patients increase (Rebok and Folstein, 1993). It has an age of onset ranging from the late 30s (rarely) to the end of life and a prevalence of as much as 6% of the current living population (Terry and Katzman, 1992). These figures are greatly increased in old age, with as much as 50% of the population over the age of 85 meeting criteria for AD (Evans *et al*., 1989). Most studies note that the course of the illness is around 10 years from the first identifiable symptom, unless the patient does not survive this period (Katzman, 1986). Risk factors for the illness are age, family history of AD, reduced educational attainment, Down syndrome, head trauma, and female gender (Cummings and Benson, 1983). The neuropathological signature of the illness includes amyloid plaques and neurofibrillary tangles, localized initially in the medial temporal cortex and hippocampus and found later in the illness in the more lateral structures of the temporal lobe, parietal cortex, and perisylvian region (Khachaturian, 1985; Huff *et al*., 1987). Plaques are irregularly shaped deposits of amyloid, whereas tangles are neurofibrillary masses that are distributed irregularly in the same general regions as plaques. The presence of these neuropathological stigmata is required for the postmortem diagnosis of AD according to all current criteria.

The clinical hallmark of AD is its progressive course. When measured with a global clinical rating scale, such as the Mini-Mental State Examination (MMSE; Folstein *et al*., 1975) or the Alzheimer's Disease Assessment Scale (ADAS; Rosen *et al*., 1984), there is an average deterioration of about 10% per year (Berg *et al*., 1987; Huff *et al*., 1987; Salmon *et al*., 1990). Thus, the expected decline in the MMSE is about 3 points per year on the average. This decline is not, however, linear. In the early and later stages of the illness the annual decline is considerably less than in the middle, leading to a curvilinear course (Morris *et al*., 1993). As a result, the expected annual loss of functioning measured globally depends considerably on the severity of illness at the time of first assessment.

There are multiple aspects of cognitive impairment seen in AD, but the presence and severity of impairment in each cognitive domain depend on the stage of illness. In fact, as the illness progresses, every cognitive function of the cerebral cortex becomes impaired eventually. Some of the cognitive impairments are seen very early on in the course of the illness and others appear later (Welsh *et al*., 1992). Of these cognitive impairments, some of them become progressively worse over time in the illness and others appear to be static after their appearance (Morris *et al*., 1993). The first measurable cognitive sign of AD is a profound deficit in secondary memory, specifically in learning and delayed recall of facts, either with or without intervening distracting information. This empirical finding is not surprising because the first subjective sign of the illness is forgetfulness and problems in learning new information. This deficit is substantial, in that patients with mild AD (MMSE > 23) have been found to learn as little as three words over the course of three exposures to a 10-item serial word list, whereas nondemented persons matched for age and education to these patients learned eight words. At delayed recall, the AD patients recalled less than one word on the average, whereas normals retained seven out of eight words that they learned (Welsh *et al*., 1991). Deficits in delayed recall do not progress with continued overall worsening of the illness, whereas new learning appears to worsen steadily with increases in overall severity of impairment (Welsh *et al*., 1992).

Following the impairments in learning and memory that appear at the earliest stages of the illness, verbal skills such as confrontation naming ability and verbal fluency appear to worsen next and progress with a roughly linear course. The next aspect of functioning to deteriorate is praxis and spatial-perceptual operations. These declines appear to be linear as well (Welsh *et al*., 1992; Morris *et al*., 1993). Thus, the curvilinear course of AD, as measured by global scales such as the MMSE, may be determined by the scaling properties of the assessment instruments as well as by the actual course of the illness. The ''accelerated'' pace of cognitive decline in the middle of the illness may be a function of the fact that more of the cognitive functions measured by the instrument are in decline in the middle of the illness than at the very early stages (where only delayed recall and verbal learning are impaired) and the late stages (where many cognitive tests are now manifesting floor effects). It must be noted that there is heterogeneity in AD across patients and these descriptions are based on average statements about large samples of patients.

There are many other aspects of cognitive assessment in AD that merit attention. Executive functioning impairment appears early in the illness. It is possible that deficits in executive functioning are exacerbated, or possibly even caused, by deficits in the cognitive components controlled by executive functions.

For instance, a profound deficit in working memory would make adequate performance on an executive functioning test such as the WCST essentially impossible. As in many amnestic conditions, procedural learning (i.e., learning of motor skills) appears to be more intact than declarative learning. Similarly, implicit memory functions (i.e., memory aided by prompts or cues) appear more intact than explicit memory, although still impaired (Zec, 1993). Recognition memory (i.e., the ability to identify previously presented information) is not spared, in contrast to findings in specific frontal lobe damage (Freedman, 1990) or HD (see later). Finally, a number of studies have suggested that interventions designed to augment memory functioning, including provision of practice and alteration of encodability of information, do not benefit patients with AD to the same extent as age-matched controls, patients with affective disorders, or patients with other dementing conditions (Weingartner *et al*., 1993).

Other significant deficits contribute to the poor performance of patients with AD on many cognitive tasks. Both motor speed and visuomotor performance are impaired quite early in the course of the illness, with some evidence that this is also a progressive deficit (Nebes and Madden, 1988; Nebes and Brady, 1992). The issue of attentional impairment in AD is a complex one. As a general statement, attentional impairment is a less salient feature of AD than deficits in learning and memory. That said, there is still considerable evidence that concentration impairment is present in the illness, especially with continued progression (Kaszniak *et al*., 1986). In the area of deficient verbal skills, there is some evidence that letter fluency is less impaired than category fluency until the very late stages of the illness, possibly because of the greater dependence of category fluency on the intactness of the temporal and parietal cortices (Randolph *et al*., 1993).

As AD progresses, function is lost to the point that by the time of death, performance on all tests is so poor that all scores are essentially zero (see Zec, 1993, for a comprehensive review of this issue). This is in contrast to some other cortical and subcortical dementias where there is preservation of many functions up until the very latest stages.

Behavioral disturbances in AD, including delusions, hallucinations, agitation, and depression, can also interfere with the assessment of cognitive functions in the illness and special care must be taken in order to ensure that low scores are based on cognitive impairments and not on behavioral abnormalities (Teri *et al*., 1992). AD is one of the dementing conditions where a low baseline level of intellectual functioning is a risk factor for the illness. Several different studies have indicated that using an estimate of premorbid functions, such as a reading level obtained from the Wide-Range Achievement Test or the National Adult Reading Test, is valid up until the severe stages of AD (e.g., O'Carroll *et al*., 1987). Thus, relative decline can be assessed against a reasonable measure of premorbid functioning.

D. Cognitive Assessment of Alzheimer's Disease

Studies of cognitive changes in AD use a variety of different assessment tools, and the aim of this section is to describe those tools briefly. Most neuropsychological assessment batteries for AD include a word list learning test with recall after a delay to assess storage and retrieval into secondary memory, measures of language, including fluency and naming, tests of constructional praxis, assessment of motor speed, and some estimate of premorbid functioning. Global, all-purpose assessment tools, such as the MMSE or ADAS described later, assess most of these functions succinctly in order to gauge the general level of the patient's cognitive intactness. A neuropsychological assessment alone is inadequate for the differential diagnosis of AD because of the very large overlap between the cognitive impairments seen in AD and other dementing conditions, such as vascular dementia. Determining the rate of cognitive decline requires reexamination after 6 to 12 months in order to document a progressive course. For patients with very mild impairments, a documented decline over 6–12 months provides convincing evidence of the prototypical cognitive impairments and decline required to correctly diagnose AD. Because delayed recall deficits are not progressive, evidence of progression in this type of memory function is clearly not to be expected. Furthermore, because praxic deficits are often absent in mild AD, a finding of no impairment in this area does not rule out the presence of the illness. Cognitive assessment is a crucial component of treatment trials in AD because cognitive enhancing drugs should have a detectable effect on many different aspects of the illness. A full discussion of this issue is contained in Mohs (1995).

E. Structured Rating Scales for Alzheimer's Disease

An alternative approach to the use of a neuropsychological battery to assess the severity of AD is the use of a structured rating scale. Several of these instruments are available and in common use, with all demonstrating high reliability. The main difference between these scales is their level of comprehensiveness.

1. Alzheimer's Disease Assessment Scale

The ADAS (Rosen *et al*., 1984) is a 21 item scale designed to assess the severity of cognitive and behavioral impairments in AD. The cognitive component includes both a short neuropsychological assessment and items rated by the interviewer on the basis of interaction with the patient and caregiver. Scores on the cognitive subscale range from 0 to 70, with scores on the noncognitive subscale ranging from 0 to 50.

2. Mini-Mental State Examination

The MMSE (Folstein *et al*., 1975) is a widely used assessment instrument designed to screen the cognitive impairments seen in a variety of dementing conditions, although the content areas focus on those associated with AD. There are 21 different items in 11 different tests, with scores ranging from 0 to a perfect score of 30. Scores of 23 or less are typically seen as reflecting dementia and meriting more detailed assessment. In patients with high levels of premorbid functioning, this cutoff should be raised to any score less than 30. It should be noted that the MMSE may be insensitive to subcortical dementia, in that one study (Rothlind and Brandt, 1993) found that patients with confirmed PD and HD were indistinguishable from normals on the MMSE.

3. Clinical Dementia Rating (CDR)

The CDR (Berg, 1988) is a global summary measure designed to identify the overall severity of dementia. Six different content areas are rated individually (memory, orientation, judgement and problem solving, community affairs, home and hobbies, and personal care). Ratings are assigned on a 0–5 point scale, (0 = absent; 0.5 = questionable; 1 = present, but mild; 2 = moderate; 3 = severe; 4 = profound; 5 = terminal). A global summary score is obtained, leading to the use of the CDR for grouping patients on severity of dementia.

4. Mattis Dementia Rating Scale (DRS)

The DRS (Mattis, 1976) is more comprehensive and longer than the MMSE and the CDR, but is also more informative. Similar to the ADAS, the DRS examines a number of cognitive functions associated with dementia. Scores range from 0 to 144, with the cutoff for normal performance at 140. The cutoff for severe dementia is a score of less than 100.

All of these instruments have a role, particularly in research where large-scale screening is required. For purposes of research-oriented assessment, the use of the ADAS or the DRS is likely to be more efficient than a full neuropsychological battery.

F. Huntington's Dementia

Huntington's disease is a neuropsychiatric disorder marked by choreoathetosis, atrophy of the caudate nucleus, and an autosomal dominant inheritance. Equally common in men and women, HD affects 3 to 10 per 100,000 people (Martin, 1984). The age of onset is typically in the early 40s, although this is quite variable. The typical course is 13–17 years with death usually resulting from pneumonia, choking, nutritional deficiencies, skin ulcers, and suicide or other self-destructive behavior (Lanska *et al*., 1988).

An initial diagnosis of HD is usually based on identification of choreoathetosis, the hallmark movement disorder associated with the disease. Choreoathetosis is a combination of jerky movements and slower, twisting movements that often result in dystonic posturing. These movements, early in the course of the disease, occur on initiation of action and include ''piano-playing'' movements of the fingers, ulnar deviation of the hands, and facial tics. Later in the course, choreoathetosis includes a virtually constant stream of movement, including severe grimacing, head bobbing and rolling, and a ''dancing gait.'' These movements, even when severe, cease during sleep. With time, choreoathetosis decreases and dystonia, with akinesis and rigidity, becomes more salient.

HD is now known to result from a gene on the terminal short arm of chromosome 4 (Mendez, 1994). The HD gene causes delayed atrophy and gliosis of the caudate nuclei, with dendritic abnormalities in small-to-medium spiny cells. The basal ganglia have decreased concentrations of the inhibitory neurotransmitter GABA and the enzymes required for GABA synthesis. Other neurotransmitters are relatively preserved. There is also early cell loss in the putamen and in the globus pallidus and the prefrontal cortex later on. Unlike AD, HD does not involve significant loss of neurons from the nucleus basalis of Meynert or loss of choline acetyltransferase activity in the cortex. As HD progresses, however, neuropathological changes in the caudate nuclei show up consistently in neuroimaging studies.

Huntington's dementia is a prototypical subcortical dementia. Cognitive impairments include slowed motor speed, decreased selective and sustained attention, decreased behavioral initiation, spontaneity and engagement, decreased performance IQ with verbal-performance discrepancy, executive deficits, faulty encoding with poor storage, faulty retrieval strategies, in the context of unimpaired recognition, deficient memory requiring effortful processing, decreased motor skill and procedural learning, decreased verbal fluency and output, abnormal egocentric spatial orientation, and abnormal visuomotor integration (Mendez, 1994). Unlike AD patients, HD patients have insight into their neuropsychiatric disorder, despite suffering personality changes.

About 50% of HD patients suffer from psychiatric disorders unrelated to dementia, with a range of about 35 to 73% (Saugstad and Odegard, 1986; Folstein, 1989; Morris, 1991). Included in these are depression, personality changes, or anxiety disorders that often precede the onset of choreoathetosis by as much as 10 years or more (Dewhurst *et al*., 1970). HD patients complain early in their illness of difficulty with attention and concentration. They do particularly poorly on the WAIS-R subtests that tap attentional capacity, as well as on the visuomotor skills, such as the Trail Making Test. HD patients have been shown to have greater attentional and concentration problems than patients with AD, PD, and progressive supranuclear palsy (Pillon *et al*., 1993; Rothlind *et al*., 1993).

There are significant executive functioning deficits in HD, with dysfunction in the areas of maintaining and changing a cognitive set, abstraction, judgment, and reasoning, as well as difficulty with planning and organization and impaired mental flexibility (Brandt and Butters, 1986; Folstein, 1989; Rothlind *et al*., 1993; Paulsen *et al*., 1995a). Patients with HD usually have verbal and visual memory deficits early in their disease. Although the deficit is not as severe as that found in patients with AD (Paulsen *et al*., 1995b) or amnesia, memory problems in HD are well documented. HD patients have flawed encoding strategies that result in poor storage (Lundervold *et al*., 1994a,b). There is a diminished ability to benefit from cuing in recall (Lyle and Gottesman, 1977), a difficulty with learning of new material (Pillon *et al*., 1993), and an impaired ability to learn items in a sequence (Caine *et al*., 1977; Massman *et al*., 1990). However, unlike AD patients, HD patients can benefit from interventions targeting their encoding strategies (Lyle and Gottesman, 1977; Bylsma *et al*., 1990), as well as from priming or cues based on prior exposure (Heindel *et al*., 1990). The importance of testing focused specifically on discriminating the ability of a patient with HD to benefit from the modification of input strategies, as opposed to simply establishing that a memory impairment exists, has been noted in the literature (Paulsen *et al*., 1995a).

Language in HD is relatively intact insofar as the ability to complete verbally mediated tasks. Confrontation naming is a strength, relative to AD patients. Whereas aphasia is not part of the cognitive picture in HD, early on in the disease there is some impairment of verbal fluency. Fluency changes include more single word or short phrase responses, as well as more

pauses in conversation, with the absolute number of words in speech sample shown to be less than that of normal controls (Gordon and Illes, 1987). The ability to understand verbal intonation (prosody) is also impaired (Speedie *et al*., 1990), as is written expression (Podoll *et al*., 1988). Impairments in visuospatial functioning have been noted in terms of lowered scores on constructional tasks, both building and drawing (Fedio *et al*., 1979; Mohr *et al*., 1991), as well as in spatial orientation (Bylsma *et al*., 1992).

Types of Age-Related Brain Lesions and Relationship to Neuropathologic Diagnostic Systems of Alzheimer's Disease

Neurofibrillary tangles, senile plaques, and neuronal loss are the three major pathologic hallmarks of Alzheimer's disease (AD); however, they are also observed in the course of normal brain aging. In recent years, the classical neuropathological description of these changes has been tentatively replaced by an integrative view, including morphological, biochemical, and molecular characteristics. The first part of this chapter focuses on the description of AD-related lesions and attempts to highlight possible relationships between their structure and hypotheses regarding their etiopathogenesis. Moreover, the time evolution and codependence of these lesions in the aged brain is discussed. The second part of this chapter provides a critical review of diagnostic systems for the neuropathological diagnosis of AD. Comparative analysis of these systems is presented with particular reference to their theoretical framework, validity, and acceptance.

I. Introduction

The two classic lesions described by Alzheimer (1907) in his first report of an early-onset demented patient, neurofibrillary tangles (NFT) and senile plaques (SP), are those currently used for the routine neuropathological diagnosis of Alzheimer's disease (AD; Figs. 6.1–6.3). These alterations are also present in normal brain aging, but they are far less severe than in AD and occur in restricted regions of the cerebral cortex (Tomlinson *et al*., 1968; Ball, 1977; Mountjoy *et al*., 1983; Ulrich, 1985). Our understanding of these lesions has progressively changed to encompass complex molecular, biochemical, and structural issues. Moreover, other structural abnormalities have been described, and recent advances in neuron counting technology have provided information on the extent of synaptic and neuronal loss in normal aging and AD (Terry *et al*., 1991, 1994; Morrison and Hof, 1997). This chapter provides an overview of current knowledge of AD-related lesion structures as well as a critical examination of the concepts that underlie the neuropathological diagnosis of AD.

II. Histopathological Changes

A. Neurofibrillary Tangles

1. Microscopic and Biochemical Characteristics

Neurofibrillary tangles, described by Alzheimer (1907), represent the accumulation and abnormal biochemical modification of components of the neuronal cytoskeleton that form paired helical filaments. These lesions are composed of intracellular argentophilic fibers that are stained intensely by histochemical stains such as thioflavin-S (Figs. 6.1a and 6.1b). Ultrastructurally, NFT are formed by an apparent pair of strands, wound around one another, with crossover repeats around 75–80 nm and widths between 5 and 22 nm, called paired helical filaments (PHF; Fig. 6.2a; Terry *et al*., 1994). A great variety of cytoskeletal proteins, such as the microtubule-associated protein tau, ubiquitin, and neurofilament triplet protein, are associated with PHF (Vickers *et al*., 1992, 1994, 1996; Trojanowski *et al*., 1993). The major protein subunit of PHF is the microtubule-associated protein tau (Iqbal, 1998). Six different tau isoforms ranging from 352 to 441 amino acids can be generated from a single tau gene by alternative splicing. The expression of tau is developmentally regulated so that all six tau isoforms are found in the adult human brain, while only the smallest isoform, known as fetal tau, is present in the fetal human brain (Bramblett *et al*., 1992; Matsuo *et al*., 1994). PHF-tau has a higher molecular weight and a more acidic isoelectric charge than normal tau (Grundke-Iqbal *et al*., 1986). Although PHF-tau are hyperphosphorylated compared to normal adult brain tau (Bramblett *et al*., 1992; Matsuo *et al*., 1994), it has been demonstrated that biopsy-derived normal adult human tau is phosphorylated *in vivo* on sites that are similar to those found in PHF-tau and that a significant dephosphorylation of normal tau takes place during the postmortem

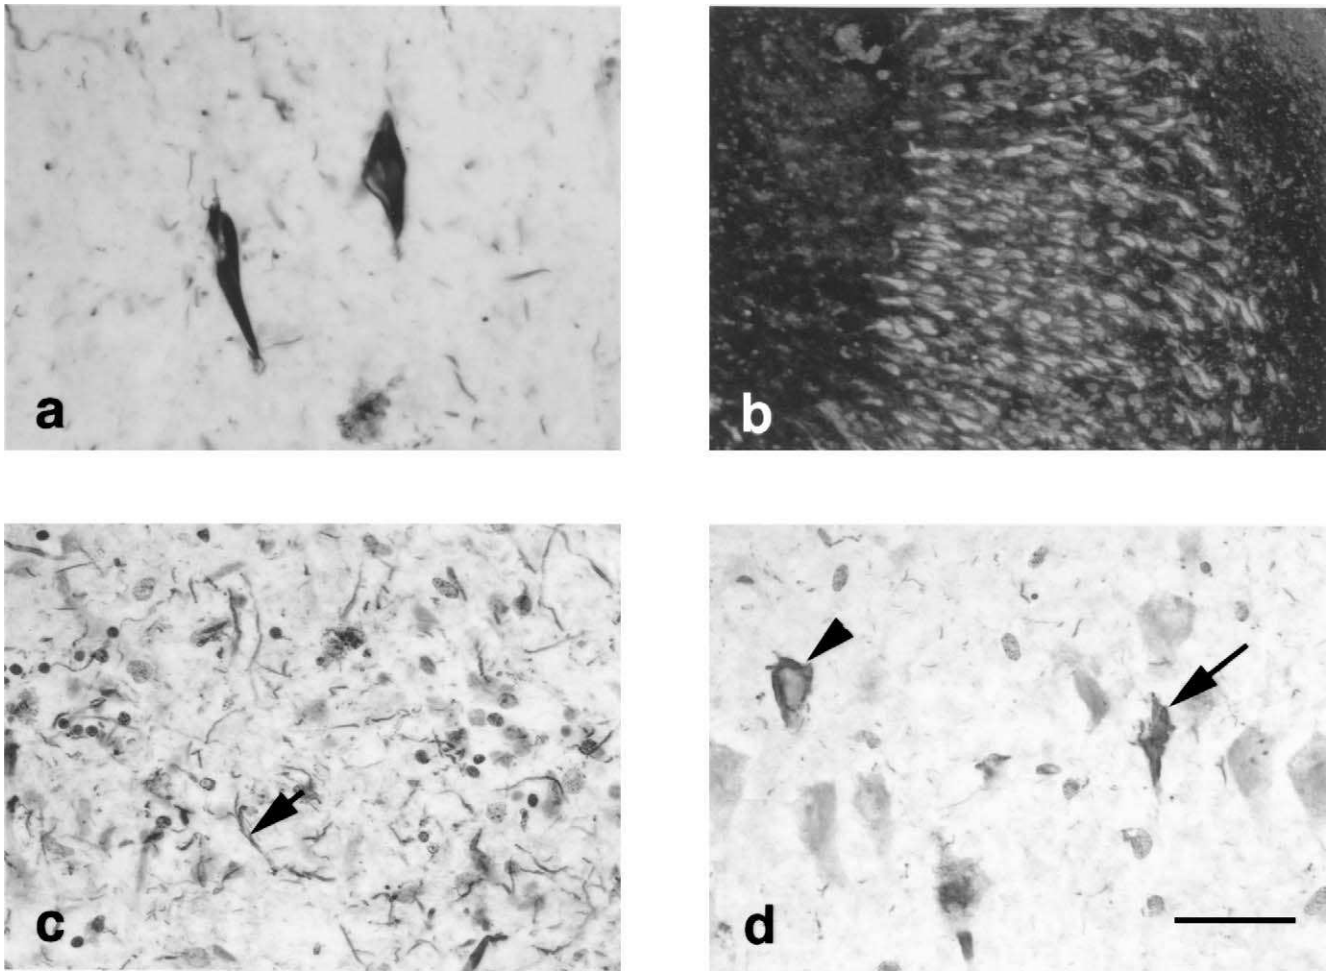

FIG. 6.1. Representative examples of cytoskeletal pathology in a 78-year-old AD case: NFT in high magnification (a), NFT in the CA1 field of hippocampus (b), neuropil threads (c; arrow), and intracellular (d; arrowhead) and extracellular (d; arrow) tangles. Materials were stained with an antibody against the microtubule-associated tau protein (a, c, d) and modified thioflavin-S stain (b) and were counterstained with Nissl stain (c, d). Scale bars: 50 (a, c, d) and 200 (b) μm.

period (Matsuo *et al*., 1994). PHF-tau inhibit the microtubule assembly-promoting activities of microtubule-associated proteins 1 and 2 and tubulin (for review, see Iqbal *et al*., 1998). It is thus possible that downregulation of phosphatases in the AD brain could induce the generation of maximally phosphorylated PHF-tau, causing disassembly of microtubules and consequently a retrograde neuronal degeneration (Matsuo *et al*., 1994). Alternatively, the formation of PHF-tau may be accelerated by key molecules, such as sulfated glycosaminoglycans (Goedert *et al*., 1996). Glycation of PHF-tau proteins, which itself could be the result of oxidative stress, induces an additional oxidative stress in neurons (Yen *et al*., 1995). In addition, NFT show immunoreactivity to a variety of proteins, such as casein kinase II, protease nexin I, fibroblast growth factor, microtubule-associated protein 5, amyloid Aβ protein, apolipoprotein E, and ubiquitin. Whether these proteins play a major role in the formation of NFT is still unclear (for review, see Terry *et al*., 1994).

2. Time Evolution of Cytoskeletal Pathology in AD: From Pretangles to Ghost Tangles

Several morphologically distinct types of cytoskeletal pathology have been described in AD brains corresponding to different evolutionary steps. At the beginning of the degenerative process, there is an accumulation of phosphorylated tau proteins in the somatodendritic compartment without PHF formation, refered to as pretangles (Bancher *et al*., 1989; Braak *et al*., 1994). Neurons displaying pretangles are ALZ-50 immunoreactive. At a following stage, neuropil threads may be identified by immunocytochemistry using both ALZ-50 and anti-PHF antibodies. Neuropil threads are abnormal neuronal processes that contain both PHF and straight filaments. They are mainly located in distal segments of axons and dendrites and share multiple tau epitopes with NFT (i.e., anti-tau and anti-ubiquitin reactivity), except those in the two high molecular weight neurofilament proteins (Fig. 6.1c; Perry *et al*.,

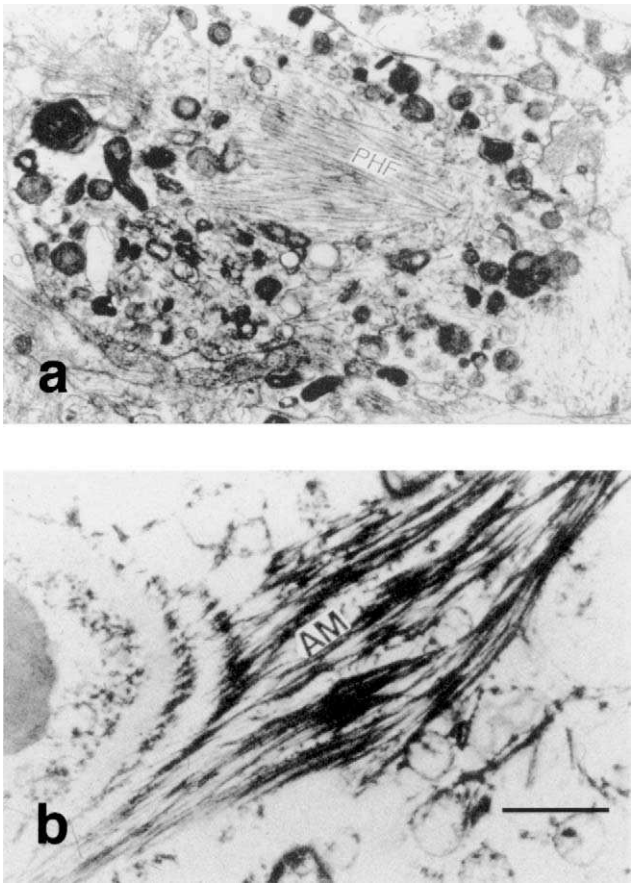

FIG. 6.2. Ultrastructural appearance of PHF in NFT (a) and amyloid fibrils (AM) in the core of a SP (b).

1991). The PHF immunoreactivity of neuropil threads progressively displaces the normal microtubule-associated protein 2 immunostaining in dendrites and is associated with a degeneration of the soma in vulnerable cortical areas (Ashford *et al*., 1998). In more advanced AD cases, fully developed NFT are seen as tightly packed bundles filling the cell body and extending into proximal dendrites (Fig. 6.1a). Following neuronal death, NFT in the cerebral cortex persist within the neuropil as extracellular or ghost tangles and are associated with degenerating neurites and neuropil threads (Fig. 6.1d; Yamagushi *et al*., 1991; Terry *et al*., 1994; Cras *et al*., 1995). Extracellular but not intracellular tangles are immunoreactive for the 40 carboxy-terminal sequence of amyloid Aβ protein (Schwab *et al*., 1998).

B. Senile Plaques

The histological description of SP has yet to be standardized, and there are substantial interlaboratory differences in the vocabulary used. Two main types of SP have been distinguished in the human brain (Fig. 6.3, see color insert). *Diffuse plaques* are formed by filamentous and nonstructured amyloid Aβ protein without a neuritic component, stain positively with silver stains but not with thioflavin-S, do not correlate with the severity of dementia, and are especially seen in oldest-old individuals (Fig. 6.3e; Hauw *et al*., 1986). In contrast, *neuritic plaques* contain dense bundles of amyloid fibrils stained by thioflavin-S and dystrophic neurites (Figs. 6.3a, 6.3b, and 6.3d). Neuritic plaques are further divided into *primitive plaques* without a dense Aβ protein core and *classic plaques*, which are composed of a central amyloid core surrounded by degenerating axon terminals, dendritic arborizations, and glial elements (Figs. 6.2a, and 6.2b; Brion, 1990; Dickson, 1997; Wisniewski and Silverman, 1997). Some of these neurites contain degenerating synaptic elements, laminated bodies, mitochondria, and lysosomes, whereas others contain PHF similar to those observed in NFT and neuropil threads. Neuritic plaques, which are PHF immunoreactive, are predominantly found in AD and are thought to be associated with clinical severity (Fig. 6.3b; Barcikowska *et al*., 1989; Dickson, 1997; Knowles *et al*., 1998). Neuritic elements are also immunolabeled for numerous proteins, such as amyloid precursor protein (APP), growth-associated protein 43, protein kinase C, tau, ubiquitin, brain spectrin, synaptophysin, and chromogranin, as well as a variety of neuropeptides (for review, see Terry *et al*., 1994). Although the exact significance of this immunoreactivity is unclear, the presence of growth-associated protein 43 indicates that regenerative sprouts occur in the vicinity of neuritic plaques. At the end of their evolution, SP are often present as a dense amyloid core with reactive astrocytes and microglial cells but without a neuritic component (Fig. 6.1c; i.e., burned-out plaques).

A prominent component of amyloid deposits is a polypeptide (Aβ) of 40–42 amino acids derived through proteolytic cleavage from a set of APP isoforms, which are encoded by a single gene on chromosome 21 (Fig. 6.2b; Brion, 1990). Three major isoforms of APP are generated from this gene by alternative splicing (APP 770, 751, 695). All of these isoforms are found in the human brain (Checler, 1995). Structurally, the APP is a protein of 110–135 kDa with a large extracellular N-terminal domain, a cell-surface domain, and a small intracellular carboxyl-terminal domain. The proteolytic cleavage of this molecule in the Aβ domain is catalyzed by a group of enzymes, known as α, β and γ secretases (Checler, 1995). It is thought that cleavage of the APP outside the Aβ domain could generate large C-terminal fragments containing the Aβ sequence, which are possibly amyloidogenic. Two distinct species of Aβ protein with different carboxyl terminals, Aβ40 and Aβ42(43), are deposited in the brains of patients with AD (Iwatsubo *et al*., 1994; 1996; Mann *et al*., 1996). In particular, diffuse plaques, which are commonly seen in normal brain aging, are immunoreactive for the Aβ42 fragment, whereas dense and reticular amyloid deposits in AD brains show an intense Aβ40 immunoreactivity (Arai *et al*., 1990; Gowing *et al*., 1994; Iwatsubo *et al*., 1994, 1996). Although this kind of distinction is not accepted unanimously, a better understanding of the molecular composition of amyloid deposits may make it possible to identify a subset of SP more closely related to AD than normal brain aging. Besides antibodies to Aβ protein, the amyloid core, as well as the amyloid fibrils in SP, is immunostained with antibodies to α_1-antichymotrypsin, protein kinase C, factors of complement, apolipoprotein E, and sulfated glycosaminoglycans. Most of these components are probably adsorbed secondarily to the amyloid in SP (Robakis, 1994).

The mechanism of SP formation is controversed. Classic SP may develop from preexistant diffuse Aβ deposits, although no consistent colocalization of these two forms of SP has been observed. Alternatively, SP may arise from amyloid in the vicinity of the blood vessel wall (see later). A third hypothesis involves a release of Aβ sequence from clusters of dystrophic neurites with the subsequent formation of diffuse Aβ deposits and classic SP (for review, see Terry *et al*., 1994).

C. NFT and SP: Concurrent or Causally Related Lesions?

Whether the consistent presence of NFT and SP in AD brains reflects a causal relationship between these lesions is still a very controversial issue. Several lines of evidence support an interdependence between these two types of lesions. In normal brain aging, AD, and Down syndrome, neuritic plaques coincide with NFT (Mann and Esiri, 1989; Bugiani *et al*., 1990); extracellular NFT contain several traits of SP such as Aβ40 protein, microglia, and astroglia (Cras *et al*., 1995; Schwab *et al*., 1998), and a subset of neuritic plaques show PHF immunoreactivity (see earlier discussion); the APP molecule contains a β-sheet conformation-dependent binding site for tau protein (Smith *et al*., 1995), and *in vitro* interaction between tau and APP proteins promotes fibrillogenesis (Giaconne *et al*., 1994); injection of PHF in rat brain induces amyloid deposits (Shin *et al*., 1993); and AD kindreds carrying APP mutations exhibit both amyloid deposition and NFT (for review, see Hardy, 1994). However, there are also strong arguments against such interdependence. For instance, amyloid deposition may occur in the absence of NFT, and the recent description of tauopathies and tau- and tangle pathology-related conditions clearly indicates that NFT may cause dementia in the absence of amyloid deposition (for review, see Jellinger and Bancher, 1998; Spillantini *et al*., 1998). Moreover, in AD brains there is no correlation between the regional distribution of NFT and SP within the cerebral cortex, at least at the early stages of the degenerative process (Giannakopoulos *et al*., 1993; van de Nes *et al*., 1998). One can conclude that although there is a high degree of pathological synergy between NFT and SP in AD, these lesions develop independently in the course of brain aging and their simultaneous presence is not a necessary condition for the clinical expression of dementia.

D. Synaptic and Neuronal Loss

Both types of loss are difficult to assess as they represent the inferred absence of something. Synaptic loss has been reported in the neocortex of elderly nondemented individuals, suggesting an age-dependent mechanism for the loss of synapses in the neocortex (Masliah *et al*., 1993). Terry and collaborators (1994) have proposed that the structural or functional loss of synapses may be the physical basis of dementia. In particular, synaptic loss has been revealed by electron microscopy studies, by confocal microscopy for synaptophysin immunostaining, and also by spectrophotometric analysis of enzyme-linked immunoassays (for review, see Terry *et al*., 1994). All these methods have demonstrated a close relationship between the extent of loss of synaptic integrity and AD severity. An average of 45% decrease in presynaptic terminal density, and a 27 to 42% synapse loss in the prefrontal cortex has been documented in AD cases (Brion *et al*., 1991; Masliah *et al*., 1991). This progressive synapse loss is accompanied by the development of an increased area of aposition between pre- and postsynaptic elements. While synaptic density is generally diminished in the cortical neuropil of AD compared to age-matched control cases, this reduction is not greater within the diffuse plaques than in the neuropil outside them. In contrast, synapse loss is more pronounced within neuritic plaques, and abnormal synapses are concentrated around dendritic neuropil threads. Numerous studies have analyzed in depth the relationships between synaptic changes and APP metabolism. APP has been localized in the presynaptic terminals in most SP dystrophic neurites, and it may be transported rapidly in the axon to the presynaptic site. These findings support a central role for synaptic alterations in AD pathogenesis. Whether synaptic changes precede the accumulation of abnormally processed APP and amyloid deposition or whether they are caused by amyloid neurotoxicity is still a matter of debate. More generally, the pathophysiology of synaptic alterations is poorly known. Possible explanations include the receptor-mediated neurotoxic effect of endogenous or exogenous substances, failure of neuronal plasticity due to altered intracellular signaling, and abnormal axonal transport (for review, see Terry *et al*., 1994).

Until recently, it was widely accepted that neuronal death is consistently associated with normal brain aging. This conviction was supported by several influential papers, some of which date back to the 1950s, demonstrating significant neuronal death in aged nondemented individuals as well as in nonhuman primates and rodents. All these studies estimated neuron densities but not the total number of neurons in a given structure. The field was reviewed extensively by Coleman and Flood (1987), who concluded that although there was an aging-related neuronal loss, the validity of data might be seriously compromised by species differences, tissue processing, and sampling design. This point of view has been further challenged by the development of stereological techniques to estimate the number of neurons in identifiable structures of interest, such as key hippocampal and neocortical areas (for review, see West and Gundersen, 1990). The main advantages of these techniques are that they obtain estimates of total neuron number within a given brain structure, which are not confounded by changes in the size of neurons, the size of the structure, and fixation parameters. Using stereological principles, it has been shown that there is only a 10% decrease in the total number of neurons in the neocortex across the age spectrum in normal individuals (Morrison and Hof, 1997; Pakkenberg and Gundersen, 1997). Most importantly, there was no evidence of age-related neuronal loss in the CA1 field and entorhinal cortex, two key areas in AD pathogenesis, in nondemented individuals (West, 1993; West *et al*., 1994; Gómez-Isla *et al*., 1996a). Although a certain decrement in neuron numbers has been reported in the hilus of the dentate gyrus and subiculum in the course of normal brain aging, this remains controversial (West, 1993; Simic *et al*., 1997). Conversely, even very mild AD cases (i.e., CDR of 0.5) display a 50% neuronal loss in layer II of the entorhinal cortex, and this percentage raises to 90% in severe AD cases (Gómez-Isla *et al*.,

1996a). Moreover, neuronal loss in the CA1 field of the hippocampus may quantitatively separate normal brain aging from AD (West *et al*., 1994) and correlate strongly with the duration and severity of AD (Bobinski *et al*., 1998). Decreased densities of larger neurons are observed not only in the AD cerebral cortex, but also in some subcortical nuclei, such as the basal nucleus of Meynert, locus coeruleus, and dorsal raphe (for review, see Terry *et al*., 1994).

The mechanisms surrounding cell death in AD are not clearly identified. Among the pyramidal neurons of the hippocampal formation, cell death appears closely related to the presence of NFT, many of which are visualized in the neuropil when the neuronal nucleus and cytoplasm disappear. In neocortical areas, both NFT-related and NFT-unrelated neuronal loss may take place, particularly in very old patients (Terry *et al*., 1987; Giannakopoulos *et al*., 1996). Several studies have indicated that neuronal apoptosis is an important mechanism of cell death in AD (for review, see Cotman and Anderson, 1995; Smale *et al*., 1995). An expanding family of genes encoding homologous proteins has been identified as the Bcl-2 family and appears to determine whether a cell will undergo apoptosis (Boise *et al*., 1993; Oltvai *et al*., 1993). Among them, the Bcl-2 and Bcl-X_L gene products can block apoptotic cell death and promote the survival of neurons (Boise *et al*., 1993; Zhong *et al*., 1993), whereas the Bax gene product (Bcl-2-associated X protein) may act as a promoter of cell death (Oltvai *et al*., 1993). In AD, Bcl-2 downregulation and Bax upregulation have been reported in neurons prone to degeneration (Su *et al*., 1996; MacGibbon *et al*., 1997), whereas a loss of Bax immunoreactivity may render neurons more resistant to programmed cell death (MacGibbon *et al*., 1997; Su *et al*., 1997). Subsequently, it has been proposed that an upregulation of Bax may act by promoting both NFT-related and NFT-unrelated neuronal loss (Su *et al*., 1997). However, Western blot analysis has shown an increase in the level of Bcl-X_L, but not Bax, protein in the temporal cortex in AD compared to nondemented cases (Kitamura *et al*., 1998). Moreover, an increase in the expression of Bcl-2 has been reported in AD brains, yet sparse and equivocal Bcl-2 staining is observed in neurons in this disorder (Satou *et al*., 1995; O'Barr *et al*., 1996). Apoptosis is not the only mechanism involved in cell death in AD (Cotman, 1998). The DNA fragmentation that occurs in the hippocampus of AD brains is not necessarily associated with an increased rate of cells displaying the morphological characteristics of apoptosis, and it has been postulated that necrosis may also play an equally important role in AD-related cell destruction (Stadelmann *et al*., 1998). Further studies, including both estimates of neurons showing DNA damage and expression of apoptosis-related proteins, are warranted to better understand the molecular mechanisms of neuronal loss in AD.

E. Other AD-Related Lesions

Two additional lesions frequently observed in AD brains are Hirano bodies and granulovacuolar degenerations. Hirano bodies are refractile eosinophilic rod-like structures that have been initially observed in specimens of Guamanian parkinsonism–dementia complex. They occur preferentially in neurons of the CA1 field of the hippocampus, and their number increases with age. In addition to their original description, they are also present in a variety of dementing conditions, including AD, Pick's disease, and dementia with Lewy bodies (Hirano, 1994). Immunocytochemical and electron microscopy studies have revealed that Hirano bodies are mainly formed by abnormal actin microfilaments, but also contain epitopes of tau protein, middle molecular weight neurofilament subunits, C-terminal fragment of β-APP, advanced glycation end products, stress-related proteins, and FAC1, a developmentally regulated protein (Hirano, 1994; Jordan-Sciutto *et al*., 1998; Munch *et al*., 1998). Although the exact role of Hirano bodies in aging pathophysiology is unknown, it is considered that they represent age-related alterations of the microfilamentous system, which are probably accelerated in various neurodegenerative diseases.

In classic histologic sections, granulovacuolar degenerations (GVD) appear as vacuoles in the cytoplasm of pyramidal neurons in the hippocampus, mainly in the CA1 field and prosubiculum. Each 3- or 4-μm-wide vacuole contains a dense hematoxylinophilic, argentophilic granule, 1 or 2 μm in diameter. Cells with GVD are scarce in normal brain aging, but their number increases markedly in several dementing conditions, such as AD, Pick's disease, multi-infarct dementia, and Fahr's syndrome (Xu *et al*., 1992). Electron microscopy shows a single membrane surrounding the vacuole and a dense granular mass. The molecular mechanism of GVD formation remains unknown. Evidence suggests a close relationship between these lesions and NFT. For instance, they are labeled by antibodies to tubulin, Alz-50, and neurofilament proteins. Moreover, they exhibit the same pattern of phosphorylated tau than NFT, yet are devoid of PHF-like structures. It has been proposed that GVD is formed through lysosomal autophagy of intraneuronal substances, in particular abnormally phosphorylated tau protein (Mena *et al*., 1992; Ikegami *et al*., 1996).

F. Vascular Pathology in AD

Pathological deposition of Aβ protein within the outer segments of the muscle layer in large vessels has long been recognized in AD and is referred to as congophilic amyloid angiopathy (Fig. 6.4a, see color insert; for review, see Kawai *et al*., 1993; Vinters *et al*., 1994). In addition, Aβ deposits occur in the abluminal aspects of the vascular basement membrane in capillaries and are often accompanied by the focal loss of endothelial cells (Fig 6.4b; for review, see Perlmutter, 1994). Although investigations of the chemical structure of Aβ vascular deposits have revealed a predominance of the 42 residue form, which represents almost 75% of the total Aβ protein in nondemented elderly individuals and patients with AD (Roher *et al*., 1993; Shinkai *et al*., 1995), widely varying amounts of the Aβ40 form are also deposited in AD vessel walls and may contribute decisively to the development of congophilic amyloid angiopathy. Furthermore, β-APP has been colocalized with white matter lesions in the human brain, and Aβ deposits have also been identified in AD white matter (Gravina *et al*., 1995). The putative source of vascular, and parenchymal Aβ deposits remains controversial in regard to whether they are of blood borne, local vascular, or central neuronal origin. The biochemical similarities between Aβ deposits

in SP and vessels and the well known permeability of the blood–brain barrier to soluble Aβ protein had initially suggested a possible blood origin of brain Aβ deposits (Joachim *et al*., 1988; Zlokovic *et al*., 1993). However, no regional correlation has been found between SP and Aβ vascular deposits within the cerebral cortex in AD (Lippa *et al*., 1993). Microglial-like perivascular cells within the vascular basement membrane express APP and may thus represent a possible source of vascular amyloid (Banati *et al*., 1994; Perlmutter, 1994; Wisniewski and Wiegel, 1994). In large vessels, Aβ protein may be produced in both APP-containing degenerating vascular muscle cells and microglial-like perivascular cells, and it is thought to be primarily deposited in periarterial interstitial fluid drainage pathways (Kawai *et al*., 1993; Wisniewski and Wiegel, 1994; Weller *et al*., 1998). Alternatively, an increased intraneuronal production and reduced clearance by microglia of the Aβ protein could contribute to a redirection of peptide processing to extracellular deposits (Frautschy *et al*., 1992).

Studies have also shown a substantial decrease in the density of capillaries in AD compared to nondemented individuals. This decrease is mainly observed in layers III and VI of the frontal and temporal cortex and correlates with the laminar densities of NFT and SP. In addition, twisted, coiled, and string vessels and glomerular loops have been reported in AD as well as in other dementing conditions, such as dementia pugilistica and Guam amyotrophic lateral sclerosis (Figs. 6.4c and 6.4d). Ultrastructurally, a conspicuous lack of endothelial cells in microvessels, as well as a significant increase in the number of normally occurring gaps in endothelial continuity, has been reported in AD compared to nondemented elderly people. Vascular endothelial cells show a decreased number of mitochondria and an increased number of pinocytotic vesicles, suggesting that a metabolic deficiency leading to an accumulation of transport carriers may be present in these cells in AD. The pathogenesis of these vascular alterations remains unclear, but it has been postulated that denervation angiopathy may be causally related to the microvascular pathology in AD. These pathologic changes may be associated with an increased blood–brain permeability and deposition of Aβ protein (for review, see Gold *et al*., 1998).

III. Neuropathological Diagnosis of Alzheimer's Disease

A. General Considerations

There is considerable subjectivity and disagreement among neuropathologists in determining the diagnosis of AD. Three main reasons may explain this phenomenon: the complex and uncertain relationship between normal brain aging and AD, the ambiguous role of the clinical history of dementia in the neuropathological diagnosis of AD, and differences in staining procedures. This section summarizes the conceptual problems related to these issues as well as their implication in the routine neuropathological diagnosis of AD.

Although there is broad agreement on the description of classical features of the AD brain, a substantial interindividual variation is seen across AD cases. Most importantly, studies have shown that the majority of elderly people displayed NFT formation in hippocampal formation even in the absence of cognitive impairment or with very mild memory impairment (Price *et al*., 1991; Arriagada *et al*., 1992a,b; Hof *et al*., 1992; West *et al*., 1994; Bierer *et al*., 1995). SP may appear early in the neocortex of intellectually preserved individuals, whereas the hippocampus is relatively spared by SP formation at the onset of the degenerative process (Pearson *et al*., 1985; Lewis *et al*., 1987; Hof *et al*., 1992). In addition, numerous neuropathological analyses of nondemented people have demonstrated the presence of NFT confined to the temporal neocortex, implying that the progression in NFT density within adjacent components of the medial and inferior aspects of the temporal cortex may take place in cognitively intact individuals (Hubbard *et al*., 1990; Arriagada *et al*., 1992b; Hof *et al*., 1992; Bouras *et al*., 1993, 1994; Bierer *et al*., 1995). Whether any observed NFT and SP represent a disease process or are age-related phenomena is still a matter of debate. It is well established that both NFT and SP frequencies in cognitively intact individuals are strongly age related (for review, see Giannakopoulos *et al*., 1996). This finding has been interpreted in very different ways. Similar to atherosclerosis in the elderly, NFT and SP in the aged brain have been considered as ubiquitous findings, which represent the same pathophysiological process as in AD (Hyman, 1997). This linear relationship between brain aging and AD is far from being generally accepted. Based on neuropathological studies of the oldest-old, which showed substantial differences in the pattern and densities of lesion distribution between very old and younger elderly people without dementia, it has been proposed that AD and brain aging are two separate conditions (for review, see Giannakopoulos *et al*., 1996). Despite their differences, both points of view imply that the diagnosis of AD should be based on the severity and topography of pathological changes rather than on the presence of a qualitative marker, at least as far as NFT and SP are concerned. In contrast, the presence of qualitative differences between brain aging and AD has been proposed (West *et al*., 1994; Gómez-Isla *et al*., 1996a; Dickson, 1997; Wisniewski and Silverman, 1997). These qualitative differences include the presence of Aβ40 immunoreactive reticular amyloid deposits and PHF-positive SP in AD, which, however, has been also reported in normal brain aging (Barcikowska *et al*., 1989; Dickson, 1997; Wisniewski and Silverman, 1997), and mainly the substantial neuronal loss in the CA1 field observed in AD but not in control cases (West *et al*., 1994; Gómez-Isla *et al*., 1996a). Both neuronal and synaptic loss in association cortices are good predictors of the severity of dementia. However, they are not specific for AD and are difficult to study because they are the inferred absence of a normal tissular structure. Moreover, tissue preparation and counting procedures influence their assessment (West and Gundersen, 1990; Terry *et al*., 1994; Gómez-Isla *et al*., 1996a).

The evolution of neuropathological criteria for AD is marked by a hesitation between two theoretical positions: one which considers that the neuropathological diagnosis of AD should be made only in the presence of clinically overt dementia and the other which proposes a clear separation between the neuropathological definition of the disease and its clinical expression. The rationale for linking neuropathological diagnostic criteria to the presence of dementia is a histor-

ical one: in Alzheimer's (1907) original case, the definition of AD is based on the correlation between the presence of a clinical history of dementia and abundant NFT and SP formation within the cerebral cortex. Although the inclusion of dementia as a sine qua non criterion for the neuropathological diagnosis of AD could eliminate the problem of false-positive neuropathological diagnoses, this practice is largely controversed in the current literature. In fact, if the neuropathological diagnosis of AD changes depending on a clinical impression, it would be of little value as a ''gold standard.'' Moreover, the clinical diagnosis of dementia may not be sensitive or reliable in the early stages of the disease. Because AD is a slowly progressive and global encephalopathy, it is probable that for a long period of time, perhaps years, the accumulation of lesions below a threshold is clinically silent. In this respect, several previous reports have indicated that a progression in NFT density within adjacent cortical components of the medial and inferior aspects of the temporal cortex may be a neuropathological hallmark of incipient dementia in elderly patients presenting with normal cognitive abilities or very mild cognitive impairment (Hubbard *et al*., 1990; Hof *et al*., 1992; Bouras *et al*., 1993). If these cases are ''negative'' because of the absence of dementia, crucial information about the very early stages of AD pathogenesis could go unrecognized (Hyman, 1997; Wisniewski and Silverman, 1997).

The third source of interlaboratory variability in the neuropathological diagnosis of AD is the use of different staining procedures, particularly in the assessment of SP densities (Vallet *et al*., 1992). The routine use of immunocytochemistry makes it possible to visualize increasing number, of lesions, including diffuse Aβ deposits, as well as the different types of SP. By striving for increased sensitivity, a more comprehensive and detailed description of positive cases has been achieved. However, although Aβ immunocytochemistry shows more alterations than classic histological methods, these changes are not as well correlated with the severity of dementia (Wisniewski and Silverman, 1997). A possible exception to this rule is the mean Aβ load in the hippocampus (i.e., the percentage of this cortical area occupied by Aβ immunoreactivity), which may be a good correlate of clinical status in AD (Cummings *et al*., 1996; Bartoo *et al*., 1997). In fact, a method that reveals the largest number of lesions is not necessarily the best one, and it should be kept in mind that less sensitive methods may allow a better distinction between classification categories. This heterogeneity in staining procedures is a major handicap when consistent quantitative criteria are used, as it may cause an unacceptable level of false-positive or -negative results.

B. Current Diagnostic Systems

The first cited diagnostic criteria for AD were elaborated by a National Institute on Aging (NIA) workshop (1997) and described by Khachaturian (1985). These criteria were intended to aid in the development of uniform procedures by proposing minimal SP densities as a function of age. Although this method may appear arbitrary, it was justified by the assumption that SP formation may be partly a benign age-related phenomenon. Implicitly, these criteria recognize that SP formation is not sufficient to cause dementia, as SP densities associated with AD at younger ages are unrelated to clinical symptoms at older ages. It is thus surprising that the presence of NFT is not considered for cases over 50 years of age. Several other criticisms of Khachaturian's criteria have been formulated: the type of SP is not specified; precise quantification of SP may be technically difficult and, most importantly, could change in function of apolipoprotein E genotype; only neocortical areas were taken into account; and the role of the clinical history remains vague (Table 6.1; Schmechel *et al*., 1993; Gómez-Isla *et al*., 1996b; Hyman, 1997; Markesbery, 1997). Khachaturian's recommendations were not broadly accepted and their validity has been questioned. In a survey

TABLE 6.1 Comparison of Diagnostic Systems for AD[a]

	Khachaturian	CERAD	Braak	NIA–Reagan
Areas of interest	Frontal cortex Parietal cortex Temporal cortex	Middle frontal gyrus Sup temporal gyrus Mid temporal gyrus Inf parietal lobule	Entorhinal cortex, hippocampus Amygdala Thalamus Isocortex	Sup temporal gyrus Inf parietal lobule Middle frontal gyrus, occipital cortex Hippocampus, substantia nigra, locus coezuleus
Staining	Silver stains Congo red Thioflavin-S	Silver or thioflavin stains	Silver stains	Silver or thioflavin stains Immunostaining (for research)
Quantification	Semiquantitative	Semiquantitative	Not specified	Semiquantitative
Effect of age	Age-related SP densities	Age-related NP densities	Not related	Not defined
Main criterion	SP formation in the neocortex	NP formation in the neocortex	NFT progression within the cerebral cortex	NFT and NP formation in the cerebral cortex
Relationship to clinical data	Unspecified	Clinical history included in the diagnostic algorithm	None	Applied to demented patients

[a]SP, senile plaques; NP, neuritic plaques; NFT, neurofibrillary tangles.

of neuropathological practices performed 2 years after the original publication, only 21% of the responders used these criteria on a routine basis (Wisniewski *et al*., 1989). Data presented by Katzman and collaborators (1988) showed that only 89% of clinically confirmed AD cases and 34% of cases with no history of dementia met Khachaturian's criteria for AD. In order to validate these criteria, Tierney and collaborators (1988) made the first attempt to integrate both NFT and neuritic plaques in the neuropathological diagnosis of AD. They proposed three sets of criteria with one or more lesions per 25 × microscopic field in the hippocampus alone, in the neocortex alone, or both. The accuracy of all three sets of criteria was relatively high (81 to 88%), yet they have not been widely used.

Subsequent to the 1985 workshop, the Consortium to Establish a Registry for Alzheimer's Disease (CERAD) proposed another set of standardized neuropathological criteria (Mirra *et al*., 1991). These semiquantitative criteria were determined as a function of the development of neuritic plaques in three age groups (less than 50, 50 to 75, and over 75). The diagnosis was based on a combination of clinical information and an ''age-related plaque score'' that reflected the maximal neocortical involvement, and a level of diagnostic certainty was assessed (i.e., definite, probable, or possible AD). These criteria are uncomplicated, limit the sensitivity and specificity problems related to quantitative criteria, and do not require extensive training. The combined CERAD categories of possible, probable, and definite AD correspond closely to cases fulfilling Khachaturian's criteria for AD (Nagy *et al*., 1998). As in these latter criteria, the hippocampal formation is ignored, despite its involvement in the pathogenesis of AD. However, the major weakness of CERAD criteria resides in that they have been inspired somewhat unilaterally by the amyloid cascade hypothesis and do not consider NFT densities in the neocortex, even though these correlate very strongly with the severity of dementia (Table 6.1). Although neuritic plaques, which are used for the diagnosis, appear to be superior than Aβ deposits in predicting the degree of cognitive impairment, neither perform nearly as well in this respect as NFT densities in the neocortex or neuronal or synaptic loss (Gómez-Isla *et al*., 1996b; Haroutunian *et al*., 1998). CERAD criteria are widely accepted, yet their validity is still poorly documented (Wisniewski and Silverman, 1997).

In 1991, the year of the publication of the CERAD criteria, Braak and Braak proposed a staging scheme for AD that was entirely dependent on the progressive development of NFT within the cerebral cortex. This scheme presupposes a predictable temporal pattern in the evolution of NFT that can be ordered in a particular regional hierarchy. In stages I and II, the transentorhinal region is preferably affected with only mild involvement of the hippocampus, the neocortex is essentially spared. Stages III and IV, referred to as ''limbic stages,'' include more abundant NFT formation in the transentorhinal and entorhinal cortex, moderate involvement of the hippocampus, and only mild neocortical pathology. Cases with stages V and VI display high NFT densities in both the hippocampus and the neocortex. In their initial report, Braak and Braak suggested that the transentorhinal stages (stages I and II) correspond to a clinically silent initial phase of AD, limbic stages to early AD, and neocortical stages (stages V and VI) to fully developed AD (Table 6.1). Although this scheme appears plausible and correlates well with clinical data (Nagy *et al*., 1999), a considerable degree of overlap without a clear-cut threshold between normal and demented cases has raised the issue of its diagnostic value (Gertz *et al*., 1998; Gold *et al*., 2000). Furthermore, it has not been demonstrated whether the precise neuropathological hierarchy proposed by Braak and Braak corresponds to stepwise decrements in cognitive function. Despite these limitations, this NFT-based staging system is a useful instrument to ameliorate probabilistic estimates of degree of dementia from neuropathological data.

In 1997, the NIA–Reagan Consensus conference attempted to integrate the experience of neuropathologists from the United States and Europe in a comprehensive set of neuropathological criteria for AD (Table 6.1). In contrast to CERAD criteria, which incorporate clinical data to provide a neuropathological diagnosis, these new criteria aim to define the likelihood that a clinically overt dementia is due to AD lesions. In other words, the neuropathologist is asking to ascertain not the presence of AD but the most likely cause of dementia. This subtle theoretical change could guarantee the role of the neuropathological diagnosis as a ''gold standard.'' The procedure takes into account both the CERAD criteria and the Braak staging scheme (Table 6.1). The use of CERAD protocols for tissue processing was adopted, but sampling and semiquantitative assessment of AD lesions must be made in several neocortical areas, hippocampal formation, substantia nigra, and locus coeruleus. In addition, the assessment of Lewy bodies with immunocytochemical methods using antiubiquitin antibodies was recommended. Conceptually, the merit of these new criteria is their attempt to conciliate the amyloid cascade hypothesis with the key role of NFT in clinicopathological correlations. Furthermore, they are rapid and easy to apply in both AD and nondemented individuals (Jellinger, 1998). Whether they are more valid than the previous ones remains to be assessed.

C. Perspectives

It has been long considered that the neuropathological assessment of AD pathologic changes provides an easy and unequivocal way to confirm the clinical diagnosis of AD. Experience accumulated since the mid-1980s suggests that the morphological diagnosis of AD depends on theoretical beliefs with respect to ''normal'' and ''pathological'' brain aging, the role of different lesions in AD pathogenesis, and the pertinence of clinical informations. What is now crucial is to decrease interlaboratory variability and ensure that the neuropathological diagnosis of AD fulfills the criteria of a ''gold standard.'' We believe that the diagnostic procedure should be influenced less by theoretical positions and consider equally NFT and SP. NFT are a good indicator of clinical progression, and their formation follows a hierarchical pattern involving the entorhinal cortex, hippocampus, inferior temporal cortex, and, later, other neocortical areas. SP are distributed widely and nonspecifically within the neocortex and are correlated poorly with AD clinical severity, yet molecular genetic data support a central role for amyloid in AD pathogenesis. We also suggest that an exhaustive description of neuropathologist's findings independent of clinical data is the only way to establish unbiased clinicopathological correlations. In the light

of these statements, the criteria proposed by the NIA–Reagan Consensus conference merit strong support.

Morphological Changes in Human Cerebral Cortex during Normal Aging

Alzheimer's disease (AD) is the most frequent cause of dementia in industrialized countries and has become one of the most studied age-related neuropsychiatric illnesses. However, the clinical assessment of AD in its early stages is still awaiting accurate and reliable tools that can be used to assess the progression of the disease and to evaluate emerging therapeutics interventions, although numerous studies have shown that results obtained from the neuropathological examination of AD brains are usually well correlated with clinical data. The major histopathologic hallmarks of AD are extracellular amyloid deposits referred to as senile plaques (SP), intraneuronal fibrillar inclusions referred to as neurofibrillary tangles (NFT), and neuronal and synaptic loss. The decline of cognitive functions observed in AD patients is reflected by the regional distribution and density of these lesions and by synapse loss and neuron death, which results in the disruption of major cortical circuits. However, SP and NFT are also present in brains from cognitively and intellectually preserved elderly individuals. A consistent neurofibrillary pathology restricted to the entorhinal cortex and the hippocampus occurs consistently in the brain of unaffected individuals and in patients with very mild cognitive impairment. Conversely, the distribution pattern of SP is variable among these individuals. Investigation of the regional and laminar localization of AD-related lesions simultaneously in nondemented subjects and patients with very mild cognitive impairment is important to understand the difference between normal aging and dementing process and to elucidate the pathogenetic mechanisms leading to the onset of the disease.

I. Histopathological Changes in Cerebral Cortex in Alzheimer's Disease (AD) and Aging

A. Neurofibrillary Tangles (NFT) and Senile Plaques (SP) Lesions in AD

Neuronal loss, NFT, and SP are the morphological signature of AD and of several neurodegenerative disorders (Mirra *et al*., 1993). NFT and SP have been extensively studied biochemically, and it is now well established that their major components are the modified microtubule-associated protein tau and the amyloid peptide, respectively (Delacourte and Buée, 1997; Hof *et al*., 1999). Conversely, it is still unclear how these compounds are involved in the pathogenic cascade leading to the onset of the disease and how they interact with each other. Neuropathological studies of brains from patients presenting with AD have shown that NFT and SP are not distributed uniformly in the cerebral cortex. Thus, NFT and SP display a preferential laminar and regional distribution and do not affect equally the different types of neurons. In fact, in severe AD cases, NFT are present in a high density in the medial temporal cortex, especially in layer III of the transentorhinal cortex, in layer II of the entorhinal cortex, and in the hippocampal formation where the CA1 field and the subiculum display the highest densities of NFT. The neocortical association areas are also severely affected in these cases, with high densities of NFT in prefrontal and temporal cortices. The NFT formation occurs selectively in the pyramidal cells of supragranular layers II–III and infragranular layers V–VI. The primary sensory and motor cortices are relatively spared by the neurofibrillary degeneration. Conversely, amyloid deposition may be present in these areas and are commonly observed in the neocortical association areas, where SP tend to be more numerous in supragranular layers than in infragranular layers (Rogers and Morrison, 1985; Arnold *et al*., 1991; Braak and Braak, 1991; Bouras *et al*., 1994).

The severity of dementia has been correlated to the distribution and density of both NFT and SP in the cerebral cortex. A significant correlation has been established between the SP frequency in several cortical regions and the dementia severity assessed within 6 weeks of death using the Blessed Dementia Scale (Tomlinson *et al*., 1970). Nevertheless, the most significant correlation that has been found is related to the density of NFT, especially in the temporal neocortex, entorhinal cortex, and hippocampus (Arriagada *et al*., 1992a; Bouras *et al*., 1993; 1994), as well as to synapse loss in neocortical areas

(Terry *et al*., 1991). Finally, the specific distribution of NFT and SP within the cerebral cortex clearly argues in favor of a vulnerability to degeneration restricted to a subset of identifiable cortical neurons. Thus, the distribution of lesions indicates that the neurons of origin of long corticocortical and hippocampal projections are highly vulnerable in AD. The dysfunction of such pathways between hippocampus and neocortex and between the neocortical association areas may represent the morphological substrate for the impairment of cognitive functions in AD (see Chapter 9).

B. NFT and SP Lesions in Normal Aging

The presence of the characteristic cerebral lesions of NFT and SP are required to ascertain the neuropathological diagnosis of AD. Nevertheless, these pathological hallmarks are also observed in the cerebral cortex of nondemented cases as well as in elderly subjects with mild cognitive impairment. Studies of cognitively intact elderly people have demonstrated that NFT formation and amyloid deposition are common features of normal brain aging and that the number of NFT, but not of SP, is increased significantly with age (Fig. 7.2). NFT regional distribution is relatively consistent across individuals, whereas the SP pattern could be heterogeneous (Crystal *et al*., 1988; Braak and Braak, 1990; Price *et al*., 1991; Arriagada et al., 1992a,b; Bouras *et al*., 1993, 1994). Thus, NFT are present in the entorhinal cortex and the CA1 in nondemented older cases, and only very rare lesions are observed in the temporal and superior frontal neocortex (Braak and Braak, 1990; Price *et al*., 1991; Arriagada *et al*., 1992b; Bouras *et al*., 1993). In cases presenting with mild symptoms of cognitive decline, NFT are always present in the medial and inferior temporal cortex, including hippocampus, entorhinal, and perirhinal cortices (Figs. 7.1 and 7.2). Lesions occur preferentially in layer II of the entorhinal cortex and, to a lesser extent, in layers III and V. Other neocortical regions display only sparse NFT (Hof *et al*., 1992; Bouras *et al*., 1993, 1994; Bierer *et al*., 1995). NFT spread out progressively in the neocortex as the dementia worsens, leading in these cases to the typical neuropathologic profile of AD with a severe involvement of association neocortical areas (Arnold *et al*., 1991). The topogaphic distribution of SP in nondemented elderly individuals shows a different pattern than NFT, as SP occur primarily in the inferior temporal neocortex (Brodmann's area 20) and in the occipital cortex. In this latter case, SP are distributed preferentially throughout layer IV (Braak *et al*., 1989). The hippocampal formation, the entorhinal and perirhinal cortices, and the frontal cortex are less often affected. SP are exclusively primitive plaques without any amyloid-dense core or crown of dystrophic neurites. In very mild or mildly demented cases, higher densities of plaques may be observed in neocortical areas and also in subcortical structures such as basal ganglia. These amyloid deposits are mainly primitive plaques that are localized preferentially in the supragranular cortical layers. While neurodegeneration is evolving, amyloid deposits affect all cortical areas and many subcortical structures and are mainly mature plaques with a dense amyloid core and dystrophic neurites. The visual areas of the occipital cortex have relatively high SP densities (Price *et al*., 1991; Arriagada *et al*., 1992a; Bouras *et al*., 1994). Finally, it should be noted that the SP distribution is not as much consistent as the NFT regional and laminar pattern described earlier.

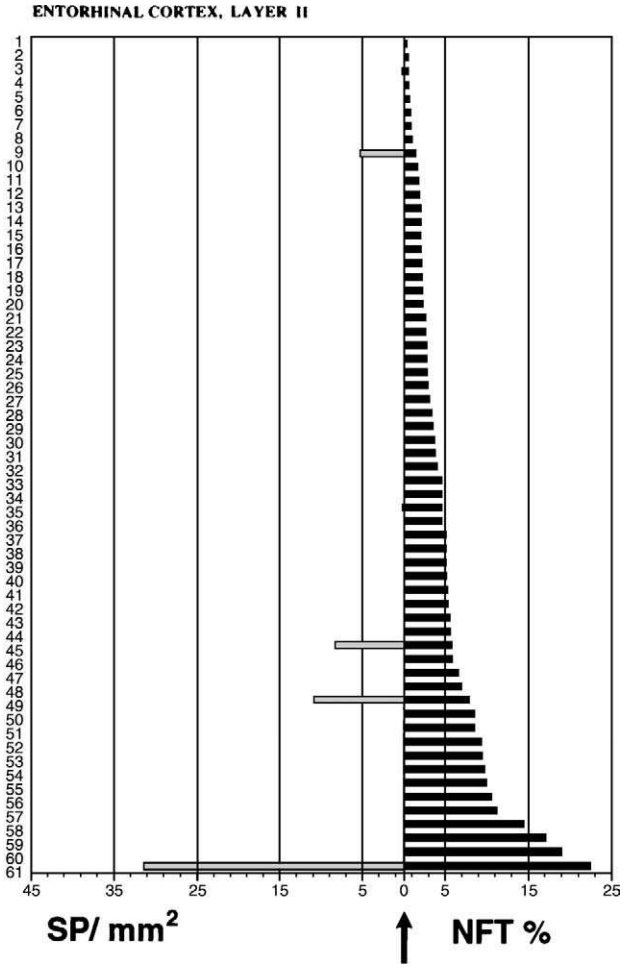

FIG. 7.1. Severity of pathologic changes in an unselected series of 61 elderly cases with no cognitive impairment (Bouras *et al*., 1993). NFT% is the proportion of neurons in layer II of the entorhinal cortex that contain a NFT (black bars at right). SP densities are shown at left and are far less prevalent. Note that all cases had at least a few NFT (cases are ordered by increasing NFT numbers).

II. Neuronal Loss in Normal Aging and AD

In addition to the amyloid deposition and NFT formation, neuronal loss also reflects the degenerative process that occurs in the brain of demented patients. Neuronal loss also takes place in the brain of patients with very mild cognitive impairment, and this pattern of minimal neuronal loss is well correlated with that of NFT distribution in the entorhinal cortex. Furthermore, the presence of more severe dementing symptoms is correlated with neuronal loss in hippocampal formation and neocortical regions (West *et al*., 1994; Gómez-Isla *et al*., 1996, 1997; Simic *et al*., 1997). Using a stereologic quantitative assessment of neuron numbers, Gómez-Isla and colleagues have compared the occurrence of neuronal loss in the entorh-

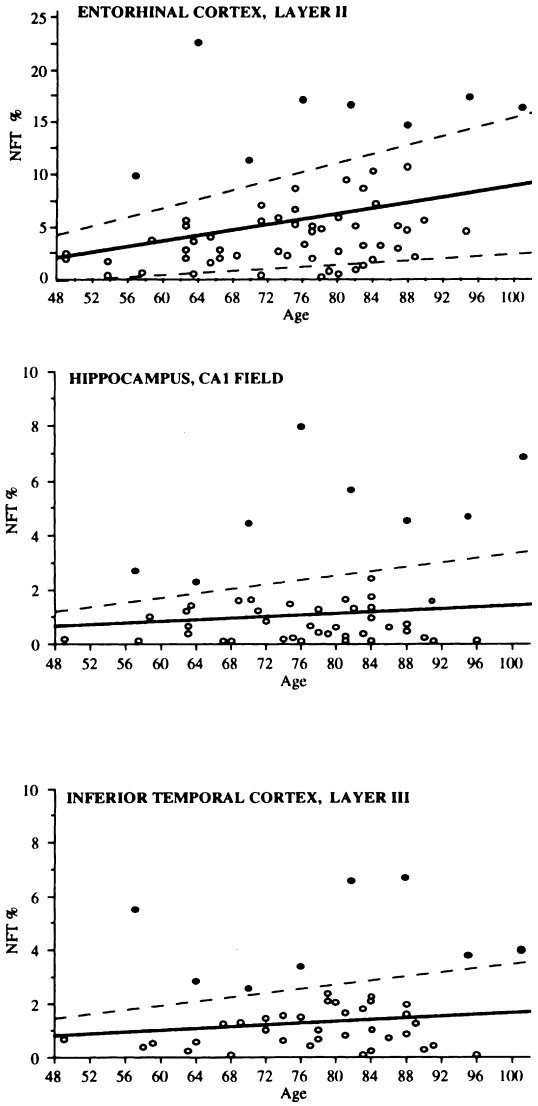

FIG. 7.2. Proportion of neurons containing an NFT in layer II of the entorhinal cortex, the CA1 field of the hippocampus, and layer III of area 20 (inferior temporal cortex) in the same population as in Fig. 7.1. There is a weak positive correlation with the age of the patients in the entorhinal cortex. Interestingly, in all three regions the same eight cases exhibit higher NFT numbers than the rest of the group (the dashed lines correspond to 1 SD of the data). These eight cases may represent individuals at higher risk to develop overt AD (Bouras *et al*., 1993).

inal cortex in subjects with different cognitive status. In the first group of cognitively normal subjects, with a clinical dementia rating (CDR) score of 0, there is no variation of the total number of neurons or neuronal densities in any layer of the entorhinal cortex between the sixth and ninth decades. Brains from patients diagnosed with very mild AD (CDR of 0.5) may show a quite extensive loss of neurons in the entorhinal cortex, especially in layers II and IV where the number of neurons is decreased by 57% in layer II and by 41% in layer IV compared with controls. Other layers of entorhinal cortex are also affected, but to a lesser extent. Finally, in severe AD cases (CDR of 3 or higher), 87% of the neurons in layer II and 69% in layer IV of the entorhinal cortex are missing, with many presumably having degenerated to end-stage NFT (Gómez-Isla *et al*., 1996). A similar stereologic study performed in our laboratory indicates that a significant neuronal loss is seen for CDR 2 cases, which seems to be a pivotal stage in the neurodegenerative process (Fig. 7.3) (Bussière *et al*., 1999b; Hof *et al*., 1999b). These two studies take into account small populations and cannot overcome the neuropathological interindividual variation. This fact might explain the discrepancy between the two studies. Nevertheless, these data suggest that a marked neuronal loss in layer II of entorhinal cortex distinguishes very mild AD from nondemented aging. Similarly, stereologic estimates of neuronal loss in the different parts of the hippocampal formation have been reported in different studies, leading to controversial data (West *et al*., 1994; Simic *et al*., 1997). In fact, the work performed by West and colleagues indicates a quantitative and qualitative difference in the regional pattern of neuronal loss between normal aging and AD. Losses in the hilus and subiculum are, respectively, 37 and 43% over the ages studied (13 to 101 years), and these hippocampal subdivisions also exhibit an AD-related neuronal loss. The major point raised by this study is the absence of evidence of neuronal loss in the CA1 field in normal aging cases, while this latter area displays the most important neuronal loss in AD. An average of 68% of neurons is lost compared to an age-matched control group (Fig. 7.4) (West *et al*., 1994). Even though data obtained by Simic and colleagues show a similar magnitude of neuron numbers in the different regions of hippocampal formation, they are conflicting with those reported by West (Simic *et al*., 1997). These authors described a significant negative regression between age and neuron numbers in CA1 and subiculum (loss of 67 and 32%, respectively), but not in other subdivisions, especially in the hilus, as described previously. In addition, neuronal loss restricted to certain regions of the CA1 field is reported as an almost constant feature of normal older brains. Furthermore, neuronal loss assessment in the CA1 of AD cases does not appear as significantly differ-

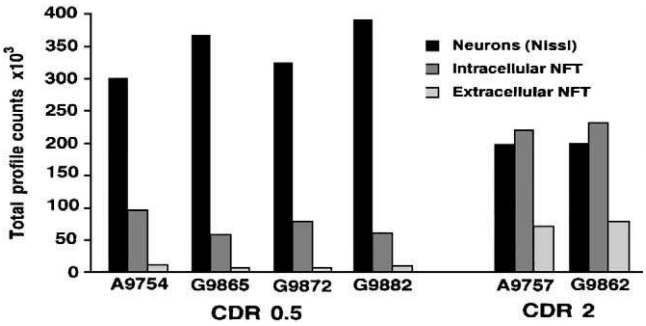

FIG. 7.3. Total number of neurons in layer II of the entorhinal cortex in CDR 0.5 and CDR 2 cases. Neuron counts were obtained stereologically and have been subdivided into normal neurons revealed by Nissl stain, neurons containing an intracellular NFT (i.e., a Nissl-stained cell labeled with an antibody to hyperphosphorylated tau protein), and extracellular ghost NFT. Note that a significant proportion of the neurons demonstrate transitional pathology in CDR 0.5 cases, but that the majority remains unaffected by NFT formation. However, in CDR 2 cases, the majority of neurons has progressed to NFT formation, as revealed by the higher proportion of intra- and extracellular NFT (Bussière *et al*., 1999b).

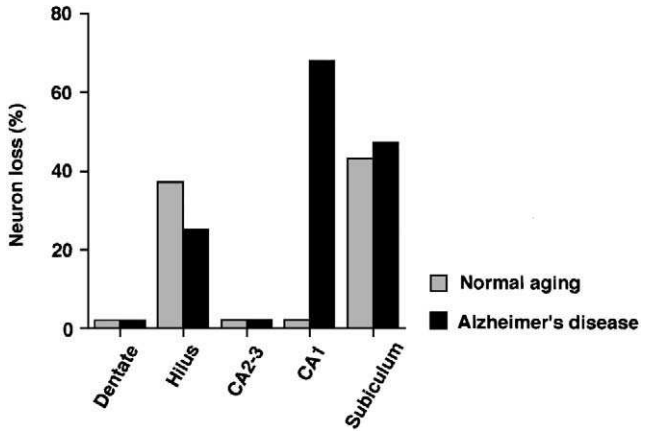

FIG. 7.4. Percentage of neuronal loss in the various subfields of hippocampal formation in normal aging and AD based on stereologic data of West *et al*. (1994). This study revealed that if a large enough population is analyzed to circumvent the problem of interindividual variability in neuronal numbers, the neurons in the hilus of the dentate gyrus and the pyramidal neurons of the subiculum are affected as severely in cognitively normal patients as in AD cases.

ent when compared to an age-matched control group, and a pronounced neuronal loss is found only in the subiculum and the dentate gyrus. Once again, the substantial anatomical variability that exists among individual human brains may explain the discrepancy. New studies including larger populations are needed to overcome the problem of interindividual heterogeneity. In this context, the stereological approach represents a powerful way to analyze the transitional state between normal aging and pathological degeneration concomitant to early AD, with the ultimate goal of such studies being to determine if neurodegeneration in AD and aging involves different processes.

III. Dynamic Neuronal Changes during Aging and AD

Existing stereologic data on the neuronal alterations in AD consist almost exclusively of total neuron counts based on the Nissl stain or of NFT counts. Both of these measurements may be misleading because they do not take into account a large and dynamic population of transitional alterations that can be identified by several neurochemical markers, such as neurofilament proteins or modified tau proteins (Morrison and Hof, 1997; Vickers, 1997; Vickers *et al*., 2000). In addition, most available studies do not take into consideration the very high variability in neuron numbers that exists among human brains and generally do not provide accurate estimates of numbers in cytoarchitecturally defined regions in the neocortex or rely on density measurements. In order to provide a more accurate reflection of the dynamic changes occurring in certain subpopulations of vulnerable neurons during aging and in the course of AD, detailed stereological analyses of several cell morphologic parameters are needed that will underline the progressive cellular pathology leading to the selective neuronal loss. These indices of cellular degeneration are investigated in correlation with specific neuropsychological measures assessing the cognitive status of the cases. Such immunohistochemical studies will permit subdividing the neuronal profiles in a manner directly relevant to the degenerative process at a much finer level of resolution than a Nissl-based quantification of total cell loss alone (Bussière *et al*., 1999b; Hof *et al*., 1999b).

Stereological measurements of pyramidal neurons containing neurofilament proteins in the superior frontal cortex may represent reliable indices to follow the progressive cellular pathology. Neurofilament as well as other cytoskeletal proteins have been implicated in NFT formation (Ksiezak-Reding *et al*., 1987; Morrison *et al*., 1987; Zhang *et al*., 1989; Vickers *et al*., 1992, 1994; Trojanowski *et al*., 1993; Morrison and Hof, 1997; Hof and Morrison, 1999), and pyramidal cells with a high content of nonphosphorylated neurofilament protein emerge as a neuron type highly susceptible to NFT formation (see Chapter 9). The laminar distribution of this subset of neurons in visual association, prefrontal, and anterior cingulate human cerebral cortices is very similar to the distribution of NFT, and the layers that have high NFT density in an AD brain also display a high density of neurofilament protein-immunoreactive neurons (Hof and Morrison, 1990, 1999; Hof *et al*., 1990, 1999b). Pyramidal neurons of the subiculum and hippocampal formation, especially layers II, III, and V of entorhinal cortex, exhibit the same profile, having a very high density of neurofilament protein-immunoreactive neurons in the normally aging human brain and presenting with a dramatic loss of these neurons in AD (Fig. 7.5, see color insert) (Vickers *et al*., 1992; 1994; Morrison and Hof, 1997). The most recent data obtained indicate that in area 9, neurofilament protein-containing pyramidal cells already undergo notable neuronal loss in CDR 2 cases, whereas a more dramatic loss of neurons overall occurs in CDR 3 cases. Accordingly, this result suggests that CDR 2 may be considered as the clinical transition stage at which considerable development of AD degenerative changes takes place in the prefrontal cortex.

IV. Neuronal Loss and Early Markers of Neuronal Degeneration

The hypothesis that considers CDR 2 stage as pivotal in the development of the neurodegenerative process is supported by quantitative analyses of early markers of the neurodegeneration, such as calpain immunoreactivity or modified tau proteins (Morrison and Hof, 1997; Gimmel *et al*., 1998; Perl *et al*., 1998; Bussière *et al*., 1999b; Hof *et al*., 1999b). Calpains constitute a family of ubiquitous calcium-dependent cysteine proteases and occur in the brain as two isoenzymes, μcalpain and mcalpain, which require micromolar or millimolar calcium concentrations, respectively, for activation *in vitro*. Calpains are involved in selective proteolytic cleavages and in the regulation of structure and dynamics of major cytoskeletal proteins that are also constituents of NFT, such as neurofilament proteins or tau proteins (Nixon *et al*., 1994; Suzuki *et al*., 1995). Pathological modifications of tau proteins, such as abnormal phosphorylation, may reduce their susceptibility to calpain-mediated proteolysis and subsequently lead to their accumulation into PHF. Finally, a direct and extensive associa-

tion of μ- or mcalpain with neurofibrillary pathology and its early involvement in the cytoskeletal disorganization and degeneration of neurons in AD has been reported (Iwamoto *et al.*, 1991; Grynspan *et al.*, 1997). Some early biochemical changes of tau proteins also constitute reliable indices of the degenerative process that occurs in neurons. Thus, the intramolecular association between the amino-terminal end and the third microtubule-binding domain of tau proteins results in a specific conformation, and the appearance of this conformation seems to precede the pathological aggregation of tau proteins into PHF and the resultant neurofibrillary degeneration. The MC1 and Alz-50 monoclonal antibodies are useful to pursue such early pathological modifications (Jicha *et al.*, 1997, 1999). TG3 is another antibody of interest to analyze early modifications of neuronal cytoskeleton, as it recognizes simultaneously the previously described altered conformation and a phosphorylated epitope of tau proteins (Vincent *et al.*, 1996; Jicha *et al.*, 1997). Previous studies realized at light and electron microscopic levels with MC1 and TG3 antibodies reveal that MC1 staining appears earlier than the TG3 staining in hippocampal CA1 neurons, suggesting that the conformational changes in tau proteins may precede the accumulation of hyperphosphorylated proteins (Anderton *et al.*, 1998).

A stereologic approach taking into account the total number of neuronal cells, indicated by the Nissl stain, as well as by the number of NFT at different stages of development, is an efficient procedure to describe the dynamic and transitional modifications that occur during aging and neurodegenerative diseases. Preliminary studies using this stereologic design have been reported (Bussière *et al.*, 1999b; Hof *et al.*, 1999b). A small number of brains from patients with different cognitive status (CDR scores ranging between 0–0.5 and 3) have been investigated for early markers of pathology revealing intracellular NFT (mcalpain and tau proteins with the MC1 epitope; Grynspan *et al.*, 1997; Jicha *et al.*, 1997, 1999) and for hyperphosphorylated tau proteins revealing extracellular NFT (AD2 or 988; Buée-Scherrer *et al.*, 1996; Bussière *et al.*, 1999a). Preliminary evidence from layer II of the entorhinal cortex and from layers III and V of area 9 suggests that the early stages of degeneration (CDR scores of 0–0.5) involve primarily the formation of neuritic changes (Fig. 7.6). Numerous dystrophic neurites show immunoreactivity for μcalpain and the MC1 epitope, but are not double labeled by antibodies AD2 or 988. Furthermore, this is observed first in the entorhinal cortex and occurs only at later stages (CDR 2) in the prefrontal cortex. Degeneration takes place secondarily in neuronal perikarya, which may represent a transitional stage prior to the final evolution of the lesion to an extracellular NFT. Moreover, the stereologic determination of the number of NFT-free cells and NFT-bearing cells in the entorhinal cortex and its relationship to the cognitive status of the cases confirm that CDR 2 represents a pivotal stage in the neurodegenerative process and subsequent neuronal loss. With respect to CDR 0 and 0.5 cases, moderate numbers of intracellular NFT are observed, whereas extracellular NFT are rare. The total number of neurons is not decreased significantly in these cases (Figs. 7.3 and 7.5). Neurofibrillary pathology becomes predominant in CDR 2 cases, with a severe increase of intracellular and extracellular NFT, whereas the total number of neurons is decreased dramatically (Bussière *et al.*, 1999b; Hof *et al.*, 1999b).

V. Synapse Loss

In addition to the classical neuropathological lesions and to the neuronal loss described previously, synapse loss is also involved in normal aging and in the pathogenesis of AD.

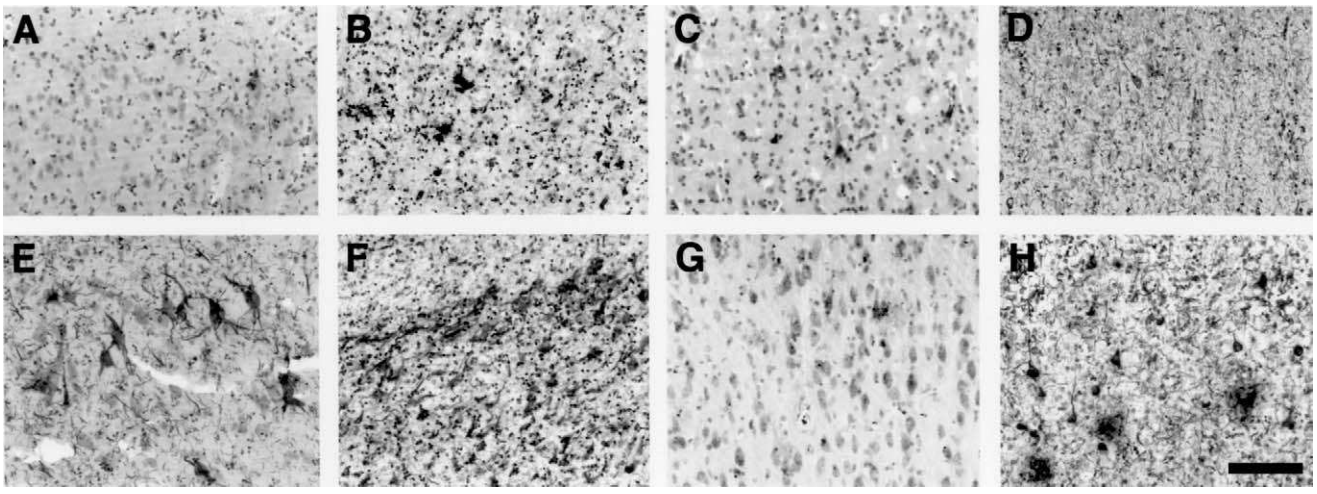

FIG. 7.6. Development of neurofibrillary changes labeled by antibodies MC1 (A–D) and AD2 (E–H) in layer II of the entorhinal cortex (A, B, E, and F) and layer III of area 9 (C, D, G, and H). For both regions each pair of photomicrographs shows a CDR 0.5 case on the left and a CDR 3 on the right. Note the parallel increase in immunoreactive profiles for these markers with disease severity. In CDR 3 cases, there is overall more profiles labeled with antibody AD2 to hyperphosphorylated tau. In CDR 0.5 cases, MC1 labels preferentially thin neurites, which may represent the earliest stage of neurofibrillary degeneration. As demonstrated previously for hyperphosphorylated tau, the pathologic changes identified with MC1 appear at later stages of the disease in the prefrontal cortex, with densities at CDR 3 that are comparable to those observed in CDR 0.5–1 cases in the entorhinal cortex. Scale bar (on H): 100 μm.

Moreover, the correlation between synapse loss and the severity of dementia assessed by the Mini Mental State or Blessed score has been shown to be stronger than the correlation with the distribution and density of NFT (DeKosky and Scheff, 1990; Terry *et al*., 1991; Sze *et al*., 1997). The quantification of synaptophysin immunoreactivity, reflecting presynaptic terminal densities, has been used by Masliah and colleagues to evaluate synaptic loss in the frontal cortex of individuals without dementia. These authors reported a significant decrease in synaptophysin immunoreactivity, with an average of 20% after 60 years of age compared to younger individuals (Masliah *et al*., 1993). Furthermore, immunochemical and immunohistochemical analyses have shown that synaptic loss is even more pronounced in AD brains, with the frontal and parietal cortices presenting the most severe and widespread loss (45%) (Fig. 7.7, see color insert; Masliah *et al*., 1991, 1993). Similarly, ultrastructural studies revealed that the number of synapses in layers III and V of Brodmann's area 9 is decreased significantly in brains from patients with mild to moderate AD compared to the number in age-matched control brains. A negative correlation has also been shown between the decrease in synapse numbers and the enlargement of postsynaptic densities, suggesting a compensatory mechanism that allows for the total synaptic contact area to remain stable (DeKosky and Scheff, 1990; Scheff *et al*., 1990). These data indicate that synaptic loss occurs in physiological conditions during aging, but to a lesser extent than in AD, and might be compensated by an increase in synaptic contact area. In AD, this compensatory process is inefficient and the decline in both synaptic number and synaptic contact area leads to the disconnection of corticocortical pathways.

VI. Conclusion

Even in elderly subjects with clinically intact intellectual functions, AD-related neuropathologic changes are a common finding. In particular, layer II of the entorhinal cortex is always affected by the neurofibrillary degeneration. Severe involvement of neocortical association areas results in the degeneration of corticocortical circuits and is required for the clinical expression of the dementia. Thus, the key to dementia may reside in the mechanisms by which pathological changes that are relatively limited to the hippocampal formation at early stages of the disease begin to involve neocortical circuits (Morrison and Hof, 1997), thereby differentiating the memory defects associated with normal aging (also known as ''benign senescent forgetfulness'') from the more generalized memory and cognitive deficits that characterize dementing disorders. Importantly, these observations imply that elderly individuals can maintain a high level of cognitive performance while sustaining a significant compromise of hippocampal circuits and that they may rely more on neocortical than on hippocampal circuits for memories essential for daily activities. It is worth mentioning that in terms of cognitive performance, healthy elders may describe difficulties in learning and retrieving new information, although in reality, the problem lies in the amount of information that one such individual can learn within a given period of time in comparison to younger subjects. The major difference with early AD patients is that after a delay, healthy elders will have retained the new information, whereas patients with very mild impairment retain little of the new information (Albert, 1996). Thus, the relatively minor cellular changes associated with normal brain aging are likely to be sufficient to cause the learning deficits experienced by healthy elders. It will be important to gain knowledge on the morphologic and molecular phenotype of the neurons affected by these minimal changes to understand the mechanisms of normal aging and develop therapeutic interventions to protect the vulnerable neuronal circuits.

Acknowledgments

We thank Dr. J. H. Morrison, D. P. Perl, P. Giannakopoulos, C. Bouras, P. Davies, and R.A. Nixon for helpful discussion. B. Wicinski, G.I. Lin, and A.P. Leonard provided expert technical assistance. Supported by NIH Grants AG02219 and AG05138 and by the Philippe Foundation.

Longevity and Brain Aging: The Paradigm of Centenarians

The exponential increase in the prevalence of Alzheimer's disease with age, as well as the consistent presence of Alzheimer's disease pathologic changes in elderly people, has induced much debate regarding the relationships between brain aging and Alzheimer's disease. In this context, the study of nonagenarians and centenarians is of particular interest because it allows one to define the spectrum and extent of changes in brain morphology that occur near the upper age limit of life and to assess whether Alzheimer's disease is on a continuum with normal brain aging. The epidemiological and neuropathological evidence summarized in this chapter supports that Alzheimer's disease is an age-related pathologic condition, which does not represent an inevitable consequence of ageing. Moreover, it suggests the presence of a particular subgroup of oldest-old individuals with high resistance to the neurodegenerative process. These observations are discussed within the theoretical framework of human longevity.

I. Introduction

The continued expansion of the elderly population and a growing awareness of age-related diseases such as dementia have prompted considerable interest in the study of the aging human brian. The aging population is rapidly growing as a result of increased accessibility of advanced medical technology and declining birth rates. By 2020 it is estimated that at least 1 billion people will be older than 60 years, representing more than 20% of the total population. The few individuals who reach very old ages are called ''longevity outliers.'' This particular group survives to challenge today's maximum of 121 years (Smith, 1997).

From a neurobiological point of view, the study of oldest-old individuals may permit to define the spectrum and extent of changes in brain morphology that occur with normal brain aging and to assess correlations between the neuropathological definition of normal brain aging and the clinical development of dementing process (Mizutani and Shimada, 1992; Giannakopoulos *et al*., 1993; Green *et al*., 2000). The increase in the number of elderly people in the general population is accompanied by high prevalence and incidence rates of Alzheimer's disease (AD), and several community-based studies of AD epidemiology have suggested that the number of affected nonagenarians and centenarians may rise steadily in the next decade (Moss and Albert, 1988; Brayne, 1991; Hofman *et al*., 1991; Evans *et al*., 1992). Whether or not AD is on a continuum with normal brain aging is thus a major public health issue. After some epidemiological and clinical considerations, this chapter summarizes the neuropathological features of nonagenarians and centenarians with particular reference to the patterns of cerebral cortex pathology in this age group and discusses their relevance with respect to the dichotomy between AD and brain aging.

II. Epidemiological Data

The increase in the number of centenarians can be, at least partly, the consequence of the demographic transition and high quality of medical care provided for the elderly (Larkin, 1999). Methodologically, census data are preferred over sample data in very old cohorts because of their completeness and the absence of sampling errors. Several census studies have revealed an exponential increase in the number of centenarians (Beregi, 1987; IPSEN Foundation, 1990; Manton and Vaupel, 1995; Perls, 1995; Asada *et al*., 1996; Geneva, 1998; Wilkinson and Sainsbury, 1998; Larkin, 1999) (Fig. 8.1, see color insert). For instance, in France there were 2104 centenarians in 1985, 3853 in 1990 (6.9 per 100,000), 3232 in 1995, and 4968 are expected in 2005 and 8201 in 2025 (13.7 per 100,000) (IPSEN Foundation, 1990; Larkin, 1999). At the time of the last census in 1990, the state of Geneva in Switzerland had 38 centenarians among its 383,000 inhabitants, which corresponds to a prevalence of 9.9 per 100,000; in 1997 there were 60 for 400,860 inhabitants (15.0 per 100,000), which

represents a 50% increase in 7 years (Geneva, 1998), Wilkinson provided data on 297 centenarians in New Zealand in 1990, giving a prevalence of 8.8 per 100,000 inhabitants, and compared these data to the 15.0 centenarians per 100,000 inhabitants in the United States population in 1990 (Wilkinson and Sainsbury, 1998). In 1987, there were 218 living centenarians in Hungary for a population of a little over 10 millions (Beregi, 1987). In the United States, there is to date almost 70,000 centenarians and between 500,000 and 4 millions are expected to be living in 2050 (Perls, 1995). A well-known paradox is the higher proportion of centenarians in the African American community (19.6 per 100,000) with a higher life expectancy after the age of 85, despite a lower life expectancy at birth (Manton and Vaupel, 1995; Perls, 1997; Wilkinson and Sainsbury, 1998). The validity of data pertaining to U.S. African Americans obtained from the census has been criticized, but has been confirmed through other sources, such as Medicare data (Manton and Vaupel, 1995). Importantly, the survival rate of siblings of centenarians in the United States is higher than in a control population of the same birth cohort who died around their 75 years, thus underlying the role of heredity to reach an advanced age (Perls *et al*., 1998). Finally, in Japan, 5593 centenarians were living in 1994 (4.5 per 100,000), with a prefectural prevalence rate ranging from 1.9 to 18.5 (Asada *et al*., 1996).

The growing evidence for a steady increase in the number of centenarians worldwide is paralleled by several studies aiming to determine possible psychobiological particularities of these individuals. For instance, centenarians were less prone to oxidative stress and are thought to have better antioxidant defenses, nutritional status, immunological profile, and endocrinological and metabolic characteristics than younger elderly cohorts (Paolisso *et al*., 1998). Psychologically, they report greater satisfaction with life and social and family relations and display lower scores for anxiety and depression and better coping abilities compared to younger elderly individuals (Dello Buono *et al*., 1998). In this age group, good health and not moving home are associated with greater intellectual activity, whereas extraversion and negative life events are associated with greater social activity (Hilleras *et al*., 1999). Moreover, an autopsy study of 490 very old individuals revealed that the frequency of cardiac causes of death decreases after 80 years with a parallel increase of noncardiac, nonvascular causes (Roberts and Shirani, 1998). Also the proportion of death in patients with cancer decreases from 83% in those diagnosed in their six decade to 49% in centenarians. A very large cancer registry study, including more than 14,000 cases, showed that colorectal cancer becomes the most common localization after the age of 90 (21%), whereas this rank is occupied by lung cancer before this age (Saltzstein *et al*., 1998). Altogether, these data support the possibility that centenarians form a select cohort with relatively slow rates of aging and increased resistance to biological and psychological stress and age-related diseases such as cancer, stroke, and heart disease (Perls, 1995, 1997; Perls *et al*., 1998).

III. Dementia in the Oldest-Old

Although prevalence and incidence data are still scarce in this age group, it has long been considered that very old age is associated with the highest prevalence of dementia (Schneider, 1999). Several earlier studies reported an increased prevalence of dementia with aging, to 100% in the 100-year age group (Adolfsson, 1986; Gottfries, 1986; Bohl *et al*., 1987). Methodological biases were present in most of these studies and limit the validity of their conclusions. First, the samples included only a limited number of nonagenarians and centenarians. Second, the clinical diagnosis of dementia made by the physician was based on the global decline of cognitive performances rather than on a detailed analysis of each cognitive function, leading to an overestimation of the prevalence of dementia in the oldest-old. In fact, epidemiological studies in larger cohorts of very old individuals showed prevalence rates that varied from 27 to 70% (Asada *et al*., 1996; Samuelsson *et al*., 1997), and Ritchie and Kildea (1995), in their meta-analysis of numerous previous studies, demonstrated that the prevalence of dementia levels off at age 95, reaching only 40%. In an epidemiological survey of 1694 patients who met criteria for probable or definite AD, Lautenschlager and colleagues (1996) also reported that the risk of AD decreases significantly after age 90. Similar results were drawn by a community-based study of 402 individuals older than 85 years who had been assessed using structured interviews in Munich (Fichter *et al*., 1995), A relative resistance of centenarians to the degenerative process is also suggested by the observations of Howieson and collaborators (1997), who performed a longitudinal study of 31 nondemented individuals older than 80 years and reported a preservation of cognitive abilities during a follow-up period of 5 years. Furthermore, a lack of association between AD and apolipoprotein E allele $\epsilon 4$, a major risk factor for late-onset AD in younger cohorts, has been demonstrated in centenarians (Rebeck *et al*., 1994; Schachter *et al*., 1994; Sobel *et al*., 1995; Asada *et al*., 1996). However, one may argue that these epidemiological findings reflect only the fact that younger cohorts are at higher risk to develop AD and do not necessarily support differential neuronal aging in centenarians.

IV. Neuropathological Changes in the Oldest-Old: Relationship to AD

A major but yet unanswered question is whether AD is on a continuum with normal brain aging. In this respect, it is of particular interest to define the final stages of normal brain aging and neuropathological characteristics of AD in the ''oldest-old'' population (Hauw *et al*., 1986; Mizutani and Shimada, 1990, 1992; Delaère *et al*., 1993; Giannakopoulos *et al*., 1993, 1994b,c, 1995, 1996, 1997). Brain aging is characterized by the formation of neurofibrillary tangles (NFT) and senile plaques (SP), as well as neuronal and synaptic loss in both cognitively intact individuals and patients with AD (Mountjoy *et al*., 1983; Braak and Braak, 1991; Arriagada *et al*., 1992b; Masliah *et al*., 1992; Bouras *et al*., 1994; Bierer *et al*., 1995). In nondemented cases, NFT are usually restricted to the hippocampal formation, whereas the progressive involvement of the association areas in the temporal neocortex parallels the development of overt clinical signs of dementia (Arnold *et al*., 1991; Arriagada *et al*., 1992b; Hof *et al*., 1992; Bouras *et al*., 1993, 1994; Giannakopoulos *et al*., 1994b; Bierer *et al*., 1995). In contrast, severe SP formation may take place in several neocortical

areas in the presence of very mild cognitive impairment (Morris *et al*., 1991, 1996), and there is no correlation between the quantitative distribution of SP and the severity of AD (Crystal *et al*., 1988; Arnold *et al*., 1991; Dickson *et al*., 1991; Price *et al*., 1991; Arriagada *et al*., 1992b; Hof *et al*., 1992; Bouras *et al*., 1994; Giannakopoulos *et al*., 1994b). With regard to neuronal loss, stereological analyses have revealed age-related decreases in total neuron number of 30 and 50% in the dentate hilus of the hippocampus and subiculum, respectively, between ages 13 and 85. Conversely, no neuronal loss was found in CA1–3 fields and entorhinal cortex where AD lesions are also observed (West, 1993; West *et al*., 1994; Gómez-Isla *et al*., 1996). These studies also showed that in AD, there is an additional depletion of neuronal cell bodies in the dentate hilus and subiculum, as well as a massive reduction in the numbers of pyramidal neurons in the CA1 field and layers II and V of the entorhinal cortex (West, 1993; O'Banion *et al*., 1994; West *et al*., 1994; Gómez-Isla *et al*., 1996). Moreover, earlier and recent studies have shown a neuronal reduction in temporal, inferior, and superior parietal and frontal cortices of AD cases (Lippa *et al*., 1992; O'Banion *et al*., 1994). Does the pattern of lesion distribution and neuronal loss change in extreme aging? To address this question, we performed several neuropathological analyses of a large cohort of prospectively assessed nonagenarians and centenarians who died and were autopsied at the geriatric or psychiatric hospitals of the University of Geneva during the years 1976–1993 (Giannakopoulos *et al*., 1993, 1994a, 1995, 1996, 1997). The results of these studies, as well as previous and recent contributions in this field, are discussed in the following paragraphs.

A first observation is that among centenarians there is a limited number of cognitively intact individuals who display low NFT densities confined to the hippocampal formation and rare neocortical diffuse SP (Karasawa and Goto, 1985; Mizutani and Shimada, 1992; Giannakopoulos *et al*., 1993; Green *et al*., 2000). These individuals, also called "supernormal centenarians," represent a rare phenotype relatively protected from AD pathology and may be thus an exemple of successful aging near the upper age limit of life. Two additional findings should be mentioned. First, centenarians display only mild synaptic loss and cerebral amyloid angiopathy compared to younger individuals (Itoh *et al*., 1998). Second, very old people with AD show a marked decrease in NFT densities in the subiculum, entorhinal cortex, and neocortical areas compared to younger cases with the same clinical diagnosis (Giannakopoulos *et al*., 1993; Green *et al*., 2000). These observations indicate that the occurrence and progression of AD-related pathologic changes are not a necessary concomitant of brain aging.

Generally, the regional patterns of NFT and SP distribution in nondemented centenarians did not differ from that reported by Braak and Braak as well as other investigators in younger subjects (Bouras *et al*., 1993, 1994; Giannakopoulos *et al*., 1994b). However, in contrast to previous observations in younger cohorts (Hof *et al*., 1992), there was a frequent involvement of areas 22, 23, and 24 in intellectually preserved centenarians, suggesting the presence of a differential cortical vulnerability to NFT after 90 years. This hypothesis has been confirmed by our quantitative analysis, which revealed several particularities in the distribution of AD lesions in this age group. For instance, the anterior, but not the posterior, CA1 field of the hippocampus showed significantly higher NFT densities in AD compared to nondemented centenarians (Table 8.1). This implies that the massive NFT formation in the anterior part of the Ammon's horn may be a crucial step in the development of AD symptomatology in this age group, whereas the posterior part of this area can be affected severely without compromise of the higher cortical functions. In contrast to previous findings in younger AD cases (Bouras *et al*., 1994), NFT densities in the entorhinal cortex were comparable between demented and nondemented centenarians. In areas 7, 22, 23, and 24, AD cases displayed significantly higher NFT densities compared to nondemented cases, whereas no signifi-

[a]Results represent NFT counts/mm^2 (± SEM) in each area. The mean age of each group is indicated in parentheses. Statistical analysis was performed by analysis of covariance controlling for age at death. Ant CA1, anterior part of the CA1 field; Post CA1, posterior part of the CA1 field; NBM, nucleus basalis of Meynert; LC, locus coeruleus. Layers are indicated by Roman numerals. ns, not statistically significant (adapted from Giannakopoulos *et al*., 1995).

cant difference was observed in NFT densities in areas 9 and 20, as well as in areas 17 and 18 between AD and nondemented cases. Interestingly, when a distinction between cognitively intact cases and cases with age-associated memory impairment included in the nondemented group was made, an association between substantial NFT formation in layers V–VI of area 20 and age-associated memory impairment was found (Giannakopoulos *et al*., 1996, 1997). In the subcortical nuclei, a statistically significant difference in NFT counts between nondemented and AD cases was observed in the nucleus basalis of Meynert, but not in the locus coeruleus and amygdala (Table 8.1). These data indicate that the regional patterns of cytoskeletal pathology differ in several aspects among centenarians and younger subjects. First, the apparent progression of NFT formation from the hippocampus to the temporal neocortex may play a less important role in the clinical expression of AD in centenarians compared to younger patients in whom it has been associated with overt dementia symptomatology (Hof *et al*., 1992; Bouras *et al*., 1994; Giannakopoulos *et al*., 1994b). Although the involvement of area 20 may account for age-associated memory impairment in this age group, overt clinical signs of AD in oldest-old individuals require both high NFT densities in the CA1 field and progressive damage of areas 7, 22, 23, and 24, which are spared in most of the cases at the early stages of the dementing process (Hof *et al*., 1992; Giannakopoulos *et al*., 1996). This distribution of NFT can be regarded as a displacement of these lesions, such that parietal and cingulate areas are more affected than is usually the case in AD, whereas superior frontal and inferior temporal association areas are relatively preserved.

The severe damage of the anterior and posterior cingulate cortex in AD centenarians could be associated with a particular clinical course of the disease in this age group. It is well documented in experimental animals that this region participates in the acquisition and performance of active avoidance and spatial memory tasks, as well as in attentional processing (Watson *et al*., 1973; Gabriel *et al*., 1980; Sutherland *et al*., 1988; Matsunami *et al*., 1989). Pardo and collaborators (1990) found that the performance of the Stroop color/word test results on a selective activation of the anterior cingulate cortex and proposed that the selection and recruitment of processing centers appropriate for task execution may depend on the integrity of this area. Moreover, the anterior cingulate cortex possesses motor areas connected in a somatotopic fashion to the primary motor cortex and is involved in the integration of complex somatic and visceral activities (Morecraft and Van Hoesen, 1992; Nimchinsky *et al*., 1996). The posterior cingulate cortex is involved in triggering appropriate motor responses to specific visuomotor stimuli (Vogt *et al*., 1990; Olson and Musil, 1992; Olson *et al*., 1993). Detailed neuropsychological testing is needed to define if these cortical functions are preferentially compromised in AD centenarians.

Another particularity of the centenarian brain resides in the laminar distribution of NFT and SP within the cerebral cortex (Fig. 8.2). Several lines of evidence suggest that the long corticocortical projection system is likely to degenerate in the course of AD, evolving to a syndrome of cortical disconnection (Pearson *et al*., 1985; Lewis *et al*., 1987; Hof *et al*., 1990; Hof and Morrison, 1990). Higher NFT densities generally observed in layers V and VI than in superficial layers of association cortices indicate that feedback and lateral corticocortical projections are affected predominantly by the degenerative process in younger AD cases (Pearson *et al*., 1985; Lewis *et al*., 1987; Hof *et al*., 1990; Hof and Morrison, 1990). In contrast, the preferential localization of NFT in layers II and III in the neocortex of demented and nondemented centenarians suggests that the feedforward corticocortical projections that are furnished principally by layer III neurons are damaged early in very old patients (Pearson *et al*., 1985; Lewis *et al*., 1987; Hof *et al*., 1990; Giannakopoulos *et al*., 1994a, 1995, 1996).

With regard to SP, several studies of centenarians indicate that there is no relationship between their formation in the neocortex and the early stages of the dementing process, as is the case in younger populations (Delaère *et al*., 1993; Giannakopoulos *et al*., 1993). However, our evaluations of centenarians with severe AD, as well as longitudinal data of Green and collaborators (2000), demonstrated a clear correlation between SP densities in areas 7, 9, 20, 22, 23, and 24 and the severity of dementia (Table 8.2) (Giannakopoulos *et al*., 1994a, 1995, 1996). These findings differ from previous studies in younger demented and nondemented cases that reported a lack of correlation between the clinical severity of dementia and SP densities (Arriagada *et al*., 1992a,b; Berg *et al*., 1993; Bierer *et al*., 1995) and imply that SP formation may not be etiologically linked to the early stages of cognitive impairment but may represent a reliable pathological hallmark of severe AD in this age group.

V. Patterns of Neuronal Loss in the Centenarian Brain

On addition to these particularities in NFT and SP distribution, very old people show a differential pattern of neuronal loss within the cerebral cortex compared to younger cohorts (Giannakopoulos *et al*., 1996). Estimates of neuron densities are summarized in Table 8.3. After correction for differential cortical shrinkage, no statistically significant difference was found in neuron densities in the hippocampus, hilus of the dentate gyrus, and subiculum between nondemented and AD cases. In contrast, nondemented centenarians displayed significantly higher neuron densities in layers II and V of the entorhinal cortex and in layers II–III and V–VI of areas 9 and 20 compared to AD cases. In comparison to nondemented cases, AD cases showed a 30.8% neuronal loss in layer II and 17.8% in layer V of the entorhinal cortex, 26.7% in layers II–III and 27.5% in layers V–VI of area 20, and 5.1% in layers II-III and 8.3% in layers V–VI of area 9. No correlation was found between NFT and neuron densities in each area and among different cortical areas, whereas SP counts in layers II–III of area 20 were correlated negatively with neuron densities in layers II–III and layers V–VI of area 20. There was no correlation between SP densities and neuron numbers in other cortical areas. The negative correlation between SP and neuron densities in area 20 was further confirmed using a multiple regression model with neuron densities as the dependent variable and NFT and SP densities as independent variables.

The absence of AD-related neuronal loss in hippocampus fields and subiculum of centenarians differs from data showing

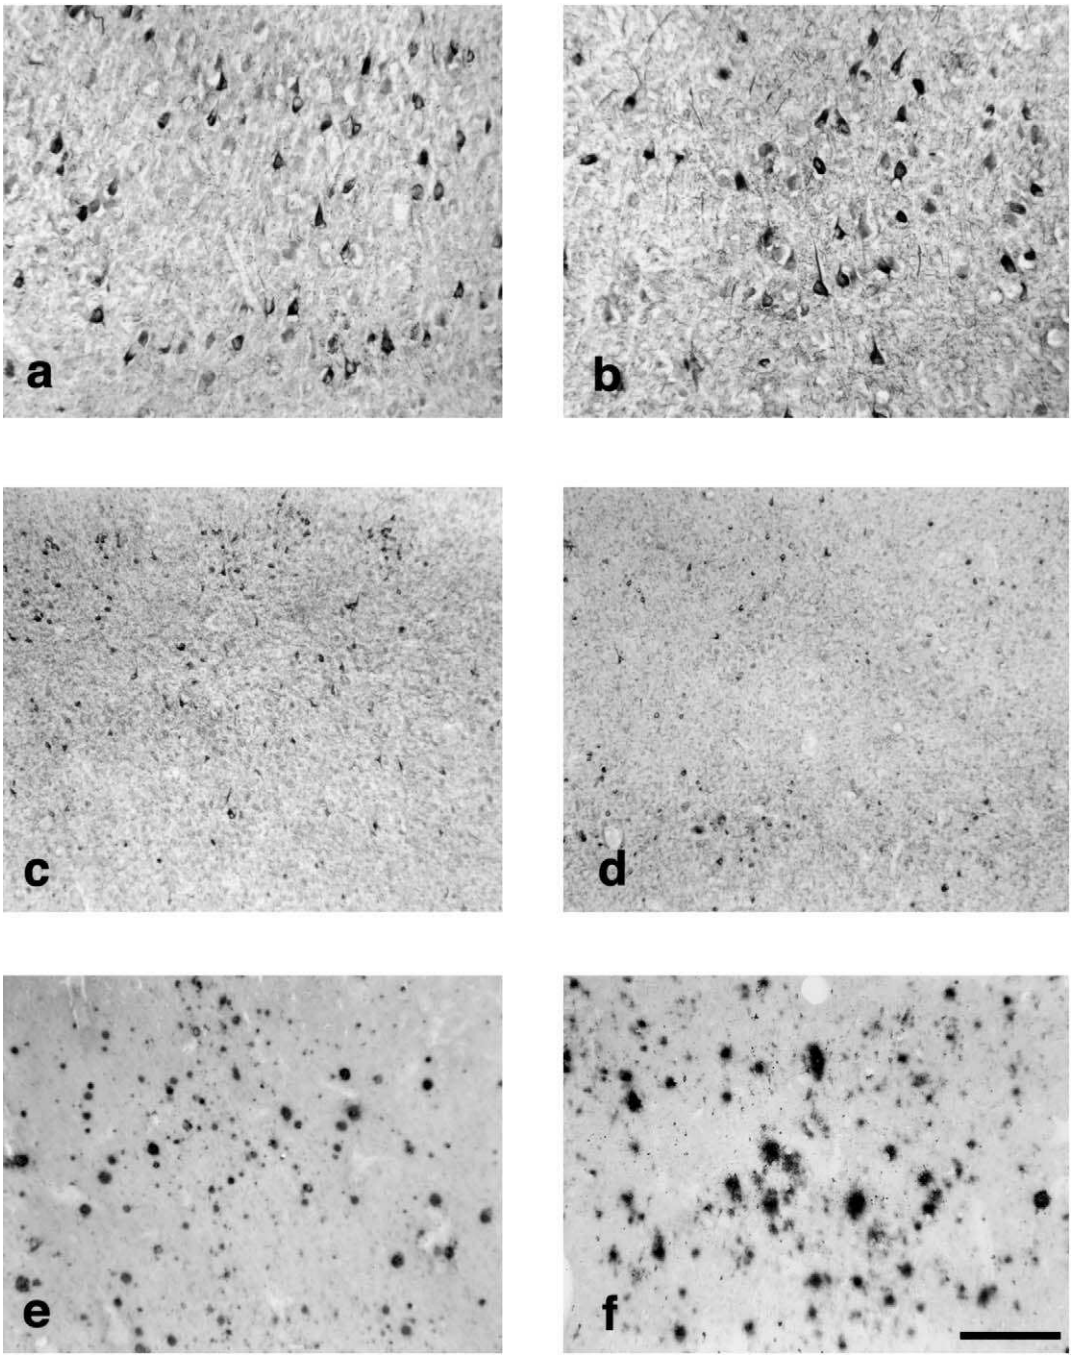

FIG. 8.2. Neurofibrillary tangles in the CA1 (posterior part) in a nondemented centenarian (a) and a centenarian with AD (b). There is no significant difference in NFT densities. Neurofibrillary tangles in the frontal cortex (area 9) of a 97-year-old AD (c) and a 65-year old AD (d). The old AD displays the highest density of NFT in layers II and III, whereas the ''younger'' AD case presents a high density of NFT in layers V and VI. The number of senile plaques in area 9 is lower in the nondemented centenarian (e) than in the centenarian with AD (f). Scale bar on a,b: 125 μm; on c,d: 500 μm; and on e,f: 250 μm.

a neuronal loss of 68% in the CA1 field and 47% in the subiculum in younger AD cohorts (West *et al*., 1994). In particular, these authors postulated that substantial neuronal depletion in the CA1 field represents a qualitative difference between normal aging and AD processes. These results suggest that despite the presence of high NFT densities, very old AD patients display no significant neuronal loss in the CA1 field. In contrast, the significant neuronal loss observed in layers, II and V of the entorhinal cortex and areas 9 and 20 AD centenarians is an agreement with earlier observations in younger demented individuals (Lippa *et al*., 1992; O'Banion *et al*., 1994; Gómez-Isla *et al*., 1996) and implies that decreasing

[a] Results represent neuron number/mm^3 (± SEM) in each area. These densities were estimated using the optical disector method. A statistically significant neuronal loss was observed in layers II and V of the entorhinal cortex and in areas 9 and 20 of AD cases. The mean age of each group is indicated in parentheses. Layers are indicated by Roman numerals. Statistical analysis was performed by analysis of covariance controlling for age at death. ns, not statistically significant (adapted from Giannakopoulos *et al*., 1996).

neuron densities in these areas are associated with AD symptomatology in any age group. More precisely, our findings for the entorhinal cortex are consistent with a report by Gómez-Isla and co-workers (1996), who estimated total neuron numbers in the entorhinal cortex of patients younger than 95 years, and reported a decrease of 60% in the number of neurons in layer II of the entorhinal cortex in patients with nondemented and of 90% in severe AD cases. However, the magnitude of neuronal loss in AD centenarians is significantly lower than that reported in younger AD cases (Lippa *et al*., 1992; Gómez-Isla *et al*., 1996), suggesting that a mild decrease in neuron numbers in cortical regions, such as the entorhinal cortex and areas 9 and 20, may be sufficient to cause dementia after 95 years of age (Hansen *et al*., 1988). The neuropathological distinction between very old and younger people is further supported by the results of our correlation analysis. First, the dissociation between NFT and neuron densities in all of the areas studied indicates that neuronal loss unrelated to the presence of NFT is the rule in the oldest-old, in contrast to elderly subjects younger than 85 where a correlation was documented (Gómez-Isla *et al*., 1996). Moreover, the negative relationship between SP densities and neuron counts in area 20 suggests that SP formation may be related to neuronal depletion within certain cortical regions in centenarians, although the biological mechanism surrounding this phenomenon is still poorly understood.

VI. Conclusions

The debate on whether there is continuity or discontinuity between normal aging and dementia has a long history and

TABLE 8.4 List of Longitudinal Studies of Centenarians

Country	Name of project	>100	90–100	Genetics
Denmark	The Danish Centenarian Study	Yes	Yes	Yes
France	Chronos	Yes	Yes	Yes
Sweden	The Swedish Centenarian Study	Yes	No	?
United States	New England Centenarian Study	Yes	No	Yes

is not merely of academic interest. The hypothesis that AD is an aging-related condition has been supported by the quasi ubiquitous presence of AD pathologic changes in the course of brain aging and the exponential increase of AD prevalence after 65 years of age. Contrasting with this concept of aging, the study of oldest-old individuals indicates that the occurrence of AD pathology is not a mandatory phenomenon of increasing chronologic age. In particular, the neuropathology of advanced aging strongly suggests that very old individuals display differential neuronal aging and susceptibility to the degenerative process of AD (Hauw *et al*., 1986; Mizutani and Shimada, 1990, 1992; Delaère *et al*., 1993; Giannakopoulos *et al*., 1993, 1994b,c, 1995, 1996, 1997). In this respect, the absence of significant neuronal loss in the CA1 field, as well as the low rate of NFT formation in areas 9 and 20 in centenarians with AD, may be related to a genetically determined resistance of these neuronal subpopulations in very old people. Importantly, evidence from genetic studies of aging and AD implies that there are a number of susceptibility genes that may modify or delay the onset of late-life brain failure. These gene families form a natural target for devising strategies for significantly delaying the onset of late-life dementia (Kaye, 1997). More generally, several prospective studies of oldest-old people have been initiated, searching to define the possible genetic background of longevity (Table 8.4) (Schachter *et al*., 1994; Manton and Vaupel, 1995; Jeune *et al*., 1996; Perls, 1997; Samuelsson *et al*., 1997; Perls *et al*., 1998). The first one started in France in 1991 and is known as the ''Chronos Project.'' Its main goal is to identify genetic factors associated with human longevity. It consists of a follow-up of more than 1200 nonagenarians and centenarians with living siblings 90 years or older (Schachter *et al*., 1994) One of the most recent, the ''New England Centenarian Study,'' includes four main axes: a population-based medical and demographic study of all centenarians living within the Boston area, neuropsychological–neuropathological correlations to define the limits of normal brain aging, population genetics to define familial patterns relating to the phenotype of extreme longevity, and molecular genetics to identify both nuclear and mitochondrial longevity enabling genes among centenarian sibling pairs, centenarian members of families highly clustered for longevity, and sporadic centenarian cases compared to younger controls. In the near future, these complex longitudinal studies may provide us with clues for a better understanding of both genetic and neurobiological dimensions of extreme aging.

Regional and Laminar Patterns of Selective Neuronal Vulnerability in Alzheimer's Disease

The pathogenetic events that lead to Alzheimer's disease (AD) are not fully understood, although the current knowledge of the pathological changes that occur in AD suggests that structurally and functionally AD is predominantly a disease of the cerebral cortex that involves only certain populations of neurons displaying specific regional and laminar distribution and connectivity patterns, whereas other neuron types are spared. Thus, differential neuronal vulnerability exists in AD that can be related to the morphologic and biochemical characteristics of identifiable neuronal populations and cortical connections. This chapter provides an overview of the relationships between the distribution of pathologic changes in AD and the localization of specific elements of the cortical circuitry that are affected by these alterations. This chapter also discusses observations that relate the neurochemical characteristics of particular neuronal types to their relative vulnerability or resistance to the degenerative process. It is possible that through such morphologic and molecular analyses, correlations will emerge among distribution of cellular pathologic changes, neurochemical characteristics related to vulnerability, and cortical circuits at risk. Such correlations may be useful for the development of preventive or protective interventions against the specific neuronal degenerative events that occur during the progression of the dementing illness.

I. Lesion Types and Distribution in Alzheimer's Disease

Alzheimer's disease (AD) is a neurodegenerative disorder classically characterized by the presence of two major types of histopathologic alterations in the cerebral cortex: neurofibrillary tangles (NFT) and senile plaques (SP) (Fig. 9.1). The distribution and density of NFT and SP have been analyzed in great detail and constitute the basis of the neuropathologic diagnosis of AD (Mirra *et al*., 1993). NFT are characterized by the accumulation of abnormal components of the neuronal cytoskeleton that form paired helical filaments, whereas SP are composed of dystrophic neurites and glial elements with or without a central amyloid core (Brion, 1990; Vickers *et al*., 1992, 2000; Hof *et al*., 1999a). These lesions are consistently observed throughout the brain and are predominant in the cerebral cortex, where NFT are located in the perikaryon of large pyramidal neurons and SP are distributed throughout the cortical regions, but are particularly numerous in association areas (Arnold *et al*., 1991; Hof *et al*., 1999a). In subcortical regions, NFT are found in large numbers in many structures connected with the cerebral cortex, including the amygdala, nucleus basalis of Meynert, ventral tegmental area, dorsal raphe, locus coeruleus, certain midline thalamic nuclei, some hypothalamic nuclei, and the olfactory bulb (Braak and Braak, 1991; Tomlinson, 1992; Kovács *et al*., 1999). Variable densities of SP are also observed in other subcortical structures, such as cerebellum and basal ganglia (Wisniewski *et al*., 1989). Other pathologic alterations commonly seen in the brain of AD patients include neuropil threads, which also contain paired helical filaments and appear early in the course of the disease, granulovacuolar degenerations, diffuse amyloid deposits, and amyloid angiopathy.

A considerable degree of neuronal loss in hippocampal formation and association regions of the neocortex, leaving primary sensory and motor areas relatively spared, is usually observed in the brain of demented patients (Ball, 1977; Terry *et al*., 1981; Mountjoy *et al*., 1983; Morrison and Hof, 1997). This neuronal loss involves large cortical neurons and is correlated with the presence of NFT in neocortical association areas (Morrison and Hof, 1997). Also, synapse loss may represent an early marker of the dementing process. In fact, a strong association between loss of neocortical synapses estimated on the basis of synaptophysin immunoreactivity and cognitive impairment has been documented (Terry *et al*., 1991; Masliah *et al*., 1991), which was stronger than that between NFT and

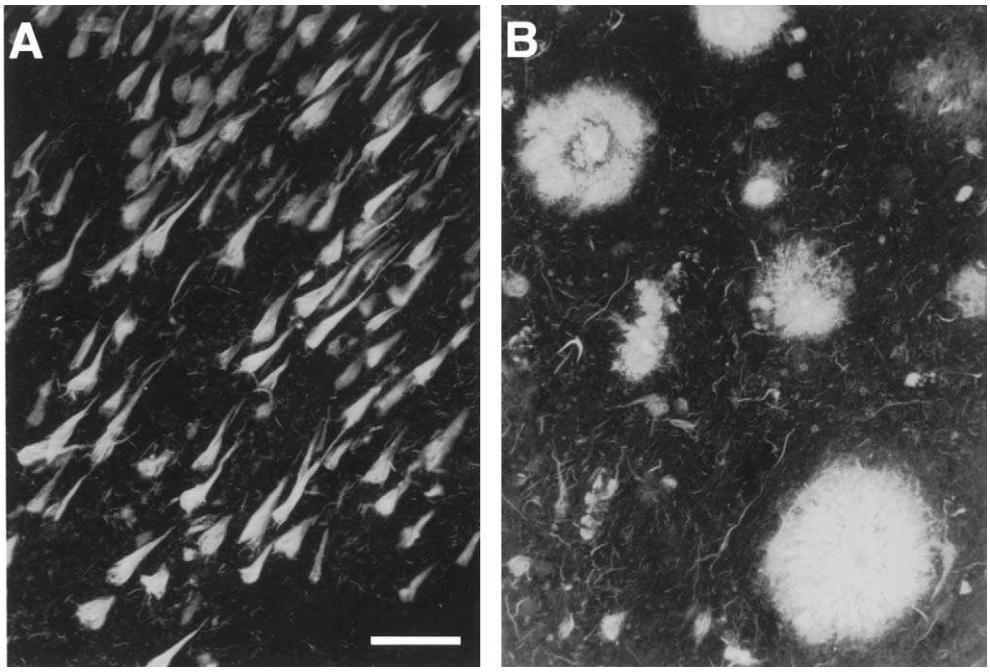

FIG. 9.1. Examples of NFT (A) and SP (B) from the hippocampus of a severe AD case. Note the flame-shaped morphology of NFT and the more variable features of SP. (B) A classical plaque with a central amyloid core and a rim of degenerating neurites, an isolated dense amyloid core, a predominantly neuritic plaque, and a few small diffuse deposits are visible. Scale bar: 50 μm.

cognitive deficit, indicating that synapse loss might be a more accurate neuropathologic indicator of dementia. Interestingly, an increase in synaptic size has been documented in the neocortex of AD cases, suggesting that despite a decrease in synaptic density, the total area of synaptic contact may remain unchanged in AD (Scheff and Price, 1993), although it is not clear how this seemingly compensatory mechanism affects the distribution of postsynaptic receptor molecules. Synaptic damage and synapse loss have also been reported in the neocortex of elderly nondemented individuals, suggesting an age-dependent mechanism for the loss of synapses in the neocortex (Masliah *et al*., 1993).

Strong correlations exist between the distribution of SP, NFT, and neuron loss in identifiable regions and layers of the cerebral cortex and the neurons of origin of certain long corticocortical and hippocampal projections (Rogers and Morrison, 1985; Pearson *et al*., 1985; Duyckaerts *et al*., 1986; Hyman *et al*., 1986; Lewis *et al*., 1987; Braak *et al*., 1989; Hof *et al*., 1990; Hof and Morrison, 1990; De Lacoste and White, 1993; Morrison and Hof, 1997). Overall, the distribution and severity of neuron loss follow closely that of NFT in hippocampal formation and neocortex (Ball, 1977; Gómez-Isla *et al*., 1996, 1997; Morrison and Hof, 1997). It has been shown that in certain regions, NFT densities are not consistently correlated to neuron loss and that differential laminar alterations have to be considered to estimate the severity of the pathologic changes. For example, it has been known for a long time that layer II of the entorhinal cortex, the subiculum, and the CA1 field of the hippocampus represent particularly vulnerable cortical domains that consistently display very high NFT densities in AD and that the most consistent observation in AD cases is the presence of large numbers of NFT in layers II and V of the entorhinal cortex (Hirano and Zimmerman, 1962; Hyman *et al*., 1984) (Figs. 9.2A and 9.2B). In the hippocampus, the most severely affected zones are the CA1 and subiculum, whereas the presubiculum, CA2 and CA3 fields, and dentate hilus are much less affected. In addition, the transentorhinal cortex located between the allocortex and the inferior temporal cortex shows a distinctive pattern of NFT formation very early in the course of AD (Braak and Braak, 1985). The distribution of SP in the hippocampal formation is variable, with certain zones displaying high SP densities, such as layer III of the entorhinal cortex, the molecular layer of the dentate gyrus, and the superficial layer of the subiculum (Hyman *et al*., 1990) (Figs. 9.2D and 9.2E).

Regionally, NFT are more numerous in the temporal cortex than in other cortical regions, the frontal cortex displays lower NFT densities, followed by the parietal cortex and the occipital cortex, and certain cortical regions, such as the posterior cingulate cortex, exhibit substantial case-to-case variability (Vogt *et al*., 1990, 1998; Arnold *et al*., 1991). NFT are found primarily within layers III and V in the neocortex (Fig. 9.2C), although their density varies considerably among cortical regions, with primary sensory and motor regions having much fewer NFT than association areas (Pearson *et al*., 1985; Lewis *et al*., 1987; Hof and Morrison, 1990; Arnold *et al*., 1991). Thus, when comparing the primary visual cortex (area 17) to the secondary visual cortex (area 18), there is an approximately 20-fold increase in the density of NFT area 18, and regions in the inferior temporal cortex that comprise high-order visual association areas are characterized by a further doubling of the NFT densities (Lewis *et al*., 1987). Similar differences

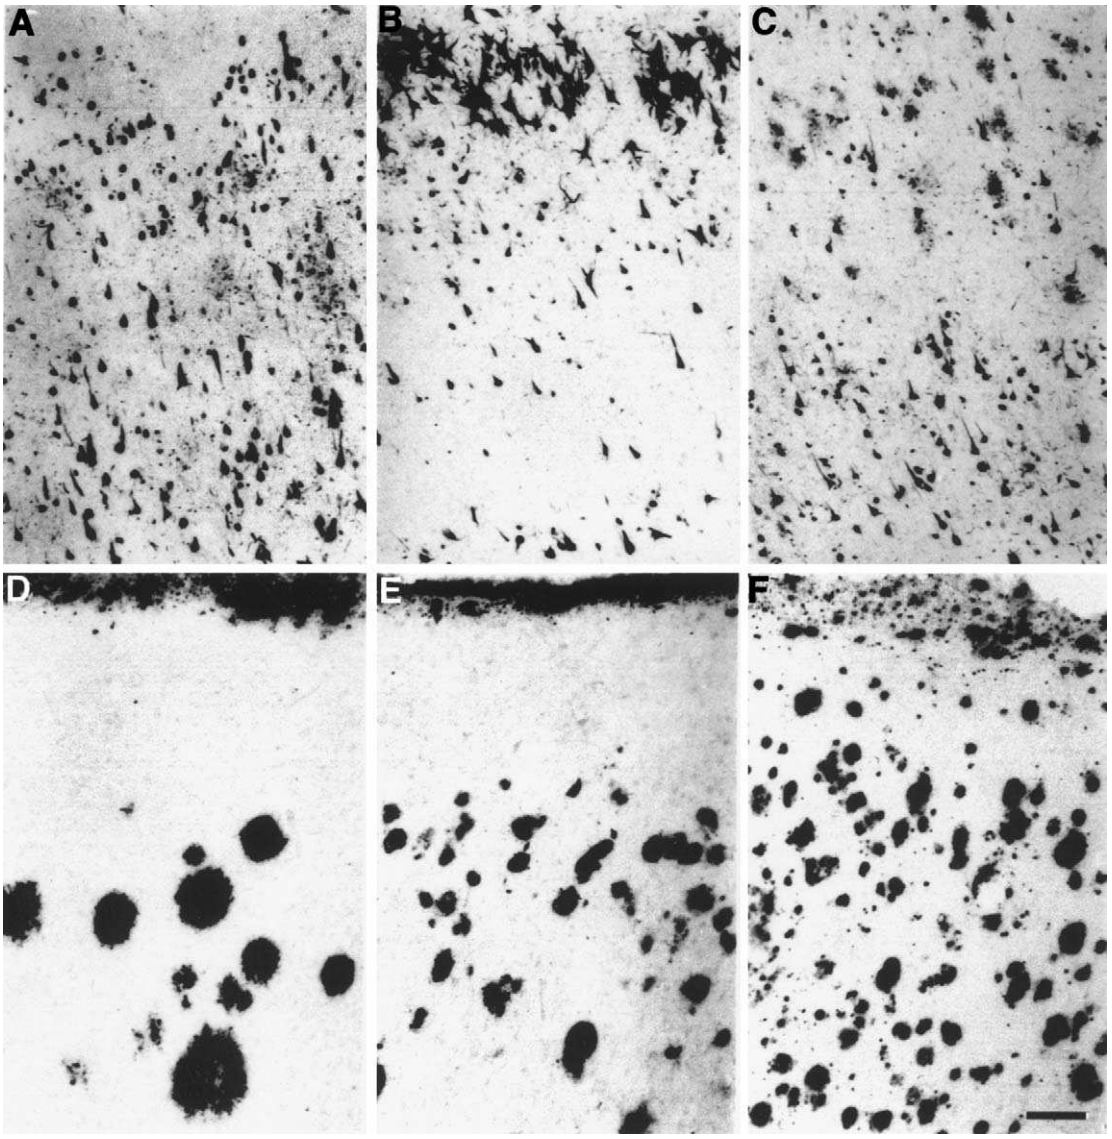

FIG. 9.2. Regional patterns of NFT (A–C) and SP (D–F) distribution in the CA1 field of the hippocampus (A and D), layers I–III of the entorhinal cortex (B and E), and layers III–V (C) and I–III (F) of area 20 in an AD case. There are high NFT densities in these regions. Layer II of the entorhinal cortex contains particularly high numbers of large NFT (B) and there are more NFT in layer V of area 20 (C). There are fewer SP in the CA1 field compared to the other regions (D–F). Scale bar (on F): 50 μm.

are found between the primary auditory cortex and auditory association areas, which display a 10-fold increase in NFT density (Esiri *et al*., 1986; Lewis *et al*., 1987). Considerable differences in laminar NFT distribution exist among neocortical regions. In areas 17 and 18, the majority of NFT are located in layer III, whereas in the inferior temporal cortex, only 40% of the NFT are found in layer III. A more striking difference exists in the auditory association cortex where only 27% of the NFT are observed in the supragranular layers (Lewis *et al*., 1987).

In contrast to NFT, SP show a relatively homogeneous distribution among cortical areas (Lewis *et al*., 1987; Arnold *et al*., 1991), although the frontal and anterior cingulate cortex contain more SP than temporal cortices (Rogers and Morrison, 1985). In the neocortex, SP are generally more numerous in layers II to IV than in layers V and VI (Rogers and Morrison, 1985) (Fig. 9.2F). Certain cortical areas are characterized by typical SP distribution patterns, such as the retrosplenial cortex, where SP occur in layer III, and area 17, where they are concentrated at the border of layer IVC and V (Braak *et al*., 1989, 1992; Beach and McGeer, 1992).

II. Alzheimer's Disease Affects Specific Elements of Cortical Circuits

The neurons of origin of corticocortical projections can be classified into three distinct categories based on their distribu-

tion in the cortical layers and by the distribution of their axonal terminals in their projection areas. Using these criteria, corticocortical projections can be categorized as feedforward, feedback, and lateral connections (Felleman and Van Essen, 1991). Feedforward connections ascend within the hierarchy of a given modality (i.e., from a primary sensory area to an association area), feedback projections descend the same hierarchy, and lateral connections link cortical regions at the same hierarchical level. Feedforward connections originate mostly from neurons located in the superficial layers and terminate in the deep portion of layer III and in layer IV of the target cortical region, feedback projection neurons are found principally in layers V and VI and project in layers I and VI, and lateral connections arise from layers V–VI and project to layers III to VI.

The preferential distribution of NFT in layers III and V indicates that elements of feedforward, lateral, and feedback projections area likely to be affected by the degenerating process of AD (Fig. 9.3). Considering that layer V contains generally higher NFT densities than layer III in association areas suggests that feedback as well as lateral projections may be at higher risk in AD than feedforward systems. Interestingly, most of the projection neurons from the occipital and temporal association cortex to the frontal and from the occipital cortex to the temporal cortex are located in layer III. However, the ratio of densities of projection neurons in layer III to layer V progressively decreases from the occipital to inferior temporal and further to superior temporal regions (Barbas, 1986): this change in laminar distribution is paralleled by a progressive shift of NFT densities from supragranular layers to infragranular layers (Lewis *et al*., 1987). In severe AD cases, only feedforward projections are affected in areas 17 and 18, as NFT predominate in layer III, which contains most of the efferent corticocortical neurons in these areas (Figs. 9.3 and 9.4). The regional and laminar distribution of SP suggests that they may be related to NFT formation. It has been proposed that, in fact, SP reflects degeneration of the terminations of projections from neurons that contain NFT (Pearson *et al*., 1985) and that the slightly higher incidence of SP in the supragranular layers and in layer IV in the association cortex reflects the involvement of feedforward projections (Lewis *et al*., 1987), although there are clear indications that multiple systems are involved in SP formation (Morrison *et al*., 1985; Walker *et al*., 1988; Vickers, 1997; Mochizuki *et al*., 2000).

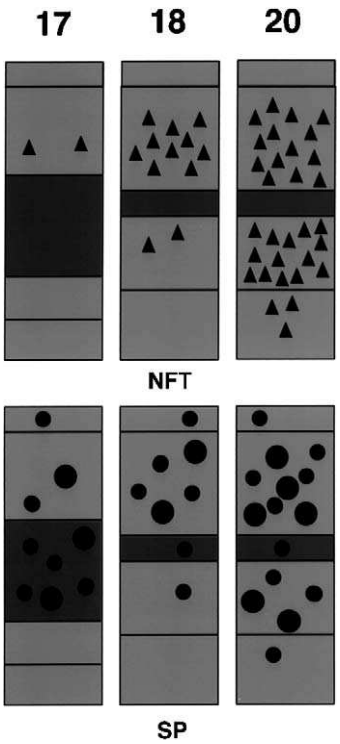

FIG. 9.3. The laminar distribution of NFT (▲) and SP (•) matches the distribution of corticocortically projecting neurons along neocortical hierarchies. In area 17, only rare NFT are seen in layer III, which projects to the superficial layers of area 18. This corresponds to the presence of consistent densities of SP in these layers in area 18. From the superficial layers of area 18, feedforward neurons projecting to higher hierarchical levels (in this case area 20) are involved, resulting in higher NFT densities. The terminal fields of the projections from area 18 in layers III and V–VI of area 20 contain higher densities of SP. In area 20, NFT are present in higher number not only in layer III, but also in layers V–VI, indicating that feedback projections may be involved by the degenerative process, which may be correlated to the high densities of SP in layers II–IV of area 17, where feedback projections from areas 18 and 20 terminate. Layer IV is shown by dark gray shading.

The distribution of NFT and SP in the hippocampal formation also parallels specific projections (Hyman *et al*., 1990). Thus, the perforant pathway that projects from layers II and III of the entorhinal cortex is severely and early involved in AD, and the presence of NFT in the neurons of origin of this pathway and its termination in the dentate gyrus are correlated with high densities of SP in the molecular layer of the dentate gyrus (Hyman *et al*., 1984, 1986; Senut *et al*., 1991). High densities of NFT in layer V of the entorhinal cortex are correlated with the degeneration of connections to the amygdala and to a number of limbic and association cortical areas, and projections from the hippocampus to the entorhinal cortex, amygdala, and neocortical areas, originating from the CA1 field and the subiculum, all consistently contain numerous NFT in AD, as do nuclei in the amygdala that project to the entorhinal cortex (Brady and Mufson, 1990; Hyman *et al*., 1990). Furthermore, SP are found predominantly in the mediobasal nucleus of the amygdala, which receives the entorhinal cortex projections, whereas SP are more numerous in layers I and III of the entorhinal cortex that correspond to the termination zone of amygdala and hippocampus afferents, consistent with the notion that the regional pathologic changes in the hippocampus correspond to the disconnection of intrinsic connections and of projections to other limbic and neocortical regions (Brady and Mufson, 1990, 1991; Hyman *et al*., 1990).

The degeneration of presumed corticocortical circuits within the neocortex therefore appears to be the necessary factor for the clinical expression of the dementia in AD (Morrison and Hof, 1997). Elderly individuals can maintain a high level of cognitive performance while sustaining a significant compromise of hippocampal circuits and may rely more on neocortical than on hippocampal circuits for memories essential for daily activities (Albert, 1996). In terms of cognitive performance, healthy elders may present with difficulties in learning and retrieving new information. In fact, the difficulty lies in the

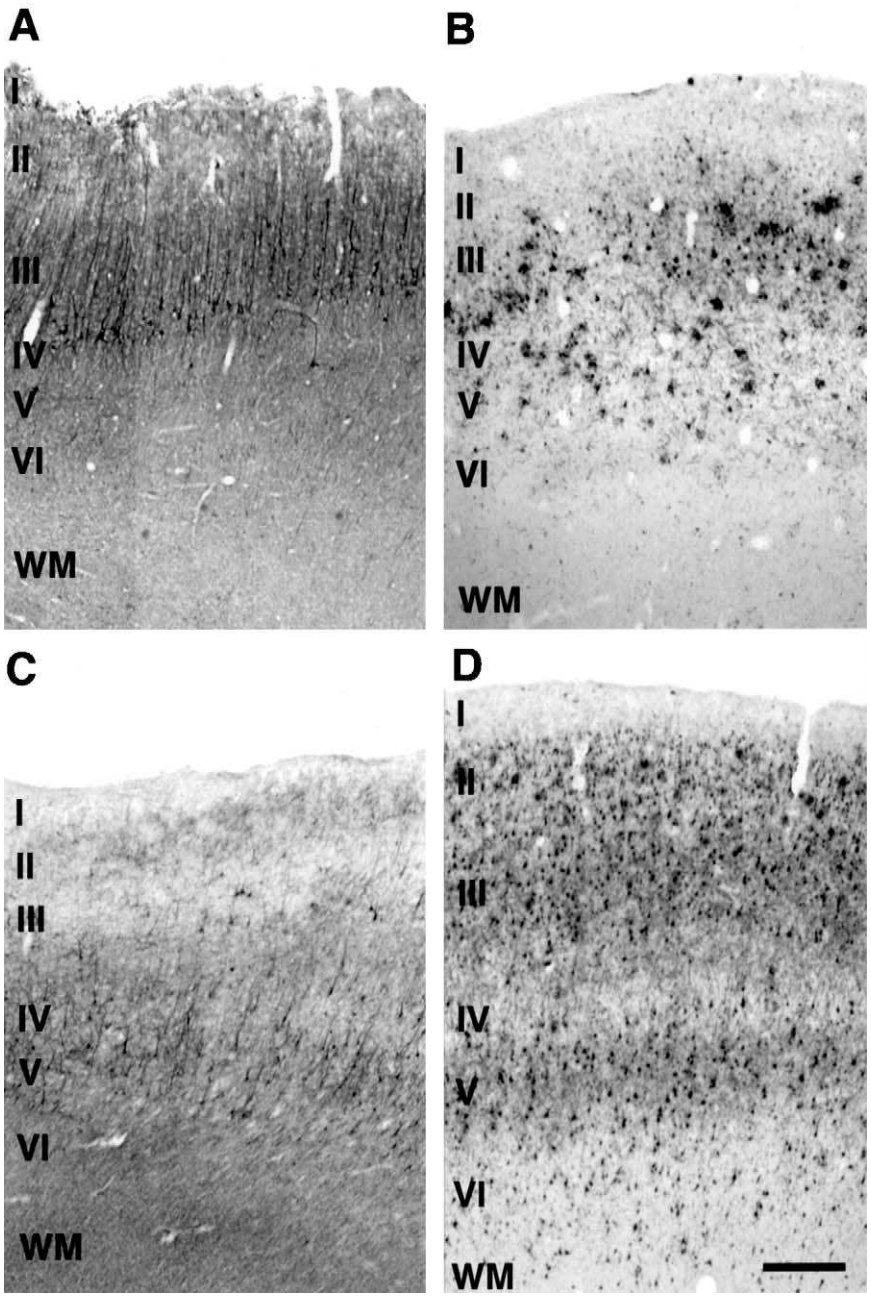

FIG. 9.4. Correlative distribution of neurofilament protein-enriched neurons (A and C) and NFT (B and D) in area 18 (A and B), and area 20 (C and D) of a severe AD case. In area 18, immunoreactive neurons are located in the deep portion of layer III and are affected moderately. Their distribution matches that of NFT (A and B). In area 20, there is a severe loss of neurofilament protein-immunoreactive neurons in layers III and V (C) that parallels the very high densities of NFT in these layers (D). Scale bar (on D): 100 μm.

amount of information they can learn within a given period of time in comparison to younger individuals. Compared to patients with early AD, healthy elders retain the new information after a delay, whereas patients with mild cognitive impairment retain little of it (Albert, 1996). This impairment in information retention that characterizes the very early stages of AD is correlated to neuronal loss in the entorhinal cortex and to volumetric changes in the temporal lobe (Albert, 1996; Gómez-Isla *et al*., 1996, 1997; Fama *et al*., 1997; Hof *et al*., 1999b). Increases in the volume of the temporal horn of the lateral ventricle may selectively reflect the loss of projections from the entorhinal cortex. Normal aging can thus be defined by intact cognitive abilities, despite the presence of scarce neurofibrillary pathology in the entorhinal cortex, which can be referred to as aging-related asymptomatic AD-like neurofibrillary pathology.

III. Morphologic and Molecular Correlates of Neuronal Vulnerability

A. Neuronal Types Prone to Neurofibrillary Tangle Formation

Not all neuron types form NFT in AD, even though NFT are distributed widely throughout the brain (Hof *et al*., 1990; Gómez-Isla *et al*., 1996, 1997; Morrison and Hof, 1997). In the neocortex, the number of NFT clearly cannot account for the total population of pyramidal neurons (Fig. 9.4). This suggests that only certain subpopulations of pyramidal neurons are selectively susceptible to paired helical filament aggregation. Specifically, large pyramidal cells in layers, III and V represent the most affected cell class, whereas smaller pyramidal neurons in layers II, VI, and in the upper part of layer III appear to be considerably more resistant to NFT formation. Also, the spiny stellate cells and small pyramidal cells in layer IV are not affected by this process as are many of the various morphological types of inhibitory interneurons. It is important to note that in terms of morphology and connectivity, all of the vulnerable neurons are efferent cells that send long projections to other cortical regions or to subcortical structures and all are large pyramidal neurons (Hof *et al*., 1990; Hof and Morrison, 1990). Similarly, in the hippocampal formation, the large pyramidal efferent neurons in layers II, III, and V of the entorhinal cortex and of the CA1 field and subiculum are all severely affected. However, other cellular characteristics than these are also linked to vulnerability in the degenerative process, as certain large efferent neurons, such as the principal cells in the CA3 field and the large neurons of the dentate hilus, are generally relatively resistant to degeneration in AD. In subcortical structures, NFT appear in several nuclei that project to the cerebral cortex. For instance, catecholaminergic cell groups in the brain stem are frequently affected as are the cholinergic neurons in the nucleus basalis of Meynert: in the thalamus, NFT are mostly restricted to relay neurons within intralaminar and limbic nuclei, whereas sensory nuclei are unaffected (Rossor *et al*., 1984; Braak and Braak, 1991; see also Chapter 19), further demonstrating the existence of a correlation between selective neuronal vulnerability and specific projection systems.

B. Neurofilament Protein Is a Marker of Neuronal Vulnerability in Alzheimer's Disease

Certain pyramidal neurons in the neocortex of both human and monkeys have been shown to be enriched in neurofilament protein (Campbell and Morrison, 1989; Hof *et al*., 1990; Hof and Morrison, 1990, 1995). Neurofilament protein immunoreactivity in the primate neocortex is restricted to the perikaryon and dendrites of a subpopulation of large pyramidal and is more concentrated in the cell body and dendrites of the largest of these neurons. Interestingly, neurofilament as well as other cytoskeletal proteins have been implicated in NFT formation (Ksiezak-Reding *et al*., 1987; Morrison *et al*., 1987; Zhang *et al*., 1989; Trojanowski *et al*., 1993; Morrison and Hof, 1997; Hof *et al*., 1999a), and pyramidal cells with a high content of nonphosphorylated neurofilament protein emerge as a neuron type highly susceptible to NFT formation.

Detailed descriptions of the cellular, laminar, and regional characteristics of neurofilament protein-containing cells in many frontal, cingulate, temporal, and occipital areas of the macaque monkey and human neocortex have revealed that extensive regional heterogeneity exists in the size, density, and laminar distribution of neurofilament protein-containing neurons (Campbell and Morrison, 1989; Hof *et al*., 1990, 1995a,b, 1996, 1997; Hof and Morrison, 1990, 1995; Campbell *et al*., 1991; Hof and Nimchinsky, 1992; Nimchinsky *et al*., 1995, 1996, 1997). The distribution of neurofilament protein-containing neurons corresponds to the distribution of corticocortically projecting cells, as demonstrated by transport studies in the macaque monkey cortex (Campbell *et al*., 1991; Hof *et al*., 1995b, 1996, 1997; Nimchinsky *et al*., 1996). For example, in the anterior cingulate cortex the labeled neurons are restricted to layer V, and most long corticocortical projections from this region originate in layer V (Barbas, 1986). Area 9 in the prefrontal cortex, as well as the superior and inferior temporal cortices, has a high density of neurofilament protein-immunoreactive neurons in layers III and V, the layers from which, in these regions, corticocortical projections originate. The correlation between origins of long corticocortical projections and neurofilament protein-containing neurons is particularly visible in area 17 of monkeys and human, where layer IVB cells and Meynert cells are the only large, strongly immunoreactive neurons, and both are known to project from area 17 to mediotemporal area V5 (Shipp and Zeki, 1989a,b; Felleman and Van Essen, 1991; Hof *et al*., 1996).

In fact, the distribution of neurofilament protein-containing cells in areas 17 and 18 differs substantially from each other and from the pattern described in the inferior temporal and prefrontal cortex (Campbell and Morrison, 1989; Hof *et al*., 1990; Hof and Morrison, 1990, 1995). In area 17, in addition to layer IVB cells and Meynert cells, smaller neurofilament protein-immunoreactive neurons occur in layers III, IVA, V, and VI. In area 18, the large, intensely labeled pyramidal neurons predominate in the deep portion of layer III, with a few in layer V. The inferior temporal and prefrontal cortex have a significantly higher density of heavily labeled cells in deep layer III than area 18 and, in addition, have a much higher density of labeled cells in layers V and VI. In contrast to the inferior temporal and prefrontal cortex, the loss of neurofilament protein-containing neurons in area 17 and 18 is minimal in AD brains and is confined to layer IVB and Meynert cells in area 17 and to deep layer III neurons in area 18 (Hof and Morrison, 1990). This indicates that the short corticocortical projections from area 17 to area 18 that originate in layer III are not affected in AD. Given the morphology and distribution of the neurofilament protein-containing neurons in area 17, the immunoreactive cells in layer IVB and Meynert cells are likely at the origin of the projections to visuomotor regions of the occipitotemporal cortex, which are the human homologue of monkey mediotemporal area V5. Studies combining retrograde transport and double-labeling immunohistochemistry in macaque monkeys indicate that virtually 100% of the neurons in layer IVB and Meynert cells in area 17 that project to area V5 contain neurofilament protein and that the projection from area 18 to area V5 originates from the neurofilament protein-containing pyramidal cells in deep layer III (Hof *et al*., 1996), where the darkly stained, large neurofilament protein-containing pyramidal cells

are found in human. Thus, although the projection from area 17 to area 18 is largely intact, and the overall neuron loss may be functionally inconsequential in area 17, it is likely that two projections to the occipitotemporal regions involved in visuomotor skills are affected in AD. These observations on visual projections demonstrate the existence of a chemically defined neuronal subpopulation that is highly vulnerable in AD and that can be correlated with a specific corticocortical projection of known function (Fig. 9.4). We have also reported in the macaque monkey that many long association corticocortical projections originate from neurofilament protein-containing neurons and that in some of them, 90–100% of the neurons of origin of the projection contain neurofilament protein (Hof *et al*., 1995b). This is particularly the case of projections from the temporal to the prefrontal and parietal neocortex that are know to be involved in networks subserving many aspects of the cognitive functions (Goldman-Rakic, 1988).

Furthermore, we have observed that neurofilament protein-containing neurons in certain neocortical and hippocampal areas in AD are affected dramatically and die through NFT formation (Morrison *et al*., 1987; Hof *et al*., 1990; Hof and Morrison, 1990; Vickers *et al*., 1992, 1994, 2000; Morrison and Hof, 1997; Vickers, 1997). The laminar distribution of neurofilament protein-containing neurons in visual association, prefrontal, and anterior cingulate in human cerebral cortex is very similar to the distribution of NFT. Furthermore, layers that have high NFT density in an AD brain no longer contain a high density of neurofilament protein-immunoreactive neurons (Hof *et al*., 1990, 1999a,b; Hof and Morrison, 1990) (Figs. 9.4 and 9.5). A comparable situation exists in the hippocampal formation, where layers II, III, and V of entorhinal cortex and the pyramidal neurons of the subiculum have a very high density of neurofilament protein-immunoreactive neurons in the normally aging human brain and present with a dramatic loss of these neurons in AD (Vickers *et al*., 1992, 1994; Morrison and Hof, 1997).

These observations demonstrate that neurofilament protein-containing neurons are highly vulnerable in AD, and quantitative analyses have demonstrated a severe loss of neurofilament protein-containing neurons in layers III and V in the inferior temporal and superior frontal cortex (Fig. 9.5). The severity of the loss correlates with the size of these neurons in that neurofilament protein-containing neurons larger than 6000 μm^3 of perikaryal volume are the most affected, with up to 60% cell loss, whereas smaller size neurons (2000–6000 μm^3 of perikaryal volume) are not affected (Hof *et al*., 1990, 1999b). In addition to regional distribution and relationship to connectivity, NFT identified by thioflavine S stain or immunohistochemistry using antibodies to neurofilament protein and microtubule-associated protein tau have revealed dynamic cellular alterations in vulnerable neuronal populations during normal aging. For instance, layer II of the entorhinal cortex

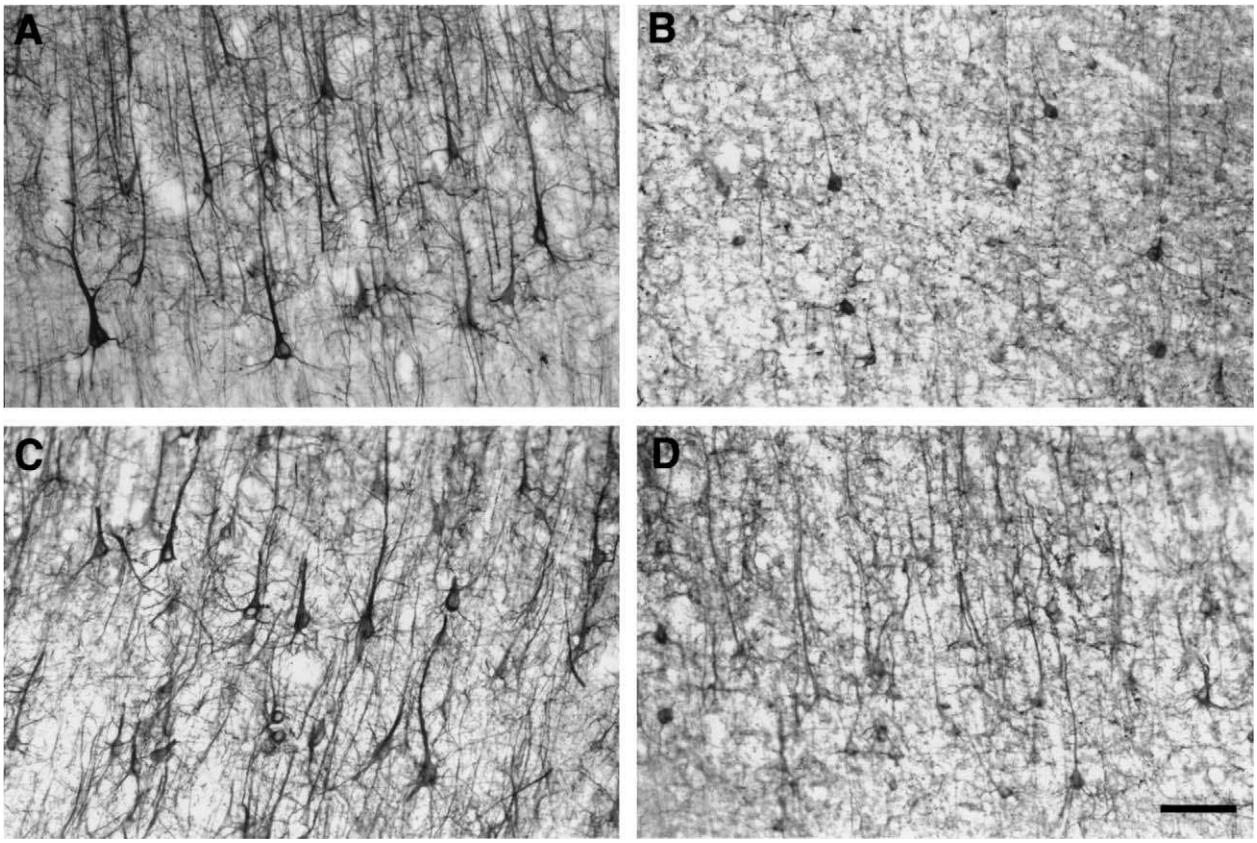

FIG. 9.5. Involvement of neurofilament protein-immunoreactive pyramidal neurons in layer III of area 9 (A and B) and area 20 (C and D), in control cases (A and C), and severe AD cases (B and D). Note the dramatic neuronal loss and changes in dendritic morphology and staining intensity in the remaining neurons in the AD cases. Scale bar (on D): 120 μm.

contains neurofilament protein-immunoreactive neurons that also display immunoreactivity to tau protein and thioflavine S-positive materials, suggesting the existence of transitional forms of NFT (Vickers *et al*., 1992; Morrison and Hof, 1997). In such cases, very rare NFT are seen in the frontal cortex, which contains preserved neurofilament protein-immunoreactive neurons in layers III and V (Fig. 9.6, see color insert). However, in AD cases, most NFT in the entorhinal cortex progress to an end stage and are no longer immunoreactive to tau and neurofilament proteins but are stained only with thioflavine S. At this stage, transitional forms of NFT are observed in the frontal cortex, indicating that a time-dependent process takes place in the formation of NFT in certain neurofilament protein-containing neurons (Vickers *et al*., 1992, 1994, 2000; Morrison and Hof, 1997; Vickers, 1997; Hof *et al*., 1999b) (Fig. 9.6). Moreover, the presence of high levels of neurofilament protein appears to be a prerequisite for the formation of NFT, as certain neurons, such as the pyramidal neurons of the CA1 field, that do not normally express detectable levels of this protein in young adults, yet are prone to NFT formation in AD, begin to show increasing levels of neurofilament protein immunoreactivity during aging (Vickers *et al*., 1994). If monkey data are considered within the context of the distribution of neurofilament protein-containing neurons and NFT in human, it is likely that human homologues of the neurofilament protein-containing, corticocortically projecting neurons of the macaque monkey are those that are highly vulnerable in AD. Thus, one of the neurochemical characteristics of the vulnerable neurons in AD is the presence of high somatic and dendritic concentrations of nonphosphorylated neurofilament proteins, although this may clearly represent only part of the neurochemical phenotype associated with selective vulnerability.

C. Other Factors Linked to Vulnerability

Disruption of glutamate metabolism and glutamate receptor-mediated excitoxicity represents one of the major mechanisms of neuron death in many neurodegenerative disorders, as well as in other pathological conditions, such as brain ischemia and epilepsy (Choi, 1988; Greenamyre and Young, 1989; Choi and Rothman, 1990; Meldrum and Garthwaite, 1991; Coyle and Puttfarcken, 1993; Blümcke *et al*., 1996; Obrenovitch and Urenjak, 1997). Glutamate receptor-mediated excitotoxicity presumably results from increased calcium flux, leading to toxic intracellular concentrations of this ion, and this mechanism is likely associated with all types of ionotropic glutamate receptors that are involved in facilitating or regulating calcium fluxes. Whereas the *N*-methyl-D-aspartate (NMDA) receptor has been the receptor subtype associated primarily with calcium flux, it is now clear that both kainate and α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) kainate receptors also increase calcium flux (Gasic and Heinemann, 1992). Interestingly, neurons in culture that possess high levels of calcium-permeable AMPA/kainate and NMDA receptors are highly sensitive to exposure to calcium load, and such neurons are much more likely to express the calcium-permeable AMPA subunits GluR1 and GluR4 than the calcium-impermeable GluR2 subunit (Lu *et al*., 1996). Several studies have shown that following ischemic brain injury, there is a downregulation in the expression of the calcium-impermeable GluR2 subunit in the CA1 field of the hippocampus (Pellegrini-Giampietro *et al*., 1992, 1994; Pollard *et al*., 1993). Thus, the glutamate receptor profile of cortical neurons and related circuits has emerged as an important parameter when correlating identified neurons and circuits with susceptibility for vulnerability to degeneration through excitotoxicity because the defining characteristics of a given glutamatergic projection with respect to ion fluxes depend on the subunit composition of the receptors that dominate that system. Importantly, glutamate-containing neurons have long been known to be prone to NFT formation (Kowall and Beal, 1991), and depletion of glutamate and certain glutamate receptors has been reported in the perforant pathway in AD cases (Hyman *et al*., 1987; Greenamyre and Young, 1989; Dewar *et al*., 1991; see also Chapter 20). Glutamate toxicity mediated through calcium-activated processes has been linked to degeneration and cytoskeletal alterations comparable to those involved in NFT formation (Sautière *et al*., 1992; Sindou *et al*., 1992, 1994; Couratier *et al*., 1995, 1996). Autoradiographic, immunocytochemical, or *in situ* hybridization studies have demonstrated considerable alterations in the distribution and density of several glutamate receptor subunits in the cerebral cortex in normal aging and AD (Armstrong *et al*., 1994; Ikonomovic *et al*., 1995, 1997; Yasuda *et al*., 1995; Armstrong and Ikonomovic, 1996; Ikonomovic and Armstrong, 1996). These issues are reviewed in detail in Chapter 20. In addition, changes in the expression of specific glutamate receptor subunits leading to functional decline without neuronal degeneration are known to occur during normal aging (Gazzaley *et al*., 1996, 1997; Duan *et al*., 1999). For instance, in aged monkeys, compared to juvenile and young adult monkeys, the NMDA receptor levels decrease specifically and consistently in the outer molecular layer of the dentate gyrus where the perforant path terminates, but there are no significant differences in the expression of AMPA or kainate glutamate receptor subunits, and no morphologic reflection of degeneration of the perforant path (Gazzaley *et al*., 1996, 1997). Similar evidence from neocortical connections began to emerge in that neurons forming long corticocortical connections undergo a downregulation in the expression of NMDAR1 and the AMPA subunit GluR2 and that a certain degree of reduction in GluR2 expression also exists in certain short corticocortical pathways (Duan *et al*., 1999). Such alterations in expression of a calcium-impermeable glutamate receptor subunit may represent a cellular correlate of the toxic increase in calcium flux and define subsets of pyramidal neurons particularly prone to degeneration. These data also suggest that the intradendritic parcellation of a particular neurotransmitter receptor is modifiable in an age-related and circuit-specific manner and that such changes may provide a substrate for age-related memory impairment (Gazzaley *et al*., 1996; Morrison and Hof, 1997; Duan *et al*., 1999).

It is also interesting to note that a population of pyramidal neurons, residing principally in layer III of the neocortex and that express the calcium-binding protein calbindin, is also vulnerable in AD (Hof and Morrison, 1991) (Fig. 9.7). Studies in the macaque monkey and humans have shown that these neurons are more numerous in the association cortex and that there is a gradient in their local densities from the primary sensory areas to the secondary and higher-order cortical regions (Hof

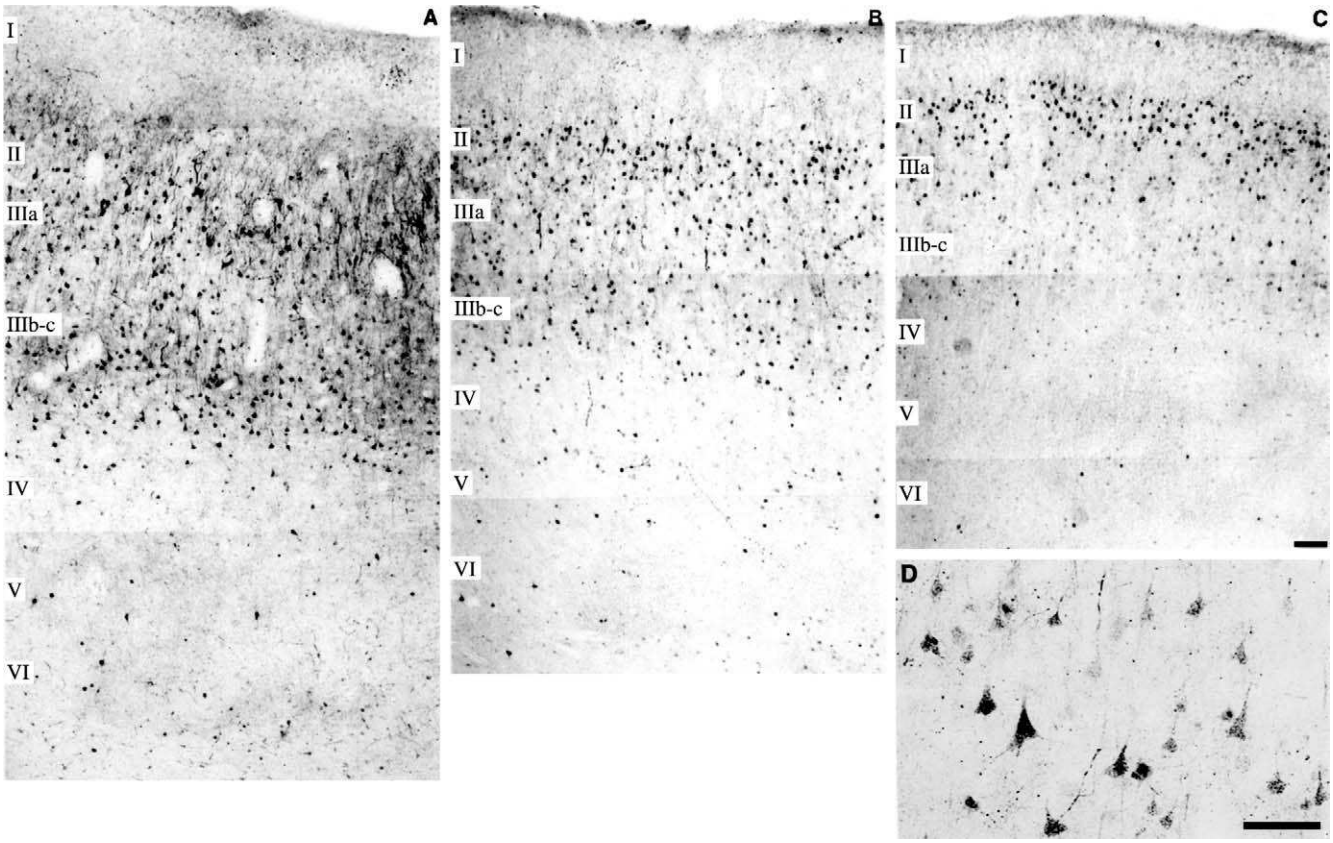

FIG. 9.7. Distribution of calbindin-immunoreactive neurons in area 9 of a control case (A), an AD case with mild cognitive impairment (B), and a severe AD case (C). There is a high number of labeled interneurons in layer II and superficial III, whereas layers V–VI have fewer neurons (A). In AD cases, there is a gradual reduction in the dendritic arborizations of these neurons, but no cell loss is apparent (B and C). In layer III there is a population of pyramidal neurons that also contain calbindin (A and D), which are affected in AD cases. Scale bars: 100 μm.

and Morrison, 1991; Kondo *et al*., 1994, 1999). These neurons have also been shown to be enriched in neurofilament proteins (Hayes and Lewis, 1992). Possible alterations in the expression of an important protein involved in intracellular calcium buffering in these pyramidal neurons might be related to their heightened vulnerability in the course of AD. Such changes combined with the decrease in aging in an AMPA receptor protein protective against calcium toxicity, such as GluR2, together with a high content of neurofilament protein could represent key factors in the dynamic definition of a neurochemical profile of cellular vulnerability in AD.

IV. Factors Conferring Resistance to the Degenerative Process

Quantitative analyses of the superior frontal (area 9) and inferior temporal (area 20) in AD have demonstrated that several classes of GABAergic interneurons containing the calcium-binding proteins parvalbumin, calbindin, and calretinin are largely resistant to the degenerative process, even in severe cases displaying very high densities of NFT and SP (Hof *et al*., 1991, 1993; Hof and Morrison, 1991; Sampson *et al*., 1997). The cellular distribution of calcium-binding proteins is known to be coextensive with that of GABA in cortical interneurons, and these proteins subdivide the GABAergic neurons into nonoverlapping interneuron populations that together account for the vast majority of the GABAergic cells (Hendry *et al*., 1989; Celio, 1990; Hof and Nimchinsky, 1992; Résibois and Rogers, 1992; Andressen *et al*., 1993; Hof *et al*., 1995a; Nimchinsky *et al*., 1997).

Parvalbumin- and calretinin-immunoreactive interneurons are resistant to degeneration (Figs. 9.8 and 9.9) and show a well-preserved morphology and staining pattern in AD, but calbindin-immunoreactive neurons display some degree of differential vulnerability (Hof and Morrison, 1991; Hof *et al*., 1991, 1993). Whereas calbindin-containing interneurons in layers II and III are strongly resistant to degeneration in AD (Fig. 9.7), those in layers V and VI are affected in AD cases with high NFT densities, possibly reflecting differential patterns of connectivity between subgroups of calbindin-containing interneurons in layer II and upper layer III and those in layer V. It is likely that layer V calbindin-immunoreactive neurons project to pyramidal cells that are more affected in AD, whereas the targets of neurons in layers II and III are less vulnerable (Hof and Morrison, 1991).

Other markers of cellular resistance in GABAergic interneurons include several neuropeptides. For example, somato-

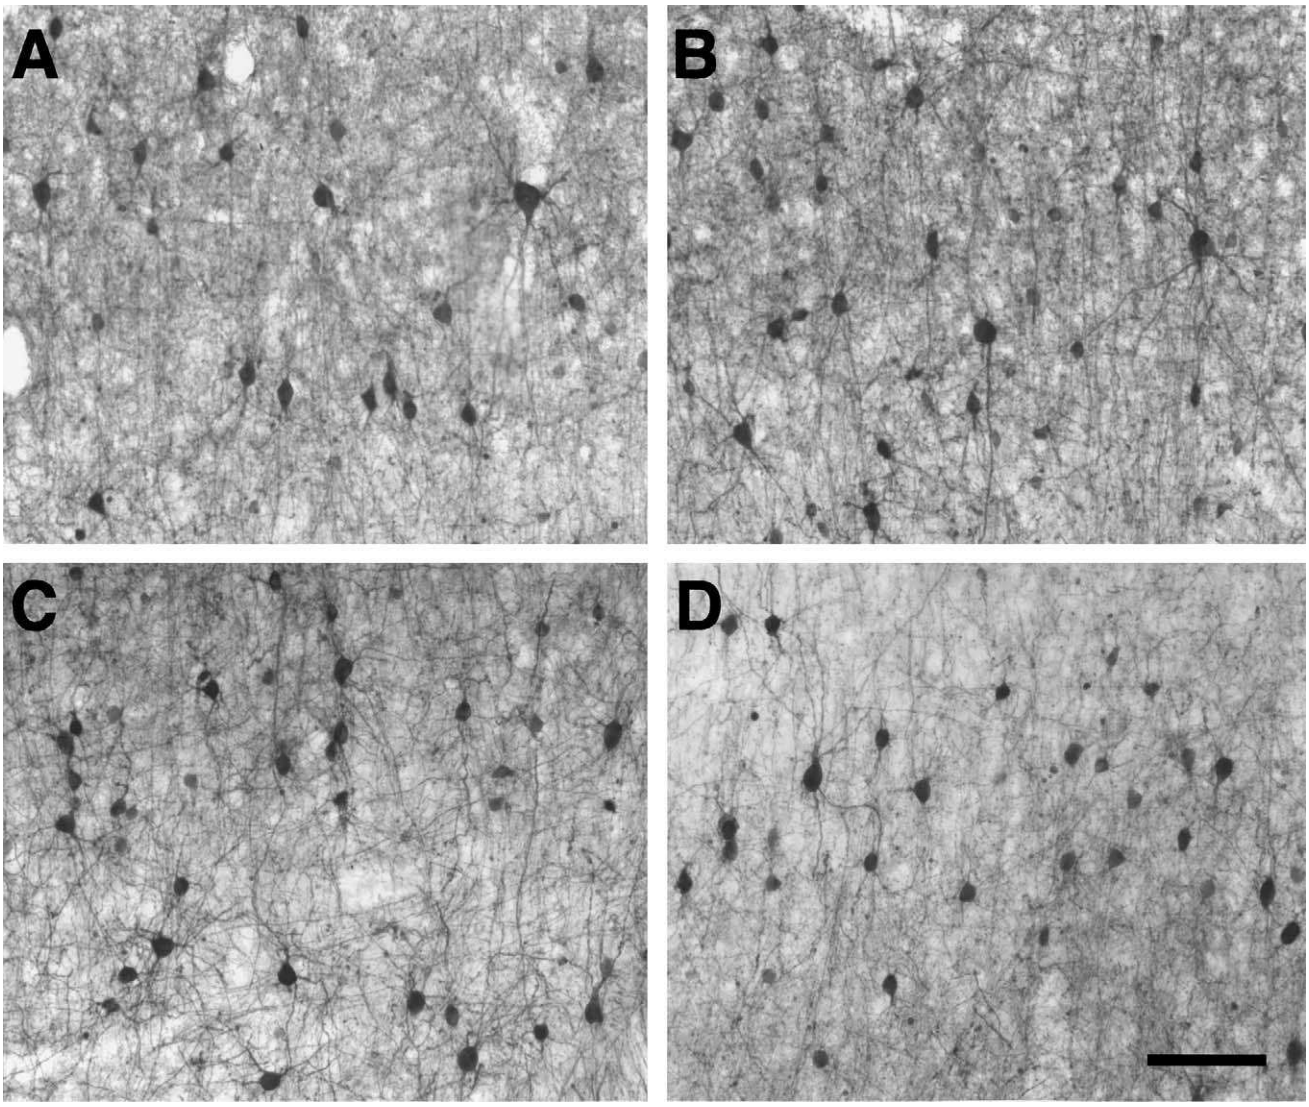

FIG. 9.8. Distribution of parvalbumin-immunoreactive neurons in areas 9 (A and B) and 20 (C and D) of a control case (A and C) and an AD case (B and D). These interneurons are present in all neocortical layers, but predominate in layers II–IV. These photomicrographs are all centered on the lower part of layer III and on layer IV. In AD cases, there is a remarkable preservation of the local density and morphology of these neurons. Scale bar: 100 μm.

statin and calbindin are colocalized in some interneurons (DeFelipe *et al*., 1989). Somatostatin-immunoreactive fibers occur in SP and thus degenerate to some degree in AD (Morrison *et al*., 1985). Interestingly, layer III pyramidal neurons are thought to be a principal target of these interneurons, suggesting that somatostatin- and calbindin-immunoreactive fibers are more vulnerable in AD than perikarya of the interneurons that contain these two markers (Gaspar *et al*., 1989; DeLima and Morrison, 1990). The differential vulnerability of the axonal portion of certain classes of interneurons may be linked to the fact that they are connecting onto a population of particularly vulnerable pyramidal neurons. Furthermore, the resistance of somatostatin neurons appears to be dependent on the colocalization of neuropeptide Y and/or NADPH diaphorase, and the density of interneurons containing neuropeptide Y, somatostatin, and NADPH diaphorase is not decreased in AD in the neocortex and hippocampus, although some of these neurons display morphologic alterations (Kowall and Beal, 1988). Corticotropin-releasing factor is found in association with parvalbumin in certain interneurons that remain unaffected in AD (Kelly and Kowall, 1989). Finally, some parvalbumin-immunoreactive interneurons in the hippocampal formation, as well as some calretinin-containing neurons, suffer dendritic alterations but are not lost and do not form NFT or associate with SP (Brion and Résibois, 1994).

Moreover, parvalbumin-immunoreactive neurons have been shown to be resistant to degeneration in the cerebral cortex of Huntington's disease, Pick's disease, Guamanian amyotrophic lateral sclerosis/parkinsonism–dementia complex, postencephalitic parkinsonism, progressive supranuclear palsy, corticobasal degeneration, and frontal lobe dementia, but not in Down syndrome and Creutzfeldt–Jakob's disease. Calbindin- and cal-

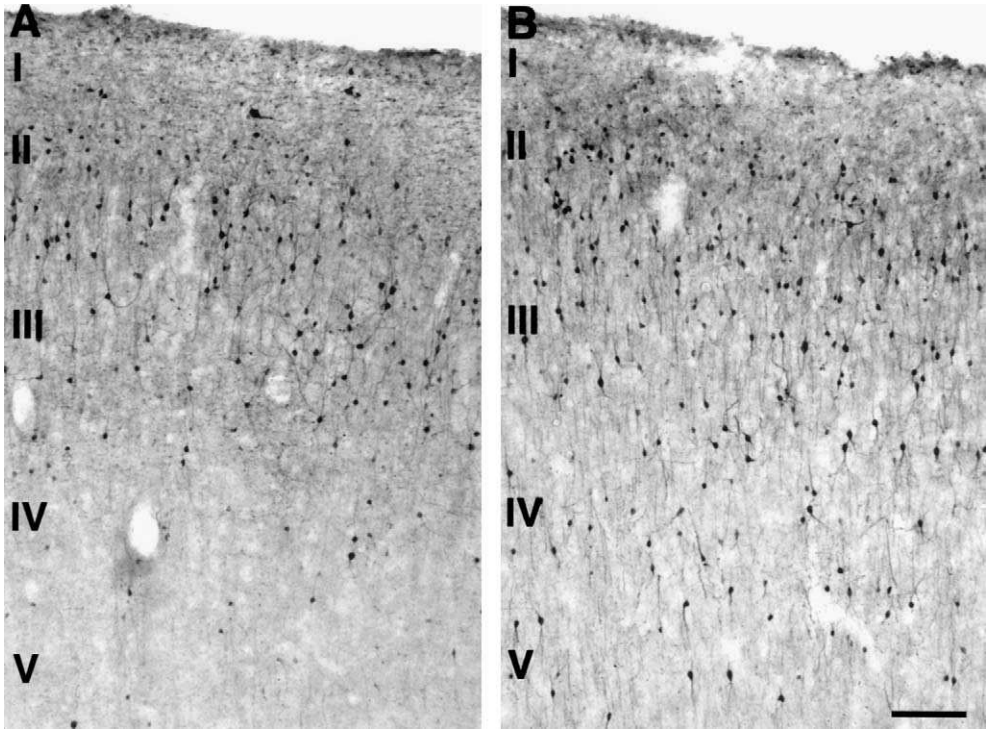

FIG. 9.9. Distribution of calretinin-immunoreactive neurons in area 9 of a control case (A) and an AD case (B). These bipolar/bitufted interneurons predominate in layers II–V. In the AD case, these neurons remain unaffected. Scale bar: 100 μm.

retinin-containing cells are also resistant in most of these disorders, except in frontal lobe dementia, where calbindin-immunoreactive neurons are vulnerable (Cudkowicz and Kowall, 1990; Kobayashi *et al*., 1990; Arai *et al*., 1991; Ferrer *et al*., 1993a,b; Hof *et al*., 1994, 1999a). The combination of factors, such as high cytoplasmic levels of calcium-binding proteins, certain neuropeptides, and GABA, with the morphological features of locally projecting interneurons may confer a heightened resistance to these neurons in a variety of neurodegenerative conditions, even at advanced stages.

V. A Synthetic Neuronal Phenotype of Vulnerability and Resistance

Selective neuronal vulnerability is a hallmark of all of the major neurodegenerative disorders and is apparent not only at the level of affected brain regions, subregions, or layers, but also at the level of specific neuron populations (Hof *et al*., 1990, 1999a; Arnold *et al*., 1991; DeLacoste and White, 1993; Morrison and Hof, 1997). The notion of differential vulnerability can be best understood in the context of a broad, yet integrative definition of neuronal typology that includes morphology, regional and laminar location, connectivity, and neurochemical phenotype. This approach is useful in delineating the cellular organization of the neocortex as well as the cellular pathologic changes in diseases such as AD, as it takes into consideration the complex relationships among these morphofunctional parameters.

In a very general sense, the most vulnerable group of cortical neurons includes large pyramidal cells and, more specifically, those providing long corticocortical projections between association neocortical areas and hippocampal projections. These systems utilize glutamate and are driven by glutamatergic inputs. However, not all corticocortical projections are equally vulnerable, as short projections from primary sensory to adjacent secondary sensory areas are resistant to degeneration. It is therefore likely that the specific neurochemical and morphologic phenotype of certain pyramidal neurons may predispose them to degeneration as well as NFT formation. In contrast to long projection neurons, GABAergic inhibitory interneurons containing the calcium-binding proteins parvalbumin, calbindin, and calretinin, as well as certain neuropeptides, are mostly resistant to degeneration in the AD neocortex. Also, the occurrence of modifications in the expression of certain glutamate receptor subunit proteins during aging or dementia, particularly the calcium-gating AMPA subunit GluR2, may determine susceptibility to calcium-mediated toxicity, which may play an important role in several aspects of the degenerative processes leading to neuronal death in AD.

The relevance and impact of pathologic changes in AD have to be understood within the context of organized systems that underlie neocortical function. For instance, integrated processing in a given sensory modality such as vision involves the simultaneous activity of numerous separable visual areas that have extensive highly ordered interconnections that establish a distributed system subserving the proper integration of the visual information. Similarly, cognition and language, which are not modality-specific functions, presumably depend strongly on the complex communication among neocortical regions provided by the corticocortical circuits, which are the particular projections that degenerate in AD, leading in turn to a

global neocortical disconnection syndrome that presents clinically as dementia (Hof *et al*., 1990, 1999a). Clearly, other degenerative processes occur in AD, and they may also contribute to the clinical characteristics of the disease, but the generalized loss of long corticocortical projections emerges functionally as the most devastating component of AD and the most directly related to dementia. Importantly, in this context, cells that provide these projections appear to be highly specialized neurons that share identifiable morphological and neurochemical features.

This interpretation of the pathological features of AD suggests that the debilitating dementia results from changes restricted to the association neocortex, whereas extensive hippocampal alterations can exist in the absence of neocortical involvement and with only minor disruptions in activities of daily living of the individual, whose memory deficits could be revealed by formal testing, but are not compatible with the diagnosis of dementing illness (see Chapter 7). As the elements of the biochemical and anatomical phenotypes, that are linked to differential cellular vulnerability in AD are increasingly recognized, it is hoped that therapeutic interventions will be developed to protect or rescue the neurons that are at higher risk in AD. The protection of these neurons appears to be an attractive strategy for the management of AD, which may have the advantage of being more achievable than the development of a cure.

Acknowledgments

Drs. C. Bouras and D. P. Perl generously provided the human postmortem materials used in our studies. We extend our special gratitude to Drs. L. Buée, T. Bussière, A. Delacourte, P. Giannakopoulos, J. H. Morrison, E. A. Nimchinsky, and J. C. Vickers for their contributions and discussion and to W. G. M. Janssen and A. P. Leonard for expert technical assistance. Patterns of Cortical Neurodegeneration in Alzheimer's Disease: Subgroups, Subtypes, and Implications for Staging Strategies

Normal brain aging into the ninth decade is associated with cognitive impairments that are quantitative in nature rather than forming subgroups of changes and it is not associated with appreciable neuron degeneration. In contrast, although age is a risk factor for Alzheimer's disease (AD), cognitive deficits form statistically unique subgroups and the patterns of neocortical neurodegeneration occur according to early deficits. There is substantial evidence for clincopathological subgroups and some studies suggest the possibility of subtypes. A subtype is comprised of cases with unique clinical deficits, pattern of brain lesions, and etiology. One possible AD subtype are patients with early spastic paraparesis associated with the deletion of exon 9 from the presenilin 1 gene, a unique type of senile plaque, and degeneration of the corticospinal tract. Also suggestive of subtypes are different laminar patterns of neurodegeneration in posterior cingulate cortex. These patterns of neuron death are not compatible with a linear regression model of large neuron death, but rather a multivariate model based on principal components analysis. Because AD is not composed of a single pattern of clinical, cognitive, and pathological lesions, staging at postmortem examination can only be used as a general guide to the level of neurofibrillary and amyloid deposition in the cerebral cortex. The presence of clinicopathological subgroups, the lack of a strong relationship between neuron death and neurofibrillary tangles, and the possibility of subtypes raise the specter that no current staging strategy precisely defines disease status. Thus, linear regression of population variables and simple staging need to be replaced by multivariate models and assessments of disease progression that accommodate many statistical and topographical subgroups and/or subtypes of AD.

I. Introduction

Neuron death is not a normal part of aging into the ninth decade. This has been shown for temporal cortex (Giannakopoulos *et al*., 1996; Gómez-Isla *et al*., 1996), posterior cingulate cortex (Vogt *et al*., 1995, 1998), and hippocampal sectors CA1–3 (West, 1993; West *et al*., 1994; Šimić *et al*., 1997). These latter studies demonstrate that although hippocampal formation does show losses in the subiculum and hilus of the dentate gyrus, these losses are qualitatively different from those observed in Alzheimer's disease (AD). Indeed, the loss of neurons previously thought to be associated with advancing age was probably associated with early stages of Alzheimer's and other dementing diseases. Because neuron loss in AD engages specific functional systems in the cerebral cortex, it should be straightforward to define which neurons degenerate and the topography of such a process. The pattern of neocortical neurodegeneration, however, is poorly understood. Such a task is daunting for a number of reasons. Cortical neurons are different sizes, they are organized into layers that differ in size and composition by cortical region, and there are so many of them that it is not possible to simply count all neurons in all areas. Finally, there is not a simple and established relationship between one or more neurodegenerative processes and the densities of neurofibrillary tangles (NFT) and senile plaques (SP). If such relationships existed, the density of NFT, for example, could be used as a surrogate marker for neurodegeneration.

The problem of defining neurodegeneration in AD is not a simple matter of blind counting all neurons in the brain. Even if such counts were available, they would be useless because one of the essential problems confronting the neurobiology of AD is conceptual; what model best fits the data? Is this a single disease with minor heterogeneity in clinical symptoms and neuropathology or is it a complex disease

with multiple genetic and environmental origins and risk factors, different ages at onset and rates of progression, different patterns of cortical outcomes, and fundamentally different lesion structures and patterns of neuron death? In this complicated neurological condition, how are neuron losses related to possible mechanisms of disease? One common strategy is to overlook diversity in the AD population and to seek "the" mechanism of neurodegeneration. As we will see, however, numerous clinical, neuropsychological, glucose metabolic, and neuropathological studies argue convincingly that AD is heterogeneous and composed of subgroups. The concept of clinicopathological subgroups must be a part of any neuron-counting protocol. In this context, a blind count of neurons in the entire cerebral cortex will not be adequate. Should early- and late-onset cases and/or familial and sporadic cases be included in each sample and in what proportions? What is the relation to neurofibrillary degeneration and neuron densities in any layer and area in a simple staging scheme (i.e., one that assumes a single progression)? To muddy the waters further, the hypothesis may eventually be proven that there are subtypes. A blind count of all neurons in all cortical areas will have no value outside the context of a specific disease model that takes into account a full range of variables, including disease onset and duration, genetic and other risk factors, and multiple mechanisms of neurodegeneration.

The numerous efforts to stage AD progression based on neurofibrillary and amyloid lesions, initiated by Braak and Braak (1991, 1997), have not resolved an essential contradiction; NFT and neuron densities do not correlate and the pattern of neurodegeneration in the temporal lobe and elsewhere may require mechanisms beyond that of tau phosphorylation. Moreover, the notion that neurofibrillary degeneration can be used to stage AD without reference to laminar patterns of neurodegeneration provides a limited and possibly unrepresentative view of the progression of AD and its clinical heterogeneity. Indeed, the Braak theory of staging requires the view that all cases fall into a single continuum and that conspicuous cell loss is not a predominant feature, even in fully developed AD.

This review evaluates current evidence for single or multiple laminar patterns of neocortical neuron degeneration and the extent to which cell death is correlated with NFT. It is observed that there is essentially no relationship between cell death and NFT and that a simple staging strategy cannot be applied to neurodegeneration nor will it explain clinical heterogeneity. Furthermore, studies of posterior cingulate cortex over the past decade clearly show that AD pathology does not cascade to a single and common end point as required by simple staging theories. More importantly, it does not begin with a single laminar pattern of neuron death and, once again, there is no substantive relationship between total neurodegeneration and NFT. These observations have led us to the use of nonlinear models to evaluate the characteristics of qualitatively independent subgroups of AD. These different laminar patterns of neurodegeneration are referred to as neuropathological subtypes within AD. Although subtypes of AD have not yet been identified, neurobiological studies support a continued effort to test the subtypes hypothesis. This review considers some of the compelling findings that support this viewpoint and multivariate statistical strategies that will be needed to test the subtypes hypothesis.

II. Neurofibrillary Degeneration, Clinical Symptoms, and Neurodegeneration

Densities of NFT and neuritic plaques are related to dementia severity in AD (McKee *et al*., 1991; Bierer *et al*., 1995; Nagy *et al*., 1995; Berg *et al*., 1998). The topographical distribution of NFT has been related to impaired cortical function and associated clinical symptoms in a general manner (e.g., Brun and Englund, 1981; Arnold *et al*., 1991), and studies evaluating specific clinical impairments and their association with cortical patterns of NFT confirm this expectation. Thus, patient populations with early signs of visual agnosia (Giannakopoulos *et al*., 1999), Bálint-like symptoms and posterior cortical atrophy (Hof *et al*., 1997), or various apraxias (Giannakopoulos *et al*., 1998) have differential distributions of NFT in areas that play a prominent role in each of these functions. For example, associative visual agnosia correlates with NFT in occipitotemporal visual association areas, whereas apperceptive visual agnosia is associated with diffuse rather than localized NFT (Giannokopoulos *et al*., 1999). In addition, SP densities appear to bear no specific relationship to this functional deficit. Thus, the density and topographical distribution of NFT can be related to selective and early clinical deficits.

Because dementia severity is highly correlated with large neuron degeneration in layers III and V (Neary *et al*., 1986), it is not surprising that NFT density is inversely linked to neurodegeneration (Mountjoy *et al*., 1983; Neary *et al*., 1986; Bondareff *et al*., 1993; Gómez-Isla *et al*., 1997). What is not clear, however, is the extent to which this relationship may explain total neurodegeneration. The following concerns about this relationship are worth considering. First, many non-NFT-containing neurons have DNA damage (Su *et al*., 1994; Sheng *et al*., 1998) and/or evidence for free-radical damage, as shown with nitrotyrosine immunohistochemistry (Su *et al*., 1997) suggesting that all neurodegeneration is not mediated by NFT. Second, the total number of NFT greatly understates total neuron loss in neocortex (Vogt *et al*., 1990, 1998; Gómez-Isla *et al*., 1997). Unless many NFT are transient, much neocortical cell death may not be associated with NFT. Third, longitudinal biopsy/autopsy studies report relatively stable NFT in patients with progressive cognitive decline (Mann *et al*., 1988; Bennett *et al*., 1993). Although earlier methods may not be as sensitive as current immunohistochemistry, NFT were stable in one study that reported neuron losses in frontal and temporal cortices, and neuron losses increased until death (Mann *et al*., 1988). It is likely, therefore, that NFT are only the tip of the neurodegeneration iceberg. It is possible that exploring the patterns of neurodegeneration with other methods will provide a greater range of information about the origins of cell death in AD. Finally, the extent to which NFT do not accurately reflect total neurodegeneration could raise concerns about staging AD based on the pattern and "spread" of markers in the temporal lobe and throughout neocortex, as implied and stated in various staging strategies.

III. Linear Model of Neurodegeneration: Temporal Cortex

Although an early study showed that large neurons degenerate in AD (Terry *et al*., 1981), it used extensive averaging

across many areas, quartile-depth measurements rather than specific laminar architectures of each area, and automatic counting at low magnification. Subsequent studies of cell death in AD also employed techniques that may have biased the outcomes. Some limited the analysis to layers III and V, which are known to have large neurons (Neary *et al*., 1986), whereas others used estimates of total neurons (Mountjoy *et al*., 1983; Gómez-Isla *et al*., 1997). None of these counting strategies provide a complete picture of the laminar patterns of cell death. A precise area and laminar analysis has not been performed throughout the cerebral cortex and it is still not known to what extent different sized neurons are involved in the pathogenesis of AD. In addition to restrictive *a priori* hypotheses, another problem with many studies is the underlying statistical assumptions and models used to analyze data.

Studies of cell death sometimes assume that neuron loss in a single neocortical area has an inverse association with age at death and disease duration. Because these associations could be used to explain a progressive decline in cognition, associations between neuron loss and disease progression are of particular importance. An inverse relation between total number of neurons and disease duration has been reported for the superior temporal cortex (Gómez-Isla *et al*., 1997). Some AD cases had neuron numbers that fell within the control range, and it was suggested that neuron losses in the superior temporal cortex were delayed in relation to the earliest functional impairments based on the Blessed dementia scale. It was also noted that neuronal changes were delayed in relation to the very earliest losses in the entorhinal cortex.

If the extent and progression of short-term memory impairment are dominated by the entorhinal cortex, this region should show a loss of neurons in relation to memory impairment and one would expect a progressive loss with aging. Gómez-Isla *et al*. (1996) provided information about neuron densities in entorhinal cortex, patient age at death, and clinical dementia rating scores (CDR) for 10 cases. Layer II neuron densities were closely related to disease severity measured by the CDR, although total neuron densities were not related to CDR. This suggests that defining cortical neurodegeneration with total neuron counts for an area will overlook important and laminar specific changes and changes that may underlie particular clinical symptoms.

To the extent that AD has an age risk, it is interesting to observe that total neurons in the entorhinal cortex do not change over three decades of AD and that there is a positive correlation between age at death and the number of neurons in layer II (Gómez-Isla *et al*., 1996). In this study, the three cases with earliest age of death (67–77 years), and presumably earliest onset, had significantly fewer neurons in layer II ($0.1 \times 10^6 \pm 0.026$; mean $\pm$ SEM) versus the seven cases with much later ages at death (85–95 years; $0.221 \times 10^6 \pm 0.048$). This latter observation suggests that the AD population is not uniform and a linear regression would not be appropriate to analyze data. There appears to be an important age-at-onset confound that cannot be extracted by the least-squares model. One solution to the paradox that layer II of the entorhinal cortex is involved early in AD and yet lacks an inverse relationship between neuron densities and age at death is that a nonlinear model of multiple subgroups better describes data than the assumption of a single underlying continuum.

IV. Neurodegeneration and NFT in Temporal Cortex

It is often assumed that neurodegeneration parallels NFT deposition, particularly in medial temporal areas; a view that has become widespread with efforts to stage disease severity with neurofibrillary changes. The facts, however, are open to a number of interpretations. For example, Gómez-Isla *et al*. (1996) concluded, "Neuronal number in AD was inversely proportional to NFT formation..." Total neuron density/$mm^3 \times 10^3$ and NFT densities in entorhinal cortex were reported for nine cases. The densities of NFT were rank ordered before performing the linear regression with neuron density, which produced an inverse relationship. The rank ordering, however, overweighed a few outlier cases and provided for limited statistical significance, and the inclusion of control cases should not have been used to power this relationship for AD. If data for each case are plotted without rank ordering, there is no relationship between total neuron densities and NFT. Finally, a study of entorhinal cortex, area CA1 of the hippocapmus, and area 20 in centenarians reported no correlation between NFT and neuron densities (Giannakopoulos *et al*., 1996). Thus, there is not an inverse relationship between neurodegeneration and NFT in entorhinal cortex and NFT cannot be used as a surrogate marker of overall neurodegeneration.

Another way to assess relationships between NFT and neuron densities in the temporal lobe is to consider an area that has a radically different cytoarchitecture than the entorhinal cortex, i.e., the lamina externa or granular layer, of the presubiculum. Figure 10.1A provides an example of this area with many small and medium-sized neurons in a control case stained for thionin. The remainder of Fig. 10.1 is from patient FG, who presented initially with dysexecutive syndrome and other evidence of frontal lobe involvement. Patient FG had the disease for 4.5 years and postmortem assessment confirmed bilateral, focal atrophy of the prefrontal cortex. This case has been discussed in detail previously (Vogt *et al*., 1999) and is considered again later. Figure 10.1B, of the granular layer stained with thionin, shows that there are very few neurons and many astrocytes in this layer. Figure 10.1C is immunoreacted for a monoclonal antibody to amyloid-β 42 peptide (Aβ42) in the external pyramidal layer of the presubiculum and shows a heavy deposit of this long form of amyloid. Figure 10.1D shows immunohistochemistry for hyperphosphorylated tau (AD2; Buée-Scherrer *et al*., 1996), counterstained with thionin, and it shows that there are no NFT in this layer. Although there is some nonspecific staining that is enhanced by the Nissl stain, no NFT or neuropil threads are in this layer. For comparison of the AD2 reaction, Fig. 10.1E shows NFT in layer II of the entorhinal cortex in a noncounterstained section from the same case. These preparations demonstrate a profound loss of neurons in this layer, absent NFT, and the abundant and diffuse deposition of Aβ42. Case FG was in Braak stage III of neurofibrillary degeneration and stage C of amyloid deposition. Thus, in medial temporal areas, small and medium-sized neurons degenerate, their degeneration may not be associated with NFT, and amyloid peptides could play a role in their death. This case provides an example of a strong match between neurodegeneration and Aβ42 deposition, while there is no association

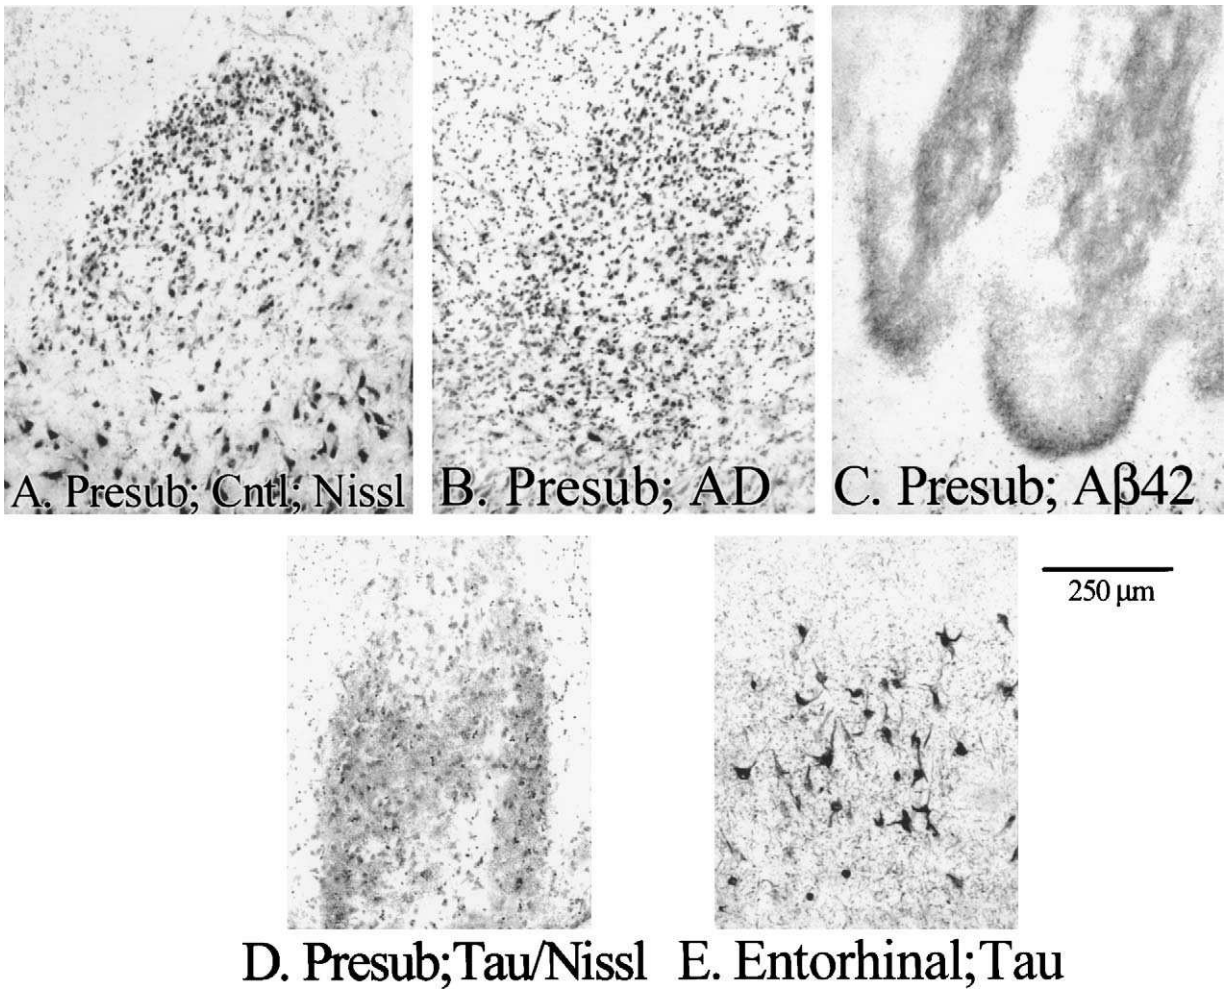

FIG. 10.1. Neurodegeneration in the presubiculum of case FG involves small and medium-sized neurons, no NFT, and substantial and diffuse deposits of Aβ42. (A) A thionin-stained section showing the external pyramidal cell layer and a few large neurons in the inner pyramidal layer from a control case. (B) A thionin-stained section from the same part of the presubiculum in case FG. Note that most neurons have degenerated along the cap of the external pyramidal layer, although some have been retained in its inner portion. (C) Aβ42 immunohistochemistry showing dense deposits in the external pyramidal layer that do not extend into the internal layer. (D) A Nissl-counterstained section of AD2 immunohistochemistry for hyperphosphorylated tau shows that no NFT are present in the external pyramidal layer. (E) The same section as in D (not counterstained) shows the level of NFT in entorhinal cortex layer II. Clearly small and medium-sized pyramidal neurons degenerate in this case without the formation of NFT as is characteristic of the entorhinal cortex.

between neuron death and NFT in the presubiculum. The only way one might make the argument for such a relationship is to assume that NFT formed early and were solubilized and cleared from the neuropil; an alternative that is cast into further doubt later where early neurodgeneration and laminar patterns of markers in posterior cingulate cortex is considered for case YW. The lack of an association between small and medium-sized neuron and neurofibrillary degeneration has consequences for global spreading and staging hypotheses of AD.

To the extent that NFT do not accurately reflect neurodegeneration, the staging scheme for neurofibrillary degeneration does not represent patterns of cell death. The possibility that there are subgroups of neurodegeneration in entorhinal cortex has important consequences for the Braak staging hypothesis. Questions have been raised as to whether clinically characterized cases express a consistent link to Braak stages. It was shown that Braak stages for CDR values of 1–3 are very similar and that the primary distinction occurs late in the disease with CDR 4 and 5 (Haroutunian *et al*., 1999). It appears that no single cortical area goes through a simple sequence of neurodegeneration, although stages can be identified with NFT. As noted earlier, even the entorhinal cortex has neurodegeneration that is greater when the disease begins earlier in life, suggesting that more than a single sequence of neuron death is at work. To the extent that neurodegeneration is (1) not substantially represented by NFT, (2) paramount to understanding the clinical syndrome, and (3) not associated with multiple and qualitatively unique patterns of NFT, the Braak staging strategy cannot provide a context for explaining clinical heteroge-

neity and it does not bear a close relationship to disease progression.

V. Posterior Cingulate Cortex: Functions and Contributions to AD Symptoms

Because our studies of posterior cingulate cortex do not support popular views of AD as a single disease that consummates in a final common pattern of neurodegeneration, we must interject here how it fits into the larger scheme of cortical connectivity, function, and dysfunction in AD. The posterior cingulate cortex is reciprocally connected with most anterior and posterior parahippocampal areas, including the entorhinal cortex and areas TF and TH (Vogt *et al*., 1979; Baleydier and Mauguière, 1980; Pandya *et al*., 1981; Insausti *et al*., 1987; Vogt and Pandya, 1987). The posterior cingulate cortex, including retrosplenial areas, is part of the medial swath of neurodegeneration that extends from the rostral and medial temporal cortex around the splenium of the corpus callosum (Brun and Englund, 1981). Furthermore, it is well documented that the cytoarchitecture and chemoarchitecture of the cingulate cortex is involved in AD, and this literature has been reviewed thoroughly (Vogt *et al*., 1997). In their topographical studies, Brun and Englund (1981) reported that the widest range of neurodegeneration (0–80%) occurred in the posterior cingulate cortex. Although this was part of their effort to grade their cases according to cell loss, gliosis, and other measures, our evaluation of this region in terms of cortical layers did not demonstrate simple relationships among large neuron degeneration, neuron losses in layers III and V, NFT and SP densities, or disease duration and age at onset (Vogt *et al*., 1990). For example, large and small neurons were lost in early or late stages of the disease, neurons were not lost in a single laminar pattern nor were they lost uniformly across all layers in all cases, and there was no simple relationship between NFT and neurodegeneration. Additionally, the progressive involvement of the cingulate cortex and its anterior thalamic afferents in AD has been considered by Braak and Braak (1991, 1993) in the broader context of their staging scheme.

Two possibilities are suggested by this large body of research. One view is that events in the posterior cingulate cortex are unique to this region alone. To the extent that area 23 is isolated from the rest of the brain, such changes can be overlooked as irrelevant to the pathophysiology and clinical symptoms of this disease. The posterior cingulate cortex, however, has massive and reciprocal connections, with many of the medial temporal regions often thought to be fundamental to the etiology of AD. Indeed, the posterior cingulate cortex shows early glucose hypometabolism in AD patients experiencing memory impairments (Minoshima *et al*., 1997). Additionally, many of our cases that were thought to have AD symptoms for 1–3 years had substantial neurodegeneration in the posterior cingulate cortex. Thus, changes in cingulate architecture, chemistry, and function occur early in the disease. *An alternative view* of the cingulate cortex in AD, therefore, forms the basis of the present assessment: the cingulate cortex is linked reciprocally to temporal cortices involved in AD, and cingulate function is impaired early and contributes significantly to the clinical syndrome. Most importantly, structural changes in this region do not fulfill the expectation that AD proceeds along a single course to a final common pathology, that there is only a weak relationship between neuron losses and NFT, and that long amyloid peptides may account for much early cell death. These views from the cingulate gyrus suggest that a reconsideration of other neocortical regions, such as entorhinal and prefrontal cortices, may lead to new insights into the one or more etiologies of this disease.

Disruption of the cingulate cortex early in AD may contribute to a number of symptoms, including visuospatial disorientation, contructional apraxias, and impairments in memory. Although all of the functions of the posterior cingulate cortex are not known, some important findings support its contributions to AD symptomatology. Single neurons in the monkey posterior cingulate cortex encode the position of the eye in the orbit, the direction and amplitude of saccadic eye movements, and large visual field patterns and visual scenes (Olson *et al*., 1993, 1996). Lesions in this region do not disrupt motor function, but they do impair spatial memory (Murray *et al*., 1989). It is possible, therefore, that neurons in the posterior cingulate cortex determine the locations of visual objects relative to the eyes and head. The convergence of eye orientation and large visual field responses is unique to the posterior cingulate cortex and belies its role in visuospatial processing and constructional praxis. Finally, the retrosplenial cortex has high basal glucose metabolism that is elevated further during a delayed alternation task associated with working memory (Matsunami *et al*., 1989).

The persistent involvement of the posterior cingulate cortex in AD likely contributes to memory and visuospatial disorientation early in the disease. In a group of patients with early memory impairment, Minoshima *et al*. (1997) reported the greatest and earliest glucose hypometabolism in the posterior cingulate cortex, and Hirono *et al*. (1998) reported a linear relationship between spatial disorientation and glucose hypometabolism in this region. Nybäck *et al*. (1991) reported substantial glucose hypometabolism in the posterior cingulate cortex, and it was significantly correlated with reduced performance on the Claesson–Dahl retention test and the similarities subtest of the Wechsler–Bellevue intelligence scale. Finally, Giannakopoulos *et al*. (1998) reported a specific correlation between constructional apraxia and the density of NFT in posterior area 23 as well as areas 7 and 19.

Before considering structural changes in the AD posterior cingulate cortex, a few comments on its organization in cognitively normal individuals serve as a basis for comparison. The structure of the human posterior cingulate and retrosplenial cortices is well known (Vogt, 1976; Braak, 1979; Zilles *et al*., 1986; Vogt *et al*., 1995, 1997). Figure 10.2 shows the cytoarchitecture of this cingulate region, including areas 29, 30, and 23, and high magnification photomicrographs of areas 29 and 23 to show the details of the cytoarchitecture for each. Area 29l is adjacent to ectosplenial area 26 and has a granular layer that is comprised to some extent of undifferentiated layers II–IV. Below this is a lamina dissecans and layers V and VI. The granular layer continues into area 29 m, where it appears to divide into layer IV and layers II and IIIab. Area 30 is dysgranular with a layer IV of variable thickness and at places the large layer IIIc and Va pyramids appear to intermingle. Also, layers II and IIIab are quite neuron dense and form a rather

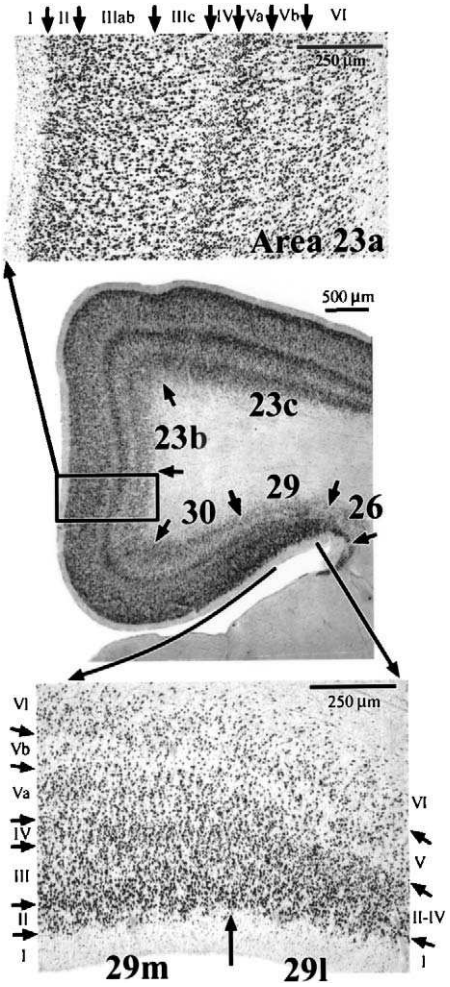

FIG. 10.2. Overview of the cytoarchitecture of the posterior cingulate gyrus with immunohistochemistry for neuron-specific, nuclear-binding protein and counterstained with thionin. One of the outstanding features of this cortex is the broad and densely stained neurons of layer V. Each area is delineated with arrows, and higher magnification photographs are provided for areas 29 m/l and 23a. The poorly differentiated granular layer II–IV is shown for area 29m as are layers IV and Va of area 23. The granular layer and layer Va in both of these areas are severely impacted early in AD, as shown in Figs. 10.5 and 10.6.

striking change at the apex of the ventral cingulate gyrus. Medial and dorsal to this is area 23a, which can be detected with the clear though thin layer IV and very large layer IIIc pyramids. These neurons contain a high proportion of intermediate neurofilaments as reported in articles cited earlier. As is true for each subdivision of area 23, layer Va in area 23a is very dense and thick. This is not true for areas 30 or 29 m, although the layer is present in these latter areas.

VI. Linear Model of Neurodegeneration in Posterior Cingulate Cortex

Although reports of large neuron losses in the neocortex are based on averaging of cell densities across many cytoarchitecturally different areas (Terry *et al*., 1981; Mountjoy *et al*., 1983; Neary *et al*., 1986), the posterior cingulate cortex should be expected to express similar changes. Therefore, we plotted the number of neurons in layer Va of area 23a, a layer with large neurons, as a function of disease duration for 69 cases of definite AD (Vogt *et al*., 1998). The number of neurons for each layer was calculated by counting perikaryal profiles in each layer through a 160-µm-wide strip of cortex. Examples of these drawings have been provided (Vogt *et al*., 1999). The counts were made from six strips and averaged to form the final mean values for control and AD cortex. As predicted, a plot of neurons in layer Va was inverse with disease duration, as shown in Fig. 10.3A (see color insert), and the correlation coefficient was significant ($r = -0.27$; $F = 6.19; p = 0.015$). Concern might be raised that two or three cases with durations of 18–25 years (circled in Fig. 10.3A) had an unusually large influence on the regression line. Indeed, removal of these three cases from the analysis reduced the correlation coefficient to nonsignificance ($r = -0.16$; $F = 1.74; p = 0.19$). Furthermore, if neurons were only lost in layers IIIc and Va, where most large neurons are located, the conclusion could have been made that neurodegeneration in the cingulate cortex occurs in an inverse pattern of primarily large neurons. However, neurons do not degenerate only in these two layers. Indeed, cases with fewer than 10 neurons in layer Va are part of a subgroup with extensive neurodegeneration in all layers. These cases are color coded with green in Fig. 10.3A and will be considered in more detail later.

The problem of ''outlier'' cases in linear regression is well recognized and has been discussed by Stevens (1984). Although all outliers do not necessarily influence regression, one or more cases can be influential and alter the results significantly. Because outlier analysis provides important clues to the composition of the population, let us consider their influence on data discussed earlier in more detail. Although it has been reported that Cook's distance is a good measure of the influence of one or more points on the regression (Kleinbaum *et al*., 1988), it is not associated with a statistical distribution that can be used for significance testing. Analysis of jacknife residuals provides a means of evaluating the veracity of a regression model and, because they are linked directly to distribution, the significance of an outlier in a least-squares model can be determined.

A residual e_i is the difference between the observed value of Y_i and its predicted value $\hat{Y}_i$ from a regression model; i.e., the discrepancy that is still present after fitting with least squares. These error terms should be independent, have a mean of zero, have a common variance, and follow a normal distribution (see Kleinbaum *et al*., 1988, for further details). The jacknife residual is calculated with the *i*th observation deleted. A graphic plot of residuals against predictor values is a way to evaluate the regression assumptions and the influence of possible outliers. A plot of jacknife residuals against disease duration for all cases is provided in Fig. 10.3B (see color insert). The dispersion of residuals plotted against the predictor variable is evidence that the basic regression assumption stating that ''the X variable must be known without error'' is not followed in this population of cases. Furthermore, the coefficient b1 has a small but nonzero value that displaces individual points from a straight line. There is a systematic divergence of the 17

members with overall severe neurodegeneration, i.e., those cases with fewer than 10 neurons sampled in layer Va. The model, therefore, appears to be inappropriate for this data set. Furthermore, the *t* value for the case with a 25-year duration is significant, confirming the expectation that it is an outlier, whereas the *t* value for the 23-year duration case was not quite significant.

A statistical rationale to delete one or more cases as outliers does not alone justify their exclusion from the regression analysis. Because this outlier in the current analysis signaled that a larger subgroup of cases share characteristics that distinguish them from the remainder of the cases, it provided an important hint that the least-squares model was invalid. The 17 cases with severe neurodegeneration are defined as those with greater than 80% neuron loss in most cortical layers. In other words, neuron losses in these cases are not only in layer Va but throughout the entire cortex. This is one rationale for considering this entire group of 17 cases as a subgroup. All of the cases with fewer than 10 neurons in layer Va were part of a larger group we refer to as neuropathological subtype severe (NSTSevere). Deleting all 17 cases from the linear regression reduces the correlation coefficient to an F value of only 0.67 ($p = 0.41$). Importantly, NSTSevere had a range of disease durations from 4.5 to 25 years, suggesting that cases with very few neurons in layer Va may be part of an independent subgroup. In this broader context, long-duration outliers are of no consequence in and of themselves. It is their membership in the larger subgroup that is important.

An assessment of jacknife residuals and outliers in this regression analysis led to the conclusion that a subgroup of cases provided all of the statistical significance for least-squares fitting of linear regression. The demonstration of at least one statistically and pathologically unique subgroup leads to the conclusion that this data set is not uniform and that regression analysis is not justified for all 69 cases together. A multivariable method is needed to define the complex relationships among laminar patterns of neurodegeneration, as well as the role of various AD risk factors, such as age at disease onset and apolipoprotein E genotype. Because multivariate analyses are well established as a means of identifying neuropsychological and clinical subgroups in AD, we begin with these observations before considering a multivariate strategy for assessing cingulate pathology.

VII. Multivariate Models of Cognitive Function: Clinical Subgroups

Aging in the normal population is associated with heterogeneous impairments of cognitive function. Valdois *et al*. (1990), for example, observed six subgroups that differed mainly in overall degree of performance. These subgroups, however, did not exhibit contrasting profiles of impaired and preserved cognitive abilities and their distinguishing features were primarily quantitative rather than qualitative in nature. In the nondemented controls evaluated by Kanne *et al*. (1998), principal component analysis (PCA) showed that only one factor accounted for the neuropsychological profiles, suggesting a functionally homogeneous group. In contrast, cognitive impairments in AD differ significantly from those in normal aging. Martin (1987) and Martin *et al*. (1986) were among the first to recognize that the cognitive onset and progression of AD do not follow a single pattern and proposed that there were neuropsychological subgroups. The claim of subgroups refers to the fact that AD patients can present with qualitatively distinct patterns of impaired and preserved cognitive abilities. These differences do not refer to disease progression and markers thereof, such as extrapyramidal signs, psychosis, and myoclonus, nor to features common to all cases, such as short-term memory disruption. The best documented subgroups consist of patients with deficits in semantic memory and word-finding ability, concurrent with normal or near normal visuospatial skills, and patients with the opposite profile (Haxby *et al*., 1985; Martin *et al*., 1986; Martin, 1987; Becker *et al*., 1988; Albert *et al*., 1990; Grady *et al*., 1990; Fisher *et al*., 1996). Kanne *et al*. (1998) observed three categories of cases with the following factors in their multivariate analysis of 407 AD patients: mental control/frontal, memory-verbal/temporal, and visuospatial/parietal. For those individuals that came to autopsy, there were high correlations with mature plaques in each cortical region and the three psychometric factors.

Disease progression in relatively focal cases is characterized by continued deterioration within the affected cognitive domain (Martin, 1987) and a widening of symptoms to other, previously intact, domains (Becker *et al*., 1988). The fact that the disease continues to progress within a single cognitive domain suggests that the progression of pathology is not random, but rather carves a course that parallels the functional organization of the affected systems. The differences are not simply quantitative and, therefore, are not related to differences in severity, disease duration, or rate of progression in any simple manner. Groups of patients like these define qualitatively distinct clinical subgroups, even though they all may have other symptoms in common, such as difficulty learning and remembering recently presented information.

The different neuropsychological profiles of clinical subgroups are associated with correspondingly different patterns of cortical dysfunction. In the first type of patient noted earlier, there was severe glucose hypometabolism of the posterior parietal cortex, especially in the right hemisphere, relative to other regions, whereas the second type of patient had most severe hypometabolism in the left temporal lobe (Martin, 1990). Cognitive and metabolic heterogeneity is also apparent in the frontal cortex. Grady *et al*. (1990) observed inappropriate behaviors in cases with greatest prefrontal glucose hypometabolism, and Mann *et al*. (1992) reported that two groups with equivalent parietal glucose hypometabolism and impaired measures of parietal function could be distinguished with frontal lobe glucose metabolism, measures of executive function, and rate of progression. Foster *et al*. (1983) observed that patients with a disproportionate failure of language function had hypometabolism in the left frontal, temporal, and parietal regions, whereas those with predominant visuocontructive dysfunction had hypometabolism mainly in the right parietal cortex. Finally, Royall *et al*. (1994) observed early impairment of executive functions in AD that could be attributed to disrupted frontal lobe function. In a review considering patient FG with dysexecutive function, we proposed that focal prefrontal atrophy may account, to some extent, for the specific neuropsychological profile (Vogt *et al*., 1999; see later).

Various multivariate models have been used to evaluate subgroup characteristics in AD. Martin *et al*. (1986), Becker *et al*. (1988), and Kanne *et al*. (1998) used principal components analysis, whereas Fisher *et al*. (1996) used a number of factor and cluster analytical techniques. In each instance, evidence for three subgroups was provided. Becker *et al*. (1988) found that the largest group had nonfocal deficits, whereas smaller subgroups had impairments in lexical/semantic function or visuoconstructional abilities. Martin *et al*. (1986) had a subgroup with equal impairment of word-finding, visuospatial, and constructional skills, a subgroup with severe word-finding concurrent with intact spatial and constructional ability, and a subgroup with the opposite profile. Fisher *et al*. (1996) observed the largest subgroup with severe anomia and constructional dyspraxia, whereas smaller subgroups had severe anomia and preserved visual-perceptual/constructional functioning and another with moderate difficulty copying overlapping figures and intact naming and nonverbal reasoning. Finally, Kanne *et al*. (1998), as reported earlier, observed three patterns of cognitive impairments that were highly correlated with mature plaques in each of the cortical regions that dominate processing in particular functional domains. These observations clearly show that cognitive impairments are not uniform, the differential patterns of dysfunction suggest selective disruption of functional subsystems, including differential impact of pathology, and there should be an equivalent heterogeneity in the cortical expression of this disease. In other words, it should be possible to identify neuropathological subgroups by applying multivariate analytical techniques.

VIII. Clinicopathological Subgroups

Very few neuropathological studies seek to assess subgroups of cases. In the context of clinicopathological subgroups, we can recast the conclusions of previous works that associated differential cortical topography of lesions with particular classes of symptoms, each of which has been cited earlier. Although most of these studies do not seek subgroups *per se*, they have identified clinical subsets of patients with unique patterns of lesions. Four striking clinicopathological subgroups include early disturbances of visuomotor and visual attention, associative visual agnosia, and ideomotor and constructional apraxias and each is associated with a different pattern of cortical lesions.

In the subgroup with early and prominent visuomotor and visual attention symptoms, there is optic ataxia and impaired visual tracking, disturbance of visual attention or simultanagnosia, and variable amounts of alexia, anomia, agraphia, and transcortical aphasia. This constellation of Bálint-like deficits was first reported in AD by Grünthal (1928) and is associated with posterior cortical atrophy as reviewed by Hof *et al*. (1997). The distribution of NFT and neuritic plaques is most prominent in the occipito-parieto-temporal junction, including areas MT and posterior cingulate cortex, whereas there is a somewhat lower lesion density in area 17 and much less in prefrontal cortex, which is relatively spared in these cases (Fig. 10.4, see color insert). In contrast, patients with early associative visual agnosia have preserved visual perception of forms, correctly copy and match items, and have preserved visual attention, but they are unable to identify objects verbally. This syndrome is quite different from the visuomotor symptoms characteristic of the Bálint-like syndrome and is correlated with a high level of NFT in areas 18, 19, and 37 (Giannakopoulos *et al*.,1999). Finally, two subgroups of AD with different apraxias have different distributions of NFT (Giannakopoulos *et al*., 1998). Visuocontructional apraxia is associated with high levels of NFT in areas 7, 19, and 23, whereas ideomotor apraxia is associated with elevated lesions in anterior cingulate area 24.

These four clinicopathological entities are subgroups because they depend on the differential distribution of a common marker, NFT and neuritic plaques. Each subgroup, therefore, could be a consequence of the same mechanism of neuron death without invoking a different etiology for each. Such subgroups are compatible with the notion that there is a stochastic expression of a single etiology of the disease. Future efforts to refine the topography of lesion distributions and neuropsychological testing will certainly uncover more examples of clinicopathological subgroups. Finally, staging the disease, particularly based on markers in the temporal lobe, is compatible with the subgroups hypothesis to the extent that all cases share a common clinical deficit(s) which is related to impairments in this region. To the extent that pathological alterations may start in other regions early in the disease in some cases, the single-model, staging strategy will not prove useful.

IX. The Subtypes Hypothesis

Jorm (1985) considered the threshold criteria for subtypes of AD. In order to demonstrate subtypes, a pattern of clinical symptoms, associated brain lesions, and different mechanisms of neurodegeneration must be identified. According to this standard, defining subtypes proceeds through three stages. Stage 1 is essentially completed and involves demonstrating statistical subgroups based on different patterns of cognitive impairments. Had all AD cases presented with the same first symptom and progressed through a uniform sequence of cognitive impairments, the subtypes hypothesis would long ago have been moot. In view of the unique presenting symptoms, differential progression of cognitive impairments, and altered patterns of cortical glucose metabolism shown with principal components analysis (e.g., Becker *et al*., 1988; Rapoport, 1991), stage 2 studies are underway. In stage 2, patients with unique and early symptoms are assessed at postmortem to determine the extent to which different patterns of neurodegeneration and disease markers can be associated with early symptoms. The observations of clinicopathological subgroups fulfill this activity. Once it is clear that there are unique patterns of cognitive impairments and associated cortical lesions, stage 3 will pursue unique etiologies for each.

According to Jorm criteria for subtypes, the report by Crook *et al*. (1998) provided evidence for a possible subtype of AD. Members of a Finnish pedigree have deletion of exon 9 of the presenilin 1 gene and present early with spastic paraparesis followed by progressive dementia. These latter symptoms include impairments in short- and long-term memory, language, and visuoconstructive and spatial abilities. Postmortem analysis shows unique SP and patterns of neurodegeneration in the cer-

ebral cortex. The SP are two to three times larger than typical for AD and there are no central cores. Although the sensorimotor cortex is not usually involved, even in late stages of AD, the unique SP are in the sensorimotor cortex, as well as other areas, and there is degeneration of the corticospinal tract in some cases. Although some cases with exon 9 deletion do not have spastic paraparesis, and other mutations, such as the splice site acceptor mutation in exon 9, also produce these symptoms, this is the first clear example of unique patterns of lesions, symptoms, and a potentially unique mechanism of neurodegeneration supporting it as a possible subtype.

In any instance in which there is a unique pattern of lesions that might require a unique mechanism of neurodegeneration, there is the possibility of a subtype. Giannakopoulos *et al*. (1996) reported that the CA1 field of the hippocampus was particularly resistant to neurodegeneration in centenarians and that there was an inverse correlation between SP and neuron densities in area 20, a finding not usually made in earlier onset cases. There was also a low rate of NFT formation in areas 20 and 9, despite neurodegeneration in these areas. Finally, a lack of association between apolipoprotein E (ApoE) $\epsilon 4$ genotype and AD over the age of 90 has been reported (Sobel *et al*., 1995; Asada *et al*., 1996). These observations suggest a differential pattern of lesions in centenarians and the possibility for different mechanisms of neurodegeneration. What is lacking to understand further the extent to which these cases form a subtype is a detailed neuropsychological profile that would indicate a unique pattern of cognitive deficits.

A preliminary case for subtypes can be made from cases with particular deletions in the presenilin 1 gene and AD in centenarians. In both instances, the pathological differences are not based solely on a differential distribution of NFT, but rather on differential patterns of neurodegeneration, some of which could be independent of NFT densities. Different laminar patterns of neurodegeneration in the posterior cingulate cortex suggest to us that it is likely that more than one mechanism of neurodegeneration will be required to explain cell death in this region. The observations discussed later, therefore, provide further evidence for neuropathological subtypes and may eventually lead to an understanding of subtypes based on Jorm criteria.

X. Multivariate Analysis of Neuron Losses and the Concept of Neuropathological Subtypes

In light of the evidence for clinical subgroups and relationships between specific clinical symptoms and the topographical distributions of NFT, it is surprising that few neuropathological studies of AD have employed multivariate strategies to address these complex and nonlinear relationships. Armstrong *et al*. (1996) entered a large number of variables into hierarchical and principal component models, including measures of brain weight, neurodegeneration in frontal cortex and the CA1 sector of the hippocampus, and NFT and amyloid deposition in many structures. Although the rationale for each measure was not provided, variables with extensive cross correlations were not removed, and the features of each subtype were not provided, these investigators suggested that five subtypes existed in their sample. Although they concluded that many of the differences underlying their subtypes were due to differential distributions of SP and NFT, neuronal losses were only measured in two cortical areas. It is possible that the multivariate strategy can be pushed further to understand the unique features of neurodegeneration and, eventually, associated patterns of clinical deficits.

The need to develop a multivariate strategy arose from our studies of the posterior cingulate cortex in postmortem cases. An objective assessment of neuron numbers in all layers of this region in cases of definite AD failed to show a single laminar pattern of neuron death and a single disease progression (Vogt *et al*., 1990). All cases with cortical or subcortical Lewy bodies were excluded from the analysis as part of the AD diagnosis to ensure that different patterns of neurodegneration were not a consequence of comorbidities with other neurological diseases. In this carefully screened series of cases, five laminar patterns of neurodegeneration were observed and each had a full range of disease durations. These findings suggested that cases with no losses in one class are not necessarily early forms of more profound cell loss in other classes. Moreover, the most severe degeneration occurred in early-onset cases and could not be the end point of neurodegeneration in classes with less severe degeneration and with a late onset. We tested the subgroup hypothesis with a sample three times as large as the earlier one (Vogt *et al*., 1998) and confirmed and extended many of the earlier predictions. Most importantly, five statistical subgroups were confirmed, the neuropathological subtype with the most severe neurodegeneration contained most of the early-onset cases and cases homozygous for the $\epsilon 4$ allele of ApoE, NFT were unrelated to the laminar patterns of neurodegeneration but did mark disease progression, and NFT were weakly related to neurodegeneration in some layers (III and V) and unrelated to cell death in others (II, IV, and VI). A reconsideration of these findings provides further statistical support for the neuropathological subtypes hypothesis and makes specific predictions for further research endeavors.

The concept of neuropathological subtypes is a hybrid concept meant to distinguish clearly different neuropathological states from those defined by the inclusive definition provided by Jorm's concept of AD subtypes. The Jorm (1985) concept correctly requires an association between unique clinical deficits and lesion patterns as well as unique mechanisms for each subtype. In contrast, a neuropathological subtype is composed of cases that are statistically unique from other cases in terms of some pattern of neuron death and the changes suggest unique mechanisms of death. It is an interim concept to allow for hypothesis testing during the decades needed to analyze this issue without being held to the currently popular view that AD is a single entity and that most cases are the same with only minor differences. As noted earlier in the discussion of neuropsychological subgroups, these differences are not simply quantitative, such as more or fewer SP or NFT. There are instances where more NFT in a region may be related to particular functional deficits; however, the differential distribution of NFT does not predict a unique mechanism for each subgroup. Rather, there might be a stochastic expression of a single mechanism in different cortical regions. In contrast, different laminar patterns of neurodegeneration suggest different mechanisms of neuron death. Selective degeneration of layer IIIab neurons, for example, likely requires a very different

mechanism of cell death than in cases where layer IIIab is intact but neurons in layers IV–V are lost. Furthermore, even when there are quantitative differences in the statistical analysis, such as moderate neuron losses in most layers or severe neuron losses in all layers, there need to be patient characteristics that distinguish qualitatively unique features between the two statistical subtypes. As noted earlier, the subtype with severe neurodegeneration is unique because it has most early-onset cases and most cases that are homozygous for the $\varepsilon 4$ allele of ApoE.

The neuropathological subtypes discussed here cannot be elevated to full Jorm subtypes until they are redefined in terms of clinical deficits and unique mechanisms of cell death have been defined for each. Although ''ST'' and the layer with greatest neurodegeneration were used previously as a short-hand way of referring to each neuropathological subtype (Vogt *et al*., 1998), we now extend this nomenclature to emphasize that a narrowly defined subtype is under consideration rather than Jorm subtypes. Thus, NSTIIIab refers to the neuropathological subtype with greatest neuron death in layer IIIab, whereas NSTSevere refers to cases with severe neurodegeneration in all layers.

Let us reconsider data used for linear regression and assessment of jacknife residuals in Fig. 10.3 in terms of a multivariate model with PCA. The PCA seeks to explain as much of the total variation in the data as possible with a few factors (Kleinbaum *et al*., 1988). Although the first few principal components explain most of the variance and are not correlated, they are difficult to interpret in terms of subsets of original variables; in this instance, numbers of neurons in layers IIIab, IIIc, IV, and Va of area 23a are calculated as discussed earlier for layer Va. A simple structure in the analysis is achieved by rotation of the data so that factor loadings for a single variable are large and those for the others close to zero. We have used orthogonal rotation of the eigenvector projections in three-dimensional graphics with the Ein*Sight statistical and pattern recognition software (InfoMetrix, Woodinville, WA). Graphic rotation was performed to identify groupings of cases that were color coded according to *a priori* hypotheses about the five laminar patterns of neurodegeneration. Figure 10.3C (see color insert) shows the optimal orientation of the three-dimensional projection where all members of each statistical subgroup segregate into a unique space. Because an objective and unbiased statistical method confirms the presence of five subgroups of laminar patterns of neurodegeneration, we can now characterize each of these subgroups by which layers have the greatest cell death and the patient characteristics for each subgroup. Moreover, this strategy can be used to evaluate other variables, such as the age of disease onset, amyloid or tau burden in one or more layers, and the contribution of particular risk factors to cell death.

The characteristics of each neuropathological subtype have been presented (Vogt *et al*., 1998, in Table 3). The independence of each can be argued from this table. There is a full range of disease durations. The only exception is NSTSevere, which has a 4- to 25-year duration because this subgroup also contains most early-onset cases, which have fewer disease comorbidities and live for a longer time with their disease. Indeed, NSTSevere is fundamentally different from all other NST with its early onset, greatest number of SP and NFT, and highest proportion of ApoE $\epsilon 4$ allele homozygotes. Another important point can be drawn from this table. The NST0 with no neurodegeneration is not simply an early stage of cell death that precedes one or more of the other subtypes because it can occur within 10 years of onset. Finally, tests were performed of the hypothesis that the ApoE genotype is associated with one or more patterns of neurodegeneration. Although there are six possible allelic associations, there was no ApoE genotype effect for each NST. This was deduced by including this risk factor in the PCA and by evaluating the proportions of the various allelic combinations in each NST. Only NSTSevere had a disproportionately high density of $\epsilon 4$ homozygotes.

The multivariate strategy is a powerful tool for analyzing complex relationships, including both patient characteristics and neuropathological endpoints. This analysis predicts that there are five laminar patterns of neurodegeneration early in the disease. Indeed, a number of cases included in the analysis discussed earlier had a short to moderate length of the disease (1–4 years). It is important that such cases remain as members in their respective NST, indicating that the same pattern of cell death occurs early in the disease.

In conclusion, multiple laminar patterns of neurodegeneration form the basis for neuropathological subtypes. This nomenclature emphasizes subtypes rather than subgroups because the neurochemical differences among different cortical layers and associated neuron death will likely require different mechanisms, as discussed briefly later. If neurodegeneration occurred according to one size class of neuron and systematically involved only one or two layers, we would have used the term subgroups as employed for evaluating clinicopathological subgroups based on differential patterns of NFT. The term neuropathological modifies the subtype designation to emphasize that, in this instance, the clinical correlates are not yet known. When the clinical and neuropsychological profiles and a unique mechanism of neuron death are identified for each neuropathological subtype, they will be graduated to the status of subtypes based on the Jorm criteria.

XI. NFT are Weakly Related to Neurodegeneration

In our first assessments of the posterior cingulate cortex using thioflavine-S-stained materials, the densities of NFT and SP were not related to the different laminar patterns of neurodegeneration (Vogt *et al*., 1990). In the expanded study there were more SP in NSTSevere, which also had the highest frequency of ApoE $\epsilon 4$ homozygotes, as noted earlier (Vogt *et al*., 1998). NFT densities, however, were about the same for all neuropathological subtypes. Most importantly, the number of NFT greatly understated total neurodegeneration. In layers III and V, there were approximately eight neurons lost for each NFT. In layers II, IV, and VI, where there are few or no NFT and often vast amounts of neuron death, there was not even a weak relationship between lost neurons and NFT.

This is not to say that the laminar distributions and densities of NFT are uninformative, they are. The distribution of NFT is altered throughout the course of the disease in NSTII–V and NSTSevere in the same manner. In early stages of the disease,

NFT are mostly in layers IIIc and Va. As the disease progresses, NFT are more prominent in layers, IIIab and Vb and, late in the disease, most are in layers II and IIIab. A multivariate model of disease duration and the density of NFT in each of three groups of layers confirmed that NFT in different layers mark early, middle, and late stages of the disease. Because this progression was observed in two neuropathological subtypes, these changes are not a feature of any one subtype but reflect a common feature of disease progression.

In conclusion, depending on the layer, there is a weak or no relationship between neuron losses and NFT. This means that the laminar patterns of neurodegeneration cannot be assessed with NFT. It also means that the clinicopathological subgroups identified with NFT may have multiple counterparts in terms of neurodegeneration that are not observable with NFT. It is still possible, therefore, that these clinicopathological subgroups represent subtypes. In order to prove this latter statement, it will be necessary to show that each subgroup has a different laminar pattern of neurodegeneration and that each are subserved by a different mechanism of neuron death.

XII. Early Changes in Posterior Cingulate Cortex

One of the tests that there are five neuropathological subtypes of AD is to evaluate early clinical stages of the disease and identify five laminar patterns of neurodegeneration that are not the result of late stage disease and are not influenced by a larger group of cases that include late-stage cases. Although our previous work included a wide range of cases, we were fortunate to have material from individuals with disease durations estimated to be 1–3 years. These short-duration cases were part of the larger subgroups reported in multivariate analyses and did not segregate into a separate statistical space in eigenvector projections. Another way to evaluate the neuropathological subtype hypothesis is to select cases with CDR of 1–1.5 and disease durations of less than 2 years. Although a complete study of this nature will require many years, we provide patient YW here to show that neurodegeneration occurs early in the posterior cingulate cortex, the pattern of cell death in this instance is compatible with NSTIV–V, this degeneration is unrelated to the formation of NFT, and, in some instances, layers with heaviest neuron loss and gliosis contain the highest amounts of long amyloid β-peptide (Aβ42).

Patient YW was 88 years old when she died of a myocardial infarction. This patient's disease evolved over a period of 2 years with an acceleration during the second year. Until the last 3 months of life, YW had a Mini Mental Status Exam of 22–23, although it was 15 at the time of death. At death there was mild cortical atrophy and NFT in entorhinal cortex and the CA1 sector of the hippocampus and only rare NFT throughout the neocortex in a pattern compatible with Braak stage II. There were a few NFT and neuritic plaques in posterior cingulate areas 29, 30, and 23, as shown with the AD2 antibody. Interestingly, there was substantial gliosis in the granular layer of area 29 (Fig. 10.5) associated with a severe loss of small and medium-sized neurons in this layer and a loss of some large, layer Va pyramids. In area 23a a similar pattern of gliosis and neuron loss was apparent (Fig. 10.6). This pattern of neuron loss fits our NSTIV–V because neurons in layers II–IIIc and Vb–VI of area 23a appear intact when compared to control cases. Note layer IIIc, for example, in Fig. 10.6.

Although there were rare NFT in posterior cingulate and other neocortices identified with the AD2 antibody, there is evidence in this case for an earlier phosphorylation of tau protein. The AT8 monoclonal antibody detects abnormal phos-

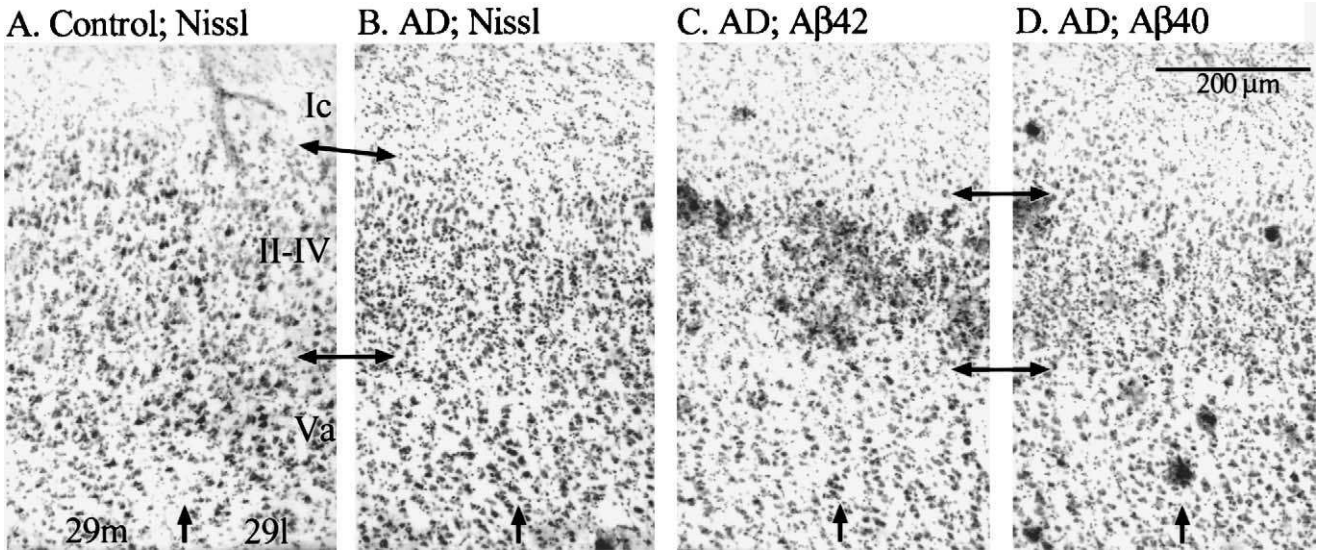

FIG. 10.5. Assessment of case YW (CDR 1.0; 2-year duration). Changes are shown for areas 29 m and 29l. Comparison with the control case shows profound gliosis and neuron losses in the granular layer and, to a lesser extent, in layer Va. There is a dense deposit of Aβ42 in granular layers II–IV, whereas Aβ40 is primarily deposited outside the limits of layers II–IV. Because there were almost no NFT in this layer (i.e., no AD2 immunoreactivity), neurodegeneration is most likely associated with the long form of the amyloid β peptide.

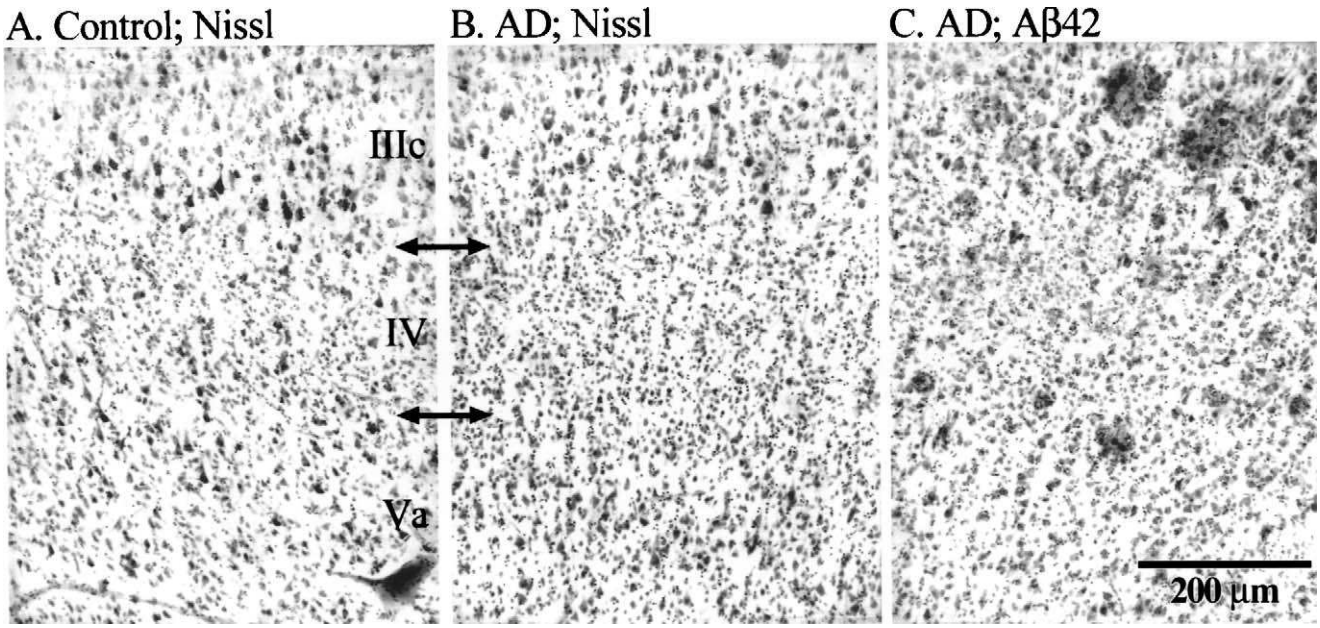

FIG. 10.6. Area 23a is compared in control and case YW. Changes is area 23a early in AD are only partially associated with large cortical neurons. In case YW, neuron losses and gliosis occur in both layers IV and Va and this laminar pattern is characteristic of NSTIV–V. Note that layer IIIc is much less impacted and that there were almost no NFT in any layer of this area (not shown). Interestingly, Aβ42 was deposited mainly in layer IIIc and, to a lesser extent, in layer Va. To the extent that Aβ42 might contribute to neuron death in the granular layer of area 29, this mechanism is not tenable in layer IV of area 23. Indeed, there is clear deposition of the peptide in layer IIIc, which is almost normal in terms of neuron densities.

phorylation of tau at Ser-202 (Goedert *et al*., 1993; DeLeys *et al*., 1996), and it has been reported that one of the earliest cytoskeletal changes in vulnerable neurons in AD might be hyperphosphorylation of neurofilaments in plaque-associated neurites (Su *et al*., 1996). In ectosplenial area 26, which is lateral to area 29, there are a large number of axons labeled with AT8. Although at a somewhat lesser density, there are also a large number of such fibers in area 29, including the granular layer as shown in Fig. 10.7. Because there are AT8-positive somata in the subiculum, it is possible that axons in the retrosplenial cortex derive from this area.

Immunohistochemistry for different length Aβ peptides shows an interesting association between deposition of Aβ42 and neuron loss in area 29. Most Aβ42 is in the granular layer where most neurons were lost (Fig. 10.5C). Although there was some loss of layer V neurons in area 29, there was almost no Aβ42 in this layer. In contrast, Aβ40 had a limited presence in the granular layer and was displaced to sites adjacent to the granular layer in layers I and V. The deposition of Aβ peptides was different in area 23 as shown in Fig. 10.6. In this instance, Aβ42 was not primarily in layer IV where maximal neurodegeneration and gliosis occurred, but rather in layer IIIc, which had a normal density of neurons, and in layer Va, where there was a clear loss of cells and even some gliosis. Interestingly, Aβ40 was rarely deposited in area 23 and had no preferential localization.

In conclusion, posterior cingulate and retrosplenial areas are damaged early in AD. Small neuron degeneration is prominent in the granular layer of area 29 and in layer IV of areas 30 and 23, yet it is not limited to layer IV. The clear involvement of large neurons in layer Va suggests that this case is an example of NSTIV–V. Furthermore, this short-duration case raises a number of important issues and questions. Neurodegeneration in the granular layer of area 29 is associated with an elevation of Aβ42 and no NFT. This is a pattern of laminar changes similar to those reported earlier for the presubiculum in

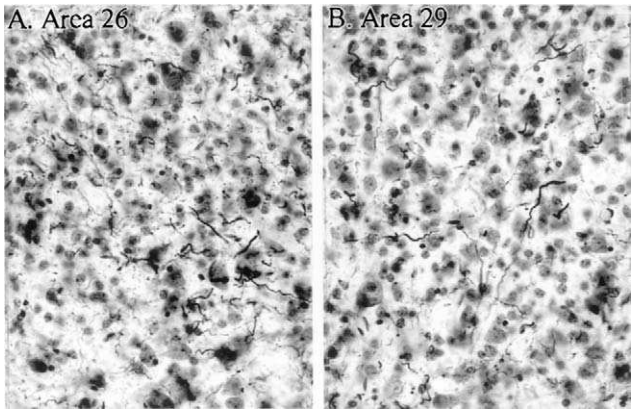

FIG. 10.7. AT8 immunoreactivity of axons in the granular layer of ectosplenial area 26 and retrosplenial area 29l. Although there were more immunoreative axons in area 26, those in area 29 are also quite dense. Because there were only rare NFT and neuritic plaques in each of these areas, it appears that the earliest phosphorylation event in this region is the cytoskeleton of axons.

another case. As suggested previously (Busciglio *et al*., 1995; Su *et al*., 1996; Tan *et al*., 1997), high levels of Aβ42 could induce early phosphorylation of tau, which may explain the AT8 immunoreactivity in area 29. Because there are no NFT in the granular layer and almost none in layer V, Aβ42 could induce cell death via protein nitration (discussed later) rather than tau phosphorylation. This direct action of the amyloid-β peptide could occur both at the somata of neurons in the granular layer and at the apical dendrites of large, layer V pyramids that pass through the granular layer.

Changes in area 23 suggest that either this and the retrosplenial cortices are involved at different time points or there may be different mechanisms of neuron death in these two areas. In layers IV–Va of area 23 there was very clear neuron death and gliosis, but no NFT, AT8-positive axons, or selective deposition of Aβ42 and Aβ40. Once again, it appears that protein nitration or some other form of free radical damage leads to neuron death in this area and that most early forms of neurodegeneration are not a consequence of tau phosphorylation. Finally, although the hypothesis that underlies staging strategies involves some form of ''spread'' of the disease, the differential involvement of the retrosplenial and posterior cingulate cortices cannot be easily understood in this framework.

XIII. Amyloid Peptides and Neurodegeneration

The case of YW suggests that, in some instances, amyloid peptides have a causal role in neurodegeneration. Although it is not possible to prove causal relationships in autopsy tissue, many findings support a preclinical and neurotoxic role for Aβ42 in AD. Autosomal-dominant mutations of the amyloid precursor protein and the presenilin genes elevate Aβ42 versus Aβ40 (Haass *et al*., 1994; Scheuner *et al*., 1996), and transgenic mice with similar mutations have elevated Aβ42 (Duff *et al*., 1996; Hsiao *et al*., 1996). Levels of Aβ42 in cerebrospinal fluid are associated with cognitive impairment in AD (Jensen *et al*., 1999) and distinguish between early- and late-onset cases, with the former having significantly lower levels (Andreasen *et al*., 1999). Because Aβ42 accumulates preclinically (Troncoso *et al*., 1998), it is a primary suspect for an early role in neurodegeneration. Finally, some transgenic systems that over-express Aβ42 have high levels of DNA damage, neuron loss, and gliosis in cortex (LaFerla *et al*., 1995).

The link between cell death and amyloid peptides was strengthened by Geula *et al*. (1998), who showed that a plaque-equivalent concentration of fibrillar, but not soluble, Aβ peptide induced microglial proliferation, tau phosphorylation, and neuronal loss in aged, but not young, rhesus monkeys. It is interesting to note that the tau phosphorylation extended beyond the area of neuron loss, raising further questions about the links between all neurodegeneration and neurofibrillary degeneration. The age dependency of this effect emphasizes the age risk factor for the role of Aβ peptides in neurodegeneration.

Concerns have been raised, however, regarding the Aβ mechanism of neuron death. Counts of SP do not correlate with neurodegeneration in entorhinal (Giannakopoulos *et al*., 1993; Gómez-Isla *et al*., 1996), superior temporal (Gómez-Isla *et al*., 1997), middle temporal (Neary *et al*., 1986), inferior temporal (Giannakopoulos *et al*., 1993), and posterior cingulate (Vogt *et al*., 1990, 1998) cortices. Biopsy studies did not show an increase in SP between the time of biopsy and death (Mann *et al*., 1988; Bennett *et al*., 1993). Finally, there does not appear to be a relationship between specific clinical symptoms, such as visual agnosia and the various apraxias, and SP densities (Giannakopoulos *et al*., 1998, 1999) nor with general measures of dementia (Neary *et al*., 1986; Mann *et al*., 1988; Bierer *et al*., 1995). Some of these studies employed methods that emphasized SP with β-pleated sheets of amyloid and structures with a high content of Aβ40, whereas the linkage to earlier events associated with Aβ42 is likely of more importance to neurodegeneration. To the extent that Aβ peptides are an early and triggering event, it need not be expected that SP correlate exactly with neurodegeneration or dementia later in the disease (Selkoe, 1997). Indeed, although Aβ42 appears in the cerebrospinal fluid of early and mild cases of AD, it declines with further disease progression (Jensen *et al*., 1999).

Although the densities of SP do not appear to correlate with neurodegeneration, there are instances in which the laminar load of Aβ42 is associated with neuron loss as in patient YW and patient FG, discussed later. Neurodegeneration in the context of laminar patterns that are not dependent on neurofibrillary mechanisms of cell death highlights the need to evaluate non-NFT pathways to neuron death. One of the problems with this approach is that there are very few compelling assessments of neurodegeneration with which to compare the laminar levels of these peptides. Realizing there need not be a 1:1 ratio of Aβ42 deposition and neurodegeneration, we present a case that has focal patterns of neurodegeneration and Aβ42 deposition and seek to characterize layers in the prefrontal, parietal, and posterior cingulate cortex where there are matches and mismatches between these markers as well as NFT.

XIV. Early Dysexecutive Syndrome and Frontotemporal Neurodegeneration

Cognitive signs of frontal lobe impairment occur early in AD. Tasks requiring concurrent manipulation of information (Lafleche and Albert, 1995) or shifting between stimulus dimensions (Sahakian *et al*., 1990) form an underlying impairment. These deficits in executive function precede language and spatial impairments in most patients (Grady *et al*., 1988; Albert and Moss, 1999) and emphasize the early and important role of prefrontal deficits in clinical symptoms.

Although most patients express some executive dysfunction, a subgroup of cases stand out as statistically unique and may have selective vulnerability of frontal cortex. A subgroup of AD patients have frontal glucose hypometabolism and a high degree of early behavioral deficits typical of frontal lobe damage. Grady *et al*. (1990) observed more inappropriate behaviors in cases with greatest prefrontal glucose hypometabolism. Mann *et al*. (1992) reported that two groups with equivalent parietal glucose hypometabolism and impaired neuropsychological measures of parietal function could be distin-

guished in terms of frontal lobe glucose metabolism, measures of executive functions, and rate of disease progression. Patients with the most rapid progression and impaired executive functions had greatest glucose hypometabolism in the prefrontal cortex. Finally, Royall *et al*. (1994) observed early impairment of executive control functions in AD that could be attributed to disrupted frontal lobe functions.

In light of the cognitive and metabolic heterogeneity of frontal lobe impairments, it is not surprising that frontal lobe pathology also is not uniform in AD. There is a wide range of neurodegeneration, with many cases having a normal density of neurons (Terry *et al*., 1981). Brun and Englund (1981) reported only modest losses of neurons in the prefrontal cortex. Furthermore, there is heterogeneity in NFT densities that are significantly different for early- vs late-onset cases (Hansen *et al*., 1988). In the context of subgroups/subtypes, the frontal cortex is a region that is differentially impacted by AD, and cases of definite AD, early behavioral deficits, and prominent frontotemporal atorphy are instructive.

Patient FG was an intelligent, right-handed man who was an electrical engineer. At the age of 85 he showed early signs of dysexecutive syndrome, including disinhibition and perseveration. Within a few years he had increased spatial disorientation and recent memory impairment. The details of this case and photographs of the focal frontotemporal atrophy at postmortem examination have been shown previously (Vogt *et al*., 1999). We also showed that this case had a prominent deposition of diffuse Aβ42 in prefrontal area 46, including highest deposits in layers II–IIIab. Although there were some NFT in superficial layers in areas 46 and 40, most were in layer V displaced from the diffuse deposits of Aβ42. Area 23 was of particular interest, not only because it is heavily interconnected with prefrontal cortex, but also because there were numerous NFT in layers II–IIIab and layer V showing a partial dissociation of Aβ42 and NFT. In layer V there was almost no Aβ42. Figure 10.8 revisits this issue in order to emphasize the relationship between heavy neurodegeneration in layers II–IIIab of prefrontal area 46. Note that there is a moderate amount of diffuse Aβ42 in layer IV, yet there is still significant neurodegeneration in this layer. Furthermore, there is almost no diffuse Aβ42 in layers V and VI, yet there is still substantial neurodegeneration in layer Va. A similar pattern appears in area 23, although at an overall lower density of diffuse Aβ42. Note also that the neurons in layer V of area 23 (thionin) are preserved more clearly than in layers II–III. Given that NFT in both areas are in both superficial and deep layers, the formation of NFT may be independent of Aβ42 deposition. Alternatively, NFT formation may be dependent on Aβ42 via the exposure of perisomatic regions to the neurotoxin in layers II–IV and the exposure of apical dendrites of layer V pyramids to the neurotoxin in layer III.

Case FG suggests that Aβ42 plays an important, although possibly nonexclusive, role in neurodegeneration. It is our impression that NFT density is related to Aβ42 deposition and that NFT do not fully account for all neurodegeneration. Substantial evidence supports the role of Aβ peptides in tau phosphorylation (Takashima *et al*., 1993; Busciglio *et al*., 1995; Le *et al*., 1997; Tan *et al*., 1997). Finally, it can be concluded from this case that focal frontotemporal atrophy in AD is due to severe neurodegeneration in layers II–IIIab and IV and, to a lesser extent, in deeper layers. To the extent that neurodegeneration in layers II–IIIab accounts for focal atrophy, as is true for Pick and other diseases that impact the frontal lobe, it is likely that the gross structural changes in this and similar cases are a consequence of early and sustained deposition of Aβ42.

XV. Free Radical Damage and Neurodegeneration in the Absence of NFT

Because NFT have a weak, and in some instances no, relationship to laminar patterns of neurodegeneration, other explanations for cell death need to be considered. This is particularly necessary in light of the significant layer IV cell death and the absence of NFT early in the disease observed in case YW. One explanation for the excess of cell death over that associated with tau phosphorylation is the direct neurotoxic actions of Aβ42 via free radical damage. Oxidative damage mediated by the nitration of proteins has been identified with immunohistochemistry for nitrotyrosine. Although nitrotyrosine occurs in NFT (Good *et al*., 1996; Smith *et al*., 1997), it is not restricted to neurons with NFT, and a number of Aβ protein-mediated mechanisms of free radical damage have been observed that do not involve NFT. These include the conjugation of lipid peroxidation products to the neuronal glucose transport protein (GLUT3) that impairs glucose transport (Mark *et al*., 1997), oxidation of RNA and DNA (Nunomura *et al*., 1999), and elevation of H_2O_2 and lipid peroxides in primary central nervous system cultures (Behl *et al*., 1994).

Having observed significant neurodegeneration in the absence of NFT in layer IV of the posterior cingulate cortex in case YW and in NSTIV–V, one wonders if this represents a wider extent of neurodegeneration in the cerebral cortex or whether this is unique to the posterior cingulate region? Su *et al*. (1997) evaluated the visual cortex in AD and found most intensely labeled neurons with nitrotyrosine in layers III and IV, the latter of which is composed of small neurons that do not usually form NFT. In addition, although many of the nitrotyrosine-labeled neurons had DNA damage, many did not. Thus, neurodegeneration outside of the context of NFT formation, including small neurons in layer IV, occurs in other posterior cortical regions, not just the cingulate cortex. The mechanisms of neuron death associated with the early deposition of Aβ42 and free radical damage may provide insight into the most common mechanisms of neurodegeneration in posterior cortical areas, including visual, cingulate, and parietal cortices.

XVI. Theories of Staging in the Context of Subgroups and Subtypes

To the extent that AD is viewed as a single entity, it is natural to stage its progression in a single continuum. An early effort at staging was made by Brun and Englund (1981), who placed their observations in the context of a graded progression in neurodegeneration and gliosis. More recently, the formal strategy of Braak and Braak (1991, 1997) provides a consistent nomenclature to evaluate the amount and distribu-

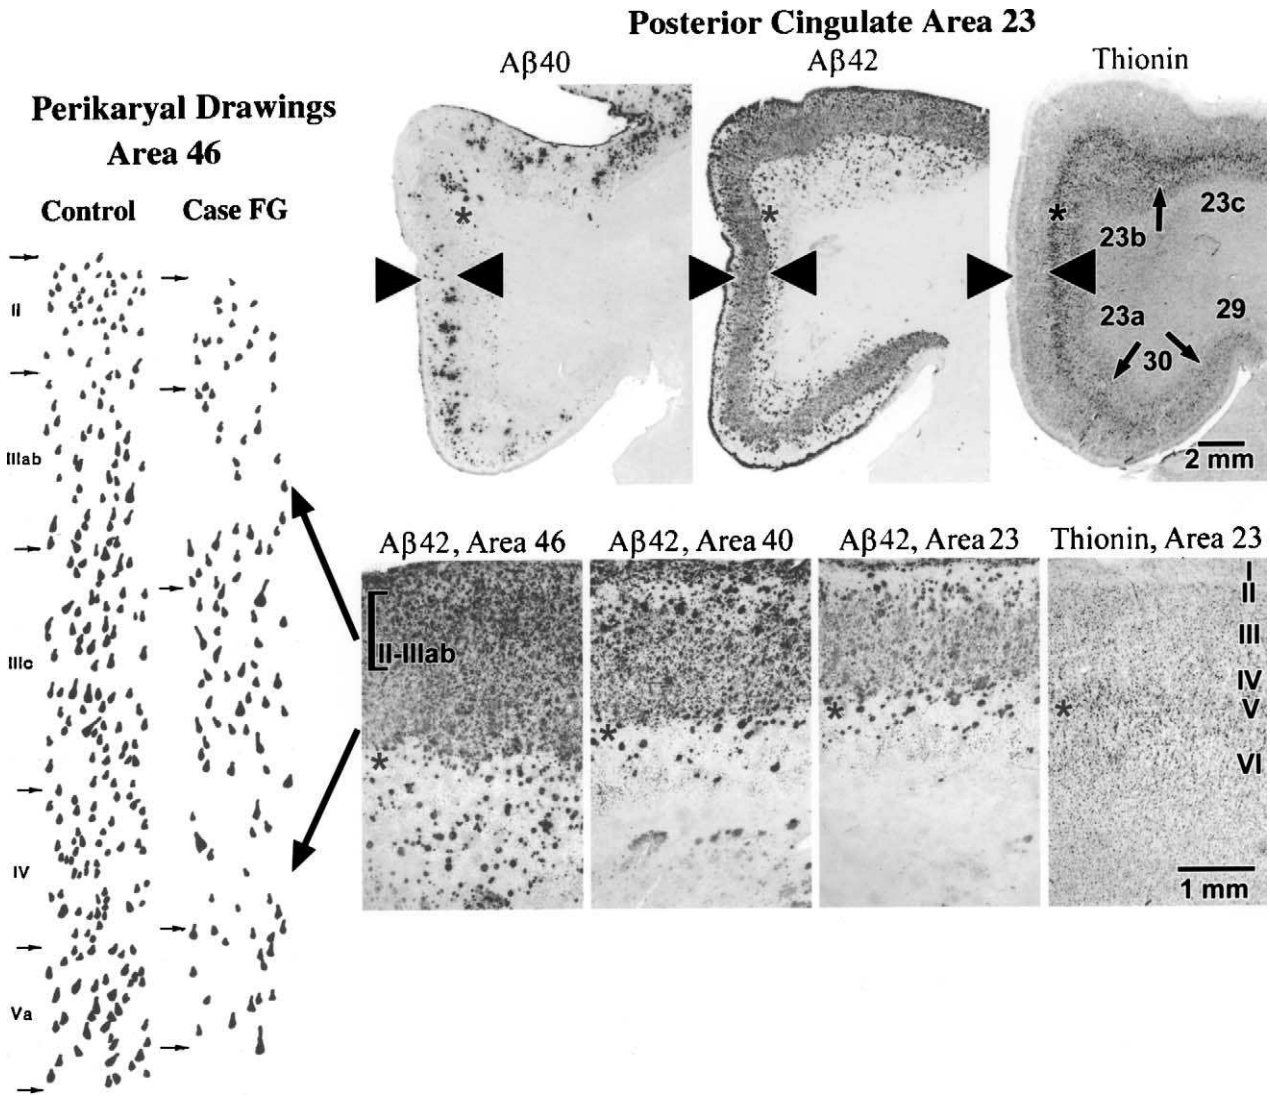

FIG. 10.8. An overview of some of the patterns of neurodegeneration in prefrontal area 46 and the posterior cingulate cortex in case FG; a case of early dysexecutive syndrome and focal frontotemporal atrophy. Comparison of perikaryal drawings with the deposition of Aβ42 shows a close relationship between both in layer IIIab, which is not the case for layer Va where there is substantial neurodegeneration but little Aβ42. Asterisks represent layer Va. Note that the greatest density of Aβ42 is in layers II–IIIab. Neurodegeneration, particularly in layers II–IIIab, may account to a large extent for the focal prefrontal atrophy in this case. In area 23, it can be seen that Aβ40 aggregates in the deep part of layer III and in layer IV, whereas Aβ42 is throughout layers II–IV. Neurodegeneration is particularly profound in layers II–IV, as shown with the thionin section between the large arrowheads. Note also in this section that layer Va is relatively spared. Once again, neurodegeneration in this case is closely associated with Aβ42 in the external layers but not in layer V.

tion of neurofibrillary and amyloid degeneration. There are instances of apparent agreement between Braak stage and a measure of the patient's disease. For example, Ohm *et al.* (1999) found that patients with one or two ApoE ϵ4 alleles were associated with a higher Braak stage for both neurofibrillary and amyloid changes. However, there is substantial variance in the data and overlap among measures of brain pathology that do not support a precise relationship. Because it is likely that the ApoE genotype does not account for most laminar patterns of neurodegeneration (Vogt *et al.*, 1998), apparent relationships between Braak stage and ApoE genotype may be misleading.

Gold *et al.* (2000) considered the Braak stages for patients over 90 years of age at the time of death in relation to CDR scores. They conclude, ''Braak staging represents a broad concept of the evolution of NFT rather than a precise hierarchical model associated with a stepwise deterioration of cognitive abilities near the upper limit of life.'' Although stages III and IV have an impact on cingulate cortex (Braak and Braak, 1991, 1997), the observations discussed earlier of a case with CDR 1 and previous work (Vogt *et al.*, 1998) show that neurodegeneration appears earlier than predicted by the Braak stages and that neurodegeneration is not closely related to neurofibrillary changes. It is unlikely, therefore, that a single series of

stages accounts for multiple laminar and topographical patterns of neurodegeneration. There are a number of reasons why staging strategies based on the hypothesis that AD is homogeneous do not work.

1. *Lack of a close relationship with disease severity–CDR*. The Braak stages explicitly attempt to relate stages of brain pathology to ''preclinical'' and clinical impairments, but studies that relate CDR scores with the Braak stage fail to demonstrate clear relationships. Perl *et al*. (1997) did not observe a close relationship between Braak stages and CDR scores for either cognitively normal individuals or AD cases with relatively mild cognitive impairments. As noted earlier, Gold *et al*. (2000) were unable to show anything more than a loose relationship between CDR scores, and NFT in cases over 90 years of age.

2. *Clinicopathological subgroups; multiple topographic lesion patterns cannot match a single pattern of "spreading" pathology.* Clinicopathological subgroups have different patterns of NFT in cases of posterior cortical atrophy and early impairments in visuomotor function and visual attention, early signs of associational visual agnosia, ideomotor and constructional apraxias, or early dysexecutive syndrome. The notion of a single ''spreading'' process arising in transentorhinal cortex and systematically penetrating neocortical areas is misleading. Some neocortical areas will be affected differentially and these clinicopathological subgroups cannot be explained by a staging scheme that requires one pathway to one end point. After all, there is no single pattern of NFT or SP deposition in neocortex.

3. *Lack of relationship between NFT and neurodegeneration*. It is well established that the loss of neurons is closely related to cognitive impairment. However, the logic of current staging theories is that neurofibrillary and amyloid changes can be used as a surrogate to mark the course of cell death, and no studies of NFT in the neocortex show anything more than a weak relationship between neurodegeneration and NFT. Thus, a single staging of NFT cannot be used to evaluate complex patterns of neurodegeneration in neocortex.

4. *Free radical damage to small, layer IV neurons*. Because there is extensive small neuron damage mediated by free radicals and not associated with NFT, staging strategies that rely on traditional markers overlook this type of cell death. To the extent that layer IV neurodegeneration occurs early in the disease, early ''stages'' such as Braak stages I and II will diagnose the primary lesions incorrectly. To the extent that defined staging strategies are sought, it may be necessary to describe the progression of neuron death with markers of free radical damage such as nitrotyrosine immunohistochemistry.

5. *Neurodegeneration in early- and late-onset disease*. Early-onset cases often have the most severe neurodegeneration (Vogt *et al*., 1998). Even when cases are matched for disease duration, early-onset disease is associated with more extensive neurodegeneration than late-onset disease. Thus, staging of cases into a single progression cannot accommodate overall differences in neurodegeneration. Indeed, different risk factors for early-onset cases, such as the ApoE $\epsilon 4$ risk, will not fit into a single pattern of neurodegeneration to the extent that it is related to early onset.

6. *Neuropathological subtypes: the ultimate test for staging strategies*. We provide two arguments for the possibility of subtypes in AD: spastic paraparesis early in the disease and its associated lesions and presenilin 1 mutation and the presence of laminar patterns of neurodegeneration in the posterior cingulate cortex that imply different mechanisms of cell death. If Jorm criteria for AD subtypes are eventually met, it will not be possible to stage the disease according to a single continuum. Rather, it will be necessary to first diagnose each subtype and then apply different criteria for progression within a subtype.

Even in the absence of proof for subtypes *per se,* the single continuum staging strategy fails to explain differential clinical outcomes associated with regional differences in cortical function and it has not been applied to patterns of neurodegeneration outside of NFT and SP. An alternate approach is to diagnose the disease according to standard practice and then devise a multigroup, staging strategy for assessing neurodegeneration directly rather than with surrogate markers. By multigroup, we mean providing stages for qualitatively different topographical and laminar patterns of neurodegeneration and different patterns of cognitive impairment. Needless to say, devising such a multigroup strategy for staging the disease will require a more thorough description of clinicopathological subgroups/subtypes with multivariate models.

XVII. The Model Matters

If first symptoms and disease progression were the same for all patients, the goal of achieving a simple staging of neuropathological variables would be valid. It would also be reasonable to expect that least-square models of neurodegeneration in one or more cortical areas would follow disease progression and provide explanations of progressive cognitive impairments. The well-documented neuropsychological and glucose metabolic subgroups based on multivariate models assure that this expectation cannot be fulfilled. Moreover, observations that there are systematic topographical differences in the expression of disease markers in association with specific cognitive deficits further assures that the simple staging strategy does not describe disease progression adequately.

In the context of clinical and neuropathological heterogeneity, linear models of changes associated with entire populations of AD patients are not justified. Although staging the disease into a single continuum may be useful for characterizing the general level of pathology, there is no *a priori* rationale for using such descriptive observations for assessing disease progression and etiology. Some would argue that it does not matter whether a linear model is used because it is a common theme in science to reduce paired variables to this simple format. Indeed it is; however, we have shown that such efforts do not support data. Rank ordering of critical variables and other efforts are used frequently to avoid the conclusion that many relationships that should hold actually do not.

Importantly, heterogeneity in cognitive impairments and cortical pathology of AD require multivariate models to characterize it. Neuron, NFT, and SP densities do not fit a simple linear model for the entire population and cannot be used as the sole analytical tool for statistical analysis. Once pure cog-

nitive and pathological subgroups have been identified, it will be possible to use least-square models to assess linear changes associated with disease progression within each subgroup.

The more difficult issue, of course, is whether statistical subgroups represent subtypes of the disease. Jorm (1985) appropriately set the bar high on this question. If there are two or more subtypes, they must differ in terms of clinical outcomes and progression, patterns of lesions in the brain, and etiology. Problems attaining these goals are obvious. The etiology(ies) of AD is/are not known. Because it has been only recently that the presence of clinical and neuropathological subgroups has been demonstrated, no studies exist that seek to address the possible differences in etiology. This does not mean, however, that there are not qualitatively different mechanisms of neurodegeneration. Although NFT and SP are the primary measures for diagnosis, the focus of mechanistic studies should be on the complete pattern of neurodegeneration early in the disease without reference to late-stage cases.

Vascular Dementia

Atherosclerotic dementia was described in the late 19th century by Binswanger (1894) and Alzheimer (1895) at a time when syphilis was a leading cause of dementia and mental illness. For most of the 20th century, senile dementia was thought to result from decreased cerebral perfusion due to vascular disease. However, in the mid-1970s, Alzheimer's disease (AD) became recognized as the main cause of dementia, and interest in dementia of vascular origin waned. Since then, the concept has broadened and newer criteria have been proposed that have taken advantage of evolving neuroimaging techniques. At the dawn of the 21st century, vascular dementia (VaD) remains an important cause of dementia and a diagnostic challenge (Bowler and Hachinski, 1996; Desmond, 1996; Gold *et al*., 1999; Chiu *et al*., 2000). Although preventive strategies are likely to be highly beneficial, effective therapeutic interventions have yet to developed (Hachinski, 1992).

I. Dementia of Vascular Origin: An Evolving Concept

Alzheimer and Binswanger believed that VaD was secondary to chronic ischemia (del Ser *et al*., 1990). They described an arterisoclerotic brain degeneration that could be distinguished easily from syphilitic disease, as it was a focal as opposed to a diffuse process. They also reported other forms of the disease, including a chronic diffuse subcortical encephalitis where subcortical fiber loss was secondary to arteriosclerosis and senile cortical atrophy also caused by arteriosclerosis (Binswanger, 1894; Alzheimer, 1895, 1898; Mast *et al*., 1995). This clinicopathological spectrum has been felt to include multiple lacunar strokes, granular atrophy, and what is currently termed Binswanger's disease (Roman, 1999). Tomlinson *et al*. (1968) believed that loss of brain tissue secondary to stroke was the underlying pathophysiological mechanism behind dementia of vascular origin and suggested that cognitive symptoms were related to the volume of affected cerebral matter. Cerebral softening of 50 ml or more occurred in one-third of demented individuals, but only rarely in nondemented individuals; cerebral softening greater than 100 ml was only encountered in demented individuals tissue (Tomlinson *et al*., 1968). However, more recent clinicopathological studies have shown a significant overlap between affected volumes in demented and nondemented elderly (Erkinjunti *et al*., 1988; del Ser *et al*., 1990). Hachinski proposed the term multi-infarct dementia to describe dementia resulting from multiple strokes of thromboembolic origin (Hachinski *et al*., 1974). The number and location of strokes were felt to be more important than the actual volume of damaged tissue. More recently, the concept has evolved to include multiple physiopathological mechanisms related to deficiencies in cerebral blood supply and the various types of brain pathology encountered in cases of VaD. These include multiple infarcts, a single strategic infarct, small vessel disease, hypoperfusion, and hemorrhage (Roman *et al*., 1993; Desmond, 1996; Olsson *et al*., 1996). This expanded concept has prompted the use of the broader term vascular dementia. However, there is still no consensus regarding the type, location, and extent of lesions required for VaD (Fig. 11.1).

II. Epidemiology

A. Prevalence and Incidence

Use of different diagnostic systems may markedly influence the results of incidence and prevalence studies of dementia in general and VaD in particular (Erkinjuntti *et al*., 1997; Kay, 1999; Chui *et al*., 2000). Inclusion of mixed dementia can significantly increase the number of reported cases of VaD. Epidemiological data regarding dementia and VaD have been reviewed in detail (Hebert and Brayne, 1995; Jorm and Jolley, 1998; Nyenhuis and Gorelick, 1998; Fratiglioni *et al*., 1999; Kay, 1999). In more recent studies, prevalence rates of dementia in individuals aged 65 years or more range from 41 to 111 per 1000 and are generally lower in Asia than in Europe or North America (Kay, 1999). The prevalence of VaD ranges from 5 to 31 per 1000 with the highest rates reported in Asia and Italy (Rocca *et al*., 1991; Prencipe *et al*., 1996; Ferini-Strambi *et al*., 1997; Rajkumar *et al*., 1997; Chiu *et al*., 1998; Woo *et al*., 1998), and the lowest rates in France (Leten-

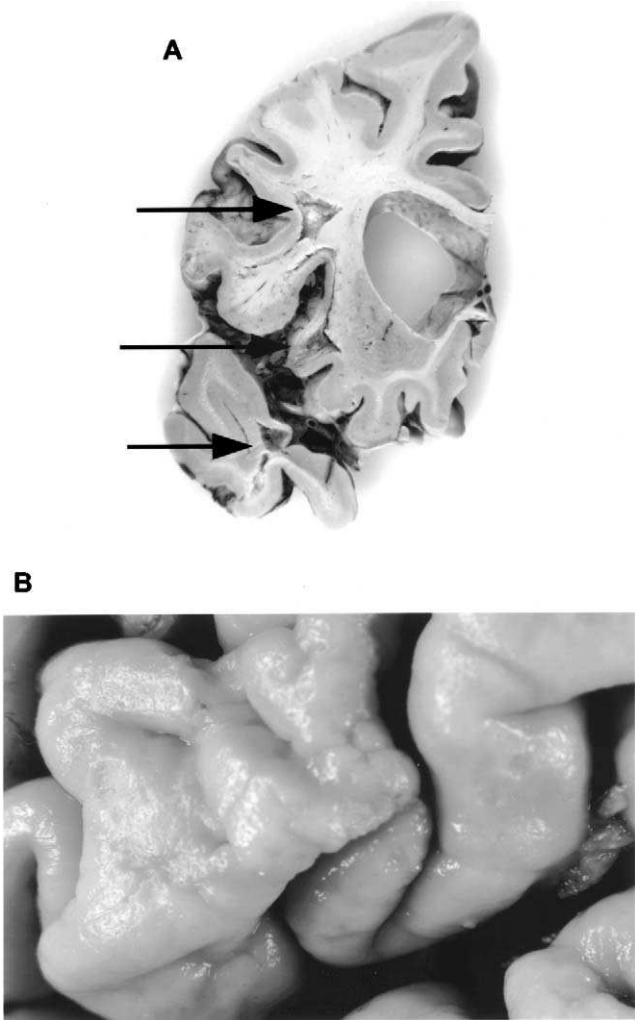

FIG. 11.1. (A) Multiple subcortical infarcts and lacunes (arrows) in the inferior frontal gyrus, anterior insula, and temporal pole of a VaD case. Large softenings are visible in the white matter of the inferior frontal gyrus. (B) Close-up of a frontal gyrus showing multiple small cortical infarcts, appearing as a surface granular atrophy due to inadequate blood flow in the terminal fields of the cortical microvasculature.

neur *et al*., 1994). However, there are marked regional variations with some Asian studies reporting particularly low rates in rural populations (H. C. Liu *et al*., 1994, 1998). Among the larger studies, the Canadian Study of Health and Aging reported a prevalence of 15 per 1000 and EURODEM a prevalence of 24 per 1000 (Rocca *et al*., 1991; Canadian Study of Health and Aging Working Group, 1994). VaD prevalence increases steeply with age, reaching 30 to 110 per 1000 in 85-year-old individuals. In most studies, AD is more prevalent than VaD; however, the proportion of dementia cases classified as VaD shows significant geographical variation and appears to be higher in Asia (38%) than in Europe (28%) and North America (10%) (Fratiglioni *et al*., 1999). While rates of AD tend to be higher in women, especially at older ages (Fratiglioni *et al*., 1997; Obadia *et al*., 1997), the opposite is true for VaD, with higher rates reported in men, although a gender effect is not always present (Hebert and Brayne, 1995; Kay, 1999).

The incidence of dementia ranges from 8 to 40 per 1000 in individuals aged 60 to 64 years, but has been reported to reach 50 to 136 per 1000 above 95 years of age (Fratiglioni *et al*., 1999). The average annual rate per 1000 of vascular dementia ranges from 11 to 16 in individuals aged 65 years or more, 19 to 43 in those aged 75 years or more, and 84 or greater in the oldest old aged 85 years or more (Kay, 1999). Despite the dearth of incidence data, it appears that new cases of VaD occur significantly less often than new AD cases in Europe and in Taiwan (Letenneur *et al*., 1994; Brayne *et al*., 1995; Aevarsson and Skoog, 1996; C. K. Liu *et al*., 1998), whereas in Japan the incidence of these two types of dementia is more similar, with VaD occurring slightly more often than AD (Yoshitake *et al*., 1995). There are conflicting data for individuals over the age of 85 years. In this age group, there was no new case of VaD in a French study (Letenneur *et al*., 1994), whereas in Sweden the incidence of VaD, in which mixed dementia was included, was greater than that of AD (Aevarsson and Skoog, 1996). In a review of pooled studies, the proportion of incident dementia cases diagnosed as VaD was 10% in North America, 28% in Europe, and 38% in Asia (Fratiglioni *et al*., 1999). However, further studies are needed to determine whether geographical variations represent true differences or whether they are related to methodological issues.

B. Risk Factors for VaD

1. Vascular Factors and Stroke

Hypertension is one of the most potent risk factors for the development of VaD, as demonstrated in several studies (Babikian and Ropper, 1987; Meyer *et al*., 1988; Gorelick *et al*., 1993, 1994; Gorelick, 1997; Rockwood *et al*., 1997; Skoog, 1998). In the Canadian Study of Health and Aging, a history of hypertension was twice as common in individuals diagnosed with VaD than in nondemented controls (Lindsay *et al*., 1997). In Japan, where the incidence of VaD is particularly high, an increase of one standard deviation in systolic blood pressure was associated with a 60% increase in the risk of VaD in older individuals (Yoshitake *et al*., 1995). A U.S. study reported that hypertension was present in 66% of patients with multi-infarct dementia as opposed to 44% of aged-matched controls (Meyer *et al*., 1988). Data on hypertension and VaD risk must nevertheless be interpreted with caution, as the presence of hypertension is included in several of the clinical criteria used to make the diagnosis of VaD. Furthermore, clinical criteria used in most research studies to establish the diagnosis of AD specifically exclude cases with symptoms or signs of cerebrovascular disease. This introduces a selection bias that tends to prevent the inclusion of subjects with vascular risk factors in AD samples. Despite this fact, several studies have suggested that hypertension may also play a role in the development of AD. Skoog and others (1996) reported that elderly individuals who developed dementia (either AD or VaD) had higher blood pressures 10 and 15 years earlier than those whose cognitive function remained unimpaired. Data from the Syst-Eur trial suggest that the treatment of isolated systolic hypertension could reduce the incidence of dementia, both VaD and AD, by 50% (Forette *et al*., 1998).

Further studies are needed, using clinical criteria that do not include the presence of vascular risk factors, in order to better delineate the relationship between hypertension and both VaD and AD. The presence of vascular risk factors is not sufficient to establish the vascular origin of a dementia.

Stroke has been closely related to dementia, particularly VaD. In the Framingham study cohort, mean Mini Mental State Examination scores decreased from 28.3 to 23.6 before and after stroke (Kase *et al*., 1998). In the Canadian Study of Health and Aging, 79.5% of patients with VaD had a history of stroke (Lindsay *et al*., 1997). Kokmen *et al*. (1996), in a population-based study, reported that the incidence of dementia was nine times higher than expected in the first year following a stroke, and Censori *et al*. (1996) found that one-quarter of a hospital-based population aged 40 to 79 years developed a dementia 3 months after an ischemic stroke. Other authors have also reported a marked increase in the occurrence of dementia following stroke (Tatemichi *et al*., 1990, 1994; Loeb *et al*., 1992; Skoog *et al*., 1993; Andersen *et al*., 1996; Inzitari *et al*., 1998). The relationship between stroke and dementia is perhaps underestimated, as asymptomatic stroke may be a significant factor in the development of dementia; patient attrition may also be a factor (Yoshitake *et al*., 1995; Desmond *et al*., 1998). However, the presence of previously unrecognized degenerative dementia may lead to an exaggerated estimate of the frequency of so-called ''poststroke'' dementia (Hénon *et al*., 1997).

Why certain individuals with stroke develop dementia while others do not remains poorly understood. Several authors have addressed this issue (Ji *et al*., 1988; Gorelick *et al*., 1993; Frisoni *et al*., 1994; Skoog, 1994; Hebert and Brayne, 1995; Prencipe *et al*., 1997; Slooter *et al*., 1997; Chapman *et al*., 1998; Nyenhuis and Gorelick, 1998; Pohjasvaara *et al*., 1998). Left-sided and recurrent lesions are associated with a higher risk of dementia, whereas infarct volume seems less important. The presence of cerebral atrophy is also a potentiating risk factor. Certain patient characteristics, such as male gender, an increasing age, a low level of education, or a low level of cognitive performance before stroke, have been shown to be predictive of dementia. Finally, the presence of vascular risk factors, including diabetes mellitus, hypertension, tobacco use, cardiac arrhythmias, and heart disease, may also increase the risk of poststroke dementia.

It is unclear whether all poststroke dementias are in fact VaD. Several cases of poststroke dementia have a progressive course more suggestive of a degenerative process. It has been reported that the incidence of AD is 50% higher in a poststroke patients compared to the general age-matched population (Kokmen *et al*., 1996). This suggests that vascular lesions may either participate in the development of AD or potentiate the deleterious cognitive effects of the AD degenerative process. The latter is consistent with the concept of mixed dementia in which cognitive impairment is due to a combination of vascular pathology and cerebral degenerative changes. This may also explain why clinical criteria for VaD based mainly on evidence of stroke or focal neurological findings are unable to satisfactorily distinguish VaD from mixed dementia.

Other vascular risk factors have been associated with VaD, including smoking (Kokmen *et al*., 1996; Galanis *et al*., 1997), diabetes mellitus (Desmond *et al*., 1993; Gorelick *et al*., 1994), increased 1 hr postprandial glucose (Ross *et al*., 1999), a history of heart disease (Yoshitake *et al*., 1995) myocardial infarction (Aronson *et al*., 1990), coronary heart disease (Ross *et al*., 1999), and atrial fibrillation (Ratcliffe and Wilcock, 1985; Gorelick *et al*., 1994). In a community-based study of 828 nondemented elderly that were followed over 7 years, alcohol consumption was associated with a two- to threefold increase in the risk of vascular dementia (Yoshitake *et al*., 1995); similar findings have been reported in a population-based study of elderly Canadians (Lindsay *et al*., 1997). However, in a French study, moderate alcohol consumption was associated with higher cognitive scores in women, whereas in another study from the same country, moderate wine drinkers had a lower incidence of dementia than nondrinkers (Du Fouil *et al*., 1997; Orgogozo *et al*., 1997).

2. Genetic Factors

The presence of an APOE $\epsilon 4$ allele is associated with an increased risk of developing AD, but its association with VaD remains controversial. Slooter *et al*. (1997) described a striking sevenfold increase in the risk of dementia with stroke in individuals homozygous for APOE $\epsilon 4$ and a twofold increase in this risk in individuals who are heterozygous for this allele compared to APOE $\epsilon 3$ homozygous individuals. However, this does not imply an association with VaD, as a significant proportion of individuals with stroke and dementia may actually have AD and concomitant cerebrovascular disease. Although many studies have explored the possible relationship between APOE alleles and VaD, they have conflicting results and this issue remains unresolved (Ji *et al*., 1988; Bétard *et al*., 1994; Frisoni *et al*., 1994; Kawamata *et al*., 1994; Stengard *et al*., 1995; Higuchi *et al*., 1996; Pirttila *et al*., 1996; Sulkava *et al*., 1996; Treves *et al*., 1996; Hofman *et al*., 1997; Katzman *et al*., 1997; Palumbo *et al*., 1997; Slooter *et al*., 1997; Wieringa *et al*., 1997; Chapman *et al*., 1998; Marin *et al*., 1998; Skoog *et al*., 1998; Tilvis *et al*., 1998). Discrepancies may, in part, be explained by the fact that these studies, with a rare exception, did not include autopsied cases and used different clinical criteria to identify dementia subtypes.

Cerebral autosomal dominant arteriopathy with subcortical infarct and leukoencephalopathy (CADASIL) and several forms of cerebral amyloid angiopathy lead to inherited VaD, but these diseases are very rare. It is likely that, in most cases, VaD is not strongly related to genetic factors. This is supported by twin studies suggesting that, contrary to AD, the environment is a more important causal factor than heredity for the development of VaD (Bergem *et al*., 1997).

III. Neuropsychological Profile of VaD

Several studies have attempted to identify neuropsychological patterns typical of VaD. It has been assumed that VaD follows a stepwise deterioration and a fluctuating course as opposed to the gradual and progressive cognitive decline of AD (Hachinski *et al*., 1974; Loeb *et al*., 1992). This is consistent with the multi-infarct model, but would not be expected within the broader modern construct of VaD. In fact, over

half of VaD patients may present with an insidious onset and follow a slowly progressive course (Fischer *et al*., 1990). It has been proposed that, as opposed to AD, VaD is associated with more marked deficits in attention, concentration, and executive function and with less pronounced memory impairment (Libon *et al*., 1990, 1996, 1998; Kertesz and Clydesdale, 1994; McPherson and Cummings, 1996; Lamar *et al*., 1997; Desmond *et al*., 1999). Individuals with VaD may perform more poorly on verbal fluency tests compared to AD cases and also exhibit more perseverations, particularly during tasks that assess frontal lobe functions (Padovani *et al*., 1995; Lamar *et al*., 1997). In an analysis of 27 studies of neuropsychological testing, VaD patients tended to have greater preservation of long-term memory and greater deficits in executive functioning than AD patients; however, language, constructional abilities, memory registration, conceptual function, and attention and tracking were similar in both types of dementia (Looi and Sachdev, 1999). In the absence of clinicopathological correlations, these proposed patterns suffer from current limitations in the clinical diagnosis of VaD and have been difficult to replicate. Furthermore, the pathophysiological heterogeneity of VaD suggests that a single neuropsychological pattern of VaD is unlikely. Further studies, including careful neuropsychological assessment and neuroimaging, as well as neuropathological examination, are needed to correlate better clinical deficits with specific cerebrovascular lesions.

IV. Clinical Criteria

Ideally, clinical criteria for dementia should apply universally to all subtypes and should be able to identify initial stages as well as established cases. However, existing criteria for dementia do not always agree. In a study of 1879 elderly subjects, the proportion of subjects with dementia varied from 3.1% with ICD-10 criteria to 29.1% with DSM-III criteria (Erkinjuntti *et al*., 1997). Generally accepted definitions of dementia are based strongly on the clinical presentation of AD and must include memory deficits. This requirement may not be appropriate for other types of dementia where behavioral disorders and marked impairment in other cognitive domains, such as executive functions and language, may precede memory impairment. Severity requirements are also an issue, particularly for VaD. This has led Hachinski (1994) to suggest that the term vascular dementia should be replaced by vascular cognitive impairment to stress early identification of affected patients across the whole spectrum of cognitive performance.

Differentiating VaD from AD is a particularly challenging endeavor. Binswanger and Alzheimer's first descriptions of arteriosclerotic brain degeneration stressed several clinical findings that were important in the differentiation between dementia of vascular origin and general paralysis. These include a relative preservation of personality, insight, and judgment and the presence of focal neurologic findings, such as aphasia, hemianopsia, hemiparesis, and hemisensory loss, as well as a fluctuating course (Binswanger, 1894; Alzheimer, 1895, 1898; Roman, 1999). Several of these findings have been incorporated into clinical criteria, some of which are still in use today.

TABLE 11.1 Hachinski's Ischemic Score

Item	Score[a]
Abrupt onset	2
Stepwise progression	1
Fluctuating course	2
Nocturnal confusion	1
Relative preservation of personality	1
Depression	1
Somatic complaints	1
Emotional incontinence	1
History of hypertension	1
History of strokes	2
Evidence of associated atherosclerosis	1
Focal neurologic symptoms	2
Focal neurologic signs	2

[a] Alzheimer's disease: $\leqslant 4$; mixed dementia: 5 or 6; and vascular dementia: $\geqslant 7$.

The Hachinski ischemic score (HIS), introduced in 1974, is the traditionally used clinical tool for the diagnosis of VaD (Hachinski *et al*., 1974) (Table 11.1). It is meant to be applied to patients with dementia in an effort to separate VaD from AD. It does not contain criteria for the diagnosis of dementia per se. It is based largely on the multi-infarct concept of VaD and may not perform as well in detecting other subtypes of VaD. Furthermore, because hypertension is one of the items favoring the diagnosis of VaD, this precludes using the HIS in epidemiological studies of the relationship between VaD and hypertension. Several modifications have sought to improve upon the HIS (Rosen *et al*., 1980; Loeb and Gandolfo, 1983). Rosen *et al*. (1980) suggested that several features of the HIS were of primary importance, such as abrupt onset, stepwise deterioration, history of stroke, and focal neurological signs and symptoms, and that others were of secondary importance, such as a history or presence of hypertension; features such as somatic complaints and emotional incontinence were deemed of questionable diagnostic value. Loeb and Gandolfo (1983) proposed a shorter version containing only four of the original HIS items (abrupt onset, focal neurological symptoms, focal neurological signs, and history of strokes), but incorporating CT scan findings. None of these modified versions have been shown conclusively to be superior to the initial HIS.

Whereas the just-described criteria are based on the simultaneous presence of cognitive impairment and evidence of cerebrovascular disease, ICD-10 and DSM-IV criteria require the presence of significant cerebrovascular disease, which may reasonably be judged to be related etiologically to the dementia (Rosen *et al*., 1980; American Psychiatric Association, 1994) (Tables 11.2 and 11.3). However, there are no instructions as to how focal neurological findings or neuroimaging data should be interpreted regarding a potential vascular etiology. Each investigator is left to make this judgment on his own. The DSM-IV is largely based on criteria for AD (criteria A and B are virtually identical in AD and VaD) and stresses memory loss and severity of disease. As stated earlier this may not be

TABLE 11.2 Summary of ICD-10 Research Criteria for VaD

Dementia as defined by
A decline in memory and other cognitive abilities that has been present for at least 6 months
Intact consciousness
A decline in emotional control or motivation or a change in social behavior manifest at least one of the following: emotional lability, irritability, apathy, coarsening of social behavior
Uneven distribution of deficits in higher cognitive functions
Focal brain damage, manifest as at least one of the following: unilateral spastic weakness of the limbs, unilaterally increased tendon reflexes, an extensor plantar response, or pseudobulbar palsy
Evidence from the history, examination, or tests of significant cerebrovascular disease, which may reasonably be judged to be etiologically related to the dementia

appropriate for VaD and may prevent early recognition of vascular cognitive impairment, thus precluding early intervention. There are several versions of the ICD-10, and the research criteria discussed here differ from the clinical descriptions and diagnostic guidelines (Wetterling *et al*., 1994). Research criteria have unusually precise requirements. The decline in cognitive abilites must include memory impairment and deterioration in judgement and thinking, such as planning and organizing; emotional changes are required and clearly outlined, and focal neurological findings are restricted to unilateral spastic weakness of the limbs, unilaterally increased tendon reflexes, an extensor plantar response, or pseudobulbar palsy. The narrow spectrum of these requirements is not consistent with the current broad view of the various pathophysiological mechanisms that may lead to VaD. The requirement for an unequal distribution in higher cognitive functions is not operationalized and thus remains investigator dependent.

Other criteria were proposed in 1992 by the State of California Alzheimer's Disease Diagnostic and Treatment Centers (ADDTC) (Chui *et al*., 1992, 2000) (Table 11.4) and in 1993 by the National Institute for Neurological Disorders and Stroke (NINDS) with support from the Association Internationale pour la Recherche et l'Enseignement en Neurosciences (AIREN) (Roman *et al*., 1993) (Table 11.5). They both require the presence of dementia, evidence for cerebrovascular disease, and, in most cases, a relationship between the two. The ADDTC definition of dementia requires two impaired cognitive domains but does not emphasize memory deficits. There must be a clear temporal relationship between the cerebral event and the onset of dementia if only one stroke has occurred, but this is not necessary if there is evidence of two or more strokes. This makes it possible to include cases with a more variable course, but leads to a diagnosis of probable VaD in any demented individual who has suffered two strokes. The ADDTC possible VaD category includes cases with a single stroke and no clear temporal relationship with the onset of dementia, as well as individuals with clinical and neuroimaging evidence for Binswanger's disease. The NINDS-AIREN definition of dementia requires impairment of memory and at least two other cognitive domains; this is more restrictive than most other criteria, including DSM-IV. The NINDS-AIREN probable criteria require clinical and radiological evidence of cerebrovascular disease, as well as a clear temporal relationship between dementia onset and stroke, which is arbitrarily set at a maximum of 3 months. However, abrupt deterioration or a stepwise course without a temporal relationship is also included in the probable VaD category. The possible VaD category includes cases with no neuroimaging, no clear temporal relationship, and an atypical course. These criteria still await prospective neuropathological validation.

Several clinical studies have compared the criteria just discussed. Verhey *et al*. (1996) applied seven different sets of VaD criteria to a sample of 124 demented patients. The frequency of VaD ranged from 6 to 32%, depending on which criteria were used; only 8 patients were diagnosed as having VaD by all criteria (Verhey *et al*., 1996). Frequencies of VaD were highest for the NINDS-AIREN criteria for possible VaD and the HIS in its initial form or as modified by Rosen; frequencies were lowest for the NINDS-AIREN and ADDTC criteria for probable VaD. However, in a study of 40 patients presenting with suspected VaD, Amar *et al*. found the ADDTC to be more sensitive than the HIS. Wetterling compared four different sets of criteria in 167 individuals who were referred for evaluation of possible dementia. While 45 cases were diagnosed as VaD according to DSM-IV, only 5 cases met all of the different sets of criteria for VaD (Wetterling *et al*., 1996). Another clin-

TABLE 11.3 Summary of DSM-IV Criteria for Vascular Dementia

Multiple cognitive deficits manifested by both
impaired memory
at least one of apraxia, agnosia, aphasia, or disturbance in executive functions
Significant impairment in social or occupational functioning as a result of the just-described cognitive deficits, representing a decline from a previous level of functioning
Focal neurological signs and symptoms or laboratory evidence of cerebrovascular disease that is judged to be etiologically related to the disturbance
The deficits do not occur exclusively during the course of a delirium

TABLE 11.4 Summary of ADDTC Clinical Criteria

Dementia definition	Deterioration in intellectual function sufficient to interfere with customary affairs of life, which is not isolated to a single category of intellectual performance and is independent of the level of consciousness
Probable VaD	Requires all the following 1. Dementia 2. Evidence of two or more strokes by history, neurological signs, and/or neuroimaging or a single stroke with a clear temporal relationship to the onset of dementia 3. Evidence of at least one infarct outside the cerebellum by CT or T1-weighted MRI The diagnosis of probable VaD is supported by 1. Evidence of multiple infarcts in brain regions known to affect cognition 2. A history of multiple transient ischemic attacks 3. History of vascular risk factors (e.g., hypertension, heart disease, diabetes mellitus 4. Elevated Hachinski ischemia scale
Possible VaD	1. Dementia and one or more of the following 2a. History or evidence of a single stroke without a clear temporal relationship with dementia onset 2b. Binswanger's disease that includes all the following: early onset of urinary incontinence or gait disturbance, vascular risk factors, and extensive white matter changes on neuroimaging
Mixed dementia	A diagnosis of mixed dementia should be made in the presence of one or more other systemic or brain disorders that are thought to be related causally to the dementia

ical study of 72 demented patients using the ICD-10 revealed that only 25% of patients fulfilling the criteria for dementia and showing vascular lesions on CT scan met the criteria for VaD, suggesting that the ICD-10 criteria may suffer from low sensitivity (Wetterling *et al*., 1994). Although clinical comparison studies are useful, the performance of different criteria is best evaluated in comparison to neuropathological findings.

In an article that pooled the results of five clinicopathological studies (174 patients for the five studies combined), the sensitivity of the HIS for the detection of VaD versus non-VaD forms of dementia was 0.42 and the specificity was

TABLE 11.5 Summary of NINDS-AIREN Clinical Criteria

Dementia definition	Decline in intellectual function affecting memory plus at least two other cognitive domains sufficient to interfere with the activities of daily living and not due to physical effects of stroke alone. Cases with disturbed consciousness and delirium are excluded
Probable VaD	Requires all the following 1. Dementia 2. Cerebrovascular disease defined by Focal signs on neurologic examination (such as hemiparesis, lower facial weakness, Babinski sign, sensory deficit, hemianopia, and dysarthria Evidence of relevant cerebrovascular disease by CT or MRI Multiple large-vessel infarcts A single strategically placed infarct (angular gyrus, thalamus, basal forebrain, or posterior or anterior cerebral artery territories) Multiple basal ganglia and white matter lacunes, or extensive periventricular white matter lesions, or combinations thereof 3. A relationship between the two disorders just described, manifested by (a) dementia onset within 3 months of a stroke or (b) abrupt deterioration in cognitive functions or fluctuating stepwise course Clinical features consistent with the diagnosis of probable vascular dementia include Early presence of a gait disturbance History of unsteadiness or frequent unprovoked falls Early urinary symptoms not explained by urologic disease Pseudobulbar palsy Personality and mood changes, abulia, depression, emotional incontinence, psychomotor retardation, and abnormal executive function
Possible VaD	May be made in the presence of dementia and focal neurological signs when 1. No neuroimaging studies exist 2. In the absence of clear temporal relationship between stroke and dementia 3. There is subtle onset and variable course of cognitive deficit and evidence of cerebrovascular disease
Alzheimer's disease with cerebrovascular disease	The term ''Alzheimer's disease with cerebrovascular disease'' should be used to classify patients fulfilling the clinical criteria for possible AD and who also present with clinical or brain imaging evidence of relevant cerebrovascular disease

0.84 (Pantoni and Inzitari, 1993). However, a meta-analysis of the HIS in 312 cases of pathologically verified dementias reported a much higher sensitivity of 0.84 and a similar specificity of 0.82 (Moroney *et al*., 1997). In another clinicopathological retrospective series of 114 autopsied cases of dementia, the sensitivity of the HIS for VaD was 0.43 and the specificity was 0.88 (Gold *et al*., 1997). These observations suggest that although the HIS performs well in excluding other causes of dementia, it remains insufficient as a screening test to detect VaD cases. Reasons for this discrepancy are unclear, but may be related to variations in HIS scoring methodology, differences in the pathological criteria used to establish the diagnosis of vascular dementia, and potential publication and selection biases. One study that included neuropathological findings as the gold standard reported relatively low sensitivities of the ADDTC (0.63) and the NINDS-AIREN criteria for possible VaD, although both were found to be more sensitive than the HIS (Gold *et al*., 1997). Mixed dementia, the simultaneous occurrence of AD and VaD, has a significant impact on the accuracy of clinical criteria. In the study described earlier, the HIS, the NINDS-AIREN, and the ADDTC behaved differently regarding mixed dementia. The HIS tended to exclude most cases of mixed dementia but failed to identify many of the VaD cases. The ADDTC and NINDS-AIREN were more sensitive for the detection of VaD, but were less able to differentiate between VaD and mixed dementia. The relatively poor performance of clinical criteria for VaD and the lack of an international consensus suggest a need for improving current diagnostic methodology. VaD can result from several pathophysiological mechanisms, leading to multiple forms of the disease, such as multiple infarcts secondary to large vessel atherosclerosis or cardioembolism, a single strategic infarct, lacunes and white matter changes secondary to small vessel disease, hypoperfusion, and hemorrhage. It is unlikely that a single set of clinical criteria can apply equally to all VaD subtypes. In this light, specific research criteria for subcortical vascular dementia have been proposed; however, they have yet to be validated (Erkinjuntti, 2000).

V. Neuroimaging

Advances in neuroimaging techniques may improve the performance of current clinical criteria. Skoog *et al*. (1993) reported a significant increase in the prevalence of vascular dementia in a population of community-dwelling elderly from 40 to 48% once CT scan findings were taken into consideration. However, in the absence of neuropathological validation, it is unclear whether this increased prevalence corresponds entirely to true cases of VaD. CT and MRI findings described in VaD include hyperintense foci in the basal ganglia and thalamus, infarctions, and white matter and irregular periventricular hyperintensities (Schmidt, 1992; Charletta *et al*., 1995; Frisoni *et al*., 1995; Fornarelli *et al*., 1996; Meyer *et al*., 1996). Although criteria that separate CT scans into grades of increasing support for VaD have been proposed, their clinical use is limited (Pullicino *et al*., 1996). In magnetic resonance imaging (MRI) and CT studies of poststroke patients, dementia has been related to multiplicity of lesions, bilaterality (Ladurner *et al*., 1982; Schmidt *et al*., 1992), atrophy (Tatemichi *et al*., 1990; Figueroa *et al*., 1992), (Liu *et al*., 1992; Schmidt *et al*., 1992; Pohjasvaara *et al*., 1998), and location in the thalamus, temporoparietal, and frontal areas. In individuals with multiple infarcts and dementia or patients with clinically defined VaD, CT or MRI findings suggestive of VaD include infarct location in the left hemisphere, thalamus and limbic structures, extensive white matter lesions, and atrophy (Erkinjuntti *et al*., 1987, 1999; Loeb *et al*., 1988; Gorelick *et al*., 1992; Charletta *et al*., 1995; Meyer *et al*., 1995a; Pullicino *et al*., 1996). Structural imaging has been proposed as a method to identify and document cerebral vascular pathology and thus help differentiate VaD from AD. However, white matter and periventricular lesions increase with age and are twice as prevalent in all dementing disorders, including both VaD and AD, compared to younger individuals (Englund *et al*., 1988; Meyer *et al*., 1992; Skoog *et al*., 1994; Frisoni *et al*., 1995; O'Brien *et al*., 1996; Englund, 1998). Furthermore, typical neuroimaging findings of AD, such as hippocampal atrophy, may also occur in VaD (Laakso *et al*., 1996).

Functionally, VaD cases usually exhibit a diffuse and asymmetric decrease of cerebral blood flow in the cerebral cortex and subcortical nuclei (Fornarelli *et al*., 1996). Furthermore, a loss of cerebral vasomotor responsiveness, a biological marker of cerebrovascular disease, is found consistently in cases with VaD or chronic hypertension (Judd *et al*., 1986; Johansson, 1992; Tamaki *et al*., 1995). In contrast, AD cases exhibit reduced CBF in temporal and parietal areas and show preserved ability to vasodilate and increase CBF in response to various stimuli (Judd *et al*., 1986; Obara *et al*., 1994; Meyer *et al*., 1995b, 1996). However, despite these differences, distinction between VaD and AD cases on the basis of SPECT CBF data remains difficult (Deutsch and Tweedy, 1987; Mielke *et al*., 1994; Starkstein *et al*., 1996; Masterman *et al*., 1997). Positron emission tomography (PET) reveals multiple focal metabolic defects in VaD as opposed to reduced regional metabolic rates in the temporal lobes in early AD (McGeer *et al*., 1986; Polinsky *et al*., 1987; Jagust *et al*., 1988, 1993; Heiss *et al*., 1991). However, a substantial decrease in glucose utilization and oxygen consumption is present in both AD and VaD, and the distinction between VaD and AD may be very difficult, particularly in severe cases (Frackowiak *et al*., 1981; Herholz, 1986; Hoyer, 1986; Heiss *et al*., 1991; Rapport, 1991; Mielke *et al*., 1994). The role of functional brain imaging in the evaluation of VaD has been reviewed: it may be limited for cortical infarcts, but it can be very valuable in assessing the impact of small subcortical infarcts on cortical function (Mori *et al*., 1999).

VI. Treatment Strategies in Vascular Dementia

The increasing body of knowledge regarding risk factors for the development of vascular dementia has led to potential preventive strategies (Gorelick *et al*., 1999). These include the treatment of hypertension, smoking cessation, control of diabetes, anticoagulation when atrial fibrillation is present, carotid endarterectomy for symptomatic patients with 70–99% carotid stenosis, and aspirin for patients at high primary vascular risk. Treatment of isolated systolic hypertension in individuals over

the age of 60 years led to a reduction in the incidence of strokes of 36% in the SHEP study (SHEP Cooperative Research Group, 1991) and 42% in the SYST-EUR trial (Staessen *et al*., 1997). In the latter trial, treatment with the calcium channel blocker nitrendipine and, as a second step, the ACE inhibitor enalapril reduced the incidence of dementia by 50% from 7.7 to 3.8 cases per 1000 patient-years when compared to placebo (Forette *et al*., 1998). The investigators estimated that 19 cases of dementia might be prevented if 1000 patients with isolated systolic hypertension were treated for 5 years. Interestingly, this reduction applied to both AD and VaD.

Once dementia has begun, the objective is to slow its progress, maximize cognitive function, and prevent new infarcts. A variety of treatments for vascular dementia have been tested. Meyer *et al*. (1989) reported encouraging results from a randomized clinical trial of 325 mg of aspirin per day in 70 patients with vascular dementia. Daily aspirin treatment improved cognitive performance and reduced or stabilized declines in cerebral perfusion in this group of patients. The authors stated that this treatment also improved quality of life and independence in activities of daily living. Nimodipine, a dihydropyridine calcium antagonist, has been proposed for the treatment of vascular dementia. This drug is reported to exert vasoactive effects by dilating predominantly small and collateral cerebral vessels and improving the blood supply to underperfused areas. In an open trial (Pantoni *et al*., 1996), 31 patients were treated with a daily dose of 90 mg nimodipine for up to 1 year and their cognitive function was shown to stabilize. Results from ongoing larger randomized placebo-controlled studies will be needed to confirm these findings (Rossi *et al*., 1999). Nicardipine, another calcium channel blocker, may also delay cognitive decline in VaD patients. Nicergoline, a thrombolytic, vasoactive ergot alkaloid, improved vigilance and information processing in patients with degenerative and vascular dementia in a double-blind, placebo-controlled study (Saletu *et al*., 1995) of 112 patients. Pentoxifylline, which has been approved for use in peripheral vascular disease (intermittent claudication), has been the subject of several studies suggesting a possible beneficial effect (Black *et al*., 1992; European Pentoxifylline Multi-Infarct Dementia Study Group, 1996). The proposed mechanism of action is through increased capillary blood flow, thereby improving tissue oxygenation. However, differences between treated patients and those given placebo were small and did not always reach statistical significance. Propentofylline, a phosphodiesterase and adenosine reuptake inhibitor, inhibits potentially neurotoxic functions of activated microglia and may have a beneficial effect on glucose metabolism in several cortical areas. It has been suggested that this drug could potentially slow the progression of dementia, but this has yet to be confirmed in large randomized, double-blind, placebo-controlled trials (Kittner *et al*., 1997; Marcusson *et al*., 1997; Kittner, 1999). A review of four phase III propentofylline trials that used DSMIIIR criteria and HIS to diagnose VaD and one phase III trial using NINDS-AIREN criteria reported a beneficial effect of unspecified magnitude on cognition but no effect on functional status, as measured by several activities of daily living scales (Kittner, 1999). In a randomized control trial of another phosphodiesterase inhibitor, denbufylline, cognitive improvements were not statistically significant compared to placebo in 110 patients with VaD or MD (Treves and Korczyn, 1999). Memantine, a *N*-methyl-D-aspartate (NMDA) receptor antagonist, is purported to provide neuroprotection from ischemia-induced apoptosis and and necrosis. Several phase III trial are ongoing (Möbius, 1999). Consumption of supplementary vitamin E was associated with a decreased likelihood of developing VaD in the Honolulu–Asia aging study; putative mechanisms include an antioxidant effect, decreased platelet adhesion, decreased carotid atherosclerosis, and neuronal protection from ischemic damage (Ross *et al*., 1999). EGb 761, an extract of the *Ginkgo biloba* tree, is prescribed in some countries for the treatment of dementia. A randomized, placebo-controlled trial carried out on 309 patients with dementia (either AD or VaD) showed a very modest effect after 52 weeks that could be measured objectively on neuropsychological testing, but could not be recognized by caregivers (Le Bars *et al*., 1997).

VII. Conclusion

The concept of vascular dementia has evolved significantly over the past century, leading to a better understanding of its underlying pathophysiological mechanisms. New clinical criteria have been developed that take into account the time relationship between vascular events and the occurrence of dementia and incorporate modern neuroimaging technology. However, further studies, including neuropsychological and functional evaluations, as well as neuroimaging and clinicopathological correlations, are needed to develop and validate better performing criteria, which could lead to a broader consensus on the clinical diagnosis of VaD and its various subtypes. Although curative therapy remains generally disappointing, epidemiological studies have led to a greater awareness of risk factors for VaD and potential preventive interventions.

Frontotemporal Dementias: From Classification Problems to Pathogenetic Uncertainties

The term frontotemporal dementia has been used to classify several clinical syndromes previously described based on a relatively homogeneous symptomatology. Patients in this diagnostic group present with an insidious and gradual change in personality and social conduct, early deficits of mental manipulation, sequencing and hierarchical organization processes, frontal-type amnesia, contrasting with preserved orientation, visuoconstructive and visuospatial abilities. Frontotemporal dementia may represent more than 20% of degenerative dementias and is currently considered as the third most common cause of dementia after Alzheimer's disease and Lewy body dementia. Biochemical and molecular genetic studies have made it possible to identify at least three biologically homogeneous subgroups of frontotemporal dementias: typical frontotemporal dementia cases with no tau or ubiquitin-positive neuronal and glial inclusions, two tauopathies, namely Pick's disease and frontotemporal dementia with parkinsonism linked to chromosome 17, and one ubiquitin-related disorder, the frontotemporal dementia with motor neuron disease. We provide here a detailed overview of current concepts regarding the clinical characteristics and etiopathogenesis of these conditions.

The evolution of the nomenclature of frontotemporal dementias (FTD) is complex and confusing. Arnold Pick (1892) provided the first detailed clinical description of FTD. Alois Alzheimer (1911) described the neuropathological lesions characteristic of Pick's disease and since then this term has been used to classify most patients with progressive early-onset dementia with massive deterioration of executive functions. Since the 1980s, several names have been proposed pointing to the predominant involvement of the frontal cortex, in contrast to the more frequent biparietal damage in Alzheimer's disease (AD), or the absence of specific histopathological lesions. In 1994, a consensus statement adopted the term FTD to cover a wide and highly heterogeneous nosographic spectrum, which includes demented patients with symptoms suggestive of either frontal lobe dysfunction, such as personality change or disinhibited behavior, or anterior temporal lobe dysfunction, such as hyperorality, associated or not with parkinsonism, motor neuron disease, and focal cortical degeneration, including progressive nonfluent aphasia and semantic dementia (Brun *et al*., 1994). Despite its evident usefulness in increasing clinical interrater reliability, the concept of FTD masks fundamental etiopathogenetic differences mainly in respect to the presence of tau pathology in neurons and glial cells. This chapter defines the clinical and neuropsychological features of the group of FTDs and provides a critical overview of recent progress in morphological, biochemical, and molecular genetic characterization of FTD subtypes.

I. Diagnosis of FTD: Epidemiological and Clinical Considerations

Frontotemporal dementia is the third most common cause of cortical dementia following AD and Lewy body disease (Neary *et al*., 1998). Estimates of its incidence vary depending on theoretical positions and nomenclature used. However, FTD is thought to represent more than 20% of degenerative dementias, raising the ratio of FTD:AD to 1:4 (Brun, 1993; Knopman, 1993; Kertesz and Munoz, 1998; Neary *et al*., 1998). The onset of disease is most commonly before the age of 65 years, yet sporadic cases with late-onset have been reported (Giannakopoulos *et al*., 1995). A positive family history of a similar disorder in a first-degree relative has been reported in as many as 50% of patients (Gustafson, 1987; Neary *et al*., 1998). Mutations in the tau gene on chromosome 17 and linkage to

chromosome 3 have been identified in a few families (Brown *et al*., 1995; Hutton *et al*., 1998; Poorkaj *et al*., 1998; Spillantini *et al*., 1998a). In particular, the identification of several intronic and exonic mutations in the tau gene in cases with FTD and parkinsonism has led to the definition of a new clinical subgroup of FTD referred to as frontotemporal dementia and parkinsonism linked to chromosome 17 (FTDP-17) (Hutton *et al*., 1998; Poorkaj *et al*., 1998; Spillantini *et al*., 1998a).

Even though FTD can be often difficult to differentiate clinically from AD, the diagnosis is based on the presence of early personality and behavioral changes, which remain prominent in the course of the disease, symmetric or asymmetric cerebral atrophy confined to the frontal and anterior temporal cortex, cortical hypometabolism in the same areas, and normal electroencephalography (Elfgren *et al*., 1993; Mendez *et al*., 1993; Brun *et al*., 1994; Neary *et al*., 1998). The most common neurobehavioral syndrome in FTD is an insidious and gradual change in personality and social conduct characterized by disinhibition, mood disorders, irritability and aggressiveness contrasting with incoherent joviality, impulsivity, early loss of social awareness, aberrant behaviors, bulimia, and hyperorality (Brun *et al*., 1994; Neary *et al*., 1998). Global intelligence, as measured by the Wechsler Adult Intelligence Scale, is relatively preserved at the beginning of the disease without the systematic dissociation between verbal and performance IQ observed in AD (Miller *et al*., 1991). Patients are usually oriented in time and place and provide correct autobiographical information. Short-term memory is equally affected in both FTD and AD at the same degree of severity, except in its visuospatial component, which appears to be better preserved in FTD. Free recall is poor as in AD, but the performance is improved by the use of specific, directed questions rather than open-ended questions and by cues and multiple-choice alternative responses. This pattern of memory impairment is consistent with a ''frontal-type'' amnesia and reflects difficulties in retrieval and organization of the information rather than a pure storage deficit (for review, see Pasquier, 1999). Language deficits, including verbal stereotypia, echolalia, and progressive language impoverishment leading to mutism or press of speech, are frequent in FTD. Conversely, comprehension, reading, and naming skills are preserved (Mendez *et al*., 1993; Neary and Snowden, 1996; Pasquier, 1999). The most marked neuropsychological feature of FTD is the failure of mental manipulation, sequencing, and hierarchical organization processes. Performances in the Trail Making Test, a classical test of executive functions, is significantly worst in FTD than in AD cases. Verbal fluency is also impaired (Miller *et al*., 1991; Pasquier *et al*., 1995). In contrast, visuospatial and visuoconstructive abilities, which are affected early in AD, remain relatively intact in FTD (Neary *et al*., 1998). It should be kept in mind, however, that FTD patients may perform poorly on formal memory, perceptual, and spatial tests as a consequence of increased distractibility, poor self-control, and lack of concern for accuracy. In these cases, correct responses by cueing and fluctuations in test performance support the diagnosis of FTD (Neary *et al*., 1998; Pasquier, 1999). In most typical FTD cases, parkinsonian signs emerge only during late stages, but in FTDP-17, there are early key features of parkinsonism, such as muscular rigidity, slowness of movement, postural instability, and rarely tremor. These symptoms do not respond to pharmacologic treatment, which is usually successful in ameliorating the symptoms of idiopathic Parkinson's disease. Eye movement abnormalities and early-onset incontinence are also seen in FTDP-17 cases (Knopman *et al*., 1990; Foster *et al*., 1997).

Two other prototypic clinical sydromes are part of the FTD spectrum: primary progressive aphasia and semantic dementia (Mesulam, 1982; Weintraub *et al*., 1990; Hodges *et al*., 1992; Snowden *et al*., 1992). Primary progressive aphasia is a disorder of expressive language without marked behavioral abnormalities, which do not necessarily evolve to dementia. It is characterized by nonfluent spontaneous speech with numerous agrammatisms and phonemic paraphasias, increased word retrieval latency, impaired repetition, alexia, and agraphia. Verbal comprehension, visuoconstructive and visuospatial abilities, and memory are preserved, contrasting with the classical description of AD (Mesulam, 1982; Weintraub *et al*., 1990; Snowden *et al*., 1992). In semantic dementia, there is a severe loss of both verbal and visual semantic concepts with a preservation of other linguistic abilities. Speech is fluent and gramatically correct but the content is limited to a repetitive conversational repertoire. The loss of word meaning is compensated by the use of broad generic terms and semantic paraphasias. Prosopagnosia and associative visual agnosia are frequent, resulting from impaired manipulation of visual semantics. Conversely, perceptual matching, praxis, and memory tasks are performed normally (Hodges *et al*., 1992).

The association of Pick's disease and motor neuron disease was described many years ago (Mitsuyama and Takamiya, 1979). The rare association of typical FTD and progressive aphasia with motor neuron disease was recognized later, identifying the dementia as FTD with motor neuron disease (Neary *et al*., 1990; Ferrer *et al*., 1991; Sam *et al*., 1991; Caselli *et al*., 1993). The clinical evolution is usually rapid with early death from dysphagia. In these cases, the development of motor neuron disease symptomatology in patients with behavioral or language disorder would support the diagnosis of FTD or progressive aphasia, respectively. Although the coexistence of motor neuron disease and FTD is an epidemilogically marginal phenomenon, studies demonstrated that its biochemical background differs from that of typical FTD cases (for review, see Ince *et al*., 1998), suggesting that FTD with motor neuron disease represents a biologically separate entity.

II. Morphological Basis of FTD

Until the mid-1990s, the most widely accepted neuropathological definition of FTD was based on the presence of circumscribed frontal and/or anterior temporal atrophy and nonspecific histopathological changes, such as neuronal loss, spongiosis, and gliosis. Pick's disease had an equivocal place, as it was considered by some authors as a simple variant of FTD and by others as a true clinical entity (Knopman *et al*., 1990; Brun *et al*., 1994; Giannakopoulos *et al*., 1995). Progress in the biochemical characterization of filamentous nerve cell inclusions, as well as the detailed analysis of tau gene expression in FTDP-17 cases, has contributed to change this

TABLE 12.1 Tau Pathology Patterns in FTD Subtypes and Selected Tauopathies[a]

Disorder	Neuronal inclusion	Glial inclusion	Tau protein electrophoretic profile
Typical FTD	–	–	Six tau isoforms 55, 64, 69 kDa
FTDP-17	Globose NFT	+/–	55, 64, 69 kDa 64, 69 kDa
Pick's disease	PB	+	55, 64 kDa
FTD with MND	–	–	Six tau isoforms 55, 64, 69 kDa
CBD	Coiled/thread like	AP	64, 69 kDa
PSP	Globose NFT	TA	64, 69 kDa
AD	NFT	Rare	55, 64, 69 kDa

[a]PB, Pick bodies; CBD, corticobasal degeneration; MND, motor neuron disease, PSP, progressive supranuclear palsy; AP, astrocytic plaques; TA, tufted astrocytes. See text for details.

simplistic point of view radically. Although a global understanding of the molecular background of FTD has yet to be achieved, one can schematically consider that this group includes a large but poorly defined subgroup of typical FTD cases, two tauopathies, namely Pick's disease and FTDP-17, and one ubiquitin-related disorder, FTD with motor neuron disease (Table 12.1). The morphological and biochemical characteristics of each of these categories are summarized next.

A. Typical FTD

The neuropathological features of FTD consist of moderate to severe atrophy confined to the frontal and temporopolar regions and ventricular dilation (Brun, 1993; Mann *et al*., 1993; Neary *et al*., 1993; Fig. 12.1 top). The atrophy is symmetrical, but cases with asymmetrical gyral atrophy have also been reported (Knopman *et al*., 1990; Neary *et al*., 1993). According to the new neuropathological criteria for FTD, frontal and temporopolar cortices show a differential degree of loss of pyramidal cells, mainly in layers II and III, whereas those of layer V are affected mildly. Spongiform degeneration of layers II and III is often seen along with moderate to severe astrocytic gliosis in the gray and white matter (Brun, 1993; Mann *et al*., 1993; Brun *et al*., 1994). These lesions spread frequently to the insula and cingulate gyrus, whereas the posterior temporal, parietal, and occipital cortex are devoid of lesions in most cases. Although the involvement of the hippocampus, amygdala, and subcortical regions is mild in most patients with FTD, several authors reported cases with prominent cell loss and astrogliosis in the striatum, thalamus, and limbic structures and proposed the existence of possible neuropathological subgroups of this disorder (Knopman *et al*., 1990; Knopman, 1993; Neary *et al*., 1993). Such a possibility is supported by a neuropathological study of 32 FTD cases, which defined four subgroups (Giannakopoulos *et al*., 1995). The first group showed moderate to severe neuron loss and gliosis in the frontal and/or temporopolar cortex without

FIG. 12.1. Lateral surfaces of the cerebral cortex in a typical FTD case (top) and a Pick's disease case (bottom). Note the marked frontal atrophy in the FTD case as compared to the ''knife-edge'' atrophy of the temporopolar cortex in the Pick's disease case.

subcortical involvement. In the second group, neocortical cell loss was widespread and the striatum and substantia nigra displayed differential degrees of gliosis but no neuron loss. Another group of patients exhibited lesion distribution comparable to that observed in the second group, but with severe neuron loss in at least one subcortical region. Finally, a few cases were characterized by the preservation of the pyramidal neurons in the neocortex and variable subcortical changes (Fig. 12.2). Despite these differences in the topography of pathological changes, the crucial criterion for the diagnosis of FTD is the absence of tau- or ubiquitin-positive distinctive subcellular dysmorphic features, such as Alzheimer changes (except mild ones compatible with age), Pick bodies, Lewy bodies, and swollen neurons (Table 12.1; for review see Mann, 1998). It is worth noting that there is no clear relationship between the regional distribution of cell loss and clinical syndromes within the FTD spectrum. For instance, a positron emission tomography study has revealed a marked hypometabolism in the left posterior inferior temporal gyrus in cases with semantic dementia and significant anterolateral temporal atrophy. In these cases, clinical symptomatology

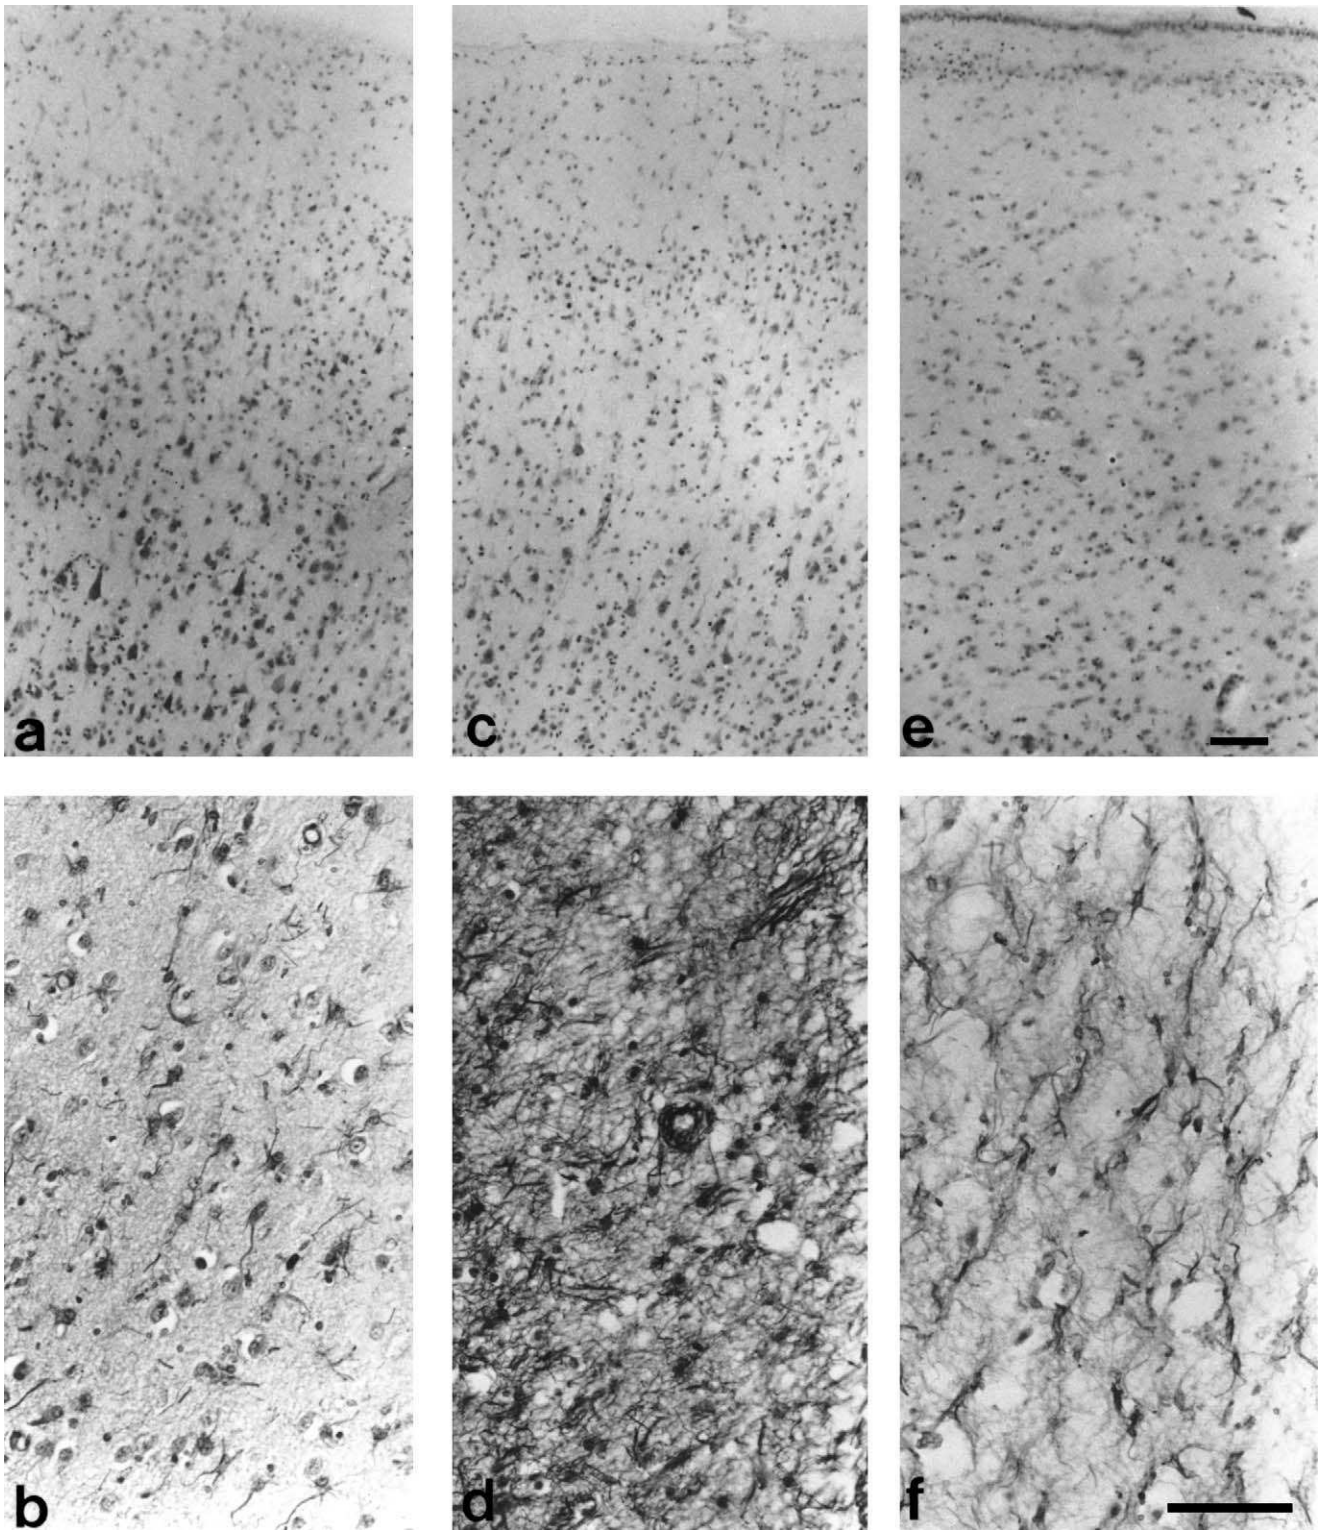

FIG. 12.2. Representative examples of pathologic changes in the frontal cortex (a–d) and striatum (e and f) in three typical FTD cases (a and b, c and d, e and f). Note the mild neuron loss in layers II and III (a) and the mild reactive astrocytosis (b) in the first case and the moderate loss of nerve cells (c) and the presence of both moderate gliosis and spongiform changes (d) in the second case. There is a marked depletion of striatal neurons (e) and mild reactive gliosis (f) in the third case. Materials were stained with cresyl violet (a, c, e) and Holzer (b, d, f) stains. Scale bar (on f): 100 μm. Reproduced with permission from Giannakopoulos *et al*., (1995).

depends on the disruption of temporal lobe circuits in regions distant from the structural damage (Mummery *et al*., 1999).

B. FTD-Related Tauopathies

The term ''tauopathies'' is applied to a highly heterogeneous group of disorders sharing filamentous tau protein deposits as their main pathological feature. Except for Pick's disease and FTDP-17 (Fig. 12.3), this group includes AD, Down syndrome, ''tangle-only'' dementia, argyrophilic grain disease, corticobasal degeneration, progressive supranuclear palsy, and several rare conditions, such as amyotrophic lateral sclerosis/parkinsonism dementia complex of Guam, Niemann–Pick disease type C, myotonic dystrophy, subacute sclerosing panencephalitis, and postencephalitic parkinsonism (for review, see Tolnay and Probst, 1999). Early language impairment, frontal symptoms, and personality changes support a diagnosis of Pick's disease and FTDP-17, whereas prominent akinetic-rigid syndrome, extrapyramidal motor dysfunction, apraxia, dystonia, and postural abnormalities suggest the presence of an atypical parkinsonian tauopathy such as corticobasal degeneration, progressive supranuclear palsy, and postencephalitic parkinsonism. However, the differential diagnosis is often very difficult. Extrapyramidal and subcortical involvement is well documented in Pick's disease, and clinical cases of corticobasal degeneration have been described with pathological features of Pick's disease (Riley *et al*., 1990; Rinne *et al*., 1994; Feany *et al*., 1996). Neuropathologically, progressive supranuclear palsy and postencephalitic parkinsonism are characterized by substantial neurofibrillary tangle (NFT) formation in the pallidum, subthalamic nucleus, substantia nigra or pons, and, to a lesser extent, in the striatum, oculomotor nuclei, medulla, and cerebellum (Hauw *et al*., 1994). In contrast to any other disease showing NFT, electron microscopy studies in progressive supranuclear palsy have revealed the coexistence of paired helical filaments (PHF) of the Alzheimer type and 15 nm straight filaments (Cervós-Navarro and Schumacher, 1994). Corticobasal degeneration is defined by the presence of achromatic neurons and tau-immunoreactive inclusions in both substantia nigra and neocortical layer II and by severe neuronal loss in the substantia nigra and basal ganglia (Hauw *et al*., 1994; Litvan *et al*., 1996). Although the introduction of NINCDS neuropathological criteria for progressive supranuclear palsy and related disorders has improved the accuracy of their neuropathological diagnosis, the differential diagnosis of these disorders remains challenging (Hauw *et al*., 1994; Litvan *et al*., 1996).

1. FTDP-17

The only neuropathological criterion that makes it possible to distinguish this condition from typical FTD is the abundant filamentous tau deposits in neurons and, in some cases, glial cells (Figs. 12.3a–12.3c; for review, see Foster *et al*., 1997; Spillantini *et al*., 1998b). The type of pathology in FTDP-17 depends largely on the location of mutations in the tau gene

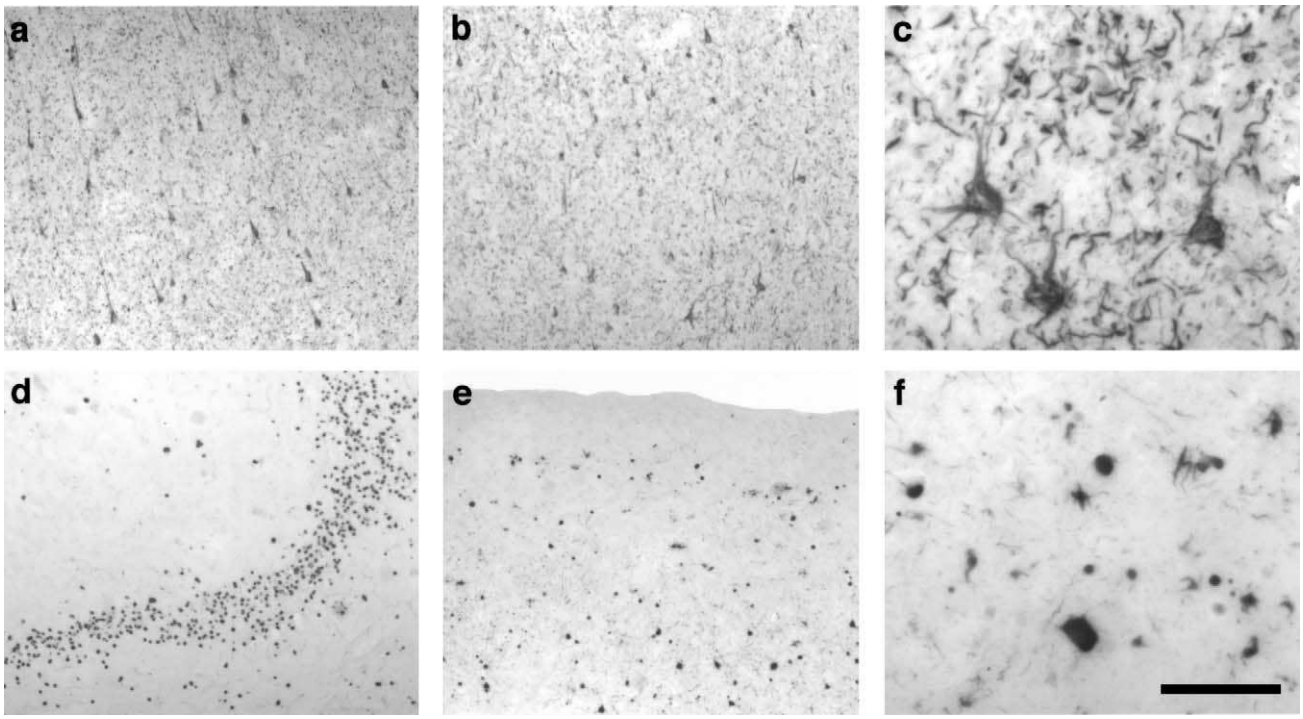

FIG. 12.3. Examples of characteristic lesion types and distribution in FTDP-17 (a–c) and Pick's disease (d–f). FTDP-17 displays moderate to high densities of NFT in the hippocampal formation (a, CA1 field) and neocortex (b, inferior temporal cortex). (c), A higher magnification of typical NFT and neurites stained with an antibody to hyperphosphorylated tau proteins in the temporal neocortex of an FTDP-17 case. Pick's disease is characterized by very high numbers of Pick bodies in the granule cell layer of the dentate gyrus (d) and in layers II and VI of the neocortex (e, frontopolar region). (f) Characteristic features of Pick bodies in the frontal neocortex as well as glial tangles, stained with an anti-tau antibody. Scale bar (on f): 150 μm (a, b, d, e) and 50 μm (c, f).

TABLE 12.2 Tau Inclusions in FTDP-17[a]

Mutation site	Biochemistry	EM	Pathogenesis
Introns (5′ splice site)	4 > 3 repeat tau	Twisted ribbons	Gain of function
Exons 9, 12, 13	Normal 4/3 repeat tau ratio	AD-PHF and SF	Loss of function
Exon 10	Mutant 4 repeat tau	Twisted ribbons	Loss of function

[a]EM, electron microscopy; PHF, paired helical filaments; SF, straight filaments. See text for details.

(Table 12.2). This gene contains 15 exons, and the six tau isoforms are encoded by 11 of them by alternative splicing of exons 2, 3, and 10 (Andreadis *et al*., 1992). Exons 9–13 encode four microtubule-binding repeats of 31 or 32 amino acids in the carboxy-terminal half of the tau molecule. The alternative splicing of exon 10 generates four or three repeat tau isoforms (Goedert *et al*., 1989). The most common FTDP-17 intronic mutations are located close to the splice-donor site of the intron following exon 10 and act by increasing splicing in exon 10 and production of the four repeat isoforms (Hutton *et al*., 1998; Spillantini and Goedert, 1998; Grover *et al*., 1999). This may result in an excess of tau over available binding sites on microtubules, thus inducing a gain of toxic function with unbound excess tau available for assembly into filaments (Goedert *et al*., 1998). Tau inclusions are found in neurons and glial cells as 6 to 22 nm-wide ribbons twisted every 90–300 nm quite similar to those reported in corticobasal degeneration (Spillantini *et al*., 1998c). Exonic mutations in FTDP-17 are missense mutations that induce microtubule destabilization by reducing the ability of mutated tau to interact with microtubules (partial loss of function). For instance, some of the exonic mutations in exons 10, 12, and 13 have been shown to decrease the microtubule-binding affinity of tau and to promote microtubule assembly (Hasegawa *et al*., 1998). The ratio of four to three repeat tau isoforms is preserved in FTDP families with missense mutations in exons 9, 12, and 13. Tau inclusions contain all six tau isoforms, and filaments are ultrastructurally comparable to those seen in AD (for review, see Hardy *et al*., 1998; Spillantini and Goedert, 1998; Spillantini *et al*., 1998c). Exon 10 mutations result in tau inclusions, which contain the mutant four repeat form and by electron microscopy filaments are similar to those obtained in intronic mutations.

2. Pick's Disease

Pick's disease is characterized by a progressive frontotemporal lobar atrophy, gliosis, severe neuronal loss, αB-crystallin-immunoreactive ballooned neurons, and the presence of argyrophilic (but Gallyas-negative) neuronal inclusions, the Pick bodies, in the cerebral cortex and some subcortical structures (Figs. 12.3d–12.3f). The ''knife-edge'' cortical atrophy is frequently asymmetric and predominates in the frontal and temporopolar regions, with the posterior part of frontal and temporal lobes being less affected (Yoshimura, 1989; Brion *et al*., 1991; Kosaka *et al*., 1991; Fig. 12.1 bottom). In these regions, cortical atrophy mainly involves the supragranular layers. The parietal and occipital cortices are usually spared, but panencephalitic and parietal variants of Pick's disease have been reported (Cambier *et al*., 1981; Shibayama *et al*., 1983). The hippocampal formation displays severe atrophy accompanied by high densities of Pick bodies, especially in the dentate gyrus, where very high densities were reported (Hof *et al*., 1994). In subcortical structures, pathologic changes are observed frequently in the basal ganglia, amygdala, nucleus basalis of Meynert, substantia nigra, locus coeruleus, and central gray matter (Forno *et al*., 1989; Arima and Akashi, 1990; Brion *et al*., 1991; Kosaka *et al*., 1991). The distribution of Pick bodies in neocortical layers differs from that of NFT in AD in that there is a preferential involvement of small pyramidal neurons in layer II and the superficial portion of layer III. Moreover, layer VI is affected severely in Pick's disease, suggesting that certain corticosubcortically projecting neurons are involved in PD that may be resistant in AD (Hof *et al*., 1994).

Ultrastructurally, Pick bodies consist of bundles of disorganized 10 to 15 nm straight filaments, which may be mixed with PHF-like of 130 to 160 nm periodicity, and share antigenic determinants with NFT (Hof *et al*., 1994; for review, see Delacourte *et al*., 1996). In particular, Pick bodies are associated with phosphorylated neurofilament epitopes identical to those found in NFT, as well as with other markers, such as the microtubule-associated protein tau and ubiquitin, indicating that, like NFT, Pick bodies may derive from altered components of the neuronal cytoskeleton. Moreover, there is a coexistence of Pick bodies and NFT in the brains of most patients with Pick's disease, whereas diffuse Aβ deposits are also found in 30% of cases (Hof *et al*., 1994). Observations in aged transgenic mices expressing the human medium molecular weight neurofilament protein subunit revealed the formation of lesions morphologically similar to Pick bodies and NFT in the neocortex. These findings suggest that although the laminar distribution of neuropathological lesions differs between AD and Pick's disease, common biochemical mechanisms leading to alterations of comparable cellular constituents exist in these disorders (Katzman and Kawas, 1994).

In addition to neuronal pathology, there is a marked neuritic and glial tau pathology in Pick's disease (Table 12.1; Buée-Scherrer *et al*., 1996; Feany *et al*., 1996; Probst *et al*., 1996). Immunostaining with phosphorylation-dependent anti-tau antibodies showed a dense network of immunoreactive axons in the vicinity of Pick body-containing neurons that could be differentiated easily from AD dendritic threads. In contrast to AD, several types of glial cytoskeletal alterations have been described in Pick's disease and appear to be a consistent finding in progressive supranuclear palsy, post-encephalitic parkinsonism, and corticobasal degeneration,

indicating that in these diseases, glial elements may participate significantly in the pathologic tau profile (Feany and Dickson, 1995; Buée-Scherrer *et al*., 1996; Feany *et al*., 1996). Tau- and ubiquitin-immunoreactive cortical and white matter astrocytic inclusions are mostly observed in the middle and temporal gyri, which are the most severely affected cerebral regions. In progressive supranuclear palsy, widespread glial tangle pathology referred to as tufted and thorn-shaped astrocytes and coiled bodies has been reported in the striatum, thalamus, and cerebral cortex, whereas consistent amyloid-negative cortical astrocytic plaque formation has been observed in corticobasal degeneration (for review, see Chin and Goldman, 1996). It is also worth noting that tau filaments in Pick's disease contain only three repeat isoforms (Delacourte *et al*., 1998), whereas only four repeat isoforms are found in progressive supranuclear palsy and corticobasal degeneration (Mailliot *et al*., 1998). These differences in the molecular composition of tau protein, as well as the electrophoretic patterns described later, permit a reliable identification of Pick's disease cases among tauopathies (Table 12.1).

3. Biochemical Characterization of FTD-Related Tauopathies

Electrophoresis of tau proteins is a powerful tool for discriminating FTD-related tauopathies. The electrophoretic mobility of tau protein, is slowed by excessive phosphorylation. Hyperphosphorylated tau proteins in brains from AD, Down syndrome, Pick's disease disease with NFT, and nondemented elderly individuals appear as the tau 55, 64, and 69 triplet (Delacourte *et al*., 1990; Lee *et al*., 1991). A similar immunoblotting pattern has been found in postencephalitic parkinsonism and FTDP-17 family Seattle A (Spillantini *et al*., 1996; Buée-Scherrer *et al*., 1997). As in progressive supranuclear palsy and corticobasal degeneration, some FTDP-17 families displayed the tau 64 and 68 doublet (Ksiezak-Reding *et al*., 1994; Buée-Scherrer *et al*., 1996; Spillantini *et al*., 1998b). Among tauopathies, typical Pick's disease cases with Pick bodies, but without NFT, are the only one to show the tau 60 and 64 doublet (Table 12.1; Delacourte *et al*., 1996).

If these observations in brain tissue are highly promising, this is not the case for the biochemical analysis of cerebrospinal fluid. In fact, such data in FTD cases are still very scarce and contradictory. An elevation of cerebrospinal fluid tau concentrations has been reported in FTD, but not in progressive supranuclear palsy and corticobasal degeneration (Arai *et al*., 1997; Green *et al*., 1999). A specific increase in the concentrations of the monoamine metabolite 3-methoxy-4-hydroxyphenylglycol, as well as a decrease in corticotropin-releasing factor, and somatostatin levels have been reported in the cerebrospinal fluid of FTD cases compared to controls (Minthon *et al*., 1997; Sjögren *et al*., 1998), although the significance of these observations has not yet been demonstrated.

C. FTD with Motor Neuron Disease: A Separate Case?

The lesion distribution in FTD cases with motor neuron disease differs from that observed in typical FTD cases in that there is a preferential involvement of hippocampus and subcortical structures and, in typical cases, marked hypoglossal and anterior horn degeneration (Deymeer *et al*., 1989; Ferrer *et al*., 1991). Immunocytochemically, this disorder is characterized by the presence of ubiquitin-positive and tau-negative intraneuronal inclusions. The term ''ubiquitin-specific inclusions'' has been introduced to designate these inclusions, invisible on classical histological stains, which are principally found in the dentate gyrus and frontal cortex of FTD cases with motor neuron disease. The main constituent of these inclusions has not yet been identified (for review, see Ince *et al*., 1998). The ubiquitin-specific inclusions are also observed in amyotrophic lateral sclerosis and neuroaxonal dystrophy, and it has been postulated that these diseases may have a common origin (Arima *et al*., 1998; Tolnay and Probst, 1999). However, several FTD cases without clinical symptoms of motor neuron disease exhibit these inclusions, pointing to the necessity for further studies to better delineate these entities.

III. Conclusions

As is frequently the case in dementia research, the existence of complex relationships between clinical and biological descriptions is a source of confusion. Despite this, progress in the morphological and biochemical characterization of FTD has contributed to define the spectrum of these syndromes better. Clearly, the clinical umbrella of FTD, although conceptually weak, had the merit to increase the diagnostic reliability among clinicians. Until neuropsychological, neuroimaging, and biochemical markers become available to allow for a valid premortem distinction among the different subgroups of FTD, the broad use of the term FTD (including its prototypical clinical syndromes) is recommended. However, detailed postmortem investigations of FTD cases using modern morphological and biochemical techniques is warranted to classify them in biologically homogeneous diagnostic groups. Recent advances in the understanding of FTD-related tauopathies have demonstrated that the events leading to a filamentous tau pathology are sufficient for neurodegeneration and onset of dementia in the absence of significant amyloid pathology. In this respect, one kindred with FTDP-17 (Seattle family A) displayed tau ultrastructural and biochemical characteristics identical to those found in AD, raising the question of the relationship between these two disorders (Goedert *et al*., 1998). Moreover, the ubiquitin-related immunocytochemical patterns in FTD with motor neuron disease and amyotrophic lateral sclerosis suggest intriguing biological similarities between these disorders. Although these observations imply that the biological background of some forms of FTD could be defined better in the near future, the pathogenesis of most typical FTD cases remains obscure. An immunocytochemical study of presenilin-1 and apoptosis-related proteins in these FTD cases revealed that neurons containing presenilin-1 are preserved in affected cortical areas, but Bax and Bcl-x_L were not activated (Giannakopoulos *et al*., 1999). This is consistent with a report showing that the glutamate-induced death of cerebellar granular cells in culture does not involve Bax expression and suggests that alternative mechanisms of cell death that do not require the activation of this protein occur in typical FTD (Dessi *et al*., 1993;

Giannakopoulos *et al*., 1999). Conceptually, the biological research on FTD should aim at resolving two enigmas to permit the development of an etiological classification of these disorders: (1) how the same symptoms correspond to several, biologically distinct groups, which in turn converge into clinically unrelated dementing conditions, and (2) what mechanisms are involved in cell loss in FTD.

Acknowledgments

We thank Drs. N. K. Robakis and A. Delacourte for generously providing antibodies to tau and Aβ amyloid proteins and M. Surini and P. Y. Vallon for expert technical assistance. Supported by Grants 31-45960.95 (CB and PG) and 4038-44006 (PG) from the Swiss National Science Foundation and by NIH Grant AG05138 (PRH).

Progressive Supranuclear Palsy and Corticobasal Degeneration

Progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD) are sporadic neurodegenerative disorders of mid to late adult life that have shared clinical and pathologic features, but also notable differences that warrant their separation as clinicopathologic entities. Among shared clinical features are extrapyramidal signs similar to Parkinson's disease, but neither PSP nor CBD is responsive to levodopa therapy. Motor abnormalities in PSP are usually symmetrical, whereas asymmetry is the hallmark of CBD. Focal cortical signs, such as apraxia and aphasia, are common in CBD, but rare in PSP. Dementia is more common in CBD than PSP. Severe vertical gaze palsy early in the disease course is common in PSP, but is uncommon or a late manifestation of CBD. Pathologically, both PSP and CBD are associated with neuronal and glial filamentous inclusions that are composed of tau protein. The morphology of neuronal and glial lesions differs in PSP and CBD, but there are a number of lesions with transitional or overlapping features. Distribution of the lesions shows considerable overlap, but the overall distribution of the lesions differs in PSP and CBD. Cortical gray and white matter lesions are prominent in CBD, whereas deep gray matter lesions are more common in PSP. Biochemical studies of brain tissue from PSP and CBD show similar alterations in tau protein. Abnormal tau proteins in PSP and CBD are relatively insoluble and hyperphosphorylated. Furthermore, they appear to be composed of tau enriched in specific tau mRNA splice forms, specifically tau derived from alternative spicing of exon 10, which generates tau with four repeat regions in the microtubule-binding domain. It is unclear if this is due to disease-related differential expression of these tau isoforms, involvement of cell types that express these isoforms preferentially, or selective assembly of these specific tau isoforms in the lesions. Both PSP and CBD are considered to be nonfamilial or sporadic ''tauopathies,'' but genetic studies suggest that polymorphisms in the tau gene may confer some degree of genetic risk for these disorders. Given the relative rarity of these conditions, further clinical and pathologic studies are needed to define the diagnostic boundaries and to develop biologic markers for their clinical and pathologic differentiation.

I. Introduction

Progressive supranuclear palsy (PSP) and corticobasal degeneration (CBD) are sporadic neurodegenerative disorders of mid to late adult life that have only recently been recognized as clinicopathologic entities. They were first reported in the medical literature in the 1960s (Steele *et al*., 1964; Rebeiz *et al*., 1967), and the term CBD was coined in the 1980s (Gibb *et al*., 1989). Molecular methods have been applied to these disorders, and these studies raise questions about how PSP and CBD might be related, as the biochemical changes in the brain are very similar (reviewed in Buée and Delacourte, 1999). Although some clinical and pathological features are shared by PSP and CBD, there are notable differences that warrant their separation as clinicopathologic entities (reviewed in Litvan and Agid, 1992; Litvan *et al*., 2000).

Among the shared clinical features are extrapyramidal signs. Individuals with CBD and PSP have bradykinesia, rigidity, and gait abnormalities that bring to mind Parkinson's disease. However, neither PSP nor CBD typically has a sustained clinical response to levodopa like Parkinson's disease. Furthermore, rest tremor, one of the cardinal clinical features of Parkinson's disease, is uncommon in PSP and CBD. Motor abnormalities in PSP are usually symmetrical, whereas asymmetry is the hallmark of CBD. Focal cortical signs help differentiate CBD and PSP. Apraxia and aphasia are common in CBD, but are decidedly atypical in PSP. Dementia is common in CBD, and retrospective studies of pathologically confirmed cases of CBD indicate that this may be one of the most common presentations of CBD. Dementia is not prominent in PSP, but many individuals develop a frontal lobe syndrome in advanced stages of the disease. Supranuclear gaze palsy early in the disease course, which is common in PSP, is another clinical feature that distinguishes PSP from CBD.

Pathologically, both PSP and CBD are associated with neuronal and glial filamentous inclusions that are composed primarily of the microtubule-associated protein tau. The distribution of neuronal and glial lesions shows a considerable

degree of overlap, but the overall pattern differs (Dickson, 1999b). For example, cortical and white matter pathology is more prominent in CBD, whereas deep gray matter areas are affected more in PSP. The morphology of neuronal and glial lesions is different in PSP and CBD (Komori *et al*., 1998), but there are no clear boundaries that make individual lesions pathognomonic.

Biochemical studies of brain tissue from PSP and CBD show alterations in tau protein (reviewed in Buée and Delacourte, 1999). These abnormal tau proteins, which are probably derived from the filamentous lesions, are relatively insoluble and hyperphosphorylated. In PSP and CBD there is also evidence of enrichment of specific tau mRNA splice tau in the abnormal tau isolated by detergent extraction. Whether there is differential overexpression of these tau isoforms or differential assembly of specific tau isoforms in the lesions remains to be determined. Given the pivotal role that tau abnormalities are increasingly felt to play in neurodegenerative diseases, PSP and CBD are considered members of the class of neurodegenerative disorder referred to as ''tauopathies'' (Hardy and Gwinn-Hardy, 1998). Other disorders in this class include Pick's disease and frontotemporal dementia with parkinsonism linked to mutations on chromosome 17 (FTDP-17) (Foster *et al*., 1997; Poorkaj *et al*., 1998; Spillantini *et al*., 1998a). All tauopathies have selective neurodegeneration with filamentous inclusions containing tau protein. Some are sporadic (Pick's disease, PSP, and CBD), whereas others are hereditary (FTDP-17). Given the relative rarity of these conditions, it is not surprising that the range of clinical and pathologic phenotypes of these disorders is in a state of flux. Of particular note are transitional cases with overlapping clinical and pathologic features, even among those tauopathies with a defined genetic basis. Further studies will shed light on the relationship of genotype to phenotype.

II. Clinical Features

A. Progressive Supranuclear Palsy

PSP is one of the major causes of levodopa-nonresponsive parkinsonism (Rajput *et al*., 1984). Given the fact that it is associated with additional clinical features not typical of Parkinson's disease, it is considered one of the ''parkinsonism-plus'' syndromes. One of the earliest clinical features of PSP is unexplained falls. Later in the course the characteristic clinical picture emerges, which features postural instability, vertical gaze paresis, nuchal rigidity, and dysarthria (Rajput *et al*., 1991; Golbe, 1993). PSP is an uncommon disorder, with prevalence rate estimates of about 1.5 per 100,000 (Golbe *et al*., 1988; Bower *et al*., 1999a), compared to 100 to 150 per 100,000 for Parkinson's disease. New cases occur at a rate of about 3–4 per million population per year (Rajput *et al*., 1984). Along with falls, gait disturbance is common in early stages of PSP (Golbe, 1993). Gait problems are progressive and disabling, leading eventually to confinement to chair or bed within about 5 years.

Eye movement abnormalities are the hallmark of the clinical presentation of PSP (Steele *et al*., 1964) and are characterized initially by impairment of downward gaze, followed later by difficulties with upward gaze and even horizontal gaze. There is usually preservation of the oculocephalic reflexes (''dolls eye'' test). Blepharospasm and low blink rate are also common (Golbe, 1993). A supranuclear downward gaze palsy may develop in the course of CBD, but it is not usually as prominent as in PSP.

Other clinical features seen to varying degrees in PSP include dysarthria and dysphagia. As noted previously, focal cortical signs, such as aphasia or apraxia, are absent in PSP. Some degree of mental dysfunction, but not severe dementia, is common in PSP (Maher *et al*., 1985). Cognitive dysfunction in PSP is consistent with a subcortical and frontal lobe disorder. Attention is impaired and cognitive processing is slowed (Dubois *et al*., 1988). Frontal lobe signs may be prominent (Agid *et al*., 1987; Litvan *et al*., 1989; Grafman *et al*., 1990).

Structural imaging is of limited value in differentiating PSP from other parkinsonism-plus disorders. Narrowing of the anteroposterior midbrain diameter (usually < 15 mm, normal being > 18 mm) and dilation of the third ventricle are characteristic, but not completely diagnostic (Golbe, 1993; Gimenez-Roldan *et al*., 1994). SPECT and PET scanning show bilateral frontal hypoactivity in PSP (D'Antona *et al*., 1985; Foster *et al*., 1988; Leenders *et al*., 1988). Striatal dopaminergic deficits are also common in PSP (Baron *et al*., 1986; Brooks *et al*., 1990). Studies show loss of both dopamine and dopamine receptors. In contrast, Parkinson's disease is associated with decreases in striatal dopamine with preservation of dopamine receptors (Brooks *et al*., 1992). This reflects the fact that in PSP there is not only damage to dopaminergic neurons projecting from the substantia nigra to the striatum, but also to intrinsic neurons of the striatum.

There are no specific diagnostic tests for PSP and it is not uncommon for an individual to carry a diagnosis of Parkinson's disease for years before a correct diagnosis is made (Rajput *et al*., 1991). Indeed, in retrospective autopsy series, cases with pathologically confirmed PSP have been found to carry a clinical diagnosis of Parkinson's disease (Bower *et al*., 1999b). It has been suggested that only with longitudinal evaluation is it possible to accurately diagnose parkinsonian disorders (Rajput *et al*., 1991).

The disorders most often mistaken for PSP are multiple system atrophy (MSA), CBD, and diffuse Lewy body disease (DLBD) based on evaluation of brains submitted to the Society for Progressive Supranuclear Palsy brain bank (unpublished data). Cases submitted to the brain bank with a diagnosis of PSP were found to have PSP 75% of the time with MSA, CBD, and DLBD accounting for most of the misdiagnoses. Individual cases with basal ganglia infarcts or Alzheimer's disease (AD) were also misdiagnosed as PSP.

Of the disorders that can be mistaken for PSP, two of them are not associated with tau pathology, but rather by inclusion bodies composed of synuclein (Dickson, 1999a). These are MSA, with its synuclein-positive, glial cytoplasmic inclusions (Lantos, 1998), and DLBD, which is characterized by Lewy bodies composed of synuclein (Dickson, 1999a).

B. Corticobasal Degeneration

CBD was first described in 1967 as ''corticodentatonigral degeneration with neuronal achromasia'' in a patient with an asymmetrical cortical syndrome (Rebeiz *et al*., 1967, 1968).

While prevalence rates have not been estimated, it is generally accepted that CBD is less common that PSP. True prevalence rates of CBD are difficult to estimate as clinical and pathologic criteria for diagnosis of CBD are undergoing reappraisal. The range of clinical presentations for CBD is expanding based on recent clinicopathologic studies (Lang *et al*., 1994). Original descriptions of CBD emphasized a progressive asymmetrical apraxia and rigidity syndrome (Gibb *et al*., 1989; Riley *et al*., 1990), but more recent reports have indicated that individuals with postmortem findings of CBD may also present with focal cortical syndromes, such as frontal dementia and aphasia (Gibb *et al*., 1989; Paulus and Selim, 1990; Arima *et al*., 1994; Lang *et al*., 1994; Bergeron *et al*., 1996, 1998; Ikeda *et al*., 1996). Furthermore, the clinical syndrome of progressive asymmetrical apraxia and rigidity can be due to a variety of pathologic disorders (Boeve *et al*., 1999), suggesting that CBD is a focal cortical degenerative disorder and that the clinical phenotype is a reflection of the location of the dominant cortical pathology. The typical clinical phenotype corresponds to damage to the dorsal perirolandic, superior frontal, and superior parietal cortices, whereas cases with aphasia show pathology in the perisylvian region.

The initial signs of typical cases of CBD are unilateral or asymmetrical apraxia, rigidity, and dystonia. This may be associated with myoclonic jerks, grasp reflex, cortical sensory impairment, and alien limb sign. The affected hand may develop dystonic flexion contractures. Cognitive impairment is not universal in CBD, but is seemingly more frequent than in PSP. As mentioned previously, some cases come to autopsy with a primary diagnosis of degenerative dementia, without asymmetrical cortical signs ever noted in clinical records. Dementia in CBD most often has features of a frontal lobe dementia marked by personality change, disorder of conduct, impaired attention, and distractibility. Frontal lobe signs, including grasp reflex, forced groping, utilization behavior, and intermanual conflict, characteristically are unilateral at onset and markedly asymmetric in CBD.

The alien limb phenomenon, which describes involuntary movement, such as elevation of the arm or leg into the air (Doody and Jankovic, 1992), is often emphasized in CBD, but it is neither specific to CBD nor found in many cases. Cortical sensory deficits due to parietal lobe involvement and characterized by graphesthesia and astereognosis are frequent in CBD.

Structural imaging may be helpful in CBD, where magnetic resonance imaging may show asymmetrical atrophy of the superior parietal lobule variably extending into frontal regions, with less prominent atrophy elsewhere (Soliveri *et al*., 1999). Structural changes become more obvious as the disease progresses. Initial evaluations may show no asymmetrical cortical atrophy. These findings are not specific, as Pick's disease, nonspecific frontotemporal dementia, primary progressive aphasia, and some individuals with FTDP-17 may have asymmetrical cortical atrophy. Magnetic resonance imaging scans in CBD may show hyperintense signals in white matter in regions of brain atrophy and sometimes in the corpus callosum (Yamaguchi *et al*., 1998; Doi *et al*., 1999).

Functional imaging is often informative in CBD. The hallmark finding is asymmetrical hypometabolism in superior frontal and parietal lobes (Sawle *et al*., 1991; Blin *et al*., 1992). Hypometabolism is sometimes also detected in caudate, putamen, and thalamus. PET scans assessing dopamine metabolism [^{18}F]DOPA may show reduction of striatal and medial frontal uptake (Sawle *et al*., 1991). Striatal uptake is usually most severely impaired contralateral to the clinically most affected limbs.

III. Neuropathology

A. Progressive Supranuclear Palsy

Gross examination of the brain may be unrevealing in PSP, but the most common pathological findings are a mild degree of frontal and midbrain atrophy (Fig. 13.1). The third ventricle and aqueduct of Sylvius may be dilated (Fig. 13.1). The substantia nigra invariably shows some degree of depigmentation (Fig. 13.2). In most cases the substantia nigra shows marked pathology. In contrast, the locus ceruleus shows less pigment loss. The subthalamic nucleus may be noticeably smaller than expected (Fig. 13.3), and the superior cerebellar peduncle and the hilus of the cerebellar dentate nucleus may be attenuated and gray due to myelinated fiber loss (Fig. 13.2).

Microscopic findings include neuronal loss and fibrillary gliosis affecting multiple systems. Nuclei with the most marked and consistent pathology are the globus pallidus, subthalamic nucleus, and substantia nigra. Other parts of the basal ganglia, diencephalon, and brain stem are affected to a variable degree. PSP is a multisystem degeneration with involvement of corticopontine, olivopontocerebellar, dentatorubrothalamic, pallidoluysolnigral, and corticostriatal systems. The reticular activating system is also affected. The basis for selective vulnerability of these mostly extrapyramidal motor systems to degeneration is unknown.

In addition to the changes visible with routine histologic methods, silver stains or immunostaining for the tau protein reveal neurofibrillary tangles (NFT) as well as glial inclusions (Fig. 13.4). The distribution of pathology is highly characteristic of PSP. In fact, pathologic diagnosis (Hauw *et al*., 1994) is contingent on pathology in specific nuclei and tracts as there is no single pathognomonic lesion (Jellinger and Bancher, 1992; Lantos, 1994; Feany *et al*., 1996). The globus pallidus and pars reticularis of the substantia nigra may show, in addition to neuronal loss, gliosis, and NFT, extensive iron pigment deposition and granular neuroaxonal spheroids. The striatum and thalamus, especially ventral anterior and lateral nuclei, may have gliosis, but neuronal loss is usually too subtle to detect with routine methods. The basal nucleus of Meynert usually has mild cell loss, but more noticeable neurofibrillary pathology. The brain stem regions that are affected include the superior colliculus, periaqueductal gray matter, oculomotor nuclei, locus ceruleus, pontine nuclei, pontine tegmentum, vestibular nuclei, medullary tegmentum, and inferior olives. The cerebellar dentate nucleus is frequently affected and may show grumose degeneration (Arai, 1987; Mizusawa *et al*., 1989; Cruz-Sanchez *et al*., 1992b). The latter is a type of degeneration associated with clusters of degenerating presynaptic terminals around dentate neurons (Fig. 13.5). Grumose degeneration is not specific for PSP, but PSP may be the most common condition in which it is routinely detected. The

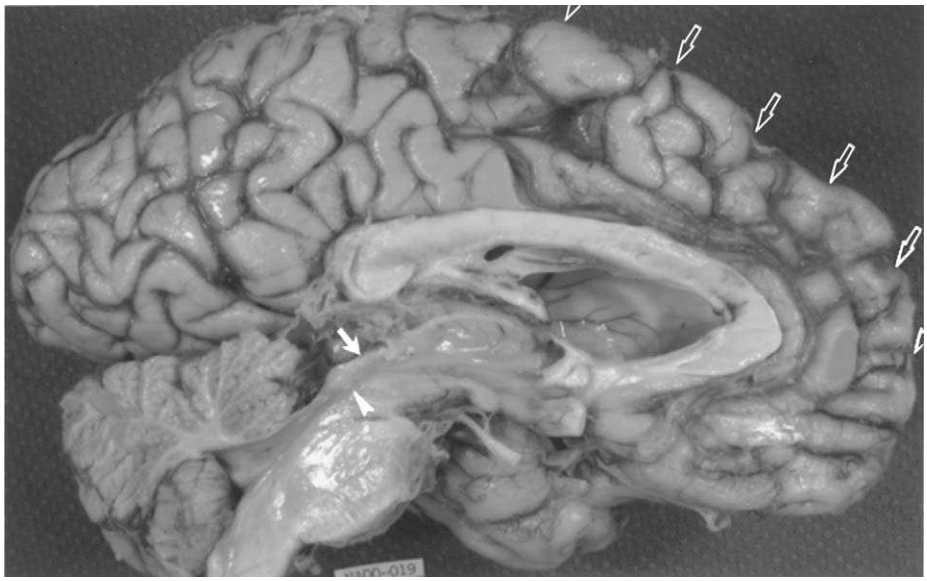

FIG. 13.1. The medial surface of the brain in PSP often shows mild frontal atrophy (open arrows), whereas midbrain atrophy is more consistent and often marked. The midbrain tectal plate (closed arrow) is small and the aqueduct of Sylvius (arrowhead) is dilated.

dentatorubrothalamic pathway consistently shows fiber loss (Fig. 13.5). The cerebellar cortex is generally preserved, but there may be mild Purkinje and granular neuronal loss with scattered Purkinje cell dystrophic axons (''torpedoes''). A more consistent finding in the cerebellum is the presence of glial cells with fibrillary inclusions in the cerebellar white matter. Spinal cord involvement is common, where neuronal inclusions can be found in anterior horn and intermediolateral cells (Jellinger and Bancher, 1992).

Neuronal loss is usually greatest in the ventrolateral tier of the substantia nigra, as in Parkinson's disease, but there is often more extensive neuronal loss throughout all regions of the substantia nigra (Jellinger, 1971). Dopaminergic neurons of the ventrolateral tier of the pars compacta project to the striatum, and loss of this population of neurons presumably accounts for extrapyramidal symptoms. Neuronal cell loss is accompanied by fibrillary gliosis and globose-shaped NFT (Fig. 13.6). Neuronal loss and NFT may be prominent in the globus pallidus. Large striatal neurons appear especially vulnerable, and loss of up to 30–40% of these cells has been reported (Oyanagi *et al*., 1988). Neuronal loss in the basal nucleus of Meynert ranges from 13 to 54% (Tagliavini *et al*., 1984), but neuronal lesions are common. The involvement of the basal nucleus accounts for cholinergic deficits that have

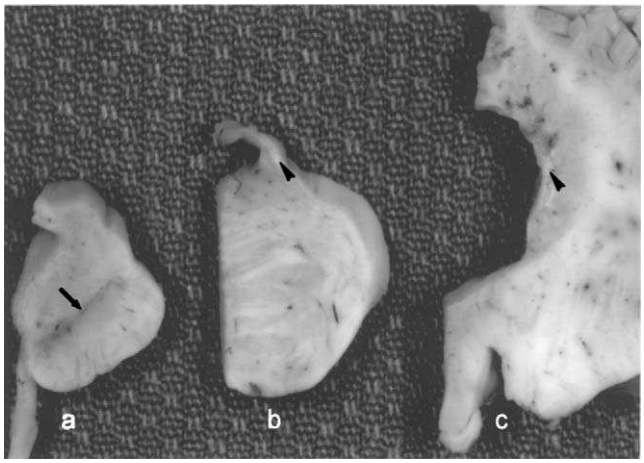

FIG. 13.2. Sections of brain stem and cerebellum in PSP show variable, often marked loss of pigment in the substantia nigra (a, arrow) and locus ceruleus. The superior cerebellar peduncle in the pons (b, arrow) is often attenuated and gray colored due to loss of myelinated fibers. The cerebellar dentate nucleus is typically atrophic and the hilus is soft and gray (c, arrow) due to myelinated fiber loss.

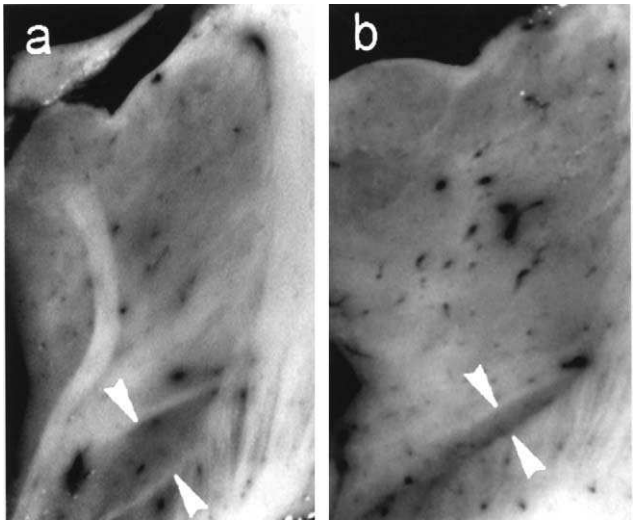

FIG. 13.3. The subthalamic nucleus in PSP is typically small (b, arrowheads). In contrast, the subthalamic nucleus is normal in most other neurodegenerative disorders (a, arrowheads), including Alzheimer's disease, Lewy body disease, and CBD.

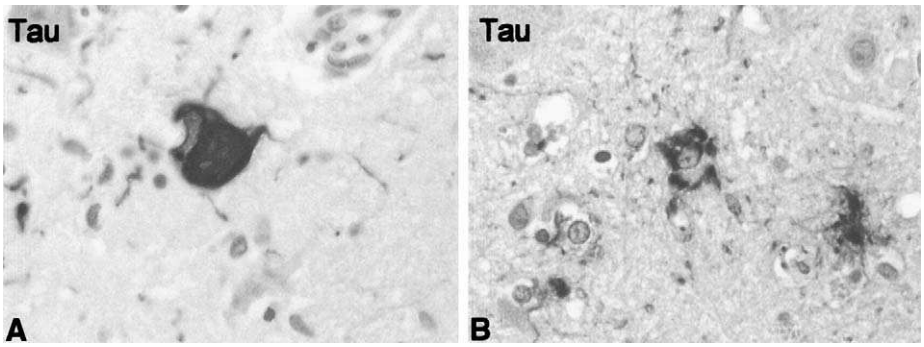

FIG. 13.4. Tau immunostaining reveals the two cardinal lesions in PSP: neurofibrillary tangles (A) and tufted astrocytes (B). The tufted astrocytes are most abundant in motor cortex and the corpus striatum, whereas NFT are prevalent in a number of basal ganglia and brain stem nuclei. Tau-immunoreactive inclusions in oligodendrocytes (''coiled bodies''; see Fig. 13.10) are found to a variable degree in white matter tracts, especially in the thalamic fasciculus.

been reported in PSP (Agid *et al*., 1987). Nuclei in the pontine base have NFT, whereas glial lesions are less abundant than in the basal ganglia (Fig. 13.6).

Cortical gray matter pathology is less pronounced than deep gray matter pathology, but lesions are common in motor and premotor cortices (Hauw *et al*., 1990; Hof *et al*. 1992; Vermersch *et al*., 1994) (Fig. 13.6). Early studies emphasized the lack of neocortical pathology in PSP (Steele *et al*., 1964; Ishino and Otsuki, 1976), but more recent studies using immunocytochemical and special silver impregnation methods

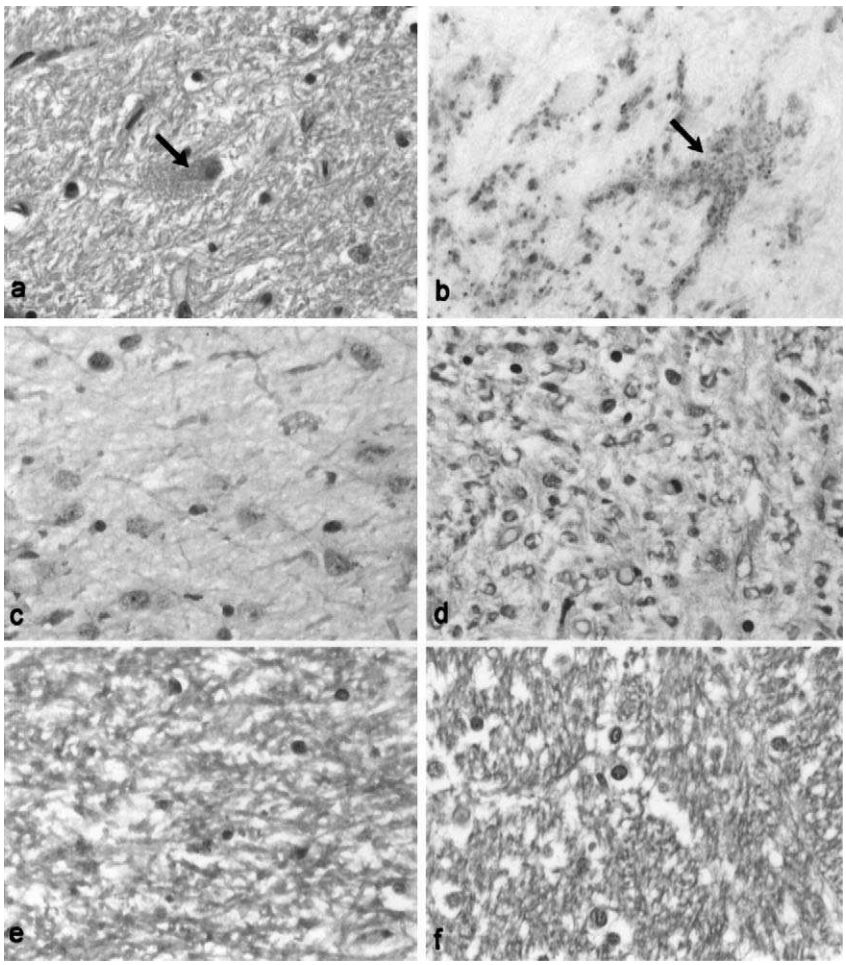

FIG. 13.5. The cerebellar dentate nucleus and its outflow pathway show pathology in typical cases of PSP. On hematoxylin–eosin stained materials the number of neurons is decreased and many of them have ill-defined indistinct borders (a) due to increased dystrophic synaptic terminals, which can be best illustrated with synaptophysin immunostaining (b). The dentate hilus (c) and the superior cerebellar peduncle (d) are depleted of myelinated fibers (Luxol fast blue stain for myelin), whereas nearby myelinated fibers are preserved (e, amiculum of dentate nucleus; f, middle cerebellar peduncle).

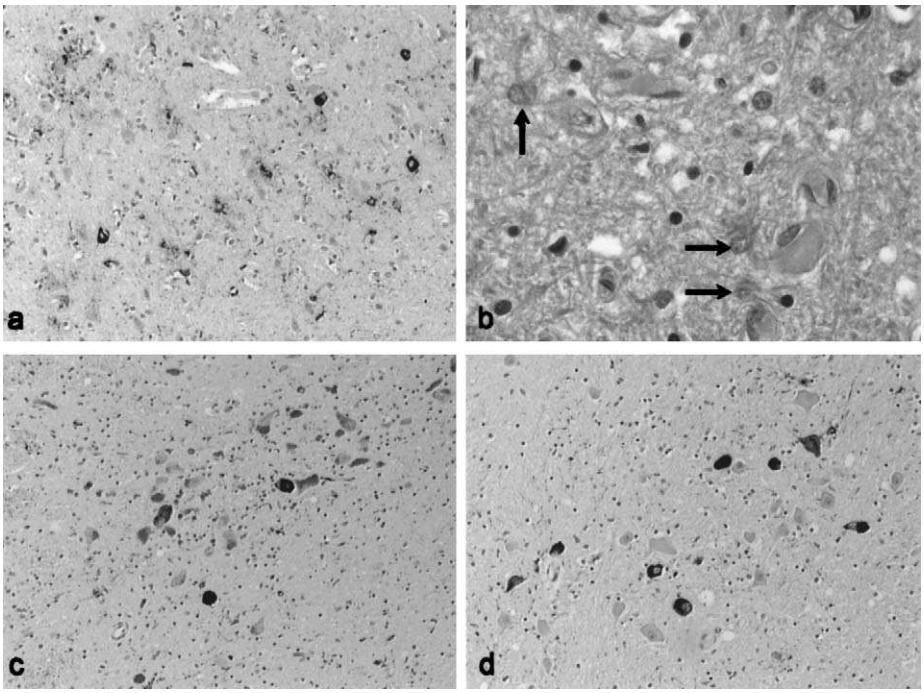

FIG. 13.6. The motor cortex has tau-immunoreactive lesions in the form of tufted astrocytes and scattered NFT (a). The subthalamic nucleus (b) and substantia nigra have marked neuronal loss accompanied by reactive fibrillary astrocytes (arrows) that can be detected readily with hematoxylin–eosin stains. The substantia nigra (c) and pontine nuclei (d) have neurons with NFT. When the neuronal loss is extensive, there may be only a small number of NFT in the substantia nigra (c).

indicate consistent involvement of the frontal cortex in PSP (Hauw *et al*., 1990; Hof *et al*., 1992; Braak *et al*., 1992; Vermersch *et al*., 1994; Bergeron *et al*., 1997; Bigio *et al*., 1999). Neocortical NFT and glial tangles are concentrated in the precentral gyrus (Hauw *et al*., 1990; Hof *et al*., 1992). Studies suggest that cortical neurofibrillary pathology may be greater in cases of PSP with dementia (Bigio, *et al*., 1999). The white matter beneath the motor cortex is also the site of glial pathology. More widespread cerebral white matter pathology is uncommon in PSP, although scattered glia may be encountered in cerebral white matter throughout the cerebrum.

The limbic lobe is relatively preserved in PSP. Neurofibrillary pathology in the hippocampus is variable and not intrinsic to PSP, but is rather more consistent with concurrent age-related pathology (Braak *et al*., 1992). When present, the distribution of NFT in the hippocampal formation is qualitatively similar to that seen in aging and AD. The exception to this rule is the frequent involvement of the dentate granule cells in PSP (Hof *et al*., 1992). The degree of neurofibrillary degeneration may correlate with the degree of cognitive impairment in PSP as in aging and AD (Braak and Braak, 1991).

While NFT in PSP often have a rounded or globose appearance, flame-shaped NFT are also detected. The Gallyas silver iodine method is sensitive to pathological structures in PSP and demonstrates, in addition to NFT, fibrillary inclusions in glial cells and cell processes. As in AD, NFT in PSP contain abnormally phosphorylated tau protein (Iqbal *et al*., 1989; Greenberg and Davies, 1990). Immunocytochemistry for tau protein is a sensitive method for detecting NFT in PSP, but it also reveals a wide variety of inclusions in both neurons and glia, including pretangles, neuropil threads, and tufts of abnormal fibers. Pretangles are neurons with nonfilamentous granular cytoplasmic tau immunoreactivity. The neurons that are most vulnerable to degeneration display this change, which is felt to be a precursor to the filamentous lesion. Antibodies that are most sensitive for detecting pretangles are those that recognize phosphorylated epitopes or conformational changes in tau proteins (Jicha *et al*., 1999).

The tufts of abnormal fibers are most common in motor cortex and striatum (Fig. 13.6). They have been shown to be fibrillary tau inclusions in astrocytes (Nishimura *et al*., 1992; Yamada *et al*., 1993; Iwatsubo *et al*., 1994). Tufted astrocytes account for much of the cortical pathology observed in PSP. Tau immunohistochemistry also reveals tau-positive fibers, so-called ''neuropil threads'' (Braak *et al*., 1986; Probst *et al*., 1988; Ikeda *et al*., 1994), and small round glial cells in the white matter of areas affected by PSP. The tau-positive glial cells in white matter, also referred to as ''coiled bodies,'' have been shown to be oligodendroglial inclusions (Yamada *et al*., 1992; Iwatsubo *et al*., 1994; Nishimura *et al*., 1995; Yamada and McGeer, 1995). The thread-like processes in white matter are not as numerous as in CBD, but in both disorders have been shown to be within both axons and the outer mesaxon of myelinated fibers (Arima *et al*., 1997). In gray matter, tau-positive threads are much less common in PSP than in AD (Davis *et al*., 1992) and CBD.

The NFT in PSP may be distinguished from NFT in AD by the paucity of ubiquitin immunoreactivity (Bancher *et al*., 1987; Cruz-Sanchez *et al*., 1992a). They are also far less fluorescent with thioflavin S stains. In fact, NFT may be completely missed if thioflavin S is the only method used to evaluate neuropathology in PSP. Certain neurofilament

epitopes may also distinguish NFT in PSP from those in AD (Schmidt *et al*., 1988). A more recent study with a panel of anti-tau antibodies recognizing epitopes along the length of the tau molecule suggested that full-length tau proteins are incorporated into the lesions in both AD and PSP (Schmidt *et al*., 1996). The observed differences must therefore reflect differences in packing, conformation, or posttranslational modification. While NFT in AD are composed mostly of 22 nm-diameter paired helical filaments (PHF) and a minor component of 15 to 18 nm diameter straight filaments (Terry, 1963), NFT in PSP are composed of straight 15 to 18 nm filaments (Tellez-Nagel and Wisniewski 1973; Powell *et al*., 1974; Roy *et al*., 1974; Bugiani *et al*., 1979; Yagashita *et al*., 1979). The abnormal filaments in glial cells in PSP also contain straight filaments (Nishimura *et al*., 1992).

B. Corticobasal Degeneration

The gross examination of the brain characteristically reveals asymmetrical narrowing of cortical gyri, most marked in pre- and postcentral regions. The atrophy is often best appreciated from a dorsal view rather than from a lateral or medial view (Figs. 13.7 and 13.8). This dorsal frontoparietal atrophy merges with less severe atrophy in ventral frontal and posterior parietal regions, whereas the temporal and occipital cortical regions are relatively preserved. The brain stem and cerebellum are not consistently reduced in size, but pigment loss is common in the substantia nigra (Fig. 13.8 and 13.9). There may also be mild atrophy of the midbrain tegmentum and enlargement of the aqueduct of Sylvius. In contrast to PSP, the superior cerebellar peduncle and the subthalamic nucleus are grossly normal.

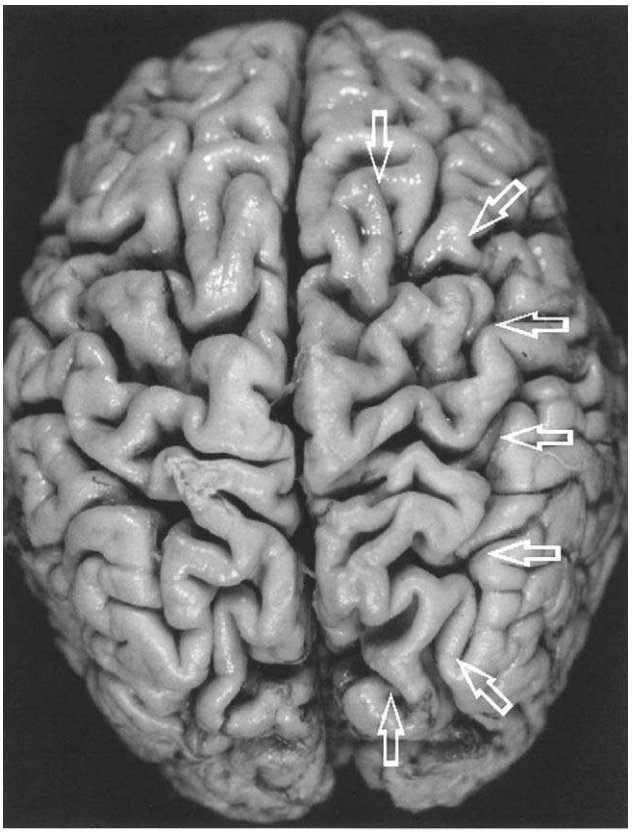

FIG. 13.7. The cortical atrophy in CBD is often best appreciated from a dorsal perspective. The superior frontal gyrus and superior parietal lobule are affected preferentially (arrows) in typical cases of PSP.

The cerebral white matter in affected areas is often attenuated and may have a gray discoloration or a gelatinous consistency in severe cases. The anterior corpus callosum is sometimes thinned and the frontal horn of the lateral ventricle is frequently dilated. Thinning of the corpus callosum has been used as a diagnostic feature of CBD in clinical imaging studies (Yamaguchi *et al*., 1998). The anterior limb of the internal capsule may show attenuation as well, but other white matter tracts, such as the optic tract, anterior commissure, and fornix, are preserved.

On microscopic examination, sections of atrophic frontoparietal cortex show moderately severe nerve cell loss and subcortical myelin pallor with gliosis. There is disruption of the normal pattern of cortical lamination, superficial spongiosis, and diffuse astrocytic and microglial proliferation. These findings are not dissimilar to those of nonspecific focal cortical degenerations, but several histologic features readily distinguish CBD from dementia lacking distinctive histopathology (Knopman *et al*., 1990).

In affected areas, especially the superior frontal gyrus, swollen and vacuolated cortical neurons, referred to as ballooned neurons (Fig. 13.10), are scattered in middle and lower cortical layers (Figs. 13.10 and 13.11) Ballooned neurons may be found in anterior cingulate, amygdala, and claustrum, where they are of less diagnostic significance, as they can be found in the limbic lobe in several different disorders. In contrast, ballooned neurons in the superior frontal and parietal lobes are decidedly uncommon in other disorders and nearly specific for CBD. The only exception is Pick's disease. In Pick's disease, ballooned neurons are most numerous in frontotemporal distribution, but a few may occasionally be detected in the parietal lobes (Constandinidis *et al*., 1974; Dickson, 1998). Ballooned neurons are eosinophilic and weakly argyrophilic. They may show irregular or tortuous swelling of proximal dendrites. Some ballooned neurons contain granulovacuolar bodies. They lack apparent Nissl substance, which was the basis for the term ''achromasia.'' Ballooned neurons are also referred to as ''Pick cells'' in Pick's disease (Dickson, 1998).

Ballooned neurons are strongly immunoreactive for phosphorylated neurofilaments (Dickson *et al*., 1986; Smith *et al*., 1992) and αB-crystallin (Lowe *et al*., 1992). They show variable immunoreactivity for tau and ubiquitin (Smith *et al*., 1992; Feany and Dickson, 1995; Halliday *et al*., 1995). They are negative for epitopes specific to neurofibrillary tangles (Dickson *et al*., 1986). Ultrastructurally, the cytoplasm of the ballooned neurons contains accumulations of intermediate-sized filaments 9–16 nm in diameter, interspersed with other cytoplasmic elements (Clark *et al*., 1986).

In addition to ballooned neurons scattered neurons in atrophic cortical areas have tau immunoreactivity. Tau-immunoreactive neuronal lesions are structurally pleomorphic. In some neurons the immunoreactivity is densely packed into a small inclusion body somewhat reminiscent of a Pick body or a small NFT. In other neurons the filamentous inclusions are

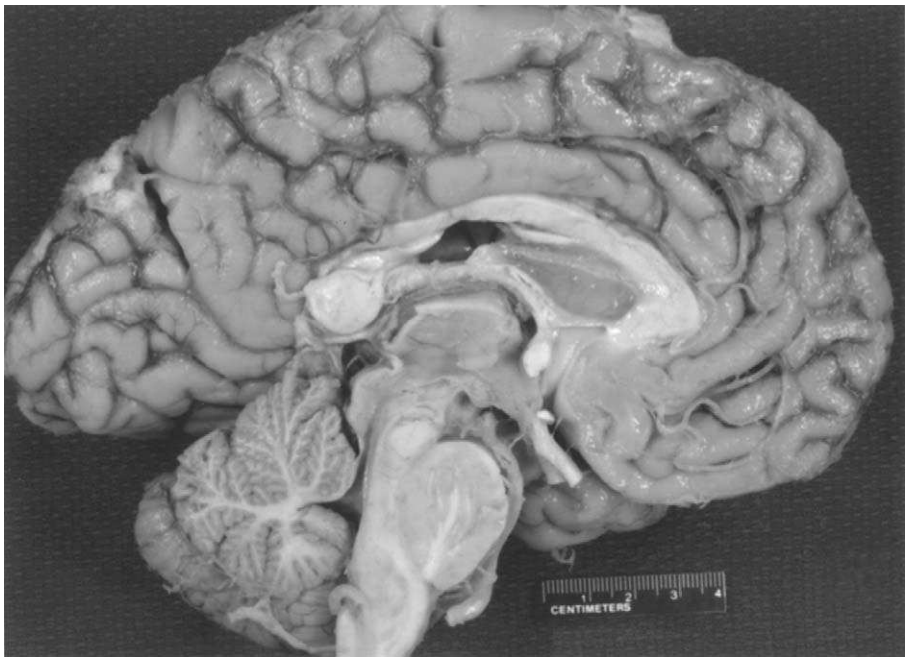

FIG. 13.8. The medial view of the brain in CBD may be unrevealing. Specifically absent is noticeable brain stem atrophy. The midbrain tectum is preserved. The aqueduct of Sylvius is not dilated.

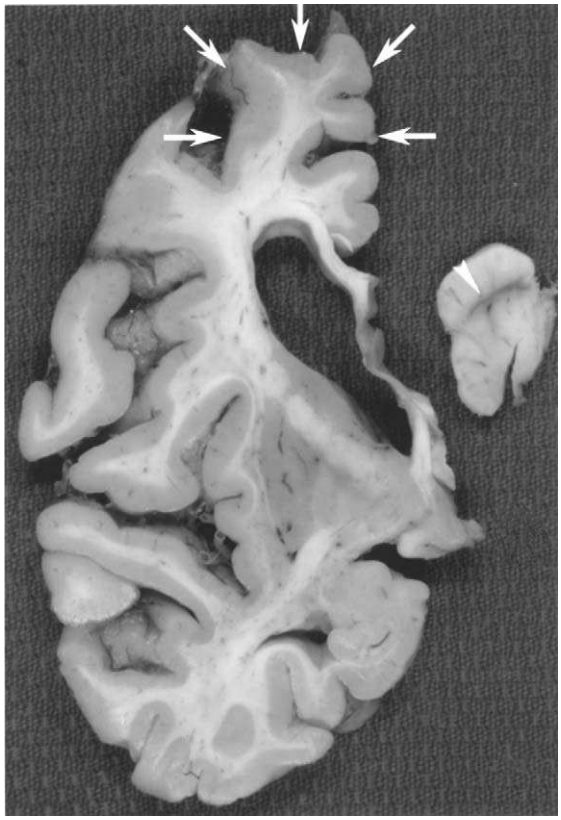

FIG. 13.9. On coronal sections of the brain, atrophy of the superior frontal gyrus (arrows) is disproportionate to that seen in any of the other gyri. Even the adjacent cingulate gyrus may be normal. The frontal horn of the lateral ventricle is typically enlarged. Midbrain sections show loss of black neuromelanin pigment in the substantia nigra (arrowhead), but there may also be an increase in rust-colored pigment.

more dispersed and disorderly. In contrast to NFT of AD, where lesions are readily detected with a host of diagnostic silver stains and even with thioflavin fluorescence microscopy, neuronal lesions in CBD are not easily seen and are often completely negative, especially with thioflavin S. This points to the fact that tau pathology in CBD is different from that in aging and AD. Other differences in neurofibrillary pathology in CBD compared to AD include less ubiquitination and a restricted tau isoform composition. These features are shared with the neurofibrillary pathology of PSP. Neurofibrillary lesions in brain stem monoaminergic nuclei, such as the locus coeruleus and substantia nigra, sometimes resemble the globose NFT of PSP, but more often are ill-defined amorphous inclusions (Fig. 13.12).

In addition to fibrillary lesions in perikarya of neurons, the neuropil of CBD invariably contains an assortment of tau-immunoreactive cell processes (Wakabayashi *et al*., 1994; Mori *et al*., 1994; Feany and Dickson, 1995; Takahashi *et al*., 1996) (Fig. 13.10). While these lesions are sometimes referred to as ''neuropil threads'' (Komori *et al*., 1997) after the lesions described in AD (Braak *et al*., 1986), it may be incorrect to use this term in CBD. In AD, virtually all neuropil threads are neuronal in origin as demonstrated by immunoelectron microscopy (Yamaguchi *et al*., 1990). In contrast, in CBD only a small fraction of thread-like structures are double labeled with neurofilament antibodies (Feany and Dickson, 1995), which indicates that many thread-like processes in CBD are probably glial rather than neuronal. In CBD, thread-like processes and shorter, stubbier tau-immunoreactive lesions with fuzzy rather than smooth profiles. They are usually profuse in affected areas of gray and white matter. The predominance of tau immunoreactivity in cell processes is an important attribute of CBD and a useful feature in differentiating it from other disorders. In other disorders with which CBD

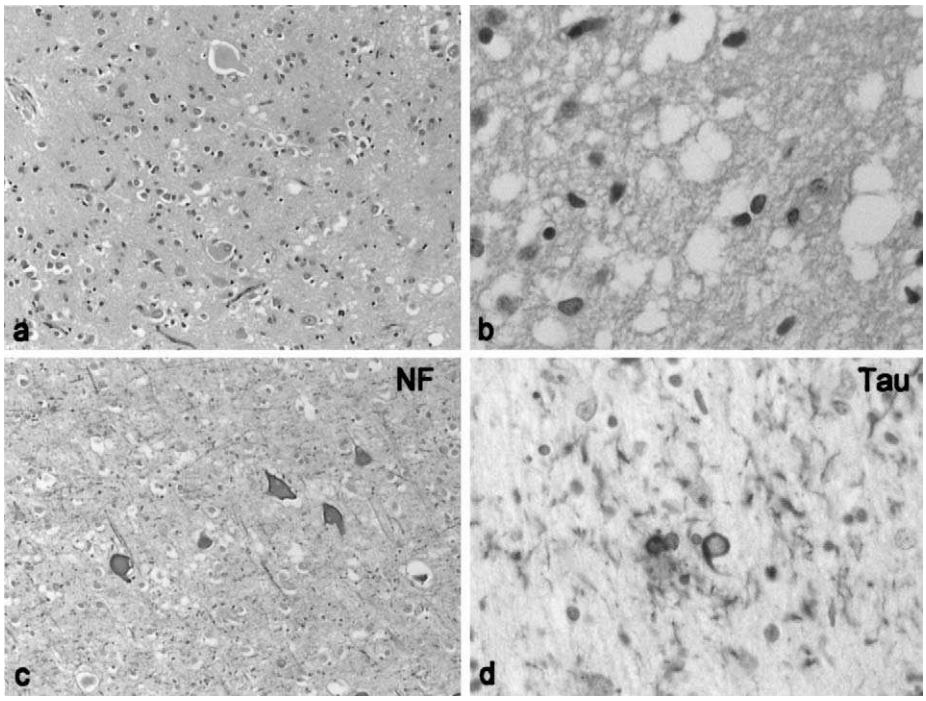

FIG. 13.10. The superior frontal and parietal cortices typically have microvacuolation and scattered swollen neurons (a). Microvacuolation often produces a spongiform appearance in the superficial cortical layers (b). The swollen or ballooned neurons are detected easily with neurofilament immunostaining (c). Tau immunostaining reveals many cell processes in both gray and white matter, as well as numerous coiled bodies that have been shown to be inclusions in oligodendrocytes (d).

can be confused, tau-related pathology is more often located in cell bodies (e.g., NFT and Pick bodies) and the proximal cell processes of neurons and glia.

A host of tau-immunoreactive astrocytic lesions have been described in various neurodegenerative diseases, including CBD. Astrocytic tau-immunoreactive lesions have been referred to as ''tufted astrocytes,'' ''star-like tufts,'' ''spiderlike radiating fibers,'' ''thorn-shaped astrocytes,'' and ''gliofibrillary tangles'' (reviewed in Chin and Goldman, 1996; Komori, 1999). The terminology is not standardized, and it is likely that the different morphologies and terms for the lesions reflect methodological as much as biologic differences. In particular, the morphology of the lesions varies dramatically, depending on the thickness of the tissue section. In routine 5- to 7-μm-thick sections, only a small cross-sectional sample of the lesion is included, whereas in thicker (40–100 μm) sections the lesions are visible in their entirety. The different morphologies of tau-immunoreactive astrocytic lesions may also be a function of which type of astrocytes (protoplasmic vs fibrous, subpial vs parenchymal) is affected.

The most characteristic tau-immunoreactive astrocytic lesion in CBD, particularly in the neocortex, is an annular cluster of short stubby processes that may be highly suggestive of an Alzheimer-type neuritic plaque (Uchihara *et al*., 1994;

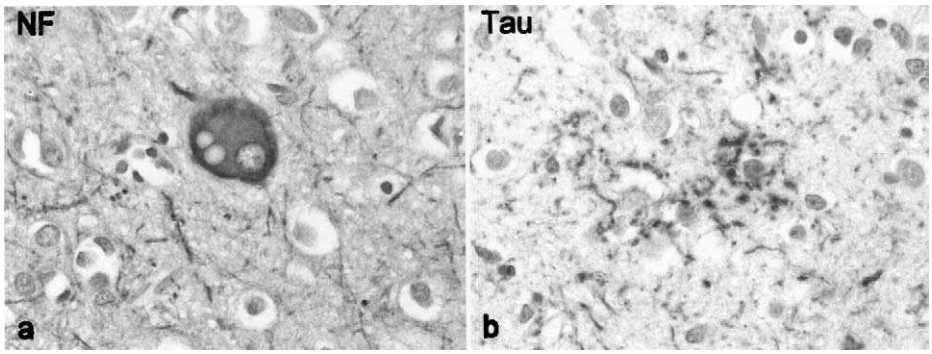

FIG. 13.11. Cardinal lesions in CBD—ballooned neurons (a) and astrocytic plaques (b)—are best demonstrated with immunostaining for neurofilament (or αB-crystallin) (a) and for tau (b). In the cortex, astrocytic plaques are characterized by radial arrays of short stubby and irregular cell processes around a central nucleus that can be shown to be an astrocyte with double immunostaining with astrocyte markers such as GFAP.

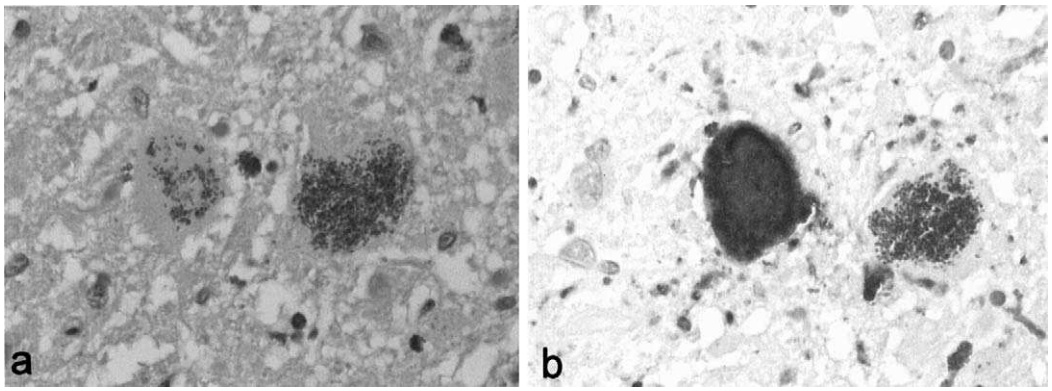

FIG. 13.12. In brain stem monoaminergic nuclei, neurons have amorphous ill-defined slightly basophilic inclusions (''corticobasal bodies'') with hematoxylin–eosin (a) that can be shown to be intensely positive for tau with immunostaining (b). These neuronal lesions are most common in neurons that also contain neuromelanin [small dark granules in neurons at the right of each corticobasal body in (a) and (b)].

Feany and Dickson, 1995). These lesions, in contrast to Alzheimer plaques, do not contain amyloid based on histochemical, fluorescent, and immunocytochemical methods for detecting amyloid. The only exception is in rare cases of coexistent CBD and AD. In further contradistinction with neuritic plaques in AD, most of the tau immunoreactivity is not within dystrophic neuronal processes, but rather processes of glial cells. Double immunostaining for tau and glial fibrillary acid protein, vimentin, or CD44, which are all markers with varying degrees of specificity for astrocytes, demonstrates that the tau-positive cell processes in these lesions are derived from astrocytes (Feany and Dickson, 1995). These lesions are called ''astrocytic plaques'' (Feany and Dickson, 1995) (Fig 13.11). Astrocytic plaques differ from the tufted astrocytes seen in PSP, and the two lesions do not appear to coexist in the same brain (Komori *et al*., 1998). When the astrocytic plaque, with its distinct annular array of tau-immunoreactive processes, is detected with Gallyas silver stains or immunocytochemistry in the neocortex or neostriatum, it should suggest a diagnosis of CBD until proven otherwise. The astrocytic plaque may be the most specific histopathologic lesion of CBD. Other less distinctive tau-immunoreactive astrocytic lesions are also seen in CBD, and the latter, in particular, may have overlapping morphological features with tau-positive astrocytes of other tauopathies.

In addition to cortical pathology, deep gray matter is consistently affected in CBD. In the basal ganglia, thread-like processes are often extensive in the pencil fibers of the striatum. There may also be a few astrocytic plaques in the striatum. Neuronal inclusions are also common in the striatum and globus pallidus. The internal capsule often has many thread-like processes, especially in the vicinity of the thalamic fasciculus. The subthalamic nucleus usually has a normal neuronal population, but a few neurons may have tau inclusions and there may be a number of thread-like lesions in the nucleus. Fibrillary gliosis typical of PSP is not found in the subthalamic nucleus in CBD, but it is not uncommon to find tau-positive processes, glial inclusions, and a few pretangles in the subthalamic nucleus.

The substantia nigra usually shows moderate to severe nerve cell loss with extraneuronal neuromelanin and gliosis. Many of the remaining neurons contain ill-defined neurofibrillary inclusions, so-called ''corticobasal bodies'' (Gibb *et al*., 1989) (Fig. 13.12). These inclusions have a homogeneous or faintly whorled or amorphous morphology with enmeshed granules of melanin pigment. Immunocytochemical studies have shown that corticobasal bodies are indistinguishable from globose NFT of PSP, but they are less fibrillar. The specificity of the corticobasal body remains to be seen. The locus coeruleus and raphe nuclei have similar inclusions. In contrast to PSP, where neurons in the pontine base almost always have at least a few NFT, the pontine base is largely free of NFT in CBD. However, tau inclusions in glia and in cell processes are frequent in the pontine base in CBD (Dickson and D'Aversa, 1997). NFT are also detected in the tegmental gray matter.

In other subcortical regions the globus pallidus and putamen show nerve cell depletion with gliosis and occasional NFT. The nucleus basalis of Meynert has a few NFT. The red nucleus and subthalamic nucleus also show mild neuronal depletion and astrocytic gliosis and may have NFT. Thalamic nuclei may also be affected, particularly the ventrolateral nucleus. Mild neuronal depletion of the dentate nucleus occurs, but grumose degeneration is much less common than in PSP.

The Gallyas silver stain is a sensitive way of demonstrating pathology in neurons and glia in CBD (Horoupian and Chu, 1994; Matsumoto *et al*., 1996). This is due to the fact that the Gallyas stain, for reasons that are not clearly known, detects abnormal filamentous tau protein (Iqbal *et al*., 1991). Immunocytochemistry with monoclonal antibodies to tau protein gives comparable results (Mori *et al*., 1994; Wakabayashi *et al*., 1994; Feany and Dickson, 1995) and have wider usage given the commercial availability of tau antibodies. Tau immunostaining also requires less technical expertise. It has been claimed that glial lesions in PSP and CBD are distinguished more clearly with the Gallyas method than immunostaining (Komori, 1999), but section thickness needs to be taken into account. Typical preparations for Gallyas stains employ sections that are 10 times thicker than conventional histology sections.

In CBD the filaments have a paired helical appearance at the electron microscopic level, but the diameter is wider and the periodicity is longer (Ksiezak-Reding *et al*., 1996; Tracz *et al*., 1997). These structures have been referred to as twisted

ribbons. Similar filaments are found in some cases of FTDP-17, particularly those associated with overexpression of specific isoforms of tau containing exon 10 (see later). There is no evidence to suggest that specific isoforms of tau are overexpressed in CBD, but studies addressing this question are needed given the similarity of the lesions in CBD to FTDP-17.

C. Mixed and Transitional Pathology

While the majority of clinically well-characterized patients with PSP have distinctive postmortem findings, several reports suggest that the match is not always perfect (Collins *et al*., 1995; Gearing *et al*., 1994; Davis *et al*., 1985). Cases of PSP may present with dementia or rarely focal cortical syndromes that resemble CBD clinically. The pathologic substrate of the asymmetrical rigidity and apraxia syndrome typical of CBD is diverse and includes AD, PSP, Pick's disease, nonspecific frontotemporal dementia, and Creutzfeldt–Jakob disease (Boeve *et al*., 1999). Whereas ballooned neurons are not common in PSP and a useful histopathologic feature for differentiating PSP from CBD, there are reports of some cases of PSP with ballooned neurons (Mackenzie and Hudson, 1995; Mori *et al*., 1996; Mori and Oda, 1997). There are also reports of CBD without ballooned neurons (Kawasaki *et al*., 1996). In most of these reports, ballooned neurons are limited to limbic and paralimbic cortices. As mentioned previously, this distribution of ballooned neurons does not carry the diagnostic specificity as does ballooned neurons in non-limbic neocortices.

Some cases of PSP have transitional pathology with more widespread cortical pathology than typical PSP, where neurofibrillary degeneration is limited to the motor cortex. These cases can be difficult to differentiate from CBD with sparse ballooned neurons (Schneider *et al*., 1997). It is important to note that pathology in CBD is bilateral, but sampling the side with less pathology may also produce confusion. In particular, ballooned neurons may have a relatively restricted distribution and not be detected in less affected cortical areas. In case of doubt, it is best to sample the cortical areas with most atrophy or areas known to be most vulnerable to cortical pathology, particularly the superior frontal cortex.

Some cases of PSP have a paucity of neurofibrillary lesions. It is unclear if these cases are merely early pathologic stages of the disorder. They must be differentiated from cases of postencephalitic parkinsonism, a diagnosis that depends on an appropriate clinical history (Geddes *et al*., 1993).

Finally, PSP and CBD can be mixed with other pathologies (Lantos, 1994). Most common are infarcts, Alzheimer-type plaques, and Lewy bodies. These cases are best considered to be combinations of two or more separate disorders, although one could also argue that cases with mixed pathology represent distinct pathologic entities. It is also challenging to diagnose CBD when there are age-related amyloid plaques in the cortex as well as astrocytic plaques. Double staining for tau and amyloid will usually allow identification of what appear to be ''neuritic'' plaques without any amyloid deposits. The latter are astrocytic plaques. In contrast, Alzheimer-type plaques will have amyloid within the center of the tau-positive cell processes. Significant neurofibrillary degeneration in the limbic lobe is not typical of either PSP or CBD. When this is encountered it is likely due to mixed AD.

Another pathology that is common to the limbic lobe and that is relatively common in PSP and CBD is argyrophilic grain disease (Braak and Braak, 1989; Jellinger, 1998). Grains are tau-positive neuronal inclusions that have been localized to dendritic segments (Ikeda *et al*., 1995; Tolnay *et al*., 1998). Some of the tau-positive lesions in PSP, particularly CBD, may resemble grains. Unlike argyrophilic grain disease, the short granular processes (''grain-like'' lesions) in PSP and CBD are not restricted to the limbic lobe and certain hypothalamic nuclei (Braak and Braak, 1989). Nevertheless, grains can be detected in PSP and CBD (Martinez-Lage and Munoz, 1997; Jellinger, 1998). Another particularly difficult situation is the fact that most cases of AGD have BN, but in argyrophilic grain disease, ballooned neurons are limited to the limbic lobe, especially the amygdala (Tolnay and Probst, 1998).

IV. Tau Biochemistry

Given the presence of tau-immunoreactive neuronal and glial lesions in PSP and CBD it is not surprising that most recent biochemical studies have focused on tau protein abnormalities in PSP and CBD compared to normal control brains and abnormal tau proteins in AD (Ksiezak-Reding *et al*., 1994; Delacourte and Buée, 1997; Mailliot *et al*., 1998; Buée and Delacourte, 1999). The tau protein is a microtubule-associated phosphoprotein that promotes tubulin polymerization and stabilization of microtubules. It is present in neurons, preferentially in axons, and until recently was felt to be specific to neurons (Binder *et al*., 1985). More recent immunochemical evidence suggests that the tau protein is also expressed in glial cells, especially in pathologic conditions. It undergoes posttranslational modification, such as phosphorylation, which controls its functional state (reviewed in Buée and Delacourte, 1999). Phosphorylated tau is less efficient in promoting tubulin polymerization. The tau gene is located on chromosome 17, and it has 16 exons, 3 of which are alternatively spliced (Andreadis *et al*., 1992). In the amino-terminal half of the molecule are conserved 30 amino acid tandem repeats that are essential for interaction of tau with microtubules. One of the repeat domains is the product of exon 10 and is alternatively spliced. The various splice combinations generate six tau isoforms (Buée and Delacourte, 1999). In PSP and CBD exon 10-containing isoforms predominate (Sergeant *et al*., 1999).

In normal brain, tau is a natively unfolded, soluble protein that is heat stable. The pathological tau protein has altered solubility properties, being soluble in detergents, and it forms abnormal filamentous structures. Western blots of normal brain tissue homogenates show six bands in a range of 50–62 kDa. Homogenates of detergent-soluble tau protein from PSP and CBD migrate at a higher molecular weight due to increased phosphorylation. In addition the immunoblotting pattern is reduced to two major bands at about 64 and 68 kDa (Flament *et al*., 1991; Ksiezak-Reding *et al*., 1994; Buée and Delacourte, 1999) (Fig. 13.13). There are conflicting reports about whether exon 10 is expressed in the pathological tau protein of CBD (Ksiezak-Reding *et al*., 1994; Delacourte and Buée, 1997; Mailliot *et al*., 1998). This is due to the fact that the amino acid sequences in the repeat regions are very similar. Antibodies raised to exon 10 often cross-react with sequences

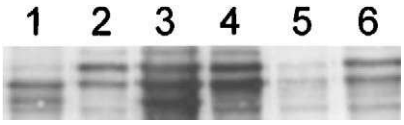

FIG. 13.13. Western blot of detergent-soluble fraction from several neurodegenerative disorders: Pick's disease (1), FTDP-17 (2), Alzheimer's disease (3), CBD (4), and PSP (5 and 6). Note that Pick's FTDP-17, CBD, and PSP have two prominent bands, whereas three are present in AD. Note also that the two bands in Pick's disease migrate at lower molecular weights than those in FTDP-17, CBD, and PSP. Western blots kindly provided by Drs. W.-K. Liu and S.-H. Yen.

in the other repeat regions, especially exons 9 and 11. The weight of current evidence suggests that the pathologic tau protein in CBD is generated preferentially from transcripts that contain exon 10. This is based on analysis not only with exon 10-specific antibodies, but also by immunoblotting tau preparations after extensive dephosphorylation. Analysis with antibodies specific to exon 3, another alternatively spliced exon, suggests that exon 3, in contrast to exon 10, is underrepresented in the pathological tau protein of CBD (Feany *et al*., 1995; Nishimura *et al*., 1997).

Given the abundance of tau pathology in glial cells in PSP and CBD, an unanswered question is how much the observed difference in tau isoform composition reflects tau derived from glial cells compared with tau from neurons. Interestingly, nonneuronal cells appear to express tau containing exon 10 (Vanier *et al*., 1998), and there is also exon 10 containing tau in white matter than gray matter (Janke *et al*., 1996). Another explanation for the selective involvement of specific splice forms of tau, namely tau containing four repeats, might be more abundant in the pathologic tau of PSP and CBD is that this form is overexpressed. Chambers *et al*., (1999) suggested that this may be the case, at least in some brain regions of PSP. This study needs to be confirmed in a larger series of cases and by sampling more areas that are vulnerable or relatively resistant to PSP and CBD.

Other disorders with neuronal and glial tau pathology share immunoblotting patterns with PSP and CBD. For example, Western blots of detergent-soluble tau protein from some cases of FTDP-17 have predominantly two bands (Ksiezak-Reding *et al*., 1994; Delacourte and Buée, 1997; Mailliot *et al*., 1998; Buée and Delacourte, 1999). Interestingly, abnormal tau in Pick's disease is also characterized by two major bands on Western blots, but they appear to be different from those in PSP and CBD (Buée and Delacourte, 1999). In Pick's disease the proteins migrate at estimated molecular weights of 55 and 64 kDa (Fig. 13.13). Evidence suggests that in Pick's disease pathological tau protein isoforms lack exon 10 (Delacourte *et al*., 1996; Sergeant *et al*., 1997), whereas those in PSP and CBD preferentially contain exon 10 (Spillantini and Goedert, 1998). This supports the concept that PSP and CBD may have common pathogenesis, despite differences in clinical and pathologic features.

Interestingly, tau protein isolated from the entorhinal cortex of PSP brains contained not the doublet characteristic of PSP, but the triplet found in AD material (Vermersch *et al*., 1994). These results support the suggestion that allocortical pathology in PSP is similar to that in AD.

V. Genetics

A. Clinical Studies

There are only a few reports of autopsy-proven familial PSP (Brown *et al*., 1993; Tetrud *et al*., 1996; de Yébenes *et al*., 1995; Gazeley and Maguire, 1996; Rojo *et al*., 1999). Nevertheless, it may be more common than previously thought given the heterogeneity in the clinical presentation of early-onset cases of PSP. Similarly, almost all reported cases of CBD have been sporadic, but there are rare familial reports of CBD (Brown *et al*., 1996). Whether these are actual cases of CBD or FTDP-17 remains to be determined by evaluation of these purported familial CBD cases for tau mutations. FTDP-17 has a number of clinical and pathologic features that are similar to CBD (Bugiani *et al*., 1999) and in some families to PSP (Reed *et al*., 1997). In particular, familial multisystem tauopathy (Spillantini *et al*., 1997, 1998b) and familial pallidopontonigral degeneration (Reed *et al*., 1998) have many histological, ultrastructural, and biochemical similarities. FTDP-17 has been shown to be caused by tau mutations in either coding or noncoding regions (Hutton *et al*., 1998). The location of the mutation, especially as it relates to exon 10 and the microtubule-binding region, contributes significantly to the clinical and pathologic phenotype and to the nature of the tau that accumulates in the fibrillary lesions (Hutton, *et al*., 1998). The mutations identified in tau directly affect its ability to interact with microtubules, suggesting a pathogenetic mechanism for neurodegeneration (Hong *et al*., 1998; Yen *et al*., 1999).

B. Tau Gene

A dinucleotide repeat polymorphism in the tau gene was reported to be associated with greater than chance frequency with PSP (Conrad *et al*., 1997). The number of dinucleotide repeats varied from 11 (a0) to 14 (a3). In PSP more than 95% of the cases had a0. The fact that a tau polymorphism was associated with PSP raised the possibility that specific forms of the tau gene might confer genetic risk for PSP, analogous to the apolipoprotein E genotype for AD (Mayeux *et al*., 1998). Given the fact that 75% of the normal population has the a0 polymorphism and yet PSP is such an uncommon disorder, it suggests that any risk conferred by the polymorphism must be minor. The increased frequency of this tau polymorphism in PSP has been confirmed in several studies among different ethnic groups (Oliva *et al*., 1998; Higgins *et al*., 1999; Hoenicka *et al*., 1999; Morris *et al*., 1999; Baker *et al*., 1999). Interestingly, a0 is more common in controls in Japan than in Western population and has been speculated to account for a possible increased frequency of PSP in Japanese patients (Conrad *et al*., 1998).

Additional studies of the genetic structure of the tau gene revealed a number of polymorphisms that were inherited in a nonrandom manner. Careful analysis suggested that the polymorphisms were inherited as extended haplotypes. Essentially, two ancestral forms of the tau gene have been identified: H1 and H2 (Baker *et al*., 1999). Most cases of typical PSP are H1 and a surprising large number of PSP patients are H1/H1 homozygous. There is some preliminary evidence to suggest greater variability in the disease phenotype in PSP cases that

are heterozygous (H1/H2), but this remains to be verified. Heterogeneity in phenotype can also be due to additional pathologies, most notably Alzheimer-type pathology. It is presently unclear whether CBD is also associated with an increased frequency of H1 haplotype. One report suggested that a0 polymorphism was not increased in CBD, but this study was based on a small sample size (Morris *et al*., 1999). Further limitations of studies of this type are the evolving clinical and pathologic criteria for CBD and the rarity of the disorder. Finding a genetic association will necessitate common diagnostic criteria, preferably autopsy confirmed, and a large sample size obtained from a number of cooperating centers. Such a multicenter study is currently in progress. If CBD should prove to have a similar genetic risk factor as PSP, it would add support to the relationships between PSP and CBD.

Neurobiology of Disorders with Lewy Bodies

Lewy body disease (LBD) and Alzheimer's disease (AD) continue to be the most common disorders causing dementia in the elderly population. Disorders with Lewy bodies comprise a diverse group of diseases. A consensus paper by McKeith and others has proposed comprehensive criteria in an attempt to reconcile the disagreements within the current terminology. Although the precise cause of these disorders is currently unknown, neuropathologically the common denominator is the degeneration of neuronal populations within the nigral dopaminergic system and mesial temporal regions, LB formation, extensive neuritic degeneration, and spongiform vacuolization. Previous studies have shown that cognitive alterations in these disorders are associated with synaptic damage. Injury to the synapse may be associated with an altered function of synaptic proteins. Among them, studies have shown that abnormal aggregation and accumulation of synaptic proteins such as α-synuclein (or the precursor of the non-Aβ component of AD amyloid, NACP) may be associated with plaque formation in AD and Lewy body formation in LBD. Further reinforcing the argument that α-synuclein plays a major role in the pathogenesis of these disorders, work has shown that mutations which alter the conformation of this molecule are associated with familial forms of LBD and that α-synuclein is a major component of Lewy bodies. The mechanisms by which altered function or aggregation of α-synuclein leads to neurodegeneration are not completely clear; however, new evidence points to a potential role for this molecule in synaptic damage and neurotoxicity via amyloid fibril formation and mitochondrial dysfunction. This chapter reviews data linking α-synuclein to the pathogenesis of LBD.

I. Introduction

Lewy body disease (LBD) is a leading cause of dementia, second only to Alzheimer's disease (AD) (Hansen and Crain, 1995), and it accounts for 15–25% of the cognitively impaired elderly, most of whom were diagnosed as AD during life. Previous studies have shown that cognitive alterations in these disorders are associated with synaptic damage (DeKosky and Scheff, 1990; Terry *et al*., 1991). Injury to the synapse might be associated with the altered function of synaptic proteins (Masliah, 1998a). Among them, studies have pointed to α-synuclein, or the precursor of the non-Aβ component of AD amyloid (NACP), as a major player in the pathogenesis of AD and LBD (Masliah, 1998b) (Fig. 14.1). α-Synuclein was first isolated by Maroteaux *et al*. (1988) by expression screening of a Torpedo cDNA library using an antiserum against a purified synaptic vesicle. The term synuclein was proposed because immunoreactivity was observed in the presynaptic terminal and nucleus. Later on, Nakajo (1990) and Tobe (1992) *et al*. purified a presynaptic phosphoprotein (PNP14) very similar to synuclein from bovine brain; PNP14 is now known as β-synuclein.

Synuclein biology became particularly interesting in 1993 when Saitoh and colleagues identified α-synuclein as NACP, which was copurified with amyloid from the brains of AD patients (Ueda *et al*., 1993). Then, NACP is the human homologue to murine α-synuclein; however, for practical purposes we will refer to NACP as α-synuclein; which was also found to be a highly abundant synaptic protein in the mammalian brain (Iwai *et al*., 1995). Subsequently, Jakes and Goedert purified both α-synuclein and β-synuclein from human brain using monoclonal antibodies raised against neurons displaying granulovacuolar degeneration (Jakes *et al*., 1994) (Fig. 14.1). During the same time, Clayton and colleagues identified synelfin, the avian homologue of α-synuclein, whose expression was downregulated dramatically during a critical period for song learning in the canary (George *et al*., 1995), suggesting that synelfin may play a critical role in neural plasticity. More recently, γ-synuclein was isolated as the D3 synuclein-like molecule, which was expressed predominantly in peripheral sympathetic neurons (Akopian and Wood, 1995). γ-Synuclein was later cloned from the EST library as the breast cancer-specific gene (BCSG1) whose expression was observed in the invasive types of breast cancer (Ji *et al*., 1997). Finally, and most importantly, in 1997, Polymeropoulos and colleagues identified a missense substitution of alanine to threonine at 53 (A53T) of α-synuclein in Italian and Greek families of autosomal dominant types of Parkinson's disease (PD), and Kruger *et al*. (1998) identified a missense mutation alanine to proline at 30 (A30P) of

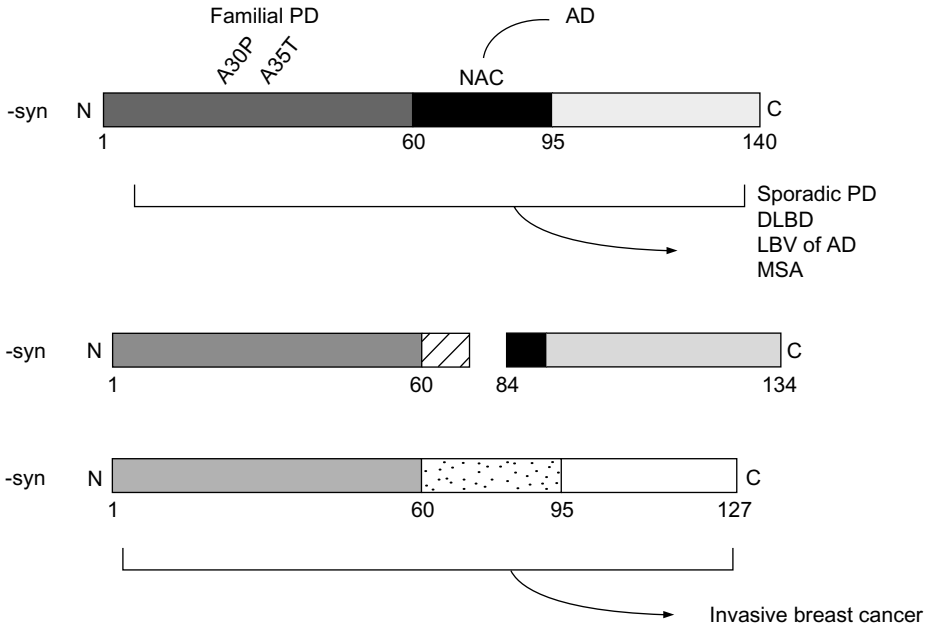

FIG. 14.1. Synuclein family of proteins and their relationship to neurodegenerative disorders. AD, Alzheimer's disease; DLBD, diffuse Lewy body disease; LBV, Lewy body variant; MSA, multiple system atrophy; PD, Parkinson's disease.

α-synuclein in a German family. Subsequent neuropathological and biochemical studies established that abnormal aggregates of α-synuclein are major components of inclusion bodies and dystrophic neurites in LBD (Wakabayashi *et al*., 1995; Spillantini *et al*., 1997; Takeda *et al*., 1998b). In this context, the main objective of this chapter is to review the pathogenesis of LBD and its relationship to α-synuclein.

II. Nosology of Disorders with Lewy Bodies

Patients with LBD present clinically with parkinsonism, hallucinations, and rapidly progressive dementia (Salmon and Galasko, 1996). The presentation and severity of these symptoms are highly variable and their relationship with specific neuropathological alterations is under investigation. Disorders with Lewy bodies comprise a diverse group of diseases, including a Lewy body variant of AD (LBV) (Hansen *et al*., 1990), diffuse Lewy body disease (DLBD) (Dickson *et al*., 1989), and PD (Gaspar and Graf, 1984). The so-called LBV has also been referred to by others as combined AD and PD or senile dementia of the Lewy body type (Dickson *et al*., 1987; Perry *et al*., 1990). No fewer than 18 different labels have been affixed to LBD characterized by dementia and varying degrees of motor parkinsonism (see Table 14.1). Because such demented PD patients will invariably have at least a few neocortical as well as subcortical LBs (Hughes *et al*., 1992), they could literally be construed as examples of LBD. Most investigators, however, did not apply terms such as ''diffuse Lewy body disease'' (Dickson *et al*., 1987) or ''Lewy body dementia'' (Perry *et al*., 1997) to clinically diagnosed PD patients who developed dementia, but rather to patients presenting with dementia who may have been mildly parkinsonian and whose brains were found to harbor Lewy bodies.

In an attempt to resolve some of these controversies, an international consortium published in 1996 consensus guidelines for the clinical and pathologic diagnosis of LBD (McKeith *et al*., 1996). This group recommended that if dementia occurs within 12 months of the onset of extrapyramidal motor symptoms, the patient should be assigned to a

TABLE 14.1 Nosologic Diversity in Lewy Body Disease

Lewy body disease, group A, diffuse type
Lewy body disease, group B, transitional type

TABLE 14.2 Clinical Features of Dementia with Lewy Bodies

Progressive cognitive decline
Fluctuating cognition with variations in attention and alertness
Visual hallucinations, usually repeated and detailed
Spontaneous motor parkinsonism, typically mild
Repeated falls
Transient loss of consciousness
Neuroleptic sensitivity
Systematized delusions
Hallucinations in other modalities

primary diagnosis of possible LBD. If the clinical history of parkinsonism is longer than 12 months, PD with dementia will usually be a more appropriate diagnostic label. Thus clinically defined, LBD was endorsed as a generic term to include cases referred to previously as DLBD (Dickson *et al*., 1987), senile dementia of the Lewy body type (Ince *et al*., 1991), LBV (Hansen, 1997; Hansen and Samuel, 1997), and AD plus PD (Mirra *et al*., 1993; Hulette, 1995). The LBD rubric, which neuropathologically requires only the presence of brain stem and neocortical Lewy bodies, was chosen as an all-encompassing designator with the understanding that it acknowledged the presence of Lewy bodies without specifying their relative importance in symptom formation with respect to other degenerative (i.e., AD) or vascular pathology that might be simultaneously present (Table 14.2).

More recently, the genetic basis for these disorders has begin to be elucidated (Table 14.3) (Hashimoto and Masliah, 1999). This adds a new level of complexity to the problem, but holds the promise of reclassifying these heterogeneous disorders according to the molecular alterations. α-Synuclein, which has now been implicated in the pathogenesis of the Lewy body, is an incompletely understood protein found primarily in neurons, where it is localized predominately at axon terminals or synapses (Trojanowski and Lee, 1998). α-Synuclein is the same protein previously designated as NACP (Ueda *et al*., 1993). Nigral and neocortical Lewy bodies and dystrophic nigral neurites in PD and DLB contain α-synuclein immunoreactivity (Irizarry *et al*., 1998). An Ala 53 Thr mutation in the α-synuclein gene has been found associated with PD in four chromosome 4-linked families with autosomal dominant PD (Polymeropoulos *et al*., 1997); however, sporadic cases of PD are not associated with linkage to this gene. Because both neurofilaments and α-synuclein have been detected immunohistochemically within Lewy bodies, it seems reasonable to speculate that aberrant interactions of one with the other might lead to the abnormal accumulation of these proteins into pathological Lewy bodies (Trojanowski and Lee, 1998).

TABLE 14.3 Genetic Risk Factors for Parkinson's Disease

Gene	Chromosome	Inheritance
α-Synuclein (PARK1)	4	Autosomal dominant
Parkin (PARK2)	6	Autosomal dominant
PARK3	2	Autosomal dominant
4p haplotype	4	Incomplete penetrance
UCH-L1	4	Autosomal dominant

III. Neuropathology of Disorders with Lewy Bodies

Neuropathologically, the common denominator is the degeneration of neuronal populations within the nigral dopaminergic system and mesial temporal regions, Lewy body formation, extensive neuritic degeneration, and spongiform vacuolization (Hansen *et al*., 1989). The substantia nigra displays significant pallor associated with neuronal loss (Fig. 14.2A, see color insert). Lewy bodies are intracytoplasmic eosinophilic neuronal inclusions (Fig. 14.2B), and in pigmented neurons of the brain stem they typically appear as dense eosinophilic cores surrounded by less densely staining peripheral halos (Fig. 14.2B). Neocortical Lewy bodies are more subtle and appear in the perikarya of pyramidal neurons in layers V and VI as spherical, homogeneous, slightly eosinophilic inclusions lacking a concentric laminar structure (Fig. 14.2C). Neocortical LBs are preferentially found in the cingulate cortex, insular region, temporal cortex, and occasionally in the frontal cortex and hippocampus and have long been underreported because they are so subtle with hematoxylin and eosin stains (Hansen, 1997). Ubiquitin antibodies stain many of the neuronal inclusions associated with neurodegenerative diseases, including Lewy bodies (Fig. 14.2D), Pick bodies, and neurofibrillary tangles (Love *et al*., 1988). Ubiquitin is a highly conserved protein in evolution and its function is to target other proteins for breakdown by cytosolic proteases. Lewy bodies are formed, at least in part, from altered neuronal cytoskeletal elements, and immunohistochemical studies of these inclusions have identified neurofilament, microtubular, and paired helical filament epitopes (Iwatsubo *et al*., 1996). Electron microscopic examination of nigral Lewy bodies discloses a dense central core of circular profiles surrounded by a peripheral rim of radiating 7- to 20-nm filaments (Kosaka, 1978). Neocortical Lewy bodies are composed of amorphous material and 10- to 20-nm filaments with irregular contours (Kosaka, 1978). The filamentous ultrastructure of the Lewy body and its immunohistochemical profile have been interpreted as suggesting that disturbed neurofilament metabolism or transportation is at the core of Lewy body formation (Iwatsubo *et al*., 1996).

A minority of LBD brains have only Lewy body-related pathology, which consists of neuron loss and gliosis with Lewy body formation in the remaining neurons in the substantia nigra, locus coeruleus, and nucleus basalis of Meynart. Neocortical Lewy bodies occur in medium-sized pyramidal neurons of the deeper cortical layers, especially in the limbic cortex (Wakabayashi *et al*., 1995). Many cases also display ubiquitin, neurofilament, and α-synuclein positive Lewy neurites in CA2–3 of the hippocampal formation, the amygdala, the nucleus basalis of Meynert, and in brain stem nuclei (Dickson *et al*., 1991; Kim *et al*., 1995) (Fig. 14.3A, see color insert). Dementia with Lewy bodies brains with only Lewy

body pathology can be construed as pure DLBD and pathologically resemble idiopathic PD, which has been shown to feature neocortical Lewy bodies in almost all cases and Lewy neurites in many (Churchyard and Lees, 1997). It may be that such pure DLBD patients are less demented that those whose brains have both LB and AD (Salmon and Galasko, 1996; Samuel *et al*., 1997a), but unequivocal dementia does occur in brains with only Lewy bodies and Lewy neurites. Dementia in LBD correlates with neocortical Lewy body counts. Such correlations have been found in studies of LBV (Samuel *et al*., 1996), LBD (Perry *et al*., 1997; Samuel *et al*., 1997a), DLBD, and even PD with dementia. Lewy neurites in the hippocampus may contribute substantively to cognitive impairment, but they are also found in some nondemented PD patients (Churchyard and Lees, 1997). Neuropsychiatric complications in neuropathologically pure PD overlap those of LBD, DLBD, LBV, and senile dementia of the Lewy body type and may in fact differ only in the timing of their onset relative to motor parkinsonism (Churchyard and Lees, 1997).

Many LBD brains display a striking spongiform vacuolization of the neuropil, which strongly resembles that seen in Creutzfeldt–Jakob disease at both light and electron microscopic levels of magnification (Hansen *et al*., 1989). This vacuolar abnormality is negative for anti-prion antibodies and is nontransmissible. Spongiform vacuolization is usually confined to the entorhinal cortex, temporal neocortex, amygdala, and sometimes the cingulate gyrus (Fig. 14.3B, see color insert). Recent findings indicate that these vacuoles may derive from the degeneration of terminal axons of large pyramidal neurons resident in layers IIIC and V of the transentorhinal cortex and with disappearance of their ubiquitin-containing granular processes (Iseki *et al*., 1997).

The neuropathologic substrate of dementia in clinically diagnosed PD is itself a complicated topic. About one-third of demented PD patients have AD pathology, 10% have widely distributed Lewy bodies and the remaining 55% have only the typical pathology of PD (Hughes *et al*., 1992). The severity of the dementia in these disorders is associated with the density of Lewy bodies and in AD cases with the Braak stage and apolipoprotein E (APOE) genotype. Synaptic injury and altered neurotransmitter (acetylcholine and DOPA) release may also be important. In this regard, neocortical cholinergic activity (choline acetyltransferase) is depleted far more severely in LBD than in AD (Perry *et al*., 1997). The extent of neocortical choline acetyltransferase loss correlates well with dementia in LBD (Samuel *et al*., 1997a) and is attributable to neuron loss in the nucleus basalis of Meynert. Other cholinergic deficits affect intrinsic striatal cholinergic neurons in the caudate nucleus and the reticular nucleus in the thalamus, which receives cholinergic projections from both the basal forebrain and brain stem pedunculopontine nuclei. Loss of striatal dopamine in LBD is comparable to that seen in PD and greatly exceeds any such loss in AD (Langlais *et al*., 1993). It is reasonable to attribute motor parkinsonism, and perhaps visual hallucinations, in LBD to disruptions of striatal dopaminergic input. Finally, the role of programmed cell death (namely apoptosis) in DLBD is currently being explored; however, results are inconclusive at this point (Lassmann *et al*., 1995).

IV. Contribution of Alzheimer's Pathology to Disorders with Lewy Bodies

As indicated in the previous section, most, but not all, DLB brains have more AD pathology than age-matched controls (Ince *et al*., 1991; Gentleman *et al*., 1992; Gearing *et al*., 1995; Kosaka and Iseki, 1996; McKenzie *et al*., 1996; Perry *et al*., 1997; Samuel *et al*., 1996, 1997a; Hansen, 1997). This fact is invariably entangled with questions about how much AD pathology is necessary to warrant a diagnosis of AD and how much can be attributed to normal aging, or so-called ''pathologic aging.'' If neocortical amyloid is one hallmark for a neuropathologic diagnosis of AD, then most LBD brains have concomitant AD. Most LBD brains not only have as much neocortical amyloid as AD specimens when measured immunocytochemically (Gentleman *et al*., 1992), but typically have as many neuritic plaques as AD brains (McKenzie *et al*., 1996) and far more than age-matched controls. Therefore they meet 1985 NIA criteria for AD (Khachaturian, 1985), and because many of the plaques are neuritic, albeit usually lacking tau-positive neurites (Samuel *et al*., 1997b), they also typically qualify as ''definite'' or ''probable'' AD according to criteria from the consortium to establish a registry for AD (Mirra *et al*., 1993). Apolipoprotein E (APOE) $\epsilon 4$ is overrepresented in LBD, just as it is in AD, and is related to increased amyloid plaque pathology in both conditions (Gearing *et al*., 1995; Olichney *et al*., 1996; St. Clair, 1997). Apolipoprotein E $\epsilon 4$ is not increased in PD or in neuropathologically pure DLBD lacking amyloid plaques (St. Clair, 1997).

Some authorities are dismissive of this amyloid overlap in LBD and AD, as they interpret such pathology as so-called ''pathological aging'' (Dickson *et al*., 1987, 1991). These experts contend that only abundant microtubule-associated protein tau abnormalities in the neocortex constitute conclusive evidence of AD (Strong *et al*., 1995), and therefore insist upon the presence of numerous neocortical neurofibrillary tangles, neuropil threads, or tau-positive swollen neurites in neuritic plaques for a diagnosis of AD. Such criteria run contrary to the recent Consensus Recommendation for the Post-Mortem Diagnosis of AD from the National Institute on Aging and the Reagan Institute Working Group on Diagnostic Criteria for the Neuropathological Assessment of AD, which was of the opinion that ''any Alzheimer lesions should be considered as pathological'' (Hyman and Trojanowski, 1997). Even if only tau pathology in LBD is ruled admissible as evidence for concomitant AD, the situation is made more complicated by the presence of more tau pathology in the medial temporal lobes of most, but not all, DLB brains than in age-matched controls (Ince *et al*., 1991; Samuel *et al*., 1996, 1997a; Hansen, 1997; Hansen and Samuel, 1997). Most, but not all, LBD brains occupy higher Braak stages of AD neurofibrillary pathology (Braak and Braak, 1991) than age-matched controls, but lower stages than brains with pure AD. Because Braak staging is based on entorhinal and hippocampal neurofibrillary tangles and neuropil threads, it seems that most, but not all, LBD brains have more tau pathology than controls, but less than AD. Correlational studies in LBD with dementia have shown statistically strong relationships between cognitive impairment and Braak stages of AD pathology (Jellinger,

1996; Samuel *et al*., 1996, 1997a). Still, as stated earlier, a minority of LBD brains lack AD pathology altogether and yet come from clinically demented patients.

V. α-Synuclein in Lewy Body Disease

The discovery of missense mutations in α-synuclein gene led to extensive neuropathological studies that culminated in the identification of α-synuclein in Lewy bodies and Lewy neurites. Spillantini *et al*. (1997) found that Lewy bodies and Lewy neurites in sporadic PD and DLBD cases are immunoreactive with antibodies against α-synuclein. Both cortical and subcortical Lewy bodies were strongly immunoreactive with anti-α-synuclein antibodies, and this immunoreactivity was observed with several antibodies recognizing different regions of α-synuclein, including both N- and C-terminals (Spillantini *et al*., 1998,; Takeda *et al*., 1998a,b) (Fig. 14.3C, see color insert), indicting that full-length and/or partially truncated α-synuclein is accumulated in Lewy bodies. Semiquantification by immunohistochemical procedures has revealed that staining for α-synuclein was more extensive than that for ubiquitin (Spillantini *et al*., 1998). Until then, the most sensitive marker for Lewy bodies and Lewy neurites was ubiquitin (Kuzuhara *et al*., 1988) and, to a lesser extent, neurofilaments (Schmidt *et al*., 1991). In contrast, neither β- nor α-synuclein immunoreactivity was found in Lewy bodies and other amyloid lesions in various neurodegenerative disorders (Spillantini *et al*., 1998). These results were subsequently confirmed by a number of reports. Takeda *et al*. (1998b) showed that α-synuclein immunoreactivity was detected in all variants of LBD, but not in neurofibrillary tangles, neuropil threads, Pick bodies, ballooned neurons, and glial tangles (most of which were tau positive). Moreover, α-synuclein immunoreactivity has also been found in other neurodegenerative disorders, including multiple systemic atrophy (Arima *et al*., 1998; Wakabayashi *et al*., 1998) and amyotrophic lateral sclerosis (Mezey *et al*., 1998), creating a new category of so-called α-synucleopathies (Hardy and Gwinn-Hardy, 1998).

Iwatsubo and colleagues have prepared monoclonal antibodies using highly purified Lewy bodies from brains of DLBD patients and corroborated biochemically that α-synuclein was accumulated in Lewy bodies (Iwatsubo *et al*., 1996; Baba *et al*., 1998). Furthermore, their results suggested that a partially truncated α-synuclein also exists in Lewy bodies (Baba *et al*., 1998), although the mechanism of fragmentation was unclear. The altered conformation of the structure may be essential for the aggregation and accumulation of α-synuclein in Lewy bodies and other cellular sites. Supporting this contention, immunoelectron microscopic studies have shown that the pattern of immunogold labeling obtained by the C-terminal antibody is distinct from that of the N-terminal antibody (Spillantini *et al*., 1998). Furthermore, α-synuclein immunoreactivity was enhanced significantly by formic acid and proteinase K treatment, suggesting that the structure α-synuclein may be dynamically changed, associated with altered epitopes of antibodies (Takeda *et al*., 1998a). In fact, utilizing this similar approach to reveal hidden epitopes, we have found that the anti-C-terminal antibody against α-synuclein immunostained after proteinase K (but not formic acid) treatment, neurofibrillary tangles of AD, progressive supranuclear palsy, and corticobasal degeneration and glial inclusions of progressive supranuclear palsy and corticobasal degeneration, as well as Pick bodies (Takeda *et al*., 1999). In contrast, in LBD, plaques (Fig. 14.3D, see color insert), astroglial cells, and granular neurons were immunostained only after formic acid pretreatment with the anti-NACP antibody. The N-terminal region antibody recognized only the lesions of LBD cases, but not of other neurodegenerative disorders (Fig. 14.3). These results support the view that different fragments of α-synuclein may play an important role in the pathogenesis of several neurodegenerative disorders.

α-Synuclein belongs to the synuclein family of peptides, which also includes β- and γ-synucleins (Clayton and George, 1998) (Fig. 1). α-Synuclein is a 140 amino acid protein with little or no secondary structure (Weinreb *et al*., 1996), which is divided into three domains: (1) the N-terminal region composed of an incompletely repeated KTKEGV motif, (2) the NAC domain in the middle of region that is extremely hydrophobic, and (3) the C-terminal region with a negative charge (Clayton and George, 1998). α-Synuclein is encoded by a gene located on chromosome 4. Interestingly, both the A53T and the A30P mutations lie in the N-terminal region, suggesting that the N-terminal domain may be critical for amyloidogenesis (Fig. 14.1).

α- and β-synuclein have been shown to inhibit specifically the activity of phospholipase D2 in a cell-free system (Jenco *et al*., 1998), raising the possibility that a conserved function shared by synucleins may be involved in certain specific signal transduction pathways. In this context, it is noteworthy that α-synuclein conferred increased invasive property to breast cancer cells (Jia *et al*., 1999) and also selectively degraded neurofilaments in primary cultured neurons (Buchman *et al*., 1998), suggesting that synucleins may influence the integrity of cytoskeleton networks. Finally, synphilin-1 was identified as a cytosolic-binding protein of α-synuclein using a yeast two-hybrid method. Further characterization of this molecule may provide clues as to the physiological function of α-synuclein (Engelender *et al*., 1999).

VI. α-Synuclein as a Genetic Risk Factor for Parkinson's Disease

The great majority of PD cases are probably sporadic, and strong environmental factors inducing oxidative stress may play an important role (Markesbery and Carney, 1999). However, a small percentage of PD cases are familial and inherited in either an autosomal dominant or recessive manner (Veldman *et al*., 1998). Progress in genetic research in PD has provided new insights into the involvement of specific genes in familial PD (Table 14.3). In 1996, Polymeropoulos and colleagues identified a linkage of markers at chromosome 4q21 to the autosomal dominant type of PD in a large Italian family, mapped the gene locus sucessfully, and identified an A to G mutation at position 209 in exon 4 of the α-synuclein gene, resulting in a missense substitution of alanine to threonine (A53T) in this family and also in three Greek families

(Polymeropoulos *et al*., 1997). In 1998, Kruger and colleagues identified another missense mutation, alanine to proline (A30P), in a German family. Because both of these cases were autosomal dominant, it was predicted that a possible gain of function of α-synuclein may cause these rare familial type of PD (Table 14.3).

Although α-synuclein mutations have not been found in subsequent cohorts of cases with sporadic PD (Chan *et al*., 1998; Farrer *et al*., 1998; Group, 1998; Vaughan *et al*., 1998), the α-synuclein pathway has been regarded as being situated at the center of the pathogenic pathways leading to sporadic LBD. This could be similar, in a way, to the role of amyloid precursor protein (APP) in the pathogenesis of AD. Despite the fact that only a small percentage of familial AD cases exhibit APP mutations, Aβ protein is regarded as a crucial player in the amyloidogenesis of AD. In this regard, Kruger *et al*. (1999) have found a highly significant difference between sporadic PD patients and control individuals regarding the combination of APOE4 and allele 1 of the α-synuclein promoter polymorphism, suggesting a role for interactions or combined actions of these proteins in the pathogenesis of sporadic PD.

Other genes responsible for familial PD have been identified, including parkin (PARK2) (Kitada *et al*., 1998), UCH-L1 (Leroy *et al*., 1998)), and 4p haplotype (Farrer *et al*., 1998), which cause autosomal recessive, penetrate incompletely, and autosomal dominant inheritances, respectively (Table 14.3). It was also reported that chromosome 2p13 was linked to certain autosomal dominant PD (Gasser *et al*., 1998) and designated PARK3 (Table 14.3), although the corresponding gene has not been identified. It is important to determine whether these risk factors are involved in the α-synuclein pathogenic pathway. For example, because UCH-L1 is a thiol protease, functional disturbance of this protein due to gene mutation might result in the altered proteolysis, which may affect aggregation and ubiquitination of α-synuclein. Notably, it has been reported that UCH-L1 is immunoreactive in Lewy bodies (Lowe *et al*., 1990). Finally, previous genetic studies have indicated that the presence of a mutant allele on the CYP2D6 gene (Saitoh *et al*., 1995) and/or the APOE gene (Seeman *et al*., 1978) might confer increased susceptibility to LBD; however, controversy still exists as to the significance of these findings. In summary, these studies suggest that genetic alterations in synaptic proteins with amyloidogenic potential might lead to LBD via oxidative stress and conformational changes in the molecules that might lead to abnormal aggregation (Hashimoto and Masliah, 1999).

VII. Modulators of α-Synuclein Aggregation in Lewy Body Disease

In LBD, the protein level of α-synuclein is not so high in substantia nigra where dopaminergic neurons are predominantly degraded. Thus, it is possible to predict that such a discrepancy may reflect the regional availability of other modulators, which directly or indirectly affect the aggregation of α-synuclein. In AD, it has been well characterized that the aggregation of Aβ protein is potently stimulated by several factors, including apoE, α_1-antichymotrypsin, and proteoglycans (Ma *et al*., 1994; Snow *et al*., 1994; Wisniewski *et al*., 1994). These molecules have been shown to be coaccumulated with Aβ protein in the extracellular space or senile plaques, leading to the concept of pathological chaperones during neurodegeneration (Wisniewski *et al*., 1994). In this context, it is reasonable to hypothesize that certain molecules may act as pathological chaperones for the aggregation of α-synuclein and might be coaccumulated with α-synuclein in Lewy bodies in the PD brain. In this regard, it has been shown that the aggregation of α-synuclein *in vitro* is modulated by various factors, such as Aβ protein (Yoshimoto *et al*., 1995; Jensen *et al*., 1997; Paik *et al*., 1998), NACP (Paik *et al*., 1998), and lipids (Davidson *et al*., 1998). It is noteworthy that in Down syndrome and many familial AD cases with both presenilins (1 and 2), APP mutations exhibit LB formation in certain brain areas associated with the enhanced aggregation of α-synuclein, suggesting that the Aβ protein may be involved in the intracellular aggregation of α-synuclein in these types of AD (Lippa *et al*., 1998). Although it has been described previously that amyloid precursor protein, but not Aβ protein, was detectable in Lewy bodies of PD and DLBD (Arai *et al*., 1992), more detailed biochemical and immunocytochemical analyses will be necessary to clarify this issue.

α-Synuclein may be proteolytically degraded to give rise to short fragments containing the NACP region, which tend to be more prone to be aggregated than the full-length α-synuclein and to be part of the amyloid plaques in AD and LBD (Fig. 14.3D). Such short fragments might become the core of aggregation and further induce aggregation of α-synuclein. Indeed, the degraded product of α-synuclein was detected in highly purified Lewy bodies from the brain of LBD patients. Furthermore, it was shown that an α-synuclein mutant deleted with the C-terminal region was aggregated more easily than the wild type (Crowther *et al*., 1998). Apparently, lipids seem to participate in the regulation of α-synuclein aggregation. Immunoelectron microscopic studies showed that some gold particles decorated synaptic vesicles (Iwai *et al*., 1995) in the nervous system and secretory vesicles and plasma membrane in platelets (Hashimoto *et al*., 1997). Consistent with this, synelfin, the avian homologue of α-synuclein (George *et al*., 1995), was shown to be associated with membranous fractions. A further study showed that α-synuclein binds to phospholipids associated with a certain conformational change of structure (Davidson *et al*., 1998). Thus, the altered composition of lipids of membranes in neurodegeneration may be a prerequisite for the aggregation of α-synuclein.

At the present time, it has yet to be determined whether these molecules could explain the mechanism by which the aggregation of α-synuclein occurs preferentially in the LBD brain. Because dozen of molecules have already been identified as constitutes of LBs (Pollanen *et al*., 1993), some of them might turn out to be candidates for regional specific factors for the aggregation of α-synuclein in the PD brain.

Iron may also play an essential role in the elevated oxidative stress conditions in the PD brain (Youdim *et al*., 1989), as the substantia nigra contains elevated levels of iron, which can act as a free radical catalyst via the Fenton reaction. In this line, our data showed that α-synuclein was aggregated preferentially in the presence of ferric ion (Hashimoto *et al*., 1999a). Although ferrous ion was not effective by itself, it potently aggregated α-synuclein in the presence of hydrogen peroxide.

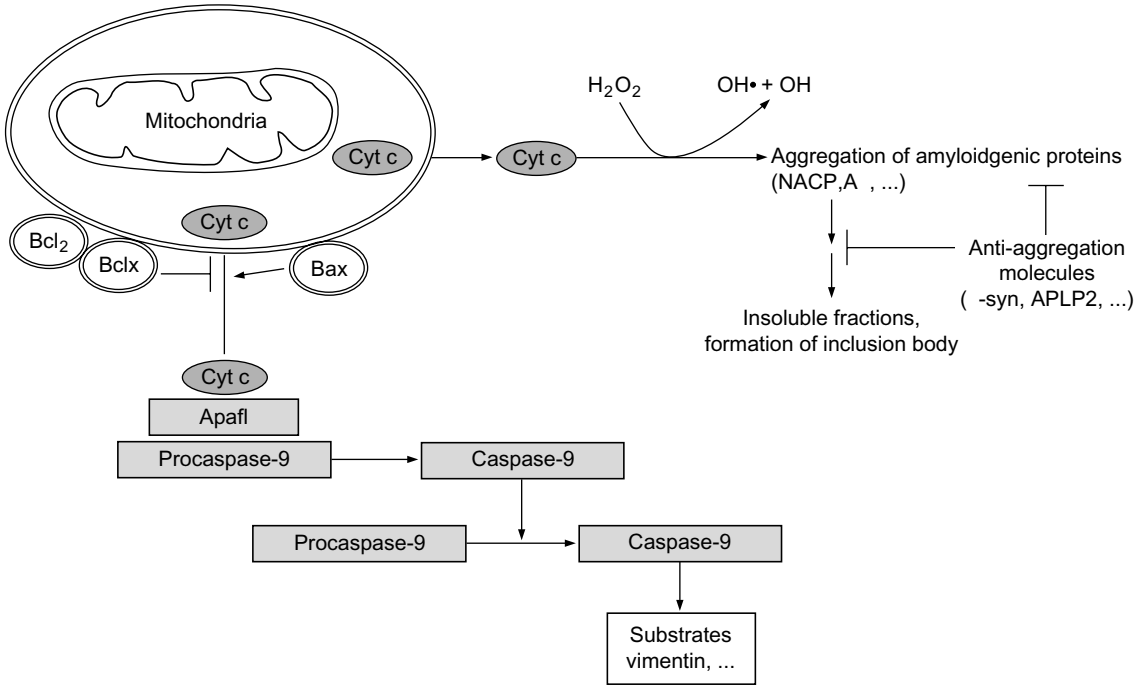

FIG. 14.4. Possible mechanisms of cell death in Lewy body disease.

The aggregates of α-synuclein displayed both Thioflavine-S reactivity and Congo red birefringence, reminiscent of amyloid-like fibrils. These results suggest that an aberrant accumulation of ferric ion might act as a risk factor for the aggregation of α-synuclein in the PD brain. Indeed, it has been suspected that the shift from ferrous to ferric ion may be a risk factor for PD. Riederer *et al*. (1989) showed that the ratio of ferric to ferrous ion in the substantia nigra of the patient with advanced PD was remarkably increased compared to controls. Furthermore, it was shown that neuromelanin, which acts as an endogenous chelator of ferrous/ferric ions in substantia nigra, differentially regulates the rate of hydroxyl radical production depending on the redox state of the iron ion (Pilas *et al*., 1988). Therefore, if the iron-catalyzed oxidative reaction plays a significant role in α-synuclein aggregation *in vivo*, either an antioxidant or a iron chelator could be used as a possible therapeutic strategy. Other metal ions may also contribute to the aggregation of α-synuclein in neurodegeneration. For example, aluminum ion potently stimulates the aggregation of α-synuclein (Paik *et al*., 1997), and copper ion induces aggregation of α-synuclein in the presence of a specific cross-linker. Finally, it has been suggested that the mitochondrial heme protein cytochrome C may participate in the aggregation of α-synuclein in the PD brain (Hashimoto *et al*., 1999b). *In vitro*, recombinant α-synuclein was coinduced to be aggregated in the presence of cytochrome C/hydrogen peroxide, which was inhibited by *N*-acetyl-L-cysteine. In the brains of patients with LBD, cytochrome C immunoreactivity was detected in Lewy bodies in substantia nigra, whereby approximately half of the α-synuclein-immunoreactive Lewy bodies were also cytochrome C-immunoreactive. The cytochrome C staining was specifically observed in Lewy bodies in substantia nigra, but not in other lesions, such as cortical Lewy bodies, senile plaques, and neurofibrillary tangles. Cytochrome C is localized in the intramembrane of mitochondria and is released upon apoptotic stimuli into cytoplasm where it triggers apoptotic cascades (Green and Reed, 1998). Taken together, these results suggest that the aggregation of α-synuclein may be closely related to mitochondrial dysfunction and apoptosis in neurodegeneration in LBD (Hashimoto and Masliah, 1999) (Fig. 14.4).

Amyotrophic Lateral Sclerosis/ Parkinsonism–Dementia Complex of Guam

I. Introduction

Guam is the largest of the Marianas islands, an archipelago consisting of 15 relatively small islands in the Western Pacific. The Marianas are part of Micronesia, a broader group of Pacific islands that, in addition to the Marianas, consist of the Caroline, the Marshall, and the Gilbert islands. Guam is the southernmost island of the Marianas chain and, although it is a relatively small island, it represents the largest land mass in the Western Pacific. Guam is approximately 30 miles long and varies from 4 to 9 miles wide (with a total area of approximately 212 square miles). Located 3500 miles west of Hawaii, 1500 miles south of Tokyo, and 1500 miles east of Manila, Guam occupies a central and strategic location in the Western Pacific (Fig. 15.1). In 1898, as part of the settlement of the Spanish–American War, the United States obtained Guam as a territorial possession. In an era of coal-burning, ocean-going ships, Guam served as a valuable site for steamships needing to take on fresh water and other vital supplies. Its strategic central location in the Western Pacific, from a military perspective, was also an important feature. The U.S. Navy administered the island through the first half of the 20th century. In 1950, with the passage of the Organic Act of Guam, the inhabitants of Guam were finally granted citizenship to the United States. In addition, the residents of Guam were allowed to elect a local governor and an island legislature, as well as a nonvoting representative in the U.S. Congress. They vote in the American presidency elections, serve is the U.S. military, and pay federal taxes (although all collected federal tax revenues remain on the island for local use).

The 1990, the population of Guam was 123,203, of which 43,000 inhabitants were identified as Chamorros, 30,043 as Filipino, 22,318 as migrants from the U.S. mainland, and 6166 as other Micronesians, mostly originating from the Caroline islands. The Chamorros are a local indigenous population that has continuously inhabited Guam since approximately 1500 B.C., when they are believed to have originated from the Malay Archipelago. The Chamorros of Guam first encountered European explorers when Ferdinando Magellan, the Portuguese explorer, landed near the village of Umatac in southern Guam in 1521. Magellan and his crew were in the process of circumnavigating the world and stopped, after a long journey across the Pacific, in Guam to take on supplies. Following his leaving Guam, Magellan took his fleet to the Philippines, where he was unfortunately killed in a violent native dispute.

The presence of a high incidence focus of neurodegenerative disease on Guam was first brought to medical attention by Dr. Harry M. Zimmerman, a pathologist who was assigned in 1944 to Guam by the U.S. Navy. On December 8, 1941, the day after the Japanese attack on Pearl Harbor, Japanese forces also occupied Guam. For most of World War II, the Japanese military held Guam in a rather brutal occupation. However, in the summer of 1944, U.S. military forces retook the island from the Japanese. Due to the relatively large size and strategic position of the island Guam played a significant role in the latter stages of the Pacific campaign, serving as a major staging area and take-off site for bombing attacks of the major cities of Japan. In the final year of World War II, large numbers of military personnel to support these operations were assigned to Guam, including Dr. Zimmerman. During his stay on Guam, Dr. Zimmerman identified a number of cases of amyotrophic lateral sclerosis (ALS) among the native population who were being cared for in the local hospital. As a pathologist with neuropathology training, he subsequently confirmed the diagnosis at autopsy on two affected individuals. Zimmerman recognized that ALS was a relatively uncommon disorder and that this represented an inordinately high prevalence of the disease. He therefore wrote to his naval supervisors in Washington, DC with his observations and wondered if this might represent an unusual genetic focus of ALS in an island-bound and presumably inbred population. Apparently his message was taken seriously, as after the end of the war a series of clinicians and epidemiologists were sent to Guam to investigate the situation further. Based on their initial findings, a major commitment of the National Institutes of Health (NIH) was made to determine the nature of the disorder and, in

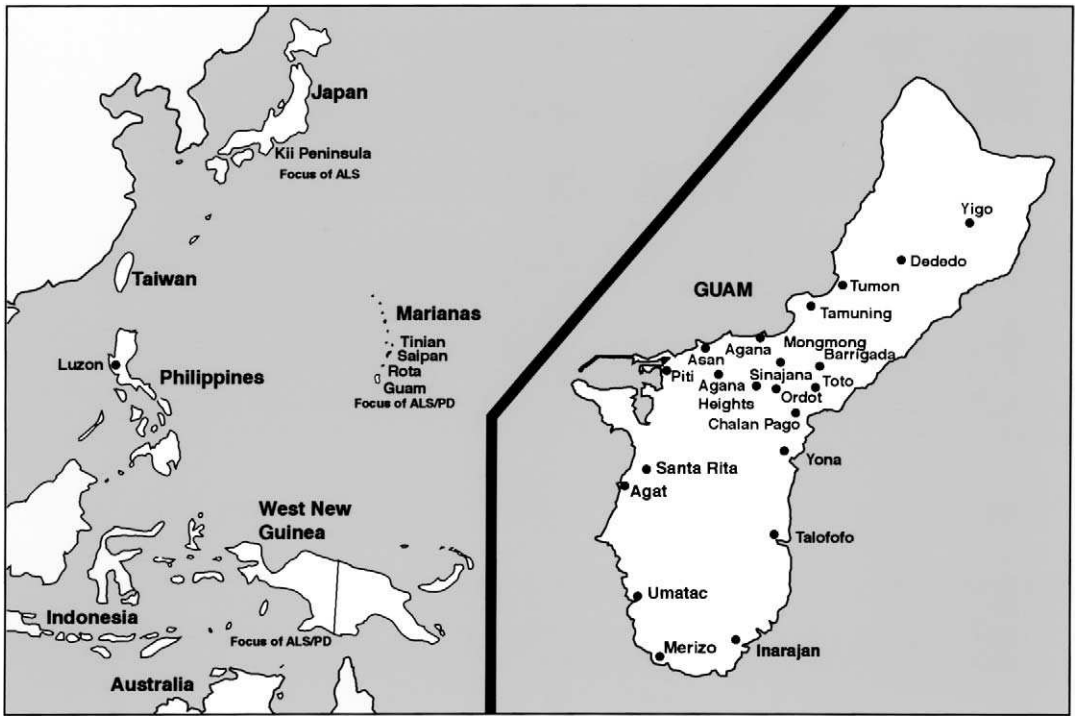

FIG. 15.1. Map of the Western Pacific demonstrating Guam and the location of other foci of neurodegeneration on the Kii Peninsula in Japan and in the Irian Jaya in southwestern New Guinea. Insert shows the island of Guam.

particular, its etiologic basis. This commitment evolved into the establishment of an NIH-associated research station, which was maintained on Guam for approximately 30 years by the National Institute for Neurological and Communication Diseases and Stroke (NINCDS). This research station was eventually abandoned in 1984, but efforts to unravel the etiology of this remarkable focus of age-related neurodegenerative disease continue to this day.

Initial research studies on the island supported the observations of Dr. Zimmerman, namely that there was a high prevalence of amyotrophic lateral sclerosis on Guam (Arnold *et al*., 1953). However, in the process of doing door-to-door surveys of all neurologic diseases on the island, it was soon noted that a second form of neurodegenerative disease was also highly prevalent among the native Guamanian Chamorros. This disorder had components of parkinsonism and was accompanied by relatively severe dementia, reminiscent of Alzheimer's disease, and was subsequently called parkinsonism–dementia complex of Guam. It was later recognized that both ALS and parkinsonism–dementia complex had been present on Guam for many years prior to its ''discovery'' by Dr. Zimmerman. At the time of Dr. Zimmerman's stay on Guam, both ALS and parkinsonism–dementia complex were referred to by the Chamorros by specific terms in their native Chamorro language as ''lytico'' and ''bodig,'' respectively. The term ''lytico'' is said to originate from the Spanish ''paralytico,'' referring to the progressive paralysis associated with anterior horn cell degeneration in ALS. The origin of the term ''bodig'' is more obscure, but is defined loosely as ''slow'' or ''lazy'' and refers to the parkinsonism–dementia form of the disorder. Remarkably, archival death certificate records maintained by U.S. Navy personnel dated from the first decade of the 20th century survived the extensive destruction of facilities on Guam during the hostilities of World War II. These meticulously detailed records carefully document virtually every adult death from that era and contain numerous entries with diagnoses of amyotrophic lateral sclerosis, as well as other entries with ''presenile degeneration of the brain and spinal cord.'' Furthermore, folklore accounts suggest that the disease had been present on Guam at least as early as the beginning of the 19th century. It is clear that whatever causes this remarkable outbreak of neurodegenerative disease has been present on Guam for hundreds of years and preceded the arrival of Western industrialized society to the island.

II. Clinical Features

Both ALS and parkinsonism–dementia complex of Guam were initially described as separate and distinct clinical entities, which were highly endemic among the native Chamorro population living on Guam. Clinical and epidemiologic approaches to the study of neurologic disease on Guam have attempted to consider them as two different nosologic entities. Nevertheless, as will be discussed later, there is a considerable amount of evidence, both clinical and neuropathologic, for overlap between the two diseases. Many researchers with extensive experience in the clinical and neuropathologic evaluation of Guam cases have noted such overlap and suggested that this may actually represent a single disorder with a broad spectrum of neurodegeneration, ranging

from relatively ''pure'' ALS to parkinsonism with dementia to an exclusively dementing form of the illness. These concepts will be discussed further later. Nevertheless, the three major forms, namely ALS, parkinsonism–dementia, and so-called ''Marianas dementia,'' will be described separately.

III. Amyotrophic Lateral Sclerosis of Guam (or the Marianas Form of ALS)

Initial observations indicated that Guamanian patients with ALS were clinically indistinguishable from patients encountered with the sporadic form of the disorder elsewhere in the world (Kurland and Mulder, 1954; Kurland *et al*., 1956). On Guam, the disease typically begins in an insidious fashion with complaints of weakness, clumsiness, and/or unexplained weight loss. Early signs include muscle weakness, atrophy accompanied by widespread fasciculations, and hyperreflexia. The disease progresses inexorably, and within a year or more, prominent muscular atrophy, weakness, and a flaccid paralysis are present. In the absence of identifiable muscular wasting, spasticity is seen at presentation in approximately 10–15% of cases. In later stages of the illness, prominent dysphagia and dysarthria are noted as the level of paralysis proceeds in an ascending fashion. As will be discussed later, despite the fact that such patients show a rather widespread and extensive distribution of neurofibrillary tangle (NFT) formation, dementia has been noted clinically in only about 10% of ALS cases seen on Guam. Death is typically produced by aspiration and/or hypostatic pneumonia. Affected individuals generally survive for approximately 2–4 years following initial diagnosis. However, occasional patients are seen with more rapid progression of the illness, whereas others are encountered with unusually prolonged periods of survival (Uebayashi, 1984; Rogers-Johnson *et al*., 1986). Those patients with prolonged survival typically progress in a slower fashion and their disease progression may actually plateau without further deterioration in neurologic status over a period of many years. Indeed, rare individuals with the Guamanian form of ALS have been followed clinically for over 15 or more years and the diagnosis has been verified neuropathologically at autopsy.

IV. Parkinsonism–Dementia Complex of Guam

The parkinsonism–dementia complex of Guam was first recognized clinically by Kurland and Mulder and was subsequently defined as a clinicopathologic entity in the seminal papers by Hirano and colleagues (1961a,b). An earlier account of the disorder was apparently published in 1936 (Yase *et al*., 1978). The major features of the disease include parkinsonism in association with a progressive loss of cognitive function. The parkinsonian features include rigidity, bradykinesia, and gait disturbance. A 4–7 Hz pill-rolling tremor at rest of the hands may be noted in some patients, but is rarely incapacitating. A large percentage of patients also show a form of impairment of ocular motility that is reminiscent of patients with progressive supranuclear palsy (Lepore *et al*., 1988). As the disease progresses, bradykinesia and rigidity increase in severity and become a major cause of disability.

The dementia that accompanies the disorder includes severe memory impairment, disorientation, and difficulty with reasoning and simple calculations. In about 30% of cases, the dementia represents the presenting symptom with the parkinsonian features being encountered later in the course of the disease (Elizan *et al*., 1966). Personality changes, in the form of agitation, apathy, irritability, and, in some cases, aggressiveness, may be encountered in the course of the illness and have been noted in approximately one-third of cases. This is an unremittingly progressive and invariably fatal disorder that typically leads to death within 4–6 years after the initial diagnosis. Although initial therapy with levodopa may produce some mild improvement in the parkinsonian features (Schnur *et al*., 1971), eventually the Guam patients soon become refractory to its effects.

V. Marianas Dementia

In recent years, door-to-door surveys of neurologic disease on Guam have identified a significant number of Chamorros with dementia, in the absence of overt accompanying signs of amyotrophy or extrapyramidal disturbances. Such individuals have been mostly women, living in the southern villages of the island and in their early to mid-60s. Several such patients have now been followed longitudinally, and although some have gone on to develop parkinsonian features, others have shown a progressive course with progressive cognitive loss in the absence of any superimposed parkinsonian signs or motor weakness. We have tentatively referred to this entity as ''Marianas dementia,'' pending more detailed clinical, neuropsychological, and neuropathological characterization. A limited number of autopsies have been performed on such patients, and neuropathologic examination has revealed the typical changes associated with ALS/parkinsonism–dementia complex (Perl *et al*., 1994). These fascinating cases suggest that ''lytico-bodig'' may also have an onset and clinical course characterized by a progressive dementing syndrome, in the absence of amyotrophy and/or parkinsonism, and that this may represent an additional clinical profile of this disorder.

VI. Neuropathologic Features

A. Grossly Visible Features

The brains of patients with both ALS and parkinsonism–dementia complex almost invariably show prominent generalized cerebral atrophy accompanied by severely dilated lateral ventricles. The brain weight of severely affected end-stage cases is frequently less than 1000 g, and brains that weigh less than 900 g are also noted occasionally. In patients with parkinsonism–dementia complex, normally pigmented nuclei of the brain stem, namely the substantia nigra and locus ceruleus, are virtually completely depigmented on gross inspection (Fig. 15.2). Patients with ALS may show discoloration of the lateral columns of the spinal cord that is apparent

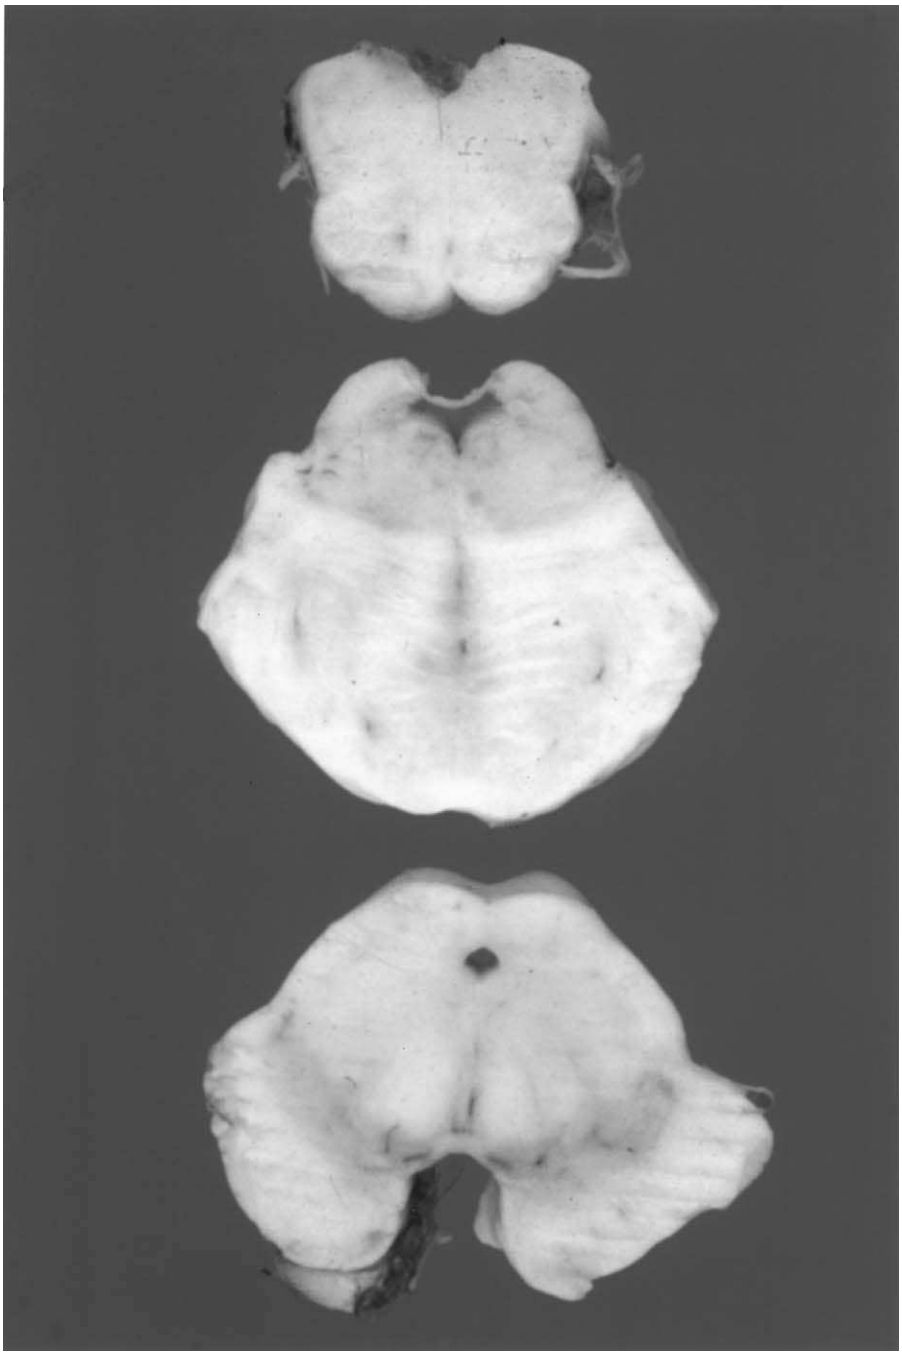

FIG. 15.2. Gross appearance of the upper brain stem of a case of parkinsonism–dementia complex of Guam. Note the lack of pigmentation of the substantia nigra.

with the naked eye. Prominent atrophy of the ventral spinal roots is also recognized readily.

VII. Microscopic Features

A. Neurofibrillary Tangles

The neuropathologic hallmark of both the Guamanian form of ALS and parkinsonism–dementia complex is the presence of severe widespread NFT formation. In the initial neuropathologic examination of cases of ALS from Guam, these NFTs failed to be identified. It was Dr. Nathan Malamud, a neuropathologist at the University of California, San Francisco, who first noted NFTs in the Guam ALS cases (Malamud *et al.*, 1961). These lesions were characterized further in the seminal papers of Hirano and colleagues (Hirano *et al.*, 1961a,b, 1967b; Hirano and Zimmerman, 1962). Severe NFT involvement is typically encountered in the hippocampus, entorhinal cortex, amygdala, and neocortex. In many cases, the

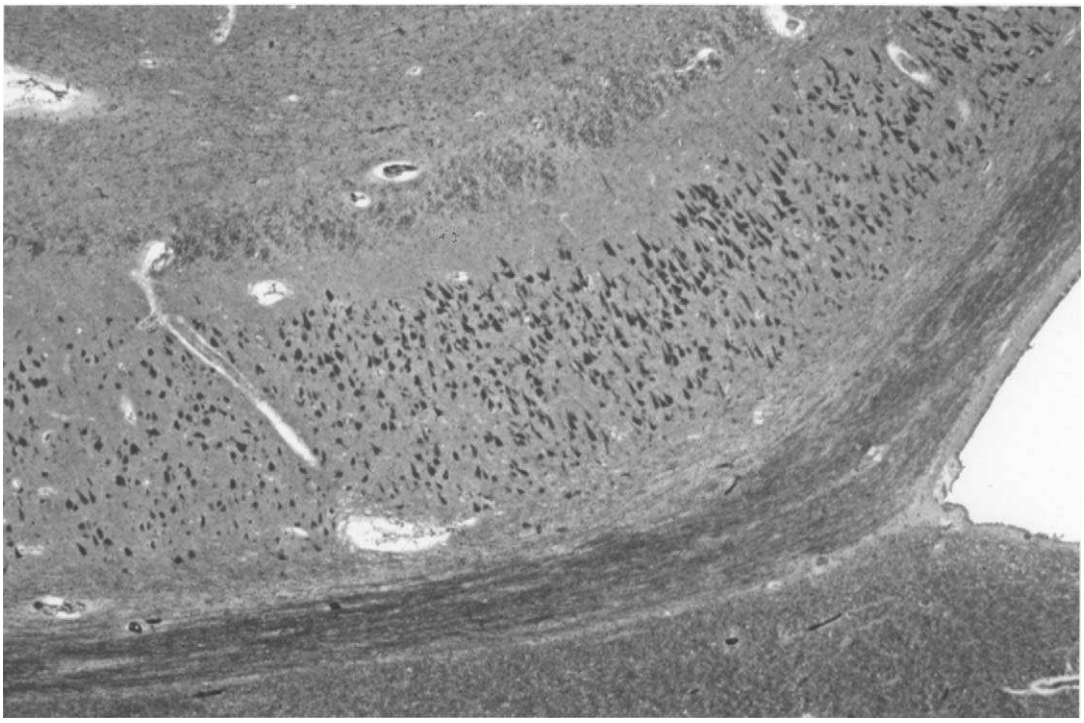

FIG. 15.3. Microscopic appearance of the CA1 region of the hippocampus, parkinsonism–dementia complex of Guam showing virtual complete involvement by neurofibrillary tangles. (Modified Bielschowski stain.)

CA1 region of the hippocampus will show almost complete involvement with virtually every pyramidal neuron containing a neurofibrillary tangle (Fig. 15.3). When NFT formation is particularly severe in the hippocampus, it is generally accompanied by extensive neuronal loss and the appearance of many extracellular ''ghost'' tangles as well as a prominent reactive astrocytic response.

It is interesting to note that patients with Guamanian ALS may show rather extensive hippocampal NFT formation at autopsy, yet were considered to have essentially intact cognitive function during life. It should be noted that in the later stages of ALS, such patients may have exhibited severe dysphonia, bordering on aphonia, and that this inherent inability to communicate may clearly preclude the proper assessment of cognitive function. Nevertheless, such patients do appear, within their physical limitations, to be able to follow and carry out verbal commands. Such observations appear to suggest that severe involvement of the CA1 of the hippocampus by NFTs may not be associated with severe cognitive losses, particularly involving recent memory processing, as has been assumed to be operative in cases of Alzheimer's disease (AD).

In patients with marked parkinsonian features, extensive NFT formation is noted in brain stem regions, including the periaqueductal gray matter, substantia nigra, and locus coeruleus. In such regions the NFT takes on a globoid appearance, reflecting the rounded shape of the soma, as opposed to the flame-shaped configuration taken by NFTs within pyramidal neurons (Fig. 15.4). Cases with particularly severe NFT formation may display such lesions in the dentate nucleus of the cerebellum (Fig. 15.5), inferior olivary nuclei, and even anterior horn cells in the spinal cord.

Immunohistochemical and electron microscopic studies have shown the NFTs encountered in patients with ALS/parkinsonism–dementia complex to be virtually identical to those encountered in cases of AD seen elsewhere in the world (Hirano *et al*., 1968; Hirano, 1973; Shankar *et al*., 1989). Ultrastructural studies have shown that while the NFTs of the Guam cases contain paired-helical filaments, they commonly also show additional straight filaments. NFTs react with antibodies directed against tau protein (Buée-Scherrer *et al*., 1995a,b), apolipoprotein E (Buée *et al*., 1996), lactotransferrin (Leveugle *et al*., 1994), β-amyloid peptide (Ito *et al*., 1991), and ubiquitin, all of which are constituents of NFTs in AD cases. Buée-Scherrer and co-workers (1995a,b) demonstrated that PHF-tau derived from cases of ALS/parkinsonism–dementia complex are abnormally phosphorylated and have biochemical and immunological properties that are identical to the PHF-tau of AD. Studies have shown that the PHF-tau associated with ALS/parkinsonism–dementia complex is phosphorylated at the identical amino acid residues as is the PHF-tau of AD (Mawal-Dewan *et al*., 1996).

We have shown (Hof *et al*., 1991; 1994b) that the pattern of neocortical involvement by NFTs in cases of ALS/parkinsonism–dementia complex differs significantly from what is seen in cases of Alzheimer's disease. In cases of ALS/parkinsonism–dementia complex, NFTs of the neocortex are situated most densely in layers II–III when compared to the extent of involvement in layer V (Fig. 15.6). This pattern of involvement differs distinctly from what is seen in cases of AD, where NFT formation is more severe in the infragranular layer (layer V), compared to more superficial aspects of the neocortex (layers II–III). The pattern of neocortical NFT formation demonstrated in cases of ALS/parkinsonism–dementia complex with layer

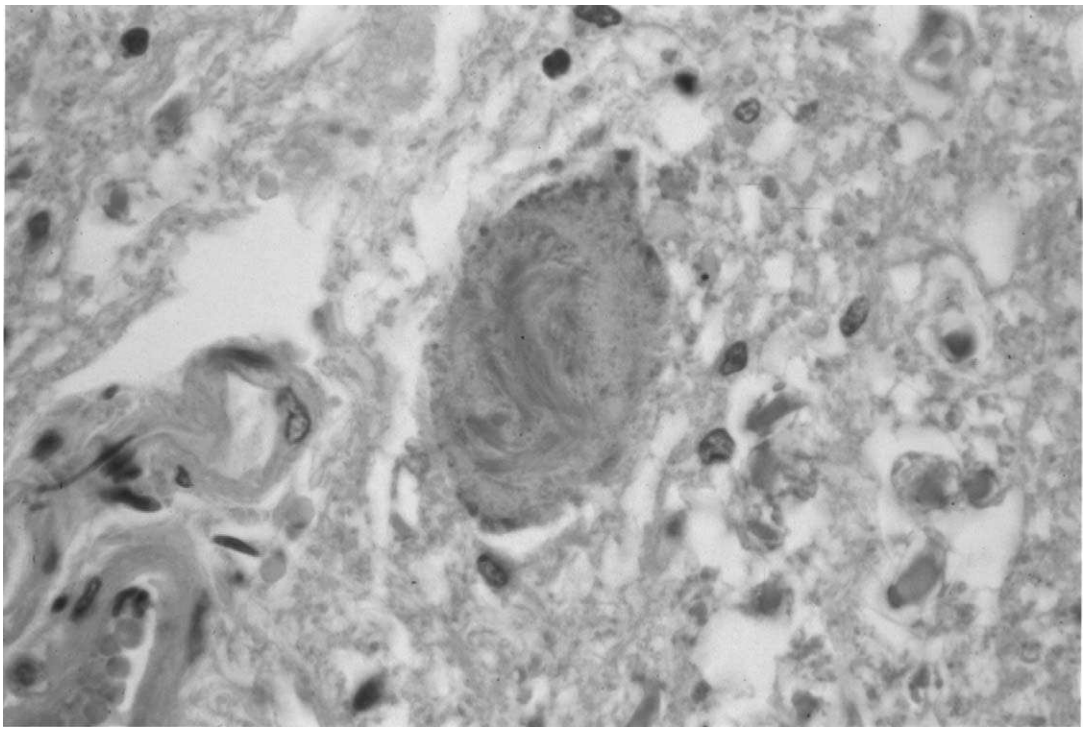

FIG. 15.4. Microscopic appearance of globoid neurofibrillary tangle in pigmented neuron of the substantia nigra, parkinsonism–dementia complex of Guam. (Hematoxylin and eosin stain.)

II–III predominance is also a characteristic feature of cases of postencephalitic parkinsonism (Hof *et al*., 1992b), posttraumatic dementia (dementia pugilistica) (Hof *et al*., 1992c), and progressive supranuclear palsy (Hof *et al*., 1992a). As in cases of AD, in ALS/parkinsonism–dementia complex those neurons containing the calcium-binding proteins calbindin, calretinin, and parvalbumin tend to be spared from involvement in NFT formation (Hof *et al*., 1994a).

FIG. 15.5. Microscopic appearance of neurofibrillary tangle in neuron of dentate nucleus of cerebellum, parkinsonism–dementia complex of Guam. (Modified Bielschowski stain.)

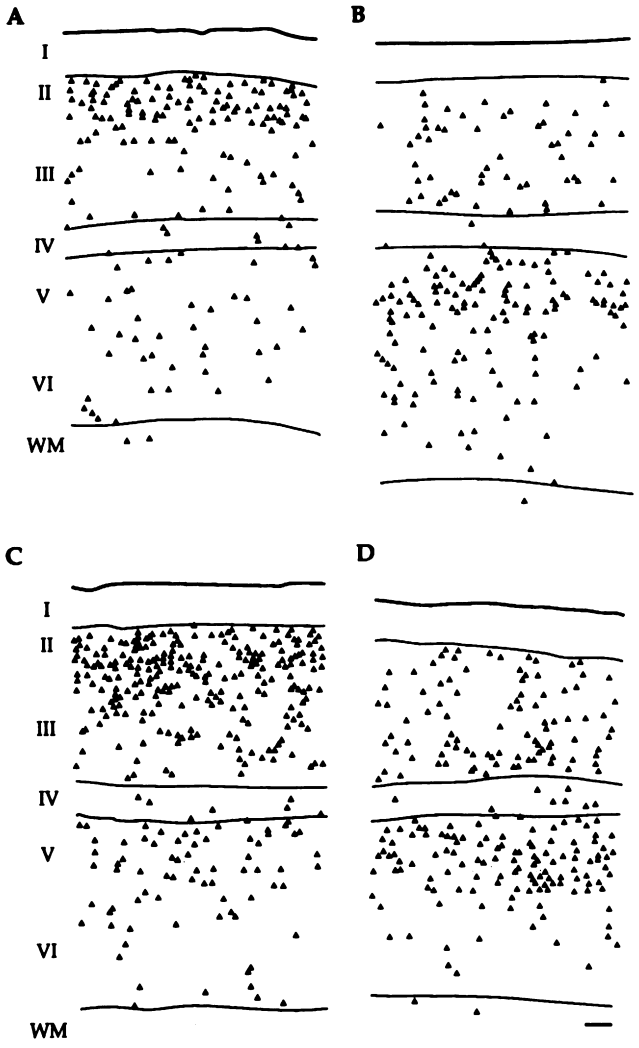

FIG. 15.6. Computer-generated maps of NFT distribution in a case of parkinsonism–dementia complex of Guam (A,C) and an Alzheimer's disease case (B,D). Maps A and B represent area 9 (prefrontal cortex) and maps C and D represent area 21 (mid-temporal gyrus). Note the difference in NFT (triangles) distribution within layers II–III and V–VI between the cases. Cortical layers are indicated by Roman numerals. Scale bar = 100 μm.

VIII. β-Amyloid Accumulation in ALS/Parkinsonism–Dementia Complex of Guam

In the classic neuropathologic descriptions of ALS and parkinsonism–dementia complex, Malamud and Hirano specifically noted that despite the presence of large numbers of NFTs, there was a distinct lack of senile plaque formation. Indeed, they noted "there is no senile plaque formation, although occasionally there are a few faintly argyrophylic coagulated structures, resembling early senile plaques" (Hirano *et al*., 1961b) and "another interesting feature was the presence of senile plaques in the hippocampus in 3 of the 22 cases [of Guam ALS], but even in these cases only 2 or 3 plaques were observed per slide" (Malamud *et al*., 1961). Guam cases that had been considered by classic neuropathologic staining techniques to be senile plaque free were studied by immunohistochemistry and remained negative for evidence of parenchymal amyloid accumulation, despite the use of formic acid pretreatment (Gentleman *et al*., 1991). However, about 20% of more recently autopsied cases indicated the presence of some degree of parenchymal amyloid accumulations. These deposits are mostly in the form of diffuse plaques and typically lack accompanying dystrophic neuritic changes. While it is true that neuritic plaques may be encountered in some cases of ALS/parkinsonism–dementia complex of Guam, in such cases the density of plaques seen is typically small. These cases should not be interpreted as representing examples of Alzheimer's disease among the native Chamorro population as the pattern of neocortical and brain stem NFT formation follows that of the Guam disorder and not AD.

In our experience, amyloid deposition in association with cerebral blood vessels is also extremely uncommon in Guamanian brain specimens. When it is present, these vascular deposits are generally quite scanty. The explanation for this observation remains unclear. Studies of cases of ALS/parkinsonism–dementia complex have failed to show evidence of mutations in exons 16 and 17 of the amyloid precursor protein (sites that have previously been associated with cases of familial AD) (Chartier-Harlin *et al*., 1993) or of tau (Pérez-Tur *et al*., 1999). Studies of 12 cases of ALS/parkinsonism–dementia complex showed an $\epsilon 3$ allele frequency of 91.7%, as opposed to 79.2% for 12 Guamanian controls (Waring *et al*., 1994). Only one patient and one control had an $\epsilon 3/\epsilon 4$ genotype and these represented the only $\epsilon 4$ isoforms identified in this study. Comparable data were obtained in another study (Buée *et al*., 1996). Although these data are scant, this study suggests that the apolipoprotein E phenotype does not represent a significant predisposing factor in the development of neurodegenerative disease among the at-risk Chamorro population, nor does it explain the distinct absence of cerebral amyloid deposits.

IX. Hirano Bodies (Eosinophilic Rod-like Inclusions)

In Hirano's original descriptions of the neuropathologic features of ALS/parkinsonism–dementia complex, he noted the presence of numerous eosinophilic rod-like inclusion bodies in the CA1 region of the hippocampus (Fig. 15.7). These prominent inclusions, encountered immediately adjacent to the pyramidal neurons, had apparently not been described previously and were initially considered to be unique and specific for the Guam disease. Subsequently, Hirano noted the presence of identical inclusions in the hippocampus of cases of AD, Pick's disease, and Creutzfeldt–Jakob disease. When seen in these settings, the number of such inclusions is typically less than is usually encountered in Guam cases. Rare examples of the rod-like inclusions may also be encountered in the brains of elderly nondemented controls elsewhere in the world (Gibson and Tomlinson, 1977; Hirano, 1994).

It appears that over the decades countless neuropathologists had examined the brains of numerous cases of AD but had failed to recognize these rather prominent inclusion bodies, although it must be noted that in most cases they are present in

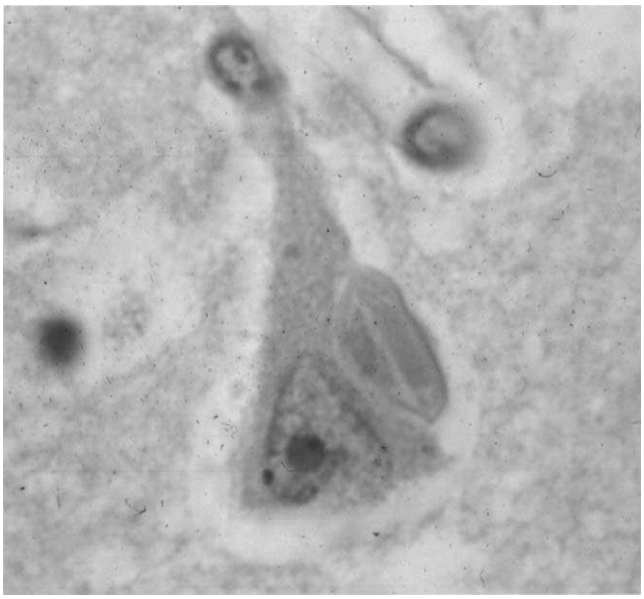

FIG. 15.7. Microscopic appearance of eosinophilic rod-like inclusion (Hirano body), hippocampus, parkinsonism–dementia complex of Guam. (Hematoxylin and eosin stain.)

relatively small numbers. However, when Hirano was presented with numerous examples of such inclusions in the specimens examined on Guam, they were readily noted and subsequently began to be characterized. Using their high density in Guam-derived cases, Hirano described the ultrastructural appearance of these eosinophilic rod-like inclusions, demonstrating their unique ''herring bone.'' Using immunohistochemical approaches, it has subsequently been shown that they contain actin and actin-associated proteins, tau (Goldman, 1983; Galloway *et al*., 1987a,b), and the middle molecular weight neurofilament protein (Schmidt *et al*., 1989b). These eosinophilic rod-like inclusions are now referred to by most neuropathologists as ''Hirano bodies'' in honor of his contributions in first characterizing this lesion. The recognition of the Hirano body in cases of Guam ALS/parkinsonism–dementia complex represents an example of how, through the presence of such a high density of lesions in such cases, important insights have been gained in our understanding of AD, and its related conditions.

X. Granulovacuolar Degeneration

Granulovacuolar degeneration is a poorly understood alteration encountered in the hippocampus of cases of AD. It consists of multiple vacuoles, each with a single internal deeply basophilic granule, which are located in the perikaryal cytoplasm of pyramidal neurons in the boundary zone of the CA1 and CA2 regions of the hippocampus. They are seen in small numbers in the elderly in association with normal cognitive function and, when present in relatively large numbers, especially in the posterior portion of the hippocampus, correlate highly with a diagnosis of AD (Tomlinson and Kitchener, 1972; Ball and Lo, 1977). Granulovacuolar degeneration may be extremely prominent in the hippocampus of cases of ALS/parkinsonism–dementia complex. In affected cases, one sees large numbers of involved neurons, and although there are no specific quantitative data, within each involved neuron the number of vacuoles present appears more numerous and the size of the individual granules appears larger. Hirano again took advantage of the extent of involvement by granulovacuolar degeneration to use Guamanian tissues to demonstrate for the first time the ultrastructural appearance of this lesion (Hirano *et al*., 1968).

XI. Other Features

In cases associated with prominent parkinsonian clinical manifestations, the degree of cell loss in the substantia nigra and locus ceruleus can be almost complete. This is accompanied by evidence of incontinent neuromelanin pigment as well as examples of phagocytosed neuromelanin granules by local macrophages and a significant astrocytic gliosis. The few remaining pigmented neurons will typically contain globoid forms of NFTs. The degree of nigral degeneration can be so severe in end-stage cases with prolonged survival that it may be difficult to identify any remaining intact neurons. In general, Lewy bodies are not encountered in cases of parkinsonism–dementia complex. However, in a large retrospective study, approximately 10% of Guam parkinsonism cases did show evidence of Lewy body formation in either the substantia nigra or the locus coeruleus. Our experience in examining many Guamanian cases is quite similar. However, it should be noted that when Lewy bodies are identified in the Guam cases, they are usually few in number and other pigmented neurons will always show evidence of the classic globoid NFTs. In the Guam cases with Lewy bodies, these inclusions are immunoreactive to ubiquitin and α-synuclein. Despite complete autopsy examination of virtually all patients from Guam who had suffered from parkinsonian symptoms over a period of over 40 years, examples of Lewy body Parkinson's disease are extremely rare. Indeed, the author is aware of only a single such case being documented at autopsy in a Chamorro native from Guam. The explanation for this absence of what is a relatively common disorder elsewhere in the world remains unknown.

Neuropil threads, a prominent feature of AD are relatively sparse in cases of ALS/parkinsonism–dementia complex (Wakayama *et al*., 1993). However, similar thread-like structures have been reported in the white matter of the spinal cord, especially in patients who exhibit more prominent amyotrophic features (Umahara *et al*., 1994).

Using antibodies raised against the protein core of heparin sulfate proteoglycans, severe morphologic abnormalities of the cerebral microvasculature were noted in brain specimens of parkinsonism–dementia complex patients (Buée *et al*., 1994). The distribution of these vascular lesions suggested that there is an association between microvascular abnormalities and a high density of NFT formation. Similar lesions have been seen in cases of AD, where they were thought to be related to sites of vascular and/or parenchymal β-amyloid deposition. The Guam cases, with their typical absence of amyloid deposition,

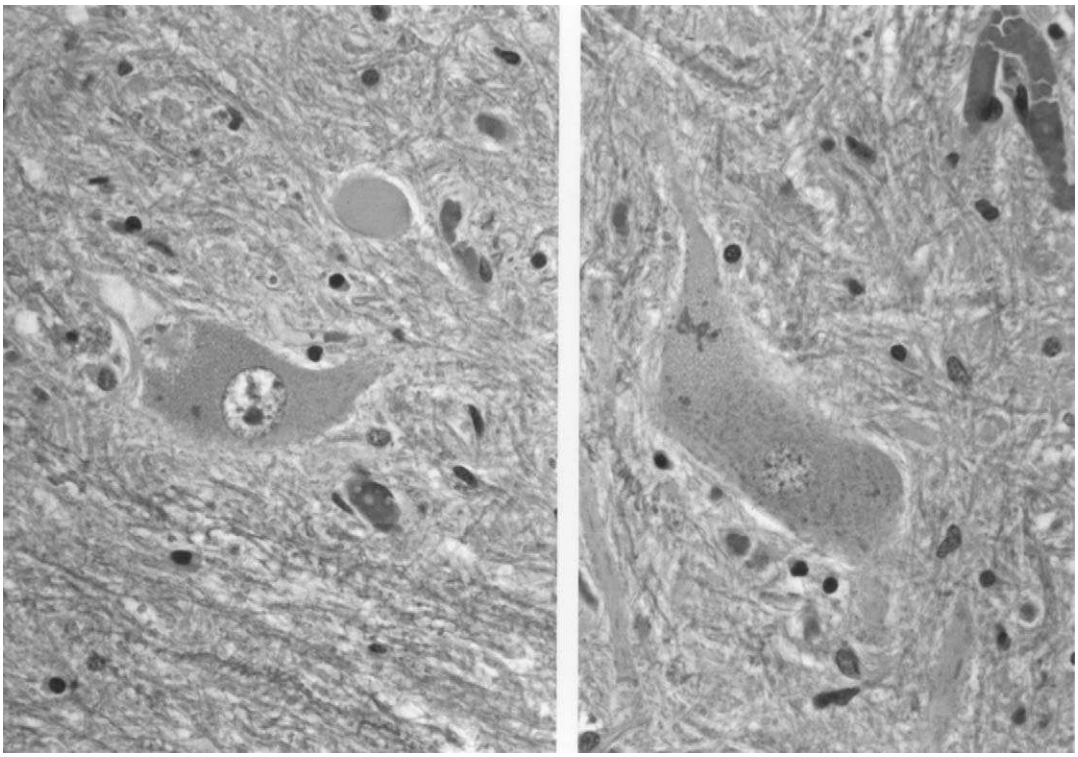

FIG. 15.8. Microscopic appearance of eosinophilic cytoplasmic inclusions (Bunina bodies), anterior horn cells, amyotrophic lateral sclerosis of Guam. (Hematoxylin and eosin stain.)

provided an opportunity to demonstrate that amyloid deposition was not required for the formation of these vascular abnormalities.

In cases of Guamanian ALS there is typically a prominent loss of anterior horn cells. The remaining anterior horn cells may be shrunken, often with pyknotic nuclei, or else swollen with perikaryal skein-like accumulations of ubiquitinated phosphorylated neurofilaments. As in classic ALS, the intervening anterior horn cells may also have a normal histologic appearance. In many Guam patients the remaining anterior horn cells may display small eosinophilic inclusions in their cytoplasm, which were first described by Bunina (1962) (Fig. 15.8). These are frequently referred to as "Bunina bodies." Similar to cases of sporadic ALS seen elsewhere in the world (Mourelatos *et al*., 1990), Guam ALS cases show fragmentation of the Golgi apparatus (Mourelatos *et al*., 1994). Upper motor neuron involvement is virtually always present in the Guam cases and results in prominent myelin loss in both lateral and anterior corticospinal tracts (Fig. 15.9). In contrast to many cases of familial ALS (Hirano *et al*., 1967a), the posterior columns of the cases of Guam ALS remain intact.

XII. Neuropathologic Studies of Neurologically Intact Guamanian Chamorros

In 1979, Anderson and co-workers reported the results of a study in which they sought to examine neuropathologically a number of Guamanian Chamorros who had died and come to autopsy but during life were considered to be free of evidence of neurologic dysfunction. The study included a total of 69 individuals, and their premortem clinical status was based on a review of available clinical records and, when possible, interviews with surviving relatives. This study revealed that 29% of those who died between the ages of 30 and 40 years and 40% of those dying between 40 and 50 years showed significant numbers of NFTs in the hippocampus and neocortex. The authors presumed those Guamanians who showed evidence of premature NFT formation were in a preclinical stage of ALS/parkinsonism–dementia complex but had not accumulated a sufficient burden of lesions for symptoms to be detected clinically. Because, at the time, ALS/parkinsonism–dementia complex was responsible for 10–20% of adult deaths and because it is likely that the disease takes many years to develop fully, the finding of relatively large numbers of individuals in the early stages of the disorder is not unexpected. Nevertheless, the extent of the problem that this study uncovered is striking. Using a similar strategy, Chen (1981) reported similar data by examining asymptomatic cases seen in the Guam medical examiner's office.

Studies of this type suggest that the brain has a considerable capacity to compensate for the accumulation of significant numbers of NFTs without the patient demonstrating overt symptomatology. Indeed, the Anderson study is remarkable, as some of the patients showed a striking density of NFTs, yet appeared to be free of discernible functional impairment. However, it should be recognized that the subjects reported in this study had not undergone detailed neurologic or

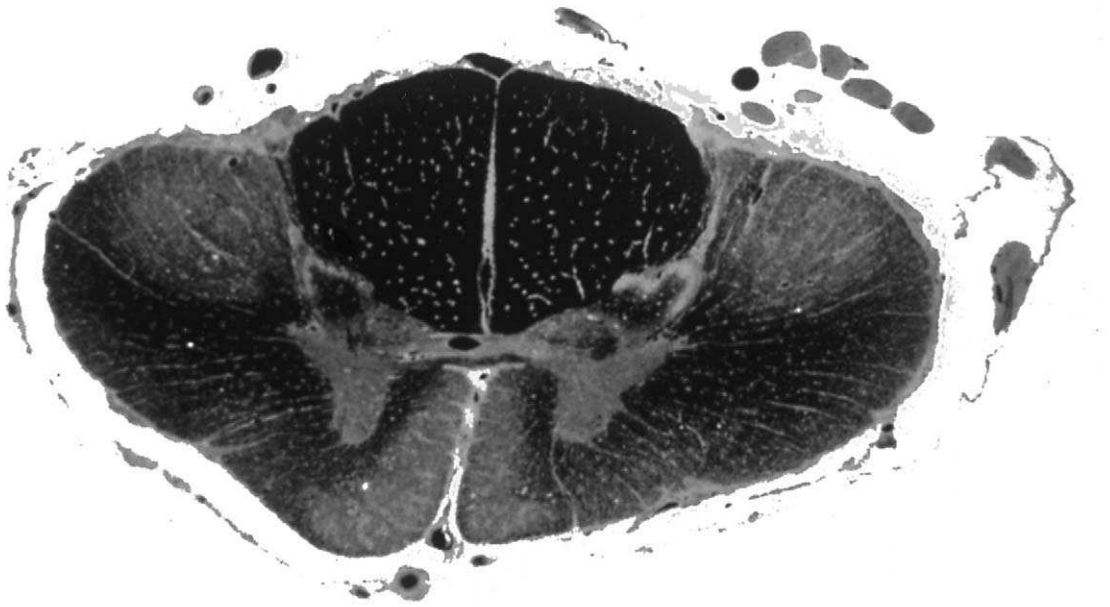

FIG. 15.9. Microscopic appearance of spinal cord showing prominent demyelination of lateral and anterior corticospinal tracts, amyotrophic lateral sclerosis of Guam. (Myelin stain.)

neuropsychological evaluation, and deficits in functioning could have been overlooked by their treating physicians and family members.

Snow and colleagues (1990) reported an important study regarding the functional integrity of the striatonigral dopaminergic system among Guamanian Chamorros. They used positron emission tomography (PET) with ^{18}F-6-fluorodopa on Guamanian subjects with both ALS/parkinsonism–dementia complex and Guam controls. This technique allows visualization and quantification of the integrity of the dopaminergic input into the striatum in living patients. With this approach they were able to assess the relative extent of damage to the substantia nigral neurons on these subjects. Parkinsonism–dementia complex cases showed a profoundly decreased fluorodopa uptake consistent with postmortem studies. Interestingly, of the eight normal Chamorro controls, two demonstrated reduced fluorodopa uptake. The degree of impaired fluorodopa uptake in these two subjects was intermediate between what was found in the parkinsonism–dementia complex cases and that of normal controls from Vancouver, British Columbia. On neurologic examination, these two individuals showed no observable extrapyramidal features and were considered to be in a preclinical phase of parkinsonism–dementia complex. The authors of the study anticipated that these two subjects would, sometime in the future, develop overt parkinsonian symptoms. At present, no follow-up data are available to determine if that prediction came true.

Finally, we have performed a study that was similar to that performed by Anderson in which we evaluated brains of Guamanian Chamorros who had died and come to autopsy, yet were free of a diagnosis of ALS/parkinsonism–dementia complex. In our study we also noted a substantial number of relatively young individuals who showed evidence of widespread NFT formation. In some cases the extent of involvement was quite striking. The pattern of involvement by NFTs paralleled that encountered in diagnosed cases of ALS/parkinsonism–dementia complex, including predominant neocortical involvement in layers II–III as opposed to layer V. Furthermore, it was noted that the more severe the NFT involvement, the more closely the pattern of NFTs approached that of the diagnosed disorder. Accordingly, we concluded that such cases did indeed represent examples of an early phase of the disorder and that the extent of lesion formation had not been sufficient to attract clinical attention and diagnosis. These findings suggest that the extent of ALS/parkinsonism–dementia complex among the Chamorro population on Guam represents a more pervasive problem than have been recognized by clinical/epidemiologic survey conducted over the years.

XIII. Epidemiology

Extensive epidemiologic surveys of neurologic disease among the inhabitants of Guam and its neighboring islands have been conducted over the years since the initial studies of Kurland and Mulder in the 1950s. These studies established that the incidence of ALS on Guam was 50 to 100 times greater than is seen in the continental United States. A similarly high incidence of the disease has been noted in the next nearest island to Guam, Rota. Rota, a much smaller and

more isolated island, is populated by approximately 1500 Chamorros. For the period 1947–1953, the average annual incidence rate for Chamorros living on Guam per 100,000 population was twice as high for men when compared to women (85 and 40, respectively) with a mean age of onset of 44 years in both sexes. ALS accounted for approximately 10% of all deaths on the island, a figure that was 50 times greater than reported for the continental United States. Subsequent studies for the period 1945–1972 indicated a steady decline in the age-adjusted incidence rate for ALS on Guam. These data included rates for men of 67/100,000 population in 1950–1954 to 21/100,000 in 1970–1972 and of 43 and 12 for women. By 1980–1982, Garruto and co-workers (1985) found the age-adjusted incidence rates to be less than 5/100,000 for both men and women. A study (Waring, 1994) reviewing data from 1954 to 1989 showed that the median age of onset of ALS among Guamanian Chamorros increased from 48 years to 52 years in men and from 42 years to 52 years in women. Furthermore, comparing the annual age-adjusted incidence of ALS per 100,000 for 1950–1954 to 1985–1989, the rates for men decreased from 65 to 10 and for women from 30 to 4. The decrease for both sexes together was 47/100,000 population to 7.

In 1961, with the identification of parkinsonism–dementia complex of Guam as a distinct clinicopathologic entity, epidemiologic studies were also initiated for this condition. This disorder was initially considered to be a form of post-encephalitic parkinsonism, possibly related to prior exposure to Japanese B encephalitis. An outbreak of Japanese B encephalitis had occurred on Guam in 1947–1948, but none of the initially reported cases of parkinsonism–dementia complex had reported a prior history of this form of infection. In 1962, Lessel and colleagues reported a prevalence for parkinsonism–dementia complex of 118/100,000 with a mean age of onset of 50 years and a male/female ratio of 2.5:1. The average annual mortality rate for the condition was 28/100,000 with a median survival of 3.5 years. Based on door-to-door surveys, Reed *et al*. (1966) reported the average annual incidence per 100,000 population for parkinsonism–dementia complex to be 33 for men and 6 for women. Again, in 1985, Garruto *et al*. reported a significant decline in the age-adjusted incidence rates for men and women with parkinsonism–dementia complex. Based on these reports, it was widely reported that the neurodegenerative diseases on Guam were going away and that before long the unique opportunity to identify important etiologic clues, which might represent avenues for understanding comparable diseases elsewhere in the world, would be completely lost (Stone, 1993). In part, based on the concept that the disease had all but disappeared from the at-risk population, the NINCDS research station on Guam was closed.

Nevertheless, in 1990 a small group of committed scientists obtained ongoing funding from the National Institute on Aging to continue studies on Guam. From this began the current Micronesian Health Study Registry, directed by the late Dr. W. C. Wiederholt. Preliminary data from this registry (Wiederholt, 1999) indicate that parkinsonism–dementia complex is not disappearing and during 1980–1989 there was an average annual incidence of 20 cases/100,000 population. Of interest is that the age of onset of this disorder had increased to 59 years in both men and women.

XIV. Overlap between ALS and Parkinsonism–Dementia Complex of Guam: One Disorder or Two?

In the initial clinical and neuropathologic descriptions, ALS and parkinsonism–dementia complex of Guam were considered to be separate and distinct nosologic entities. This concept has been retained by virtually all subsequent epidemiologic studies. Despite this, there has been a substantial amount of clinical and neuropathologic evidence that demonstrates extensive overlap between the two forms of the disease. This evidence has suggested to us (Perl, 1994) that the two forms may simply be extremes of a relatively wide clinicopathologic spectrum within what is actually a single disease entity.

It is rare for cases of ALS of Guam to show evidence of parkinsonian signs on neurologic evaluation. In 1966, Elizan and colleagues reported that only 5 of 104 cases of Guam ALS subsequently developed a definite clinical picture of parkinsonism–dementia complex in the course of their disease. In an additional 5 patients, frank parkinsonian features were identified clinically, but these were seen in the absence of any notable cognitive decline. In an extensive retrospective review, Rogers-Johnson *et al*. (1986) reported that in patients diagnosed with ALS, minimal extrapyramidal features were seen in only 5% and dementia noted in only 4% of cases.

Despite these clinical observations, ^{18}F-6-fluorodopa PET scan studies of four patients with ALS of Guam (without clinical evidence of parkinsonism) showed evidence of decreased striatal fluorodopa uptake (Snow *et al*., 1990). The degree of fluorodopa uptake loss was intermediate between that seen in parkinsonism–dementia complex of Guam cases and normal control levels. Although the number of subjects studied was small, this study suggests that Guam cases of ALS can have a significant degree of substantia nigral cell loss and yet still be free of parkinsonian signs or symptoms.

Neuropathologic studies have provided perhaps the clearest evidence of involvement of the nigrostriatal system in cases of Guamanian ALS. In the initial neuropathologic description of the Guam form of ALS, Malamud *et al*. (1961) reported widespread evidence of NFT formation. In this and subsequent reports (Hirano, and Zimmerman, 1962; Hirano *et al*., 1967b), evidence of NFT formation in the substantia nigra, locus ceruleus, and other brain stem nuclei in cases of Guam ALS were clearly demonstrated. In their review of the neuropathologic features in 209 autopsies carried out on Guam ALS cases, Rogers-Johnson and colleagues (1986) identified depigmentation and neuronal loss in the substantia nigra in 63% of cases.

Despite the striking evidence of significant nigral pathology in a majority of Guam ALS cases, why is there so little clinical evidence of accompanying parkinsonian symptomatology in such patients? One possible explanation is that the patient with ALS has at least a partial degree of denervation of the voluntary musculature. If such a patient then loses the integrity of the nigrastriatal pathways, the parkinsonian features may be clinically masked because the musculature has been effectively denervated by the pathology in the motor system. In addition, it is clear that the striatonigral dopaminergic system has a considerable degree of reserve and that the extent of nigral cell loss may not reach a sufficient level to trigger overt

symptomatology. Nevertheless, it is clear from these neuropathologic studies that in cases of ALS from Guam the substantia nigra is affected in a majority of instances.

However, in many cases of parkinsonism–dementia complex, superimposed amyotrophy is observed clinically later in the course of the illness. This was first pointed out by Elizan *et al*. (1966), who reported that 38% of parkinsonism–dementia complex cases subsequently went on to develop clinical manifestations of ALS. Furthermore, 12 cases of what was thought to be ''pure'' parkinsonism–dementia complex, who were without muscular wasting, showed electromyographic evidence of lower motor neuron damage. In data reviewed by Rogers-Johnson *et al*. (1986) of patients with a diagnosis of parkinsonism–dementia complex, 34% had a positive Babinski sign and 32% showed fasciculations and/or muscular atrophy, again suggesting the presence of superimposed upper and lower motor neuron pathology.

In their first neuropathologic report of parkinsonism–dementia complex, Hirano and colleagues (1961b) described evidence of typical morphologic changes of ALS in the spinal cords of 17 of the 48 cases (38%). Rogers-Johnson's review revealed that of 113 autopsies carried out on parkinsonism–dementia complex cases (on whom spinal cord specimens were available for examination), 35% showed neuropathologic evidence of lateral column myelin loss and anterior horn cell degeneration. Unfortunately, in this retrospective review it is unclear if the presence of motor findings in the clinical presentation influenced whether a spinal cord specimen would be taken at autopsy. Nevertheless, the overall agreement of clinical and neuropathologic data would suggest that motor neuron pathology exists in a substantial proportion of cases of parkinsonism–dementia complex.

Based on these findings, it is clear that relatively few ''pure'' cases of either ALS or parkinsonism–dementia complex are actually encountered. Accordingly, we have argued that ALS/parkinsonism-dementia complex of Guam represents a spectrum of clinical manifestations of a single, broad neurodegenerative disorder. Whether an individual patient on Guam is diagnosed with ALS or parkinsonism–dementia complex will be determined by the nature of the earliest clinical signs and symptoms that presumably correlate with the neuroanatomic site of the initiation of the neurodegenerative process. If that process initiates in the motor system, then weakness and muscular atrophy will be noted and a diagnosis of ALS will be made. Alternatively, if the process begins in the substantia nigra, then rigidity and bradykinesia will be noted, warranting a diagnosis of parkinsonism–dementia complex. Finally, if the initial process involves the hippocampus and aspects of the neocortex, then dementia will be the presenting clinical feature. Presumably, as the disease progresses it goes on to involve these other neuroanatomic sites and introduces much of the overlapping symptomatology discussed earlier.

Of interest, Elizan and colleagues (1996) followed a number of cases presenting with dementia and noted that most evolved to develop extrapyramidal signs and symptoms in the course of their illness. Certainly from the perspective of the neuropathologist it is clear that the various clinical categories encountered on Guam reflect manifestations of widespread progressive neurodegenerative process variably affecting upper and lower motor neurons, nigrostriatal dopaminergic neurons, and neurons of the hippocampus and neocortex. What mediates the relative degree of involvement in the early stages of the disease remains unclear, but eventually all of these neuronal systems become involved to some degree. This, to us, suggests a unifying process and a single disorder leading to a wide spectrum of clinical manifestations. If this concept is correct, then this has important implications for nosologic considerations for the analogous age-related diseases seen elsewhere in the world.

XV. Other Foci of ALS/Parkinsonism–Dementia Complex

In addition to the focus of ALS/parkinsonism–dementia complex identified and studied extensively on Guam, there are two other similar foci of endemic neurodegenerative disease that have been identified. These sites are in the Kii peninsula of Japan and among the Auyu and Jakai people of the Irian Jaya region of southwestern New Guinea. Kinnosuke Miura, a pupil of Charcot, published the first clinical description of a case of ALS in Japan (Miura, 1902). He subsequently claimed that ALS was more common among the Japanese than was seen in Europe and that there was an unusually high incidence of the disease on the Kii peninsula, a remote area on the southern coast of the Japanese island of Honshu (Miura, 1911). Subsequent studies indicated that the high prevalence of ALS was confined to two isolated districts in the Kii peninsula, namely Kozagawa and Hobara (Shiraki and Yase, 1975, 1991). Surveys indicated the annual incidence of ALS was 15 cases per 100,000 population in Kozagawa and 55 cases per 100,000 in Hobara.

Neuropathologic studies of ALS cases from the Kii peninsula have been reported by Shiraki and Yase (1975, 1991) and reveal a pattern of neuropathologic changes that is virtually identical to that seen on Guam. The changes documented in their studies have included widespread NFT formation in a pattern that parallels closely what is seen in the Guam cases. Since the 1980s, the number of cases of ALS encountered in Kozagawa and Hobara has diminished dramatically, similar to what has occurred on Guam. Until recently, documented cases of parkinsonism–dementia complex from the Kii peninsula had not been reported. However, Kuzuhara (1999) has now reported that such cases identified clinically and at autopsy show neuropathologic features that are virtually identical to those encountered on Guam.

The New Guinea focus was first identified by Gajdusek (1963), who briefly described a high incidence of ALS based on brief clinical observations while passing through this extremely remote and primitive region. He subsequently returned to the area and surveyed the population more thoroughly for neurologic disease (Gajdusek and Salazar, 1980). Based on his studies, he reported an average annual incidence of ALS for the period 1974–1980 of 147 per 100,000 (almost 150 times greater than what is seen in the continental United States). In his survey, the incidence of parkinsonism, both with and without dementia, was 79 per 100,000 population. The mean age of onset in the population for ALS and parkinsonism was 33 and 43 years, respectively, both significantly younger than is seen on Guam. Unfortunately, although the clinical features of

these patients appear quite similar to the disorder seen on Guam, no neuropathologic studies have ever been carried out on these cases, which reside in an extremely inaccessible region.

XVI. Etiologic Concepts

Investigation into the epidemic of neurodegenerative diseases among the Chamorro population of Guam has, from the earliest observations of Dr. Zimmerman, offered the promise that a better understanding of the underlying etiologic factors responsible for this high-risk focus would provide important insights regarding the three analogous disorders seen elsewhere in the world: ALS, Parkinson's disease, and Alzheimer's disease. From the earliest days, it was assumed that the high incidence of ALS on Guam reflected a genetic abnormality that had become magnified in an inbred, island-bound population. However, numerous studies have shown repeatedly that if genetic factors are present, and they most certainly are, they are not etiologic in nature and likely represent modifying factors influencing the individual's relative susceptibility to an as yet unidentified environmental etiologic agent (or agents). There are many reasons for this statement.

First, and foremost, is the appearance of cases of ALS and parkinsonism–dementia complex among Filipino migrants to Guam with long-term residence on the island. Since the 1950s to the present time there has been a sizable migration of individuals born and raised in the Philippines who have moved permanently to Guam. These immigrants have been mostly male, in search of stable employment, and they now make up a community of approximately 20,000 stable residents on Guam. Many have married native Chamorro women and have adopted, more or less, a Guamanian way of life. Among this Filipino migrant community, a substantial number of cases of ALS have been documented. Reed and Brody (1975) first noted such cases. Subsequently, Garruto *et al*. (1981) clinically documented nine cases of ALS and two with parkinsonism–dementia complex. Virtually all were Filipino men who moved to Guam in the late 1940s and early 1950s. Except for three cases of ALS that had developed within 3 years of arrival on Guam, the onset of disease was at least 13 years after moving to the island. In a small number of autopsies performed on ALS cases among the Filipino migrants, NFTs were documented in brain specimens in 50% of cases. The extent of NFT involvement was not as dramatically widespread as is typically encountered in the native Chamorro cases, but this finding clearly separates them from sporadic ALS, as seen elsewhere in the world, as NFTs are not a prominent neuropathologic feature of ALS, especially among relatively young patients.

Additional cases of ALS continue to be identified among the Filipino migrant community living on Guam. Neuropathologic examinations of these cases show motor neuron degeneration accompanied by widespread NFTs, ensuring that they are not merely incidental cases of sporadic ALS among this population. Importantly, the appearance of cases of parkinsonism–dementia complex among the Filipino migrant population further reinforces the concept that long-term residence on the island underlies the cause of the outbreak of neurodegenerative disease. ALS is a disorder that has been seen throughout the world, yet parkinsonism–dementia complex remains confined to the three foci of the Western Pacific discussed earlier. As mentioned previously, Garruto *et al*. (1981) reported the occurrence of a single case of parkinsonism–dementia complex in a Filipino migrant to Guam; however, this diagnosis was made on clinical grounds and no autopsy was performed on this individual.

We have had the opportunity to examine the brains of two patients with parkinsonism accompanied by dementia that occurred in Filipino migrants following more than 25 years of residence on Guam (Purohit *et al*., 1992). Both cases showed the characteristic neuropathologic features of parkinsonism–dementia complex and were virtually identical to what we commonly encounter in native Chamorro cases. In both, there was widespread, rather severe NFT formation in the hippocampus, entorhinal cortex, and neocortex in the absence of parenchymal amyloid deposition. NFTs were predominant in the superficial cortical layers. There was a severe loss of pigmented neurons in the substantia nigra and locus coeruleus with globoid forms of NFTs being seen in several remaining neurons in these nuclei. Lewy bodies were not encountered in either the pigmented neurons or the neocortex. An additional autopsy-confirmed case of parkinsonism–dementia complex occurring in a Filipino migrant to Guam was reported by Chen *et al*. (1982). These three autopsy-proven cases represent important evidence that ALS/parkinsonism–dementia complex is not a disorder that is unique to the Chamorro population, but may also be seen in Filipinos who have lived on Guam for many years. Unless there is a hitherto unrecognized focus of ALS/parkinsonism–dementia complex in the Philippine islands, then these findings strongly support the concept that long-term exposure to a putative environmental agent on Guam is responsible for the epidemic.

XVII. Genetic Factors

Over the years, researchers have considered a number of environmentally based agents as the possible etiologic cause of the high-risk foci of neurodegenerative disease in the Western Pacific. Nevertheless, a number of genetic factors have been investigated, not so much as sources of the etiology of the disease, but as potential modifying constituents that may alter relative susceptibility to develop the disease. For example, with the discovery of cases of familial ALS elsewhere in the world related to mutations in the Cu/Zn superoxide dismutase gene, this locus was investigated by Figlewicz *et al*. (1994) in ALS/parkinsonism–dementia complex families on Guam. In this setting, they reported no evidence of gene mutations in the Cu/Zn superoxide dismutase gene. Chen *et al*. (2000) reported a higher frequency of G to C mutations in exon 9 of the CYP2D6 gene in Chamorros and Filipinos living on Guam and in San Diego, California, when compared to Caucasians living in the same areas. However, they found an equivalent mutant allele frequency among both parkinsonism–dementia complex patients and healthy Chamorros. As mentioned previously, studies of the amyloid precursor protein for mutations related to familial AD among ALS/parkinsonism–dementia complex patients revealed negative results (Chartier-Harlin *et al*., 1993), as did surveys of the tau gene (Pérez-Tur *et al*., 1999). In summary, to date, despite searching for clues among the most

reasonable candidate genes, no identifiable genetic abnormality appears to segregate with neurodegenerative disease among the Guamanian Chamorro population.

XVIII. Migration Studies of Chamorros

Studies of potential environmental etiologies must take into consideration the likelihood of a considerable period of latency between initial exposure to such an agent and the eventual onset of neurodegenerative disease. Following the granting of full American citizenship to inhabitants of Guam in 1950, they were allowed to travel freely and resettle anywhere they wished in the continental United States. This newly gained freedom prompted an extensive outmigration of Guamanian Chamorros to selected locations along the West Coast. For example, significant communities of island-born Guamanians developed and continue to thrive in Chula Vista, San Jose, and Oakland, California, as well as Bremerton, Washington. In 1957, a survey of 165 adult Guamanians who had migrated to California revealed two patients with ALS, a rate that was equal to that which was then present on Guam (Torres *et al*., 1957). Those involved in the study also learned of five additional cases of ALS among this migrant population who had died prior to the initiation of the survey. In 1966–1967, a follow-up study by Eldridge *et al*. (1969) found that of 321 Guamanians over age 40 who were then living in California, two patients were suffering from ALS and two had parkinsonism–dementia complex. Finally, Garruto *et al*. (1980) conducted perhaps the broadest survey by attempting to identify all Guamanians who had migrated from the island and eventually developed ALS. They identified a total of 28 cases (some of whom were included in the two prior published surveys). There were 21 cases who had developed ALS while living in the continental United States, 3 cases who initiated in other countries (Japan, Germany, and Korea), and 4 who became ill following a return to Guam but only after long-term residence on the United States mainland. Ten of these cases had undergone autopsy studies with confirmatory neuropathologic findings indicative of the Marianas form of the disease (the finding of superimposed NFT formation). In this study, the mean age at migration from Guam was 29.4 years (range: 18 to 63 years) with an average number of years living off Guam prior to the onset of disease of 13.6 years (range: 1 to 34 years). The mean age of onset was 48.8 years, which, at that time, was 4 years younger than was seen among Chamorros who had never left Guam. Some of these cases developed following more than 20 or more years of migrating from Guam.

Using these data, Garruto and Yanagihara (1991) estimated that ALS mortality rates for Chamorros living on Guam were three times greater than for Chamorros who had migrated to the West Coast, suggesting that outmigration had significantly lowered their subsequent risk of developing the disease. Nevertheless, Chamorros living off Guam retained a 5- to 10-fold increase of developing ALS when compared to the non-Guamanian population of the United States. In addition, Guamanians migrating to the continental United States are at risk of developing parkinsonism–dementia complex, a disease that has no direct counterpart in other populations. A review of all of the migration data suggests that the enhanced risk of developing ALS/parkinsonism–dementia complex is attained within the first 18 years of life and then may be retained for many decades (perhaps even lifelong). Inherent in such considerations is the concept that whatever putative environmental agent is responsible for the development of ALS/parkinsonism–dementia complex is present on Guam but is not available to the Guamanian "diaspora." This assumption may be correct. People tend to bring with them many aspects of their culture, native foods, festivals, and so on, and this may represent opportunities for further exposure to potential environmental agents among an outmigrated community. The Guamanians have a strong attachment to their island culture, and items such as diet have accompanied them in their travels and continue to be enjoyed whenever available. Further, with the ready availability of air travel, return trips to Guam are common among this migrant community.

XIX. Environmental Agents

A. Infectious Organisms

It was the identification of parkinsonism–dementia complex that gave rise to serious consideration that the nature of the outbreak of neurodegenerative disease on Guam might be post infectious in nature. This aspect of the disorder suggested similarities to postencephalitic parkinsonism patients who had survived the epidemic of encephalitis lethargica in the early part of the 20th century. Postencephalitic parkinsonism typically displays a period of latency between the initial episode of encephalitis to the onset of parkinsonian symptoms, which may last as long as a decade or more (6 months to a year is more typical) (Yahr, 1968). Clinically, patients with postencephalitic parkinsonism may have all of the signs and symptoms of idiopathic Parkinson's disease and also demonstrate oculogyric crises. Clinical studies of Guamanian cases of parkinsonism–dementia complex failed to demonstrate oculogyric crises (Elizan *et al*., 1966), although the significance of this negative finding remains unclear. Neuropathologic features of postencephalitic parkinsonism include many encountered in parkinsonism–dementia complex of Guam. These include the finding of NFTs in remaining neurons of the substantia nigra, in the absence of Lewy bodies, and the finding of neocortical NFTs predominating in superficial layers (layer II–III) (Hof *et al*., 1992b).

Despite these similarities, studies of both serum and postmortem brain tissues have failed to show any consistent evidence of a preceding central nervous system infection. Archival death certificates dating from the beginning of the 20 century failed to document any major outbreaks of encephalitis in the community, and interviews with knowledgable elders in the community failed to provide anecdotal accounts of any notable episodes of encephalitis on Guam. Relatively restricted outbreaks of Japanese B encephalitis and mumps did occur on Guam in December 1947 and in April 1948, but subsequent interviews with patients suffering from ALS/parkinsonism–dementia complex and their families have failed to confirm a prior history of encephalitis in such cases.

It should be kept in mind that Guam represents the southernmost island of a small archipelago and one of four

inhabited islands (Guam, Rota, Tinian, and Saipan) that are in very close proximity. Commerce and other traffic among these four islands have always been extensive, as they are within direct visual sighting of each other, which would likely provide a ready means for potential access of any infectious disease-carrying vectors. The two neighboring islands of Guam and Rota have continued to show a high incidence of ALS/parkinsonism–dementia complex among their inhabitants. This is in sharp distinction to the populations living on Tinian and Saipan where repeated clinical surveys have failed to identify any significant number of cases. It is highly unlikely that a classic infectious agent could remain restricted to the two southernmost islands and not extend to the other two islands.

The possibility that Guam ALS/parkinsonism–dementia complex represents an example of a prion-related disease has also been considered. In the laboratories of Gibbs and Gajdusek (1982), numerous attempts were made to transmit neurodegenerative disease through the intracerebral inoculation of Guam-derived brain tissues into nonhuman primates and other susceptible species. All such attempts were negative, including other efforts to recover a transmissible agent through the inoculation of tissue culture. In the face of this extensive amount of negative evidence, it is difficult to consider further a possible infectious etiology for the outbreak.

XX. Cycad

Over the years, an important candidate for the etiology of ALS/parkinsonism–dementia complex of Guam has been exogenous neurotoxins in the seed of the false sago palm, *Cycas circinalis*. In 1964, Marjory Whiting first identified the cycad seed as a potential cause of the outbreak. The cycad tree is an indigenous plant of Guam and its fleshy seed has traditionally served as a food source for the Chamorros. The natives dry the seeds and then grind them into a flour, which is used to prepare tortillas, porridge, and doughnuts and to thicken soups. However, the raw seeds contain a potent hepatotoxin, making them rapidly fatal unless washed thoroughly before eating. The seeds must be soaked in many changes of water over a period of a week or more before they may be eaten safely. Whiting proposed that an additional neurotoxin might be present in the seeds and be responsible for the onset of neurodegenerative disease. This gave rise to a detailed search for putative neurotoxins in the plant. The results of these extensive toxicologic studies were published in a series of six cycad conferences, which were held under the auspices of the NIH (Proceedings of the Third Conference on the Toxicity of Cycads, 1964; Whiting, 1988). The detailed reports of these conferences provide extensive documentation on the numerous studies that were carried out in which a wide range of animals (including nonhuman primates) were exposed to high doses of either raw cycad seeds or their purified constituents.

An important finding of these toxicologic studies was the identification of cycasin (methylmethoxymethanol), a very potent alkylating agent present within the cycad seed. Cycasin comprises 2–4% by weight of the seed and metabolizes to methylmethoxymethanol, a potent carcinogen. Indeed, cycasin represents one of the strongest naturally occurring carcinogens, and many of the cycad-exposed animals eventually developed a wide variety of cancers involving the lungs, kidneys, and liver. Importantly, despite the high doses being used and the wide range of animals that were exposed, little, if any, evidence of neurotoxicity was demonstrated in these experiments. Based on this entirely negative evidence, despite a major research effort, support for the cycad hypothesis as the etiology of the Guam outbreak of neurodegeneration waned.

In 1987, Spencer and colleagues reported producing extrapyramidal dysfunction and motor weakness in cynomologus monkeys fed large oral doses of an ''unusual'' amino acid present in small amounts in the cycad seed, namely β-*N*-methyl-amino-L-alanine (BMAA). BMAA shares chemical similarities with β-*N*-oxalylamino-L-alanine (BOAA), which had been implicated in neural lathyrism, a disease characterized by nonprogressive spastic paraparesis. For up to 13 weeks, each monkey was fed a large daily dose of BMAA via gastric gavage. The BMAA was chemically synthesized by a laboratory chemist and was not derived from the natural source. The animals were reported to develop muscular weakness, masked facies, and a loss of aggressiveness, and the authors suggested their similarity to ALS/parkinsonism–dementia complex in humans. The appropriateness of these conclusions has been questioned on a number of grounds. The doses of BMAA were extremely high (100–300 mg BMAA/kg body weight/day). Duncan *et al*. (1990) reported that BMAA is present in very small concentrations in raw cycad seed (0.1% or less, by weight) and is removed readily by even brief washing. Indeed, they estimated that an adult human would have to ingest approximately 7 kg of unwashed raw seed per day to receive a dose that was comparable to that given to the exposed animals. Because raw cycad seeds are highly toxic to humans and must be washed repeatedly before it may be eaten safely, most of the BMAA would have been removed. Accordingly, a comparable dose of washed cycad seeds would require ingestion of approximately 70 kg of cycad flour per day. Additional studies have questioned whether BMAA crosses the blood–brain barrier (Duncan *et al*., 1990).

Importantly, despite reporting motor weakness, evidence of actual motor neuron loss was not demonstrated in any of the BMAA-exposed monkeys. Furthermore, neither a striatal dopaminergic deficit (indicative of nigral degeneration), nor denervation atrophy (suggesting anterior horn cell pathology) was documented in the exposed animals and it remains unclear why these monkeys displayed any of their neurologic signs. Currently, the role of cycad-containing foods in the outbreak of neurodegeneration on Guam remains unsubstantiated. With regard to BMAA, Spencer and colleagues (1993) have subsequently written that ''the changes [induced in monkeys fed synthetic BMAA] fall short of a model of the human disease.''

XXI. Toxic Metals

In 1972, Yase first suggested the possibility that the neurodegeneration seen on Guam and the Kii peninsula might be related to an abnormal accumulation of potentially neurotoxic metals. He noted that manganese was present in significant amounts in the soils of Guam and the Kii peninsula.

He also observed high levels of aluminum in the soils of both sites. Manganese poisoning is well documented to produce a parkinsonian syndrome; however, it is marked pathologically by degeneration of the striatum with sparing of the substantia nigra, pars compacta (Olanow *et al*., 1994). Aluminum, however, had been experimentally linked to neurofibrillary degeneration through the induction of tangle-like lesions in rabbits following direct exposure to aluminum-containing compounds (Klatzo *et al*., 1965; Terry and Peña, 1965).

In 1980, using the techniques of electron probe microanalysis, Perl and Brody first demonstrated evidence of aluminum accumulation in the neurofibrillary tangle-bearing neurons of AD. Subsequently, using a similar approach, Perl and colleagues showed evidence of dramatic aluminum accumulation in the tangle-bearing neurons of patients with ALS and parkinsonism–dementia complex of Guam. Additional studies indicated that the concentration of aluminum in the tangle-bearing neurons of the Guam cases was approximately 10 times greater than that of AD cases (Good and Perl, 1994). Although the association of aluminum and AD remains controversial, the finding of excess aluminum in the tangles encountered in the Guam cases has now been confirmed using five different physical methods in a number of different laboratories (Garruto *et al*., 1984; Linton *et al*., 1987; Piccardo *et al*., 1988; Good and Perl, 1993).

To date, the environmental source of these dramatic intraneuronal accumulations of aluminum remains unclear. It has been hypothesized that a deficiency in environmental sources of calcium and magnesium, physiologically essential ionic constituents, presumeably related to underlying trace elemental abnormalities of soil and water, could lead to increased aluminum uptake as an alternative dietary source of cations. However, search for evidence of calcium deficiency among Guamanians has not revealed consistent alterations (Steele *et al*., 1990; Ashkog *et al*., 1994), and other alternative explanations must be sought. Guam is partially a volcanic island with an aluminum-rich bauxite soil. The soils of Guam contain soils with 42 times the amount of elutable aluminum when compared to two other bauxite islands, namely Jamaica and Palau (McLachlan *et al*., 1989). This later study suggests that Guam soil may contain a great deal more bioavailable aluminum when compared to other volcanic islands. The extent and nature of these differences and their potential biologic significance remain unclear and largely unstudied to date.

More recent studies using laser microprobe lass analysis demonstrated that the NFTs of Guam cases contained accumulations of iron, as well as aluminum, a finding that parallels that obtained using this technique with cases of AD. Iron and aluminum excess has also been detected in the neuromelanin granules and Lewy bodies of cases of idiopathic Parkinson's disease. Iron, through the Fenton reaction, is a powerful prooxidant and is capable of catalyzing the production of the highly reactive hydroxyl radical from hydrogen peroxide, a by-product of normal dopamine metabolism. We have suggested (Olanow *et al*., 1994) that the combination of iron and aluminum may place a neuron in a state of oxidative stress because of the apparent ability of aluminium to enhance the capacity of iron to induce lipid peroxidation (Gutteridge *et al*., 1985). Findings of mutations in the Cu/Zn superoxide dismutase gene in cases of familial ALS, as well as the production of transgenic models of motor neuron disease through the introduction of such mutations, may have relevance to Guam neurodegeneration. Cu/Zn superoxide dismutase clearly plays a role in the balancing of the production of oxygen radicals through energy utilization and the body's natural defenses against the potentially damaging effects of such radical production. In some way that is still not yet understood, altering this critical balance appears to induce progressive neuronal degeneration in the form of similar neurodegenerative disorders. Whether the striking aluminum and iron accumulations identified in target neurons for neurodegeneration in cases of ALS/parkinsonism–dementia complex of Guam are truly etiologic in nature remains unknown. The source of these deposits and the mechanism by which they occur also remain to be elucidated.

XXII. General Comments

It is a mistake to dismiss ALS/parkinsonism–dementia complex of Guam as a unique and separate disorder without further implications elsewhere in the world. Instead, Guam should be viewed as a rich laboratory in which to explore the interactions between environmental factors and genetic factors in the induction of most of the cardinal features of the age-related neurodegenerative disorders. In this interaction the strongest factor appears to be environmental in nature. In a similar fashion, because important hereditary insights can be gained through the study of genetically based high-risk families in a geographic isolate such as Guam, environmentally based aspects may be addressed more easily. Despite extensive research over several decades, the mystery of the etiology of the remarkable concentration of neurodegeneration on the island of Guam remains unsolved. Nevertheless, Guam represents the richest potential laboratory in which to unravel those critical environmental factors of importance to an understanding of both the disorders seen on Guam but also the analogous disorders encountered throughout the world.

Over the many years the Chamorro community on Guam has patiently awaited for the scientists working on the problem of ALS/parkinsonism–dementia complex to come up with the answers that will lift the staggering burden of suffering represented by this tragic disorder from their shoulders. Despite over 40 years of active research requiring answering innumerable questionnaires, providing gallons of blood samples, and countless autopsy specimens on their loved ones, these answers have yet to emerge. Considering this, the indomitable patience and continuing cooperative spirit of this beleaguered community are noteworthy and remarkable. The author has often noted that if a similar outbreak of ALS/parkinsonism–dementia complex were to be noted in a comparable sized community in the continental United States, the public outcry for immediate solutions to the problem would be deafening and would result in the rapid enlistment of a major research effort to solve the problem as quickly as possible. Unfortunately, despite the fact that the Chamorros of Guam are United States citizens living on American soil, their cries for help are muted by the more than 5000 miles of Pacific Ocean

between them and the mainland. The author can only hope that someday soon the patience of the Guam people will finally be rewarded by the scientific enquiries into their plight. That day will become a cause for rejoicing on Guam and will represent a major milestone in the world's quest for an understanding of the major age-related neurodegenerative diseases for which Guam patients serve as a model.

Acknowledgments

Over the years I have had the pleasure and privilege to work with many talented and dedicated people who have contributed in many ways. I am particularly indebted to the assistance, advice, and insights of Leonard Kurland, Carleton Gajdusek, Asao Hirano, Teresita Elizan, Ulla Craig, and Wigbert Wiederholt; Patrick Hof, Paul Good, and Dushyant Purohit at Mount Sinai and Arthur Loerzel and Kwang Ming Chen on Guam have all made important contributions to our research efforts. This work has been supported by the National Institute on Aging of the NIH through Grant AG 14382. Finally, I would again like to acknowledge the people of Guam, who, in their desire to solve the major public health problem that ALS/parkinsonism–dementia complex represents, have given so generously and openly to support our efforts. Without their cooperation, this work could not have taken place.

Brain Energy Metabolism: Cellular Aspects and Relevance to Functional Brain Imaging

Brain energy metabolism and blood flow are tightly coupled to neuronal activity. Functional brain imaging techniques, such as positron emission tomography and functional magnetic resonance imaging, detect metabolic and vascular signals that are associated with neural activity. Results have clarified the mechanisms that underlie the coupling between neuronal activity and glucose metabolism. These results indicate a role of astrocytes in this coupling. During healthy aging, marked changes in brain energy metabolism are revealed by functional imaging. The patterns of changes associated with aging are distinct from those seen in Alzheimer's disease.

I. Energy Metabolism and Blood Flow

A. Glucose Is the Main Energy Substrate for the Brain

The brain represents only 2% of the body weight in humans, yet the energy-consuming processes that ensure proper brain function account for approximately 25% of total body glucose utilization. With a few exceptions that will be reviewed later, glucose is the obligatory energy substrate of the brain. (Kety, 1957; Sokoloff, 1960; Edvinsson *et al*., 1993).

In any tissue, glucose can follow various metabolic pathways; in the brain, glucose is almost entirely oxidized to CO_2 and water through its sequential processing via glycolysis, the tricarboxylic acid (TCA) cycle, and the associated oxidative phosphorylation, which yields 38 ATP per glucose on a molar basis. The oxygen consumption of the brain, which accounts for almost 20% of the oxygen consumption of the whole organism, is 160 µmol/100 g of brain weight/min and roughly corresponds to the value determined for CO_2 production. This O_2/CO_2 relation corresponds to what is known in metabolic physiology as a respiratory quotient of nearly 1 and provides the demonstration that carbohydrates, and glucose in particular, are the exclusive substrates for oxidative metabolism. In normal adults, the calculated glucose utilization by the brain is 31 µmol/100 g of brain weight/min (Kety and Schmidt, 1948; Sokoloff, 1960) and cerebral blood flow (CBF) is approximately 57 ml/100 g of brain weight/min.

Exactly like in other tissues, the metabolism of glucose, the main energy substrate of the brain, produces two forms of energy: ATP and NADPH. Glycolysis and the TCA cycle produce ATP, whereas energy under the form of reducing equivalents stored in the NADPH molecule is produced predominantly through the pentose phosphate pathway. Maintenance of the electrochemical gradients, particularly for Na^+ and K^+, needed for electrical signaling, via the action potential, and for chemical signaling, through synaptic transmission, is the main energy-consuming process of neural cells.

B. Blood Flow Regulation

Since the seminal article of Roy and Sherrington (1890), the search has been intense for the identification of chemical mediators that could couple neuronal activity with local increases in blood flow. These signals can be broadly grouped into two categories: (i) molecules or ions that transiently accumulate in the extracellular space following neuronal activity and (ii) specific neurotransmitters that mediate the coupling in anticipation, or at least in parallel, with local activation (neurogenic mechanisms).

Several products of activity-dependent neuronal and glial metabolism, such as lactate, H^+, adenosine, and K^+, have vasoactive effects and are therefore putative mediators of coupling, although the kinetics and spatial resolution of this mode do not account for all the observed phenomena. As attractive as it is, an exclusively neurogenic mechanism of coupling neuronal activity to blood flow is unlikely and moreover it still awaits firm functional confirmation *in vivo*. Nitric oxide (NO) is certainly a key element in coupling, although evidence indicates that it can only be considered as one of the mechanisms contributing to the coupling between activity and local increases in blood flow (Villringer and Dirnagl, 1995).

The consequence of the activity-linked increase in blood flow is that more substrates, namely glucose and oxygen, necessary to meet the additional energy demands are delivered to the activated area per unit time.

II. Coupling and Functional Imaging

An important principle in brain physiology is indeed the tight coupling of neuronal activity with both energy metabolism and blood flow. As noted earlier, this principle was already formulated over a hundred years ago by Roy and Sherrington (1890) : "... we conclude then that the chemical products of cerebral metabolism ... of the brain can cause variations of the caliber of the cerebral vessels ... that in this reaction the brain possesses an intrinsic mechanism by which the vascular supply can be varied locally in correspondence with local variations of functional activity." This physiological principle, which has also been validated for the coupling between activity and energy metabolism with the determination of local rates of glucose utilization with the 2-deoxyglucose technique (Sokoloff *et al.*, 1977), has provided the basis for all functional imaging techniques, as local increases in brain activity produce blood flow and metabolism signals that can be detected with various imaging techniques. Positron emission tomography (PET) can monitor the increase in cerebral blood flow (CBF) in glucose utilization and oxygen consumption (Phelps *et al.*, 1979; Frackowiak *et al.*, 1980); the degree of blood oxygenation yields the signals that are detected with functional magnetic resonance imaging (fMRI) (Ogawa *et al.*, 1992). However, PET and fMRI do not detect synaptic activity directly but measure signals that reflect energy consumption by activity-dependent neural processes. Despite the remarkable advances in imaging techniques and their extensive applications to neurology, neuropsychology, and psychiatry, the precise understanding of the cellular and molecular mechanisms that underlie the signals detected with these imaging techniques, which rely on the coupling of synaptic activity with energy metabolism and blood flow, is still quite fragmentary. Evidence indicates that astrocytes play a key role in coupling synaptic activity to glucose utilization and metabolism (Magistretti *et al.*, 1999).

III. Cellular Mechanism of Brain Energy Metabolism

A. Neuronal Activity Is Tightly Coupled to Glucose Utilization

The 2-deoxyglucose (2-DG) technique developed by Louis Sokoloff for laboratory animals (Sokoloff *et al.*, 1977) and its adaptation to PET for humans has provided a direct demonstration of the coupling between neuronal activation and glucose (Magistretti *et al.*, 1999). Despite this compelling evidence, the cellular and molecular mechanisms that underlie such a coupling are still under scrutiny. A current assumption is that neuronal signals produced by synaptic activity act directly on brain capillaries to increase locally the delivery of energy substrates. However, this view does not take into account an important cellular component of the brain: the astrocytes. Indeed, particular astrocytic profiles, the end-feet, surround intraparenchymal capillaries, whereas other astrocytic processes ensheath synaptic contacts (Peters *et al.*, 1991) and possess receptors and reuptake sites for neurotransmitters. (Magistretti and Pellerin, 1996). These features imply that astrocytes are ideally positioned to sense increases in synaptic activity and to couple them with energy metabolism.

B. Astrocytes Couple the Activity of Glutamatergic Synapses with Glucose Utilization

From the foregoing, it follows that astrocytes may play a prominent role in coupling neuronal activity to local increases in glucose utilization during activation as observed in animals and humans. To explore this hypothesis, we have studied glucose utilization by mouse cerebral cortex astrocytes in culture using the [^{3}H]-2-deoxyglucose as a marker of glucose utilization. We have shown that glutamate stimulates 2-DG uptake and phosphorylation in astrocytes in a concentration-dependent manner with an EC_{50} of approximately 80 μM. (Pellerin and Magistretti, 1994). This effect is not receptor mediated as it cannot be prevented or mimicked by glutamate receptor antagonists and agonists, respectively (Pellerin and Magistretti, 1994). Rather, it is mediated by a Na^+-dependent glutamate transporter, as supported by pharmacological evidence (Pellerin and Magistretti, 1994, 1996; Takahashi *et al.*, 1995) (Fig. 16.1).

The intracellular molecular mechanisms of this coupling indicate a critical involvement of the Na^+/K^+-ATPase, as ouabain completely inhibits the glutamate-evoked 2-DG uptake by astrocytes (Pellerin and Magistretti, 1994, 1996). The astrocytic Na^+/K^+-ATPase responds predominantly to increases in intracellular Na^+ for which it shows a K_m of about 10 mM (Kimelberg *et al.*, 1993). Because the $(Na^+)_i$ concentration ranges between 10 and 20 mM (12) in cultured astrocytes, Na^+/K^+-ATPase is set to be readily activated when $(Na^+)_i$ raises concomitantly with glutamate uptake (Bowman and Kimelberg, 1984). The effect of glutamate is likely due to the mobilization of a subunit of the pump that is highly sensitive to ouabain, probably the α_2 subunit (Pellerin and Magistretti, 1997).

There is ample evidence from studies in a variety of cellular systems, including the brain, kidney, vascular smooth muscle, and erythrocytes, that increases in the activity of the Na^+/K^+ ATPase stimulate glucose uptake and glycolysis (Parker and Hoffman, 1967; Lipton and Robacker, 1983). Consistent with this view, glutamate stimulates the glycolytic processing of glucose in astrocytes, as indicated by the increase in lactate release (Fig. 16.1). The proposed stoichoimetry of the molecular steps involved in the coupling between glutamate uptake and glucose utilization is the following: the uptake of one glutamate with three sodium ions triggers the entry of one glucose, which, through glycolysis, produces two ATPs, one of which is consumed by the pump, resulting in the extrusion of three sodium ions, whereas the other fuels the enzymatic conversion of glutamate to glutamine, an ATP-requiring, astrocyte-specific reaction catalyzed by glutamine synthase (Fig. 16.1); the glycolytic processing of glucose results in approximately two lactate molecules produced per one glucose

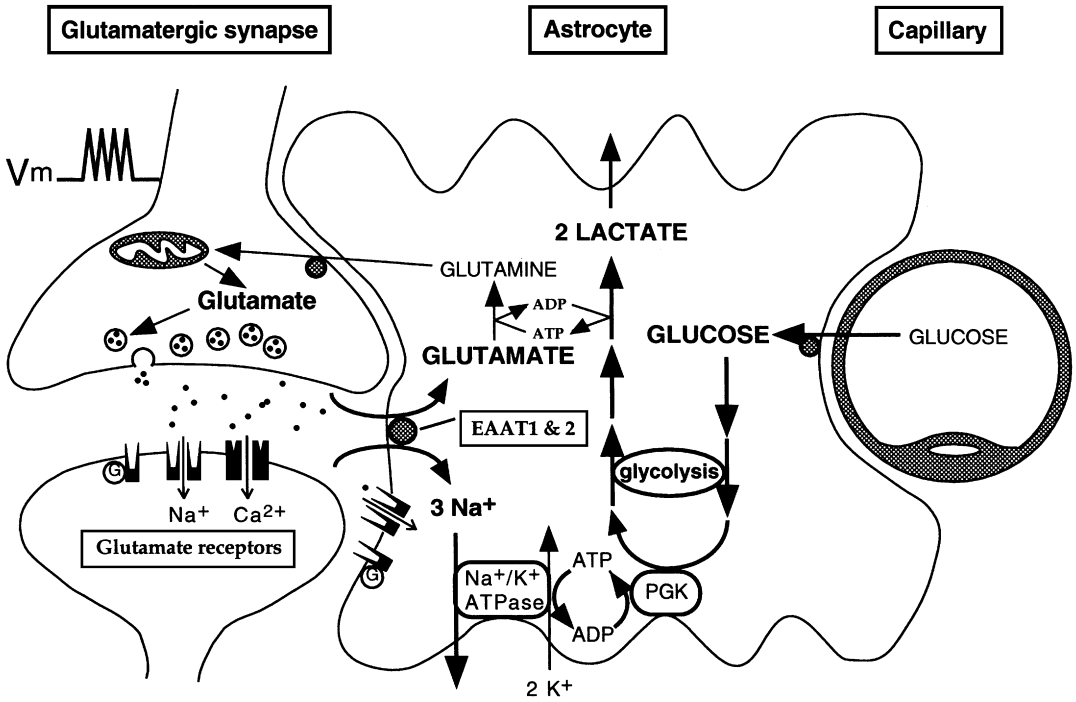

FIG. 16.1. Schematic representation of the mechanism for glutamate-induced glycolysis in astrocytes during physiological activation. At glutamatergic synapses, presynaptically released glutamate depolarizes postsynaptic neurons by acting at specific receptor subtypes. The action of glutamate is terminated by an efficient glutamate uptake system located primarily in astrocytes. Glutamate is cotransported with Na^+, resulting in an increase in the intraastrocytic concentration of Na^+, leading to an activation of the astrocyte Na^+/K^+-ATPase. Activation of Na^+/K^+-ATPase stimulates glycolysis, i.e., glucose use and lactate production. Once released by astrocytes, lactate can be taken up by neurons and serves them as an adequate energy substrate. (For graphic clarity, only lactate uptake into presynaptic terminals is indicated. However, this process could also occur at the postsynaptic neuron.) This model, which summarizes *in vitro* experimental evidence indicating glutamate-induced glycolysis, is taken to reflect cellular and molecular events occurring during activation of a given cortical area.

molecule, i.e., a stoichoimetrical relationship between glucose and lactate, as expected (Fig. 16.1).

These data indicate that glutamate stimulates aerobic glycolysis (i.e., the transformation of glucose into lactate in the presence of sufficient oxygen) in astrocytes by a mechanism involving an activation of the Na^+/K^+ ATPase. In this context, it is important to note that *in vivo*, the main mechanism that accounts for the activation-induced 2-DG uptake is represented by the activity of the Na^+/K^+-ATPase (Sokoloff, 1991).

This view raises the question of the usefulness of lactate as an energy substrate for neurons. A vast array of experimental data has accumulated over the years, indicating that *in vitro*, lactate can adequately maintain synaptic activity in the absence of glucose (Schurr *et al*., 1988; Tsacopoulos and Magistretti, 1996). *In vivo*, lactate is not an adequate substrate, as it crosses the blood–brain barrier only marginally (Pardridge and Oldendorf, 1977); however, if formed within the brain parenchyma through the mechanism described earlier (Fig. 16.1) or if applied to *in vitro* preparations, lactate may in fact be consumed preferentially to glucose, particularly during periods of intense activity (Larrabee, 1995).

Immunohistochemical data indicate a cellular distribution of lactate dehydrogenase (LDH) that is consistent with the model. LDH is the enzyme that catalyzes the interconversion of lactate and pyruvate. In the human hippocampus and visual cortex, immunoreactivity against LDH_5 (the form enriched in lactate-producing tissues) is restricted to a population of astrocytes, whereas neurons are stained only by an antibody directed against LDH_1 (the form enriched in lactate-consuming tissues) (Bittar *et al*., 1996). These data thus support the idea that some astrocytes would preferentially process glucose glycolytically into lactate, which, once released, could be transformed by neurons into pyruvate and enter the TCA cycle to serve as an energy fuel. It should be stressed that one molecule of lactate entering the TCA cycle through the LDH-catalyzed reaction can yield, in normoxic conditions, 17 ATPs.

In summary, because glutamate release occurs following the modality-specific activation of a brain region, these data and the proposed model are consistent with the view that during activation, glutamate uptake into astrocytes leads to increased glucose utilization and lactate production, which can be subsequently used by neurons to meet their energy needs. Further support for this notion of an ''astrocyte–neuron lactate shuttle'' in the brain (Fig. 16.2) has been provided by the identification of two lactate transporters, MCT-1 and MCT-2, selectively expressed in astrocytes or neurons. Thus, MCT-1 is enriched in astrocytes in culture, whereas MCT-2 is expressed predominantly in neurons (Bröer *et al*., 1997; Pellerin *et al*., 1998).

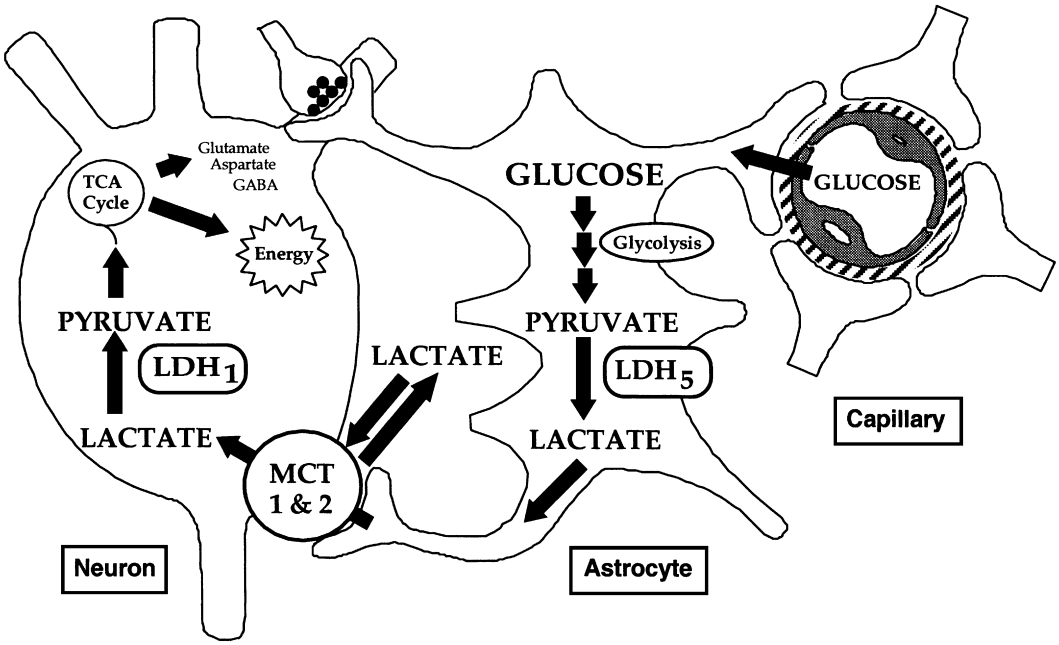

FIG. 16.2. Schematic representation of the proposed astrocyte–neuron lactate shuttle. Following neuronal activation and synaptic glutamate release, glutamate reuptake into astrocytes triggers increased glucose uptake from capillaries via activation of an isoform of the Na^+/K^+-ATPase, which is highly sensitive to ouabain, possibly the $\alpha 2$ isoform (Pellerin and Magistretti, 1994, 1997). Glucose is then processed glycolytically to lactate by astrocytes, which are enriched in the muscle form of LDH (LDH_5). The exchange of lactate between astrocytes and neurons is operated by monocarboxylate transporters (MCTs). Lactate is then converted to pyruvate, as neurons contain the heart form of LDH (LDH_1). Pyruvate, via the formation of acetyl-CoA by pyruvate dehydrogenase (PDH), enters the TCA cycle, thus generating 17 ATP molecules per lactate molecule.

IV. Relevance to Functional Brain Imaging

Results obtained in a variety of *in vivo* paradigms both in laboratory animals and in humans support the existence of such a transient lactate production during activation. Thus, marked increases in the concentration of extracellular lactate have been monitored by microdialysis studies in rat striatum and hippocampus during physiological sensory stimulation (Fellows *et al*., 1993). This activity-linked increase in lactate is completely inhibited by the glutamate uptake inhibitor THA, thus providing further support to the existence of glutamate-stimulated glycolysis during activation (Fray *et al*., 1996). Magnetic resonance spectroscopy (MRS) in humans has also revealed that during physiological activation of the visual system, a transient lactate peak is observed in the primary visual cortex (Prichard *et al*., 1991; Frahm *et al*., 1996). These microdialysis and MRS data *in vivo* would support the notion of a transient glycolytic processing of glucose during activation. PET analyses pioneered by Raichle and Fox have suggested that oxygen consumption does not increase commensurately with blood flow and glucose utilization in activated brain areas (Fox *et al*., 1988), raising the much debated possibility that an activity-dependent glycolytic processing of glucose may occur. Other investigators have found that the degree of uncoupling between glucose utilization and oxygen consumption during activation may actually vary, and even may not occur, depending on the stimulations used (Marrett *et al*., 1995). In addition, using [^{13}C]-glucose MRS, Shulman and colleagues have reported data consistent with a significant increase in oxygen utilization during activation (Hyder *et al*., 1996). Finally, results by Sibson *et al*. (1998) indicate that glutamatergic transmission and glucose oxidation monitored *in vivo* by MRS show a linear relationship with a stoichiometry of 1:1.

On the basis of studies at the cellular level, the model proposed for the coupling between neuronal activity and glucose utilization (Fig. 16.1) would be consistent with an initial glycolytic processing of glucose occurring in astrocytes during activation, resulting in a transient lactate overproduction, followed by a recoupling phase during which lactate would be oxidized by neurons.

Finally, the model proposed in Figs. 16.1 and 16.2 is consistent with the notion that signals detected during physiological activation in humans with ^{18}F-2-DG PET may reflect predominantly uptake of the tracer into astrocytes (Pellerin and Magistretti, 1994; Magistretti *et al*., 1999). This conclusion does not question the validity of the 2-DG-based techniques, rather it provides a cellular and molecular basis for these functional brain-imaging techniques.

V. Brain Energy Metabolism and Aging

A. Brain Glucose Metabolism in Healthy Aging

Studies on age-related changes in resting CMRglc have been discrepant, probably because of methodological difficulties and differences in criteria selection. For example, use of the region-of-interest approach does not provide sufficient anato-

mical references and reliability across reports. Measurements should indeed be corrected for cortical atrophy. In some studies the spatial resolution of PET-used cameras is low. A variable among studies is the selection criteria for subjects. Criteria should ideally allow the evaluation of the effect of age unconfounded by diseases associated with advancing age.

During normal aging, the brain shows a reduction in whole brain glucose metabolism (De Santi *et al*., 1995; Loessner *et al*., 1995; Moeller *et al*., 1996; Murphy *et al*., 1996; Petit-Taboue *et al*., 1998). This decline in global glucose metabolic rate ranges from 2% per decade (Moeller *et al*., 1996) to 6% (Petit-Taboue *et al*., 1998). Most studies indicate that this age-related decrease in glucose metabolism is prominent in the frontal and temporal lobes (De Santi *et al*., 1995; Loessner *et al*., 1995; Murphy *et al*., 1996). De Santi *et al*. (1995) reported a stronger metabolic change with age for the frontal lobe than for the temporal lobe. This metabolic decline in frontal lobe is more important in the premotor, orbitofrontal (Petit-Taboue *et al*., 1998), dorsolateral (De Santi *et al*., 1995), medial frontal, and frontal operculum areas (Moeller *et al*., 1996). Regional cerebral metabolic differences appear to exist within the temporal lobe (Eberling *et al*., 1995), with largest decreases in the anterior temporal cortex. Certain studies have also reported age-related decrements in glucose metabolism in the parietal cortex (Moeller *et al*., 1996; Murphy *et al*., 1996). A rCMRglc decline was also shown in the association neocortex, particularly in anterior temporal and perisylvian temporoparietal areas, the anterior cingulate cortex, and the insula, as well as in the caudate nucleus and the anterior thalamus (Petit-Taboue *et al*., 1998). In a study of 40 young and 31 old male individuals, an age-related glucose metabolism change in the hippocampus was also reported (De Santi *et al*., 1995). Posterior brain areas, such as the occipital cortex and cerebellum, may in contrast show an increased metabolic activity with age (De Santi *et al*., 1995; Loessner *et al*., 1995; Moeller *et al*., 1996; Petit-Taboue *et al*., 1998). Similar observations have been made in brain stem and basal ganglia (Moeller *et al*., 1996). In summary, there appears to be an age-related shift of regional metabolism that decreases in the anterior and lateral areas, accompanied by an increase in more posterior regions. This decreased anterior–posterior gradient may be associated with a decreased subcortical–cortical gradient.

B. Brain Glucose Metabolism in At-Risk Individuals for Alzheimer's Disease

Several factors appear to be associated with an individual at risk for AD. Familial Alzheimer disease is a form of AD with an onset before 60 years of age. At least three fully penetrant genes have been associated with the development of this early-onset AD: the amyloid precursor protein gene on chromosome 21, the presenilin-1 on chromosome 14, and presenilin-2 on chromosome 1 (see Chapter 22). Late-onset AD (after the age of 60) is familial or sporadic and is associated with a gene on chromosome 19, the apolipoprotein E (APOE). This gene has three allelic variants, types 2, 3, and 4, and five common genotypes: 2/3, 3/3, 2/4, 3/4, and 4/4; the presence of APOE4 has been validated as a risk factor for AD (Saunders *et al*., 1993). Individuals with age-associated memory impairment, having severe memory loss and no other type of cognitive impairment, show a progression to AD. Over 45% of them developed AD in a 48-month follow-up (Bowen *et al*., 1997) and up to 55% in a 54-month follow-up (Petersen *et al*., 1995). APOE4 is a strong predictor of the outcome of these patients. Two other conditions put an individual at risk for AD: twins, monozygotic or dizygotic, when discordant for AD, and Down syndrome.

Studies of cognitive normal individuals at risk for AD reveal a pattern of reduced cerebral metabolic rate for glucose in the parietal and temporal neocortex (Azari *et al*., 1994; Newman *et al*., 1994; Kennedy *et al*., 1995; Small *et al*., 1995; Reiman *et al*., 1996; Minoshima *et al*., 1997; Pietrini *et al*., 1997; see Chapter 18). Some of these studies also reveal global (Newman *et al*., 1994; Kennedy *et al*., 1995; Pietrini *et al*., 1997) and prefrontal (Wang *et al*., 1994; Reiman *et al*., 1996) hypometabolism. Two studies also reported a significant metabolic reduction in the posterior cingulate cortex (Reiman *et al*., 1996; Minoshima *et al*., 1997).

In summary, studies of individuals at risk for AD confirm that metabolic dysfunction precedes the onset of the clinical symptoms of dementia. An important consideration in evaluating the brain glucose metabolism pattern in AD and in the preclinical stages of AD is the characterization of the changes in CMRglc occurring during normal aging. In healthy aging, a global reduced metabolic rate for glucose is observed, which is most prominent in frontal, temporal, and parietal lobes. Studies of cognitively unaffected individuals at risk for AD reveal temporal and parietal hypometabolism. Some of these studies also reveal a global and a prefrontal deficit. Importantly, pattern of glucose metabolism described in the preclinical stages of AD appear to differ from that observed in normal aging, as the earliest changes in the preclinical stages of AD appear to affect mostly the posterior cingulate cortex.

Functional Imaging in Cognitively Intact Aged People

This chapter reviews the functional correlates of perception, attention, and memory deficits that occur over the course of normal aging. Two general patterns of findings emerge from functional neuroimaging studies of cognitive aging. One is characterized by age-related *declines* in brain activation in functional networks important for cognition, and the other by age-related *increases* in brain activation in other brain regions that are not typically associated with the cognitive process under study. Age-related reductions in functional brain activity are more pronounced during demanding tasks that require self-initiated processes, but are abated during supportive tasks that guide appropriate information processing. Age-related increases in functional brain networks occur during both relatively simple perceptual tasks and during more complex, demanding memory tasks and may reflect inefficient processing and/or compensatory changes in the elderly. The most direct way to distinguish these alternative interpretations is via direct investigations of the relationship between brain activity and behavioral performance. Such investigations have been carried out by only a few investigators and should be a major focus of future research, as their outcome will help shape future rehabilitation efforts.

I. Introduction

The fact that the majority of older adults live their later years free of neurodegenerative disease is reassuring, but even normal aging is associated with perceptual and cognitive changes that impinge on older adults' quality of life. Section II describes functions that decline or are spared by aging. Due to space limitations, we have limited our review to those functions that have been tested in neuroimaging studies, but interested readers are encouraged to start with the two editions of the *"Handbook of Aging and Cognition"* (Craik and Salthouse, 1992, 2000) for more thorough reviews of cognitive aging. Section III reviews results from nonhuman animal studies, neuropsychological studies of patients with brain damage, and neuroimaging studies with younger adults that help elucidate the brain regions that are important for various cognitive functions. Sections IV and V review functional neuroimaging studies that have been conducted with healthy older adults and describe how brain activation during nonmemory and memory tasks differs between younger and older adults. All of the cognitive aging studies described used positron emission tomography (PET), as studies using functional magnetic resonance imaging (fMRI) have not yet been published; however, readers interested in the effects of aging on sensorimotor functioning are referred to fMRI studies by Ross *et al*. (1997), Taoka *et al*. (1998), and D'Esposito *et al*. (1999). Finally, Section VI combines the available aging PET data and attempts to identify brain regions in which activation in the face of a cognitive challenge is consistently altered by aging.

II. Cognitive Changes and Spared Functions in Healthy Elderly

In most cognitive aging studies, particularly in neuroimaging studies of aging, strict inclusion criteria are applied in order to rule out extracognitive influences on performance. Typically, to be included in a study of cognitive aging, participants must live independently (i.e., not in a nursing home), be relatively well educated, and have normal or corrected-to-normal vision and audition. In addition, participants are screened for disease that might compromise brain function, such as cardiovascular disease, history of stroke or neurological disorders, history of psychiatric illness, or drug abuse, as well as for use of medications that might affect brain function. One result of these criteria is that the older adults tested in most studies are archetypes of ''successful'' aging, and thus may not represent the average older individual; however, one can infer that any deficits in cognition or in brain function identified in these older adults would be even greater in their less fortunate peers. With this in mind, we review below perceptual and cognitive functions that are changed or spared by normal (i.e., successful) aging.

A. Perception and Attention

The amount of stimuli present externally (e.g., visual and auditory information) and internally (i.e., thoughts) at any given moment far exceeds our attentional capacity, and thus we must selectively attend to particular aspects of the environment while ignoring irrelevant information. Older adults have been shown to be impaired in many aspects of selective attention, primarily because of distraction caused by irrelevant information in the environment. For example, relative to their younger counterparts, older adults are disproportionately slower to read words that have been perceptually degraded, such as h*o*r*s*e, than intact words (Allen *et al*., 1993), and to locate objects or faces when they are presented among distractors versus in isolation (Plude and Hoyer, 1986; Sekuler and Ball, 1986; Ball *et al*., 1990).

The distinction between ''bottom-up'' and ''top-down'' influences on attention helps explain these findings. Bottom-up influences on selective attention occur when a stimulus or stimulus feature is particularly salient, because it is the only thing in the environment, because features such as its color or abrupt onset make it stand out from the background, or because it activates a highly practiced, automated process such as word reading. In contrast, top-down influences are intentional, or goal directed, and act to prevent interference from irrelevant stimuli or stimulus features. In general, top-down processes require attentional control and are compromised by aging, whereas bottom-up processes run off more automatically and are spared by aging (Hasher and Zacks, 1977; Jennings and Jacoby, 1993).

B. Semantic Memory

The distinction between bottom-up and top-down processes also helps explain the presence and absence of age-related declines in different types of memory. Semantic memory refers to general knowledge of facts and words that has been built up over a lifetime of experience (Tulving, 1983). Numerous studies have found that the content and organization of older adults' semantic memory are comparable or even richer than that of younger adults in terms of vocabulary, general world knowledge, and the tendency to provide similar semantic associates to words (for reviews, see Light and Burke, 1988; Light, 1991). The fact that semantic memory ability does not differ between young and older adults is consistent with the notion that well-learned, highly automated abilities initiate bottom-up processes, which are spared by aging.

C. Perceptual Priming

Perceptual priming is a type of implicit memory that refers to the facilitated identification or completion of a stimulus by recent exposure to that item. Following the presentation of a list of words, participants are typically presented with incomplete stimuli and are asked to complete each stimulus with the first thing that comes to mind. Although no reference is made to the previous study episode and participants do not intentionally retrieve information from memory, there is a greater tendency to complete the stimuli with items that had been presented previously than with new items. For example, if ''string'' had been presented, participants would be more likely to complete the word stem ''str___'' with ''string'' than with ''strain'' or ''strong.'' Numerous studies have shown that perceptual priming is comparable in younger and older adults (Light and Burke, 1988; Light, 1991), which is in line with the idea that bottom-up processes guided by the stimulus environment remain stable across the life span.

D. Working Memory

An example of top-down processes in memory functioning is working memory, which refers to the active maintenance and manipulation of information held in mind (Baddeley, 1986). Examples of working memory include everyday activities, such as mental arithmetic, and laboratory tests, such as backwards digit span or tests in which participants must hold a picture or face in mind over a delay and then determine which of two perceptually similar stimuli it matches. Working memory is to be contrasted with primary memory (Waugh and Norman, 1965), which is the short-term maintenance of information with no requirement to manipulate the information (e.g., remembering a telephone number until the number is dialed). In general, age-related differences in primary memory are slight or nonexistent, whereas age-related deficits in working memory are more robust (e.g., Craik, 1986; Dobbs and Rule, 1989).

E. Episodic Memory

Semantic memory is distinguished from episodic memory, which refers to conscious memory for a particular event or episode in the past, including contextual information such as when and where the episode occurred (Tulving, 1983). For example, semantic memory allows one to know the meaning of the words ''sweater,'' ''bean,'' and ''wrench,'' but episodic memory allows one to remember that those words were presented in a memory list a few minutes ago. Numerous studies have demonstrated that episodic memory is quite vulnerable to aging in that older adults tend to remember less information and less contextual detail regarding particular events that have been presented (for reviews, see Craik *et al*., 1995; Balota *et al*., 2000). Episodic memory involves several stages of processing, including an encoding stage in which information is perceived, analyzed, and related to previously stored information and a retrieval stage in which information is searched for (via an external or self-generated retrieval cue) and brought back into consciousness. Previous research has found that older adults suffer both encoding and retrieval deficits. Evidence in favor of an age-related encoding deficit includes findings that older adults are less likely to engage in the types of operations that facilitate proper learning, such as mental imagery (Treat and Reese, 1976), elaborative encoding to make the information semantically rich and distinctive (Rankin and Collins, 1986), and active organization of information (Smith, 1980), but when older adults are instructed to use these strategies, their memory performance improves. Evidence in favor of a retrieval deficit includes the fact that episodic memory impairments are typically larger on tests of recall (free and cued recall) than on tests of recognition (Schonfield and Robertson, 1966). These findings apply to a variety of stimulus types. For example, both younger and older adults remember pictures better than words, but age-related

decrements in memory for pictures are larger when tested using free or cued recall (Puglisi and Park, 1987) than when tested using recognition (Till *et al*., 1982; Park *et al*., 1986). Similarly, Bartlett and Leslie (1986) found no age-related decline in the recognition of faces when studied faces were discriminated from new faces, but found that older adults did perform more poorly when a studied face had to be discriminated from the same face pictured from different angles or displaying different expressions. Together, these results indicate that age-related episodic memory decrements, although ubiquitous, vary considerably in magnitude depending on the encoding and retrieval demands at hand.

F. Theoretical Explanations for Age-Related Cognitive Changes

Variants of the top-down/bottom-up distinction have been formulated to explain age-related deficits in episodic and working memory. For example, Jennings and Jacoby (1993) argued that conscious recollection of a past event is impaired by aging, but automatic familiarity-driven processes remain intact. More broadly, Craik (1983, 1986) proposed that the greater the demands are for attention-demanding, self-initiated operations during encoding, maintenance, or retrieval, the worse older adults perform because the amount of attentional resources available for such operations declines with age. Conversely, the more the task stimuli or task environment guides appropriate encoding and retrieval operations (i.e., a bottom-up influence), the smaller the age-related deficit. As will be seen later in this chapter, results from neuroimaging studies indicate that these results hold at the level of brain activity; specifically, age-related decrements in brain activation appear to be greater during memory tasks that require attention-demanding encoding and retrieval processes than during memory tasks that facilitate these processes.

The neural mechanisms of cognitive aging undoubtedly are numerous and complex, but one hypothesis is particularly relevant to this discussion. A number of investigators have postulated that older adults' cognitive impairments stem primarily from frontal lobe dysfunction. This hypothesis is based both on anatomical and imaging evidence that age-related brain atrophy and hypometabolism may be exaggerated in anterior brain regions (see Madden and Hoffman, 1997; Raz *et al*., 1997; Raz, 2000; Chapter 18) and on evidence for a similarity between the types of attention and episodic memory deficits experienced by older adults and patients with frontal lobe damage (Moscovitch and Winocur, 1992; West, 1996). The major appeal of this hypothesis is that it proposes a neural basis for older adults' difficulty with ''top-down'' or controlled, attention resource-demanding cognitive processes. Indeed, many of the neuroimaging studies of younger and older adults described in Sections IV and V have found age-related differences in prefrontal lobe activity that presumably reflects age-related changes in ''top-down'' processing.

III. Brain Areas Involved in Cognition in Young Adults

Until recently, our knowledge of the functional neuroanatomy of perception and cognition was gained exclusively from work with nonhuman animals and from patients with brain damage; since the early 1990s, however, advances in functional neuroimaging techniques such as PET and fMRI have made it possible to study perception and cognition *in vivo* in healthy humans. This section reviews studies that help elucidate the neural mechanisms of perception and attention, semantic memory, working memory, and episodic memory.

A. Perception and Attention

Studies with nonhuman primates (e.g., Ungerleider and Mishkin, 1982; Felleman and Van Essen, 1991) and with patients with brain damage (e.g., Damasio *et al*., 1989; Goodale and Milner, 1992), as well as neuroimaging studies of healthy younger adults (Haxby *et al*., 1991; Sergent *et al*., 1992; Köhler *et al*., 1995), have revealed two distinct pathways in visual perception: a ventral occipitotemporal pathway involved in object perception and a dorsal occipitoparietal pathway involved in the perception of spatial relationships among objects. Neuroimaging studies also show that how an object is processed, and thus the pathway that is activated, depend on the stimulus feature to which attention is paid. For example, in a PET study conducted by Corbetta *et al*. (1991), stimulus arrays were presented that changed in shape and speed of motion, and during each scan subjects were instructed to attend selectively to one of these features. The results were consistent with the dual-pathway model; specifically, attention to shape activated ventral occipitotemporal regions, whereas attention to speed activated dorsal occipitoparietal regions; i.e., selective attention helps determine the neural mechanisms involved in processing particular features of a stimulus.

Other cognitive tasks require more complex attention. For example, in some circumstances, attention must be divided between two or more aspects of the environment, attention must be paid to one stimulus feature while other highly salient features are ignored, attention must be switched between different features of a stimulus or between parts of the environment, or directed searches must be made for additional stimulus properties. Each of these conditions has been linked to activation of the anterior cingulate, inferior parietal lobule, and dorsolateral prefrontal lobe (e.g., see Corbetta *et al*., 1990, 1991; Pardo *et al*., 1991; Kosslyn *et al*., 1994, 1995; Shallice *et al*., 1994; Fletcher *et al*., 1995; Nobre *et al*., 1997), among other brain regions depending on the particular sensory and cognitive demands of the task. These are examples of tasks that require top-down perceptual processing, and given that top-down processes are characterized as being controlled, attention demanding, and vulnerable to aging, we should find age-related declines in activation of this attentional network.

B. Semantic Memory

The use of language is one instantiation of retrieval from semantic memory. The fact that word meaning is automatically triggered by the perception of a word is perhaps best exemplified by the Stroop task (Stroop, 1935), in which reading color words printed in incompatible colors (e.g., ''red'' written in blue ink) is much more difficult than reading color words printed either in black ink or a compatible ink color (e.g., ''red'' in red ink). Early evidence from brain-damaged

patients and newer evidence using neuroimaging techniques have linked a large network of brain regions to language functioning, including Broca's area for speech production and Wernicke's area for language comprehension (for a review, see Damasio, 1981), as well as visual or auditory association cortices (depending on the mode of presentation), and left inferior frontal cortex (for a review, see Price, 1998). In particular, the left inferior frontal cortex is associated with the internally driven search through semantic memory, as it is active during verb generation tasks (e.g., Wise *et al*., 1991; Warburton *et al*., 1996), and is more active during encoding tasks that require semantic processing than tasks that require perceptual processing (Grady *et al*., 1998b; Kapur *et al*., 1994).

C. Perceptual Priming

The main result from neuroimaging studies of perceptual priming is a significant *deactivation* in posterior sensory regions. For example, in the case of visual word stem completion (described in Section II,C), reliable deactivation of extrastriate cortex (Brodmann's area 19) was shown by Buckner *et al*. (1995), Blaxton *et al*. (1996), and Schacter *et al*. (1996a). These results are similar to findings obtained from single-cell recordings in monkey cortex, in which firing rates are suppressed upon the repetition of a stimulus (see Desimone, 1996). Thus, these findings suggest that prior stimulus exposure reduces the amount of perceptual processing required by that stimulus in the future, which thereby facilitates its identification or completion.

D. Working Memory

Working memory is presumed to be more demanding of attention than maintenance rehearsal because one must simultaneously hold *and* manipulate the information held in mind; thus, it should come as no surprise that working memory and complex attention tasks activate overlapping functional brain networks. Earlier research with nonhuman animals and with brain-damaged patients has linked the prefrontal cortex to spatial working memory tasks, such as delayed alternation (Oscar-Berman and Bardenhagen, 1998), and neuroimaging studies of working memory in healthy humans have found activation of the inferior parietal lobule and dorsolateral prefrontal regions (Jonides *et al*., 1993; Paulescu *et al*., 1993; Petrides *et al*., 1993a,b; Berman *et al*., 1995; Smith *et al*., 1995; Awh *et al*., 1996; Courtney *et al*., 1996; D'Esposito *et al*., 1998). Moreover, neuroimaging studies have revealed that the left hemisphere is preferentially involved in verbal working memory, whereas the right hemisphere is preferentially involved in spatial working memory (Smith and Jonides, 1997), although activation of parietal and prefrontal areas in both hemispheres increases with the memory load (Braver *et al*., 1997; Jonides *et al*., 1997).

E. Episodic Memory

For nearly half a century now, investigators have been studying the brain mechanisms involved in episodic memory processing. Lesion studies in nonhuman animals and studies with brain-damaged patients identified medial temporal areas, namely the hippocampus and adjacent cortical areas, as crucial for episodic memory (Scoville and Milner, 1957; Zola-Morgan and Squire, 1985; Zola-Morgan *et al*., 1986, 1989; Eichenbaum *et al*., 1992; Squire, 1992). In addition, patients with frontal lobe lesions suffer moderate, but significant disabilities recalling information from memory (Wheeler *et al*., 1995). Although these approaches have been an essential tool in advancing our knowledge of the neural mechanisms of cognition, one problem with lesion approaches is determining whether memory deficits are due to encoding or retrieval impairments. This distinction is particularly relevant in the study of normal aging because one long-standing issue in the cognitive aging literature is whether encoding or retrieval plays a greater role in older adults' memory impairments (Burke and Light, 1981).

A major advantage of functional neuroimaging technology is that separate images of brain activity during encoding and retrieval can be obtained. Although early neuroimaging studies failed to find consistent activation of medial temporal lobe regions during episodic memory tasks (for reviews, see Cabeza and Nyberg, 1997; Fletcher *et al*., 1997), more recent studies have reported significant medial temporal activation during encoding and retrieval in both verbal and nonverbal domains (Desgranges *et al*., 1998). Imaging studies also identify prefrontal regions in memory, although activation of the prefrontal cortex tends to be asymmetric, with more left prefrontal activation during episodic encoding and more right prefrontal activation during retrieval. This pattern, which was named HERA (hemispheric encoding-retrieval asymmetry) by Tulving *et al*. (1994b), describes a very general functional pattern of brain activity during episodic memory and, as such, is susceptible to exceptions. For example, the left prefrontal cortex is often activated by retrieval, particularly during more difficult or demanding retrieval tasks (Nolde *et al*., 1998).

Posterior regions are also activated during episodic memory tasks. Some of these activations can be linked to the perception of the items being encoded or of the retrieval cue (see Section III,A). In addition, retrieval is frequently associated with parietal activation, both in the inferior parietal lobule (Brodmann's area 40) and in medial regions such as the precuneus (Cabeza and Nyberg, 1997; Desgranges *et al*., 1998). Finally, the nature of encoding or retrieval affects the pattern of brain activation. ''Deeper'' or more elaborative semantic encoding, relative to more ''shallow'' or perceptually based encoding, is associated with greater activation in left prefrontal (Kapur *et al*., 1994; Grady *et al*., 1998b) and medial temporal (Nyberg *et al*., 1998) regions. There is also considerable controversy over the significance of right prefrontal activation during retrieval. Some investigators have found that the right prefrontal cortex is active independently of the type of memory task or memory performance levels and have thus inferred that it reflects a general retrieval mental set, or ''retrieval mode'' (Kapur *et al*., 1995; Nyberg *et al*., 1995). Other investigators have found greater right prefrontal activation during more difficult retrieval conditions, suggesting that the activity reflects the degree of ''retrieval effort'' (Schacter *et al*., 1996a). Others have found greater right prefrontal activation during recognition tasks that consist of higher proportions of ''old'' than ''new'' items, suggesting that it is a marker of ''retrieval success'' (Tulving *et al*., 1994a;

Rugg *et al*., 1996). Still other investigators suggest that retrieval-related right prefrontal activity reflects postretrieval monitoring processes (Rugg *et al*., 1998). Such debates are the fodder on which good science feeds, and indeed neuroimaging studies of memory and aging (in which older adults often but not always perform more poorly on memory tests, and often have monitoring problems) may play an important role in the resolution of this debate.

IV. Age-Related Differences in Brain Activation during Nonmemory Tasks

We remind the readers that in neuroimaging studies of cognitive aging, care is taken to ensure that participants have normal or corrected-to-normal vision and hearing. However, even if the younger and older adults in a cognitive aging study have comparable sensory function as measured by standard acuity tests, it is possible for the functional neuroanatomy of perceptual processing to change with age.

The first PET studies demonstrating age-related differences in brain activity during cognition involved face and location perception in order to compare the effects of aging on the activation of the ventral and dorsal processing streams described in Section III,A (Grady *et al*., 1992, 1994). These studies involved a match-to-sample task for faces or locations in which the sample and two choices were present simultaneously on the computer screen, thus eliminating any demands on memory. Response accuracy did not differ between the two age groups, but the older adults were slower to respond on both tasks. Blood flow data revealed that in both age groups, face matching activated primarily the occipitotemporal cortex while location matching activated primarily the occipitoparietal cortex, a finding that is consistent with the dual-path model of visual processing. In addition, however, the young subjects showed greater activation in early visual processing regions (in prestriate cortex), and the older adults showed greater activation either along the ventral or dorsal pathways or outside of them (e.g., in frontal cortex). Grady *et al*. concluded that younger adults make more efficient use of occipital visual areas, whereas older adults rely on additional cortical networks, which results in slower performance.

This conclusion was supported by a path analysis of blood flow data from the face-matching task (McIntosh *et al*., 1994; Horwitz *et al*., 1995). Path analysis is a variant of structural equation modeling that can determine the strength and direction of influence between brain regions in a functional model and assess how these differ between tasks or subject groups (McIntosh and Gonzalez-Lima, 1994). Analysis showed that in both age groups there were positive influences from the ventral occipitotemporal cortex to anterior temporal regions, and from there to the inferior frontal cortex. However, older adults' data also showed a strong feedback influence from frontal cortex to occipital cortex. These analyses suggest that although the network of ventral regions involved in face processing may not change with age, the functional interaction between regions in this network is altered by aging, such that there is an age-related increase in the reliance on frontally mediated strategic monitoring of low-level processes.

More recently, Grady *et al*. (2000) investigated age-related differences in brain activity during the perception of degraded and nondegraded faces. In this study, response accuracy was higher for the younger adults (particularly with the degraded faces), but the two age groups did not differ in terms of response time. Brain activity during nondegraded face matching essentially replicated the earlier findings: activity was seen in ventral occipital temporal areas in both age groups, but the younger adults had greater activity in prestriate and bilateral parietal regions, whereas the older adults had greater activity in left ventral prefrontal cortex, left medial temporal, and bilateral fusiform areas. Degraded face matching should reduce the ability to rely on simple perceptual matching and should increase the need for strategic monitoring processes. Indeed, data from both younger and older adults showed that increasing levels of face degradation led to decreased activity in occipital regions and to increased activity in bilateral prefrontal regions.

Madden and colleagues (1996) conducted a PET study focusing on age-related differences in brain activity during word processing. The passive viewing of words and nonwords relative to a fixation control activated striate and inferior temporal cortices in the left hemisphere for both age groups, although the level of temporal lobe activation was greater in the younger than in the older adults. In another condition, participants were required to press a button in response to words but not nonwords, an activity that is presumed to involve semantic retrieval. In this case, relative to passive viewing of words and nonwords, widespread activation in ventral occipital, lingual, and fusiform regions was bilateral, but stronger in the left hemisphere. These activations were comparable in younger and older adults, except for an age-related decrease in activity in a small region situated between the left lingual and fusiform gyri. In another condition the words and nonwords were perceptually degraded by the inclusion of asterisks between each letter (e.g., H*O*R*S*E), and again participants were required to respond to words but not to nonwords. In this condition, relative to the processing of nondegraded words, additional activity was found in the left lingual gyrus, which did not differ between the two age groups. The older adults were slowed disproportionately by the distracting asterisks, a finding that is consistent with the behavioral results mentioned in Section II,A, yet there was no neural correlate of this effect. Madden *et al*. (1996) did not find activation of the left inferior prefrontal cortex during word processing probably because in no case was a strategic search through semantic memory required (see Section III,B). Nevertheless, results from this study demonstrated that in very simple tasks that activated well-learned, highly automated processes, such as word reading, age-related differences in brain activity are minimal.

Investigations of age-related differences in brain activity during attention tasks have also been conducted. Only middle-aged to older adults (ages 51–73) were tested in a study conducted by Johannsen *et al*. (1997). They presented visual and vibrotactile stimuli, and participants were required to detect changes in one stimulus (simple attention) or both (divided attention). Both simple and divided attention activated the prefrontal cortex (Brodmann's area 46) and the inferior parietal lobule (Brodmann's area 40) in the right hemisphere.

As mentioned in Section III,A, these are the same brain regions that younger adults have activated in previous studies of attention (e.g., Corbetta *et al*., 1990, 1991; Pardo *et al*., 1991). Thus, although it appears from this study that the brain networks involved in attention do not change as a function as age, we do not know whether younger adults would have activated these brain regions under these particular conditions, whether they would be activated to a greater or lesser extent, or whether the strength and direction of influence among brain regions (as assessed by path analysis) would differ with age.

Madden *et al*. (1997) also investigated simple and divided attention, but tested both younger and older adults. Two letters were preassigned as target letters, and on each trial a 3×3 grid of letters was presented and participants pressed one of two buttons depending on which target was present. In a ''central condition,'' a target letter appeared in the central grid position on every trial, and in the ''divided attention'' condition, one target was present on every trial, but its location in the grid varied from trial to trial. One could question whether this latter condition represents true divided attention (attending to two sources or types of information simultaneously), but it seems clear that the divided attention condition placed greater attentional demands on the participants than the other two conditions. Indeed, errors and reaction times increased with the task demands, particularly for the older adults.

Blood flow data revealed that the divided condition, relative to the central condition, was associated with increased activity along the occipitotemporal (i.e., ventral) processing stream for the younger adults, but in medial prefrontal regions for the older adults. These findings are broadly consistent with those of Grady *et al*. (1992, 1994), although the younger adults' activity was more lateral and the older adults' activity was more medial in the study by Madden *et al*. (1997), and suggest that while younger adults relied more on object processing to perform the divided attention task, the older adults relied more on strategic control and response monitoring.

Esposito *et al*. (1999) examined cerebral blood flow while participants performed Raven's progressive matrices, a task that taps problem solving and abstract reasoning. In this task, subjects are shown a 3×3 matrix with one empty cell and must select the missing element from a number of alternatives displayed beneath the matrix. Relative to a control task matched for sensorimotor demands, activation during the Raven's task was greater for the younger than the older adults in the left inferior parietal lobule, inferior and middle temporal lobe, left parahippocampal gyrus, and cerebellum. In addition, the younger adults showed more *suppression* of brain activity during the Raven's test relative to the control task in the posterior cingulate, bilateral frontal pole, and in superior temporal lobe regions. Thus, there was less difference in brain activity between the Raven's test and the control task in the older adults, which suggests that older adults were less sensitive to the demands of the task at hand.

In summary, every study of the effects of aging on brain activity during nonmemory tasks has found an age-related reduction in the recruitment of functional networks important for attention, and many of these studies have found an age-related increase in the recruitment of areas that are not activated by younger adults. We will defer our explanations for these findings until later because the same pattern of findings appears in the memory literature (see Section V), and thus any account of age-related decreases and increases of neural activity will need to encompass both nonmemory and memory tasks.

V. Age-Related Differences in Brain Activation during Memory Tasks

As noted in Section II, the magnitude of age-related memory decrements is sensitive to encoding and retrieval task demands; specifically, age-related memory impairments are greater when the encoding or retrieval task requires complex, self-initiated processes, but smaller when the task facilitates encoding or retrieval (Craik, 1983, 1986). Studies of working memory and episodic memory reveal that tasks requiring greater degrees of self-initiated mnemonic activity recruit more extensive frontal lobe involvement (e.g., Petrides *et al*., 1993a,b; Cabeza *et al*., 1997a). Thus, a reasonable prediction is that the behavioral findings will extend to measures of cerebral blood flow in that age-related decrements in brain activity during memory tasks will be greater when the task requires self-initiated encoding or retrieval activities and smaller when the memory task provides encoding or retrieval support. A small but growing number of neuroimaging studies of memory and aging are available from which this hypothesis can be tested. This section discusses age-related differences in brain activity during implicit memory, working memory, and episodic memory.

A. Perceptual Priming

Bäckman *et al*. (1997) investigated brain activity during a word stem perceptual priming task in younger and older adults. Behavioral data were consistent with previous studies (see Section II,A) in that there was no significant age-related difference in the amount of perceptual priming. Cerebral blood flow data showed a reduction in extrastriate cortex (Brodmann's area 19) activity during the word stem completion test relative to a control task, which in fact was greater in the older than younger adults. Although clearly more evidence is needed, results from this study are promising in that they demonstrate how bottom-up processing driven by external stimuli is maintained with age, as revealed by both behavior and blood flow.

B. Working Memory

One example of a task that requires working memory abilities is the Wisconsin card sorting task (WCST), in which participants sort cards differing in the number, shape, and color of stimuli onto one of four reference piles. Participants must discover the sorting rule (e.g., color), and after they have successfully sorted a series of cards according to this rule, the rule is switched without notice (e.g., to number). Thus, this task assesses a number of higher-order attention, problem-solving, and working memory abilities (Goldman-Rakic, 1987; Berman *et al*., 1995). Both Nagahama *et al*. (1997) and Esposito *et al*. (1999) examined age-related differences in cerebral blood flow during the WCST relative to a control task that matched the sensorimotor demands of the WCST. However, it should be noted that Nagahama *et al*. (1997) used

a modified WCST in which each stimulus card shared only one attribute with a reference card, and thus their task was less demanding than the original WCST. The other difference between these two studies is that Esposito *et al*. (1999) tested 41 adults between the ages of 18 and 80, and thus were able to examine linear relationships between age and behavioral performance or cerebral blood flow.

The results of these two studies were rather compatible, despite their procedural differences. Nagahama *et al*. (1997) found that the older adults were slower and made more errors (both perseverative and nonperseverative) than the younger adults, and Esposito *et al*. (1999) reported a significant negative correlation between age and WCST performance (percentage correct). Both studies found age-related decreases in activation during the WCST in the left dorsolateral prefrontal cortex and in the left inferior parietal lobule. These brain regions have been associated with other complex attention and working memory tasks (see Sections III,A and III,D), and thus these results suggest that there is an age-related decrement in the ability to activate brain networks involved in strategic processes such as problem-solving and response monitoring during complex or difficult tasks. In addition, Nagahama *et al*. (1997) reported age-related decreases in the activation of a number of posterior brain regions associated with visual processing, but they did not find any brain regions in which activation was greater in the older than in the younger adults. In contrast, Esposito *et al*. (1999) reported age-related decreases in activation of the anterior cingulate and cerebellum, as well as age-related increases in activation of the cuneus, bilateral frontal poles, and right parahippocampal gyrus; indeed, in the younger adults these latter three regions were suppressed during the WCST relative to its control. Discrepancies between these two studies are probably due to the different versions of the WCST used and to differences in their statistical power ($n = 6$ per age group in Nagahama *et al*.). Nevertheless, the finding from Esposito *et al*. that older adults activate a more extensive neural network is reminiscent of the findings from complex attentional tasks (Grady *et al*., 1992, 1994; Madden *et al*., 1997).

One study investigated age-related differences in cerebral blood flow during a more traditional working memory task (Grady *et al*., 1998a). On each trial, a stimulus face was presented and was followed by a 1, 6, 11, 16, or 21 sec delay, after which the stimulus face and a new face were presented, and participants identified the stimulus face. Thus, this task is similar to the face matching task used previously by these investigators (Grady *et al*., 1992, 1994, 2000), but with the added requirement to hold the face in mind over the delay period and then match it from memory. The younger adults were faster and slightly more accurate than their older counterparts, but the two age groups' response times increased similarly with increasing delay. Furthermore, the delay manipulation had similar effects for the two age groups on brain activation in a number of brain regions. For example, activity in the ventral extrastriate cortex and in an inferior part of the right prefrontal cortex decreased, whereas activity in left prefrontal regions increased with longer memory delays. These effects suggest that as the delay between study and test increased, there was a decrease in the participation of early visual processing and a decrease in memory retrieval, along with an increase in elaboration of the studied faces. Furthermore, these aspects of working memory for faces were invariant with age. Despite these similarities, during the working memory task as a whole, compared to the control task, the older adults had greater activity in left prefrontal regions. Grady *et al*. suggested that this result may reflect an age-related increase in the reliance on elaborative strategies, such as relating the faces to someone familiar, or an age-related increase in general working memory demands (such as response monitoring and attention). In contrast, the younger adults had greater activity in the right ventrolateral prefrontal cortex, which has been associated with the maintenance of information online in order to facilitate discrimination (Petrides *et al*., 1993a). In addition, there were age-related differences in brain activity in other regions that showed the greatest change in activity from the 1 to 6 sec delay. One of these regions was the left hippocampus, in which activity increased from the 1 to 6 sec delay in the younger adults, but decreased over these delays in the older adults, suggesting that older adults are less able to engage medial temporal lobe structures that are important for remembering (see Section III,E). In summary, this study indicated that although younger and older adults' neural response to a working memory task is similar in a number of ways, the older adults seem to approach the task less efficiently.

C. Episodic Memory

The remaining neuroimaging studies of memory and aging focused on episodic memory and scanned participants separately during encoding and/or retrieval. We discuss age-related differences in brain activity during encoding and retrieval separately because these two memory stages recruit different functional networks (see Section III,E).

Four studies investigated age-related differences in cerebral blood flow during encoding. It is important to consider the similarities and differences among their findings in terms of the study conditions used in each study because conditions that guide elaborative encoding lead to better memory performance (Craik and Tulving, 1975). As foreshadowed in Section II,F, we might expect that such conditions will ''guide'' effective functional networks, and thus lead to fewer age-related reductions in encoding-related cerebral blood flow.

First of all, Madden *et al*. (1999) presented concrete nouns and required participants to make a living/nonliving judgment on each item, a task that guides attention to the meaning of the words and leads to better memory performance (Craik and Tulving, 1975). The younger adults remembered more of the words on a later recognition memory test, but performance was above 75% (hits minus false alarms) in both age groups. The older adults' cerebral blood flow during encoding, relative to a baseline task, showed encoding-related activity in bilateral prefrontal regions, the left parahippocampal gyrus, left fusiform gyrus, and the thalamus. Curiously, there were no regions of significant encoding-related activity in the younger adults, but only in the thalamus did encoding-related activity interact with the age group, which suggests that younger and older adults activate similar encoding-related brain networks (albeit at subthreshold levels in the younger adults) when the study task guides elaborative encoding.

Cabeza *et al*. (1997b) presented moderately related word pairs (e.g., parent–piano), and participants were instructed to consider a meaningful relationship between the two words during the encoding task. Thus, this task did require some degree of self-initiated encoding, as the words were not highly related, and it was up to participants to refine the semantic association between the words. The younger and older adults' memory for these words (assessed by cued recall and recognition) did not differ, but there were significant age-related differences in encoding-related cerebral blood flow. Relative to brain activity during retrieval, there were age-related declines in encoding-related brain activity in left prefrontal cortex and in bilateral occipitotemporal regions, together with age-related increases in activity in bilateral insular regions, indicating that aging is associated with altered self-initiated encoding operations.

This same paired associate task was used by Anderson *et al*. (2000), but in this case the word pairs were presented under conditions of full or divided attention. This study was motivated by findings from the cognitive aging literature that younger adults learning under conditions of divided attention have memory impairments that closely resemble those associated with aging (Craik, 1982; Rabinowitz *et al*., 1982; Jennings and Jacoby, 1993; Anderson *et al*., 1998). One goal of the PET study was to see whether aging and divided attention were associated with similar reductions in encoding-related brain activity, and indeed very similar reductions in left inferior prefrontal cortex were found. These results suggest that the behavioral effects of aging and divided attention resemble each other because both reduce the ability to engage in elaborative encoding.

Finally, one could argue that even less encoding support was provided in the study conducted by Grady *et al*. (1995), in which unfamiliar faces were presented and participants were instructed simply to remember the faces. The younger adults recognized more of the faces on a later recognition memory task. These behavioral differences were accompanied by greater encoding-related activation (relative to baseline tasks) in the younger than in the older adults in the left inferior prefrontal cortex, the anterior cingulate, left temporal and fusiform regions, and in the right hippocampus and parahippocampal gyrus, but no regions in which encoding-related activity was greater in the older than in the younger adults. These results suggest that when elaborative encoding processes are not guided by the task, age-related declines in memory performance are associated with reductions in encoding-related brain activity.

Obviously, it is difficult to draw conclusions about the relationship between elaborative encoding and age-related differences in cerebral blood flow from only four studies. Nevertheless, these studies seem to demonstrate that older adults benefit from supportive study conditions because such conditions guide brain activity in the functional network associated with successful encoding.

Retrieval support comes most typically in the form of retrieval cues, which lessen the need for top-down or self-initiated memory search. Episodic memory tasks thus differ in the amount of retrieval support they offer, ranging from free recall in which participants are told to recall everything they can remember from the study episode to item recognition, in which the studied items are represented along with new items, and participants indicate whether each item was on the study list. Retrieval support reduces age-related memory decrements (Craik, 1986), and we might expect that it would also diminish age-related reductions in retrieval-related cerebral blood flow.

Two studies used item recognition memory paradigms, paradigms that are thought to provide the greatest amount of retrieval support of all episodic memory tasks. First of all, the study conducted by Grady *et al*. (1995) included a two-choice face recognition test for the studied faces described earlier. The younger adults showed retrieval-related brain activity (relative to control tasks) in right prefrontal regions, right parietal cortex, extrastriate regions, and the cerebellum; the older adults showed a similar pattern of retrieval-related brain activity, but with less activation of the right parietal and right extrastriate regions. Importantly, however, there were no age-related differences in right prefrontal activity during retrieval. Similarly, Madden *et al*. (1999) scanned during a yes/no word recognition test and found that younger and older adults activated right prefrontal regions comparably during recognition, relative to a baseline task. However, older adults also had prefrontal activation in the left hemisphere during recognition, whereas in the younger adults it was right lateralized. The results of these two studies indicate that in the context of a very supportive retrieval task, areas important for episodic retrieval are recruited similarly by younger and older adults, although older adults may recruit additional neural systems to enhance task performance.

One additional recognition task was used by Cabeza *et al*. (1997b), but in this case it was a semantic recognition task. After studying moderately related word pairs, participants were presented with some of the original word pairs (e.g., ''parent–piano'') and with some altered pairs (e.g., ''parent–guitar''), and participants said ''yes'' to the pairs they thought they had studied. This task requires participants to remember the specific semantic connection between the originally presented words, and in that sense resembles a recall test rather than a recognition test. Indeed, this study also included a cued recall test in which the first word of each pair was presented, and participants had to recall the second word of the pair or say ''pass.'' For the most part, brain activity during semantic recognition and cued recall was similar, and thus we will consider them together as retrieval-related brain activity. Right prefrontal retrieval-related brain activity was comparable between the younger and the older adults (Brodmann's areas 9, 10, and 47), although the younger adults also activated medial prefrontal regions. There were, however, age-related reductions in right parietal activity, and age-related increases were found in the left prefrontal cortex. These results are similar to those of Madden *et al*. (1999) in demonstrating a more extensive retrieval-related brain network in older adults.

A cued recall task was used in the study conducted by Anderson *et al*. (2000), and retrieval was conducted under conditions of full or divided attention. The younger adults recalled more words than the older adults overall, and the effect of the attention manipulation replicated previous reports of slight or no effects of divided attention during retrieval (Baddeley *et al*., 1984; Craik *et al*., 1996; Anderson *et al*., 1998). These behavioral results were reflected in blood flow data; specifically, there were age-related decreases in right

prefrontal activity during retrieval, but divided attention had no effect on retrieval-related right prefrontal activity in either age group. In addition, the older adults activated the left inferior frontal gyrus, and the younger adults activated the left middle frontal gyrus. The bilaterality of retrieval-related activity was surprising, but it should be noted that the area activated by the older adults was closer to regions associated more typically with encoding. Two conclusions can be drawn from these findings: (1) at least in the presence of a moderately helpful retrieval cue, divided attention during retrieval leaves memory performance intact because it does not interfere with functioning in right prefrontal regions that are important for retrieval from episodic memory and (2) the older adults' lower activation of retrieval-related networks may partly contribute to their lower memory performance.

Two studies used word stem cued recall tests in which the first few letters of studied words were presented during retrieval, and participants tried to complete the stems with words from the studied list (e.g., "string" for "str___"). Bäckman *et al*. (1997) found that both younger and older adults activated right prefrontal regions during this task, relative to a control task, but only the older adults showed additional activation of left prefrontal regions, a finding that is consistent with the results of Cabeza *et al*. (1997b) and Madden *et al*. (1999). In addition, the older adults showed greater activation of bilateral medial temporal lobe regions, whereas this pattern was not seen in the younger adults, which Bäckman and colleagues interpreted as reflecting an age-related increase in the use of cue-dependent—or data-driven—retrieval (see Moscovitch and Umilta, 1991). Schacter *et al*. (1996b) tested word stem cued recall following perceptual or semantic study conditions that led to low and high memory performance, respectively. In the low recall minus baseline comparison, Schacter *et al*. reported an age-related decrease in the activation of the left and right anterior prefrontal cortex. However, in the high recall minus baseline comparison, there was no significant frontal lobe activation, but significant bilateral hippocampal activation that did not differ between the two age groups. Our interpretation of these results rests on a consideration of the interaction between encoding and retrieval support. That is, in low recall conditions, relatively degraded information had been encoded into memory, and thus, even when presented with a moderately supportive retrieval cue (the word stem), participants must engage in strategic memory searches. The age-related reduction in right prefrontal activity indicates that the older adults are less able to engage the retrieval networks necessary to guide strategic retrieval. In contrast, in the high recall condition, relatively meaningful information was encoded into memory, and thus the moderately supportive retrieval cue is sufficient to retrieve information from memory in a cue-dependent or data-driven manner. In this case, medial temporal and not prefrontal regions are activated (cf, Moscovitch and Umilta, 1991), and these bottom-up processes are resilient to aging.

Finally, Cabeza *et al*. (2000) compared item recognition with temporal order memory. In the item recognition condition, participants were shown one word from a study list and one new word, and they indicated which word had been on the study list. In the temporal order condition, participants were shown two words from the study list, and they indicated which word had been shown more recently in the list. The two main regions that were activated during the item retrieval task were medial temporal lobe regions and prefrontal regions: whereas activity in temporal lobe regions was relatively comparable in the two age groups, the older adults showed less right prefrontal but more left prefrontal activity than their younger counterparts, which is reminiscent of the more extensive item retrieval-related networks in older adults reported by Cabeza *et al*. (1997b), Bäckman *et al*. (1997), and Madden *et al*. (1999). In contrast, cerebral blood flow during the temporal order task activated right prefrontal regions significantly more for the younger than older adults. Thus, this study also showed that when the memory task requires the intentional retrieval of contextual details from a previous episode, there are age-related decrements in activity in the brain networks required to perform such searches.

The conclusion that can be drawn from these studies of brain activity during retrieval is that age-related decrements in brain activity are greatest during tasks that require controlled, self-initiated retrieval searches, but are minimized during tasks that offer more retrieval support. In particular, older adults show less right prefrontal activation during difficult recall tasks, and as the study by Cabeza *et al*. (1997b) showed, even during recognition tasks that require retrieval of associative information. The other interesting finding from these studies is that these age-related decreases in right prefrontal activity during difficult memory tasks are often accompanied by age-related increases in left prefrontal activation. That is, in the face of retrieval tasks that require self-initiated memory search, the network of brain activity is more extensive in older than in younger adults.

VI. Common Age-Related Differences in Brain Activation across Studies

Two broad patterns emerge from the studies of age-related differences in cerebral blood flow during cognitive tasks. First, there are age-related decreases in brain activity in the functional networks associated with cognitive tasks, and these decrements are most pronounced during conditions that require more self-initiated processing, but are reduced in more supportive conditions. Second, under some circumstances the older adults activate more extensive networks of brain activity than do their younger counterparts. In an effort to visualize these two patterns, we selected all of the voxels in which significant age X task interactions were reported in the studies described in Sections IV and V, classified them according to the cognitive process thought to be isolated by the task in question, and visually inspected these results as a function of brain region.

Brain regions that showed clear patterns of age-related differences were the occipital cortex, the ventral and medial portions of the temporal lobes, and the frontal lobes. Figure 17.1 (see color insert) shows significant interactions with age in occipital and temporal lobe regions. The "warmer" colors (reds, oranges, and yellows) represent regions that the older adults activated more than the younger adults, and the "cooler" colors (blues and greens) represent regions that the

younger adults activated more than the older adults. The first striking finding is the age difference noted during perception. Specifically, in perception tasks, as well as in attention tasks, the younger adults were more likely to activate visual processing regions in extreme posterior regions of the occipital lobes, which suggests that younger adults perceive and attend to objects at very early stages of processing. In contrast, during perception tasks the older adults were more likely to activate regions further along the ventral processing stream in both occipital and temporal regions, a finding that indicates that perceptual analysis requires more extensive visual processing in older than younger individuals. Figure 17.2 (see color insert) shows regions in the prefrontal cortex that showed significant age X task interactions. Here we find that many sites in lateral and medial prefrontal cortex showed age-related increases in activation during perception tasks, suggesting that perceptual stimuli undergo much more elaborate processing in older adults.

It may be instructive to consider these findings in terms of Salthouse's (e.g., 1996) theory of cognitive slowing. According to this theory, the speed of perceptual-cognitive processing declines with age, such that the information available from earlier stages of information processing is incompletely analyzed when it is needed by higher stages of processing. Slowing has a cascading effect, such that at each stage information is more degraded and sometimes arrives too late to be useful for higher stages of processing. While it is impossible to ascertain from PET data whether speed is the root of the age-related differences in perceptual networks (because of the temporal constraints of this scanning technique), this theory could explain why older adults activate more extensive brain regions than their younger counterparts. That is, areas may be activated in older but not younger adults because additional neural systems may be brought on line to help decipher information delivered by earlier processing stages. The path analyses of brain activity during face matching reported by McIntosh *et al*. (1994) and Horwitz *et al*. (1995) are consistent with this view, as the older adults showed greater feedback influences from frontal to posterior brain regions, suggesting more elaborative processing was required by older adults in order to resolve the perceptual information. Indeed, in tasks that are thought to isolate other cognitive functions (e.g., memory), some of the brain regions found to be activated by older but not younger adults may be related to the resolution of perceptual information.

Turning now to memory tasks, a particular pattern seems to emerge from the age-related differences in working memory and episodic encoding activity in occipitotemporal regions (see Fig. 17.1). During working memory tasks, younger adults showed greater activity in posterior occipital regions, whereas older adults showed very few regions of greater activity. During episodic encoding tasks, the age-related increases tended to be more posterior to the age-related decreases. These results suggest that there is an age-related decrease in the ability to utilize posterior occipital lobe regions to maintain visual information in working memory, as well as an age-related decrease in the ability to process that information more ''deeply'' in anterior regions along the ventral processing stream during encoding. A more striking comparison can be seen in age-related differences in the frontal lobes, however (see Fig. 17.2). While there were few frontal sites of greater encoding-related brain activity in the older adults, there were many instances of greater encoding activity in the younger adults, and the majority of these occurred in lateral aspects of left hemisphere. The younger adults' left prefrontal activity during encoding is consistent with HERA (Tulving *et al*., 1994b) and supports the conclusion that elaborative episodic encoding declines with age.

While there is no clear pattern in the few age-related differences in retrieval-related brain activity in posterior brain regions, a pattern is much more apparent in the frontal lobes. In particular, age-related decreases in retrieval-related brain activity were found mainly in the right prefrontal cortex, whereas age-related increases in retrieval-related brain activity were found mainly in the left prefrontal cortex. That is, there is an age-related reduction in the activation of brain regions important for episodic retrieval (right prefrontal cortex), together with an age-related increase in the activation of brain regions more typically associated with encoding and other cognitive functions (left prefrontal cortex). If we return to the explanations that have been brought forth in order to account for right prefrontal activity during retrieval (see Section III,E), the ''retrieval effort'' and ''retrieval success'' hypotheses are not consistent with the data, as Cabeza *et al*. (1997b) found no age-related differences in memory performance together with age-related declines in right prefrontal activitation, whereas Grady *et al*. (1995) and Madden *et al*. (1999) found worse memory performance in the older adults together with no age-related differences in right prefrontal activation. The other two hypotheses fare better, namely that older adults may have more difficulty maintaining a general retrieval mental set or may be less efficient at monitoring retrieval. Maintaining mental set and monitoring cognitive operations have both been linked to frontal lobe functioning, and older adults are more likely to lose set on other cognitive tasks (e.g., the WCST) and to show evidence of monitoring failures (e.g., poorer inhibition of prepotent responses and higher intrusion rates) (for a review, see West, 1996). Finally, these results could also be viewed as consistent with the cortical asymmetry of reflective activity pattern described by Nolde *et al*. (1998), in which retrieval tasks that require more complex, evaluative processes (i.e., self-initiated processes) are more likely to activate the left prefrontal cortex. This view would suggest that the retrieval cue is less likely to activate the desired information in older adults, and thus there is an age-related increase in the need to engage in strategic retrieval processes mediated by the left prefrontal cortex.

Perhaps the best way to arrive at a theoretical explanation for age-related differences in cerebral blood flow during perceptual and cognitive tasks is to analyze the relationship between blood flow and behavior. Relatively few analyses of this sort have been performed, but those that have are instructive. For example, in the divided attention study conducted by Madden *et al*. (1997), response times were correlated with activity in the visual cortex in the young adults and with activity in the prefrontal cortex in the older adults. These findings highlight the conclusion that younger adults relied more on object processing to perform the attention task, whereas older adults relied more on strategic control and response monitoring. In the working memory task for faces

conducted by Grady *et al*. (1998a), right prefrontal (Brodmann's area 45/46) and left medial temporal regions were more active and were associated with *faster* responses in the younger adults, and the left prefrontal cortex was more active and was associated with *slower* responses in the older adults. These results suggest that the efficiency of the functional networks activated declined with age. In the word recognition study reported by Madden *et al*. (1999), the activation of Brodmann's area 10 in the right prefrontal cortex during retrieval did not differ between younger and older adults and was associated with longer recognition latencies for both age groups, which suggests that this location may be involved in retrieval effort or retrieval monitoring processes. Finally, in the WCST study by Nagahama *et al*. (1997), decrements in left dorsolateral prefrontal activation (which were greater in the older adults) were related to an increased number of perseverative errors on that task.

While these findings suggest that the age-related diffusion of brain networks is generally associated with poorer cognitive performance, there are other cases in which it is associated with better performance. For example, in the recognition study of Madden *et al*. (1999), increased blood flow in posterior brain regions was associated with faster responding on the part of the older adults. In the study by Grady *et al*. (2000), nondegraded face-matching activity in the left hippocampus and left thalamus was greater for older than younger adults and was associated with slower, but more accurate performance in the older adults on the degraded tasks. These findings are consistent with the suggestion that in some cases, the older adults' more extensive brain networks may reflect "functional compensation," or the use of different strategies in order to improve performance (Grady *et al*., 1994; Cabeza *et al*., 1997b).

Finally, we would like to point out one additional pattern of results that emerges from these studies of perception and memory in healthy adults. During some perceptual tasks (e.g., face matching in Grady *et al*., 1992, 1994, 2000; divided attention in Madden *et al*., 1997), the older adults showed more extensive networks of brain activity that extended into frontal cortex, and these results indicated an age-related increase in the need for more elaborative processes in order to resolve perceptual information. However, during memory tasks that required more elaborative encoding or retrieval mediated by frontal lobe regions (Grady *et al*., 1995; Schacter *et al*., 1996a; Cabeza *et al*., 1997b, 2000; Madden *et al*., 1999; Anderson *et al*., 2000), the older adults failed to activate prefrontal regions as much as their younger counterparts. How can these two seemingly contradictory patterns be integrated?

We suggest that these results are consistent with the attentional resource account (Craik, 1983, 1986) that was introduced in Section II,F. This account proposes that cognitive tasks consume attentional resources to varying degrees and that there is an age-related reduction in the amount of attentional resources available to fuel complex cognitive tasks. Neuroimaging studies are beginning to elucidate the neural correlates of attentional resources. Specifically, Goldberg *et al*. (1998) reported that performance on the WCST and on a fast-paced auditory shadowing task declined when these two tasks were performed simultaneously, a finding that demonstrates that attentional capacity was exceeded by the dual-task requirement. Furthermore, relative to the full attention conditions, activity in prefrontal cortex declined during the dual-task condition. D'Esposito (2000) considered these results in conjunction with other findings from his laboratory and hypothesized that prefrontal activity may increase to meet the attentional demands of the task, but only to the point at which attentional capacity is reached, beyond which prefrontal activity may decline. A merger of this idea of an inverted U-shaped function of prefrontal activity with Craik's (1983, 1986) reduced attentional resources hypothesis leads to the suggestion that older adults reach their asymptote more quickly.

Figure 17.3 shows a hypothetical pattern of prefrontal brain activation (relative to a control task) during four types of task of the sort reviewed in this chapter. Perception and attention tasks that engage bottom-up processes would fall in the leftmost column. During these tasks, younger and older adults show comparably little activation of prefrontal regions, as reported in the study by Madden *et al*. (1996). More difficult attention or perceptual tasks that require top-down processes would fall in the second column to the left. In this case, older adults activate prefrontal regions *more* than younger adults, as shown by Grady *et al*. (1992, 1994, 2000) and Madden *et al*. (1997), perhaps because older adults need to engage more elaborative processes in order to manage the task. At this point in Fig. 17.3, the older adults have already reached their attentional capacity, and any increases in attentional demands beyond this point will result in decreases in prefrontal activity. The decrease in older adults' level of frontal activation is evident in the third column, which represents memory tasks that guide appropriate encoding or retrieval processing. In this case, younger and older adults' degree of frontal lobe activity is comparable, as was shown in the left prefrontal cortex during encoding by Madden *et al*. (1999) and during retrieval in the right prefrontal cortex by Grady *et al*. (1995), Cabeza *et al*. (1997b), and Bäckman *et al*. (1997). Finally, memory tasks that require self-initiated encoding or retrieval operations are represented in the rightmost column, where age-related decrements in frontal lobe activity are found. This finding was reported for encoding by Grady *et al*. (1995), Cabeza *et al*. (1997b), and Anderson *et al*. (2000) and during retrieval by Schacter *et al*. (1996b), Anderson *et al*. (2000), and Cabeza *et al*. (2000). According to this hypothesis, if even more

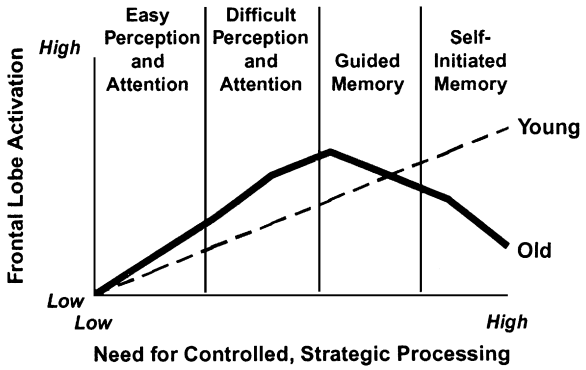

FIG. 17.3 Theoretical model of age-related differences in prefrontal brain activation as a function of the need for controlled processing (e.g., attentional demand) in the cognitive task.

attention-demanding tasks were employed, younger adults' prefrontal activity would decline and approach that of older adults. Although data available at the present time cannot confirm this model, it is nevertheless appealing because it is consistent with the reduced attentional resource hypothesis put forth by Craik (1983, 1986) and it provides an explanation for the seemingly contradictory findings of age-related increases in prefrontal activity during relatively simple attentional or perceptual tasks and age-related decreases in prefrontal activity during difficult memory tasks.

VII. Conclusions and Future Directions

The existing neuroimaging studies of aging show two broad patterns of findings. One pattern is characterized by age-related decreases in the activation of functional brain networks important for cognitive performance, particularly during complex tasks that require self-initiated operations. The other pattern is characterized by age-related increases in brain activation in regions that are not typically activated by younger adults. This more extensive functional network is in some cases associated with poorer cognitive performance and in some cases with better performance. Some brain regions are involved in both of these two patterns of age differences, depending on the task assessed. For example, older adults appear to activate frontal lobe regions to a greater extent during some perceptual tasks, but less during some memory tasks. We suggested that these results are consistent with age-related reductions in attentional resources controlled by frontal lobe systems and presented a hypothetical model (based on Goldberg *et al*., 1998; D'Esposito, 2000) of age-related differences in prefrontal involvement as a function of the attentional demands of the task.

Indeed, in recent years there has been increasing interest in what is referred to as the ''frontal lobe hypothesis'' of cognitive aging, and our review of the neuroimaging studies of aging indicates that age-related changes in prefrontal activity play an important role in distinguishing the functional networks of younger and older adults. However, we would like to emphasize that the frontal lobes never work in isolation, but rather as part of a functional network. That is, if one role of the frontal lobes is to orchestrate the participation of other brain regions, then frontal lobe deficits will result in changes in the involvement of more posterior brain regions, and functional deficits in posterior brain regions may change functioning in the frontal lobes. Thus, to understand the neural underpinnings of cognitive aging, we must consider age-related changes in the *pattern* of activity throughout the brain resulting from a cognitive challenge.

Furthermore, we need to gain a better understanding of how age-related differences in brain activation relate to differences in behavioral performance. This is a tall order, indeed, because we are only beginning to understand how brain activation is related to behavioral performance in younger adults, let alone how these relationships change with aging. The brain–behavior data available thus far provide evidence that older adults' functional networks are associated with worse performance in some cases and better performance in others. Only one study (Grady *et al*., 2000) has correlated blood flow with response accuracy in addition to response latency. It is instructive that Grady and co-workers found that increasing blood flow was generally associated with slower, but more accurate performance because it reminds us that faster performance does not always lead to better performance. Future studies should endeavor to include more than one measure of behavioral performance, as a comprehensive analysis of brain–behavior relationships will likely be our best avenue for understanding cognitive aging and for developing appropriate rehabilitation strategies.

Functional Brain Studies of the Neurometabolic Bases of Cognitive and Behavioral Changes in Alzheimer's Disease

I. Introduction

The development of sophisticated biochemical methodologies for the functional assessment of the brain has made it possible to determine the neural metabolic bases that underlie cognitive and behavioral activities in a noninvasive manner in the living human brain (Sokoloff *et al*., 1977; Sokoloff, 1981, 1982; Mazziotta and Phelps, 1986; Holcomb *et al*., 1989; Roland, 1993; Raichle, 1998; Pietrini *et al*., 1999a,b). Over the past two decades, positron emission tomography (PET) and, more recently, functional magnetic resonance imaging (fMRI) have been employed in conjunction with neuropsychological and pharmacological experimental paradigms to investigate brain activity under a variety of physiological conditions in healthy individuals as well as in those with neurological and psychiatric disorders. In the present chapter, we will review the main studies conducted with these functional brain methodologies to investigate the neurobiological bases of dementing illnesses, with particular reference to Alzheimer's disease (AD).

II. Metabolic Correlates of Neural Activity in the Brain

A brief summary of the main aspects of brain energy metabolism is necessary to understand better the functional meaning of the *in vivo* neurometabolic studies performed with PET to measure regional cerebral glucose utilization and blood flow or fMRI to assess blood-flow-related phenomena.

In physiological conditions, energy in the brain, in the form of adenosine triphosphate (ATP), is produced almost exclusively through the oxidative metabolism of glucose. Because in the mature central nervous system neurons do not replicate and neosynthetic activities are limited, the great majority of ATP is utilized to support the biochemical processes associated with the activity of the ATP-dependent sodium/potassium pumps located in the cell membrane. These pumps actively exchange Na^+ and K^+ ions between the external and the internal cell compartments (for each molecule of ATP used, three Na^+ ions get out for every two K^+ ions that get in) and thus are essential for maintaining the internally negative cell membrane potential. When neurons depolarize following an action potential, the activity of the Na^+/K^+ pumps increases significantly to restore the ionic gradients required to reestablish the negative membrane potential (Whittam, 1962; Jueptner and Weiller, 1995). Therefore, increases in functional electrical activity linked to the transmission of impulses from neuron to neuron increase the demand for ATP and, in turn, for glucose metabolism. Furthermore, as cell storage of glucose and oxygen are quite limited, increases in glucose oxidative metabolism are accompanied by parallel changes in capillary blood flow in the same brain regions as a means for supplying adequate amounts of glucose and oxygen and to remove metabolic products (Roy and Sherrington, 1890; Sokoloff, 1982; Roland, 1993). This functional link provides the basis for using measures of cerebral glucose metabolism as well as blood flow as indices of neuronal and synaptic activity.

The frequency of action potentials on one hand and the rate of glucose utilization and capillary blood flow on the other show a direct linear correlation (Sokoloff, 1981; Schwartz *et al*., 1979; Kadekaro *et al*., 1985, 1987; Jueptner and Weiller, 1995). Moreover, increments in glucose utilization or blood flow over a baseline resting state, observed when neurons are being stimulated, reflect almost exclusively increased energy demands to support the activity of the Na^+/K^+ pumps (Mata *et al*., 1980; Jueptner and Weiller, 1995) and are localized in the regions with dense synaptic contacts between axons and dendrites and not in the location of cell bodies (Kadekaro *et al*., 1985, 1987; Schwartz *et al*., 1979; Roland, 1993).

While metabolic increases indicate increased synaptic activity, conversely, decreases in cerebral glucose metabolism or blood flow represent reduced functional activity and are due

to a net decrease in regional synaptic metabolic demand. This view is supported by both PET studies in humans and autoradiographic studies in animals that demonstrated a decrease in local cerebral glucose metabolism and blood flow in relation to the inhibition of cortical neurons (Kelly and McCulloch, 1993; Roland and Friberg 1988). For instance, the intracarotid injection of the GABA-A agonist 4,5,6,7-tetrahydroisoxazolo (5,4)-pyridin-3-ol (THIP), which induces postsynaptic neuronal inhibition by increasing the membrane conductance to Cl^- and thereby enhancing the negative membrane resting potential, is associated with a dose-dependent decrease in regional cerebral blood flow (rCBF) in the cortical areas of the affected hemisphere (Roland and Friberg, 1988). These deactivations may be due to a decreased excitation (i.e., the deactivated area may receive less input from another brain structure) or to a local net increase in synaptic inhibition (Haxby *et al*., 1994; Kawashima *et al*., 1995). Therefore, changes in glucose utilization or blood flow represent valuable indices of regional changes in functional synaptic activity in the brain.

III. Cerebral Glucose Metabolism and Blood-Flow Studies in Alzheimer's Disease

Alzheimer's disease, the most common form of dementing illnesses in the elderly, typically begins with a subtle onset of memory disturbances that may represent the only symptoms for several years (Pietrini *et al*., 1993b; Linn *et al*., 1995) and that are often followed by impairments of attentional and executive functions, semantic memory, and visuoperceptual skills along with alterations in personality and behavior (Grady *et al*., 1998; Haxby *et al*., 1990; Mendez *et al*., 1990; Pietrini *et al*., 1996).

From a neuropathological perspective, AD is characterized by the presence of senile plaques, neurofibrillary tangles, and loss of neurons and their synaptic projections (Whitehouse *et al*., 1981; Terry and Katzman, 1983). Although the regional distribution of neuropathological lesions varies among patients, the areas most commonly affected include the association neocortical areas of the parietal, temporal, and frontal lobes and limbic regions (Braak and Braak, 1991; Terry and Katzman, 1983; Lewis *et al*., 1987; Hof *et al*., 1995). The progression of the neuropathological process is thought to produce the cognitive deficits associated with dementia by affecting first the medial temporal lobe structures, including the entorhinal cortex and the hippocampal formation, and subsequentely spreading to the neocortical association areas of the temporal, parietal, and frontal lobes (Lewis *et al*., 1987; Braak and Braak, 1991; Van Hoesen *et al*., 1991).

Since their first appearance in the early 1980s, functional brain imaging methodologies have been used extensively to investigate the neurophysiological correlates of cognitive decline in patients with AD at different stages of dementia severity (for reviews, see Rapoport, 1990, 1991, 1999; Grady and Rapoport, 1992; Mielke *et al*., 1998; Alexander and Pietrini, 2000; Pietrini *et al*., 2000b). Unlike postmortem examinations, which reflect only the end stage of disease and do not allow for concurrent assessment of cognitive or behavioral features, assessments by PET with 18-fluoro-D-deoxyglucose (18-FDG) provide *in vivo* metabolic measures of brain function. With PET, one can examine regional changes in metabolic indices of brain activity in disease during life and correlate such findings with clinical and cognitive features, even in the initial stages of the disease or, as we will discuss later, prior to the onset of symptoms in subjects at risk for developing the disease (Pietrini *et al*., 1993a, 1997a; Small *et al*., 1995, 2000; Reiman *et al*., 1996). Further, *in vivo* PET studies can be repeated over time to follow the development of the neuropathological process and to evaluate the brain response to potential therapeutic interventions (Grady *et al*., 1988; Haxby *et al*., 1990; Pietrini *et al*., 1993a; Nordberg, 1996).

A. Cerebral Glucose Metabolism in the "Resting State"

1. Metabolic Reductions Affect Mostly the Neocortical Association Areas

In agreement with the distribution of the neuropathological lesions revealed by the autopsy studies, the *in vivo* measurements of regional cerebral metabolic rates for glucose (rCMRglc) using PET in the "resting state" (i.e., eyes covered/ears plugged, minimal sensory stimulation) have been consistent in showing that rCMRglc reductions in patients with AD affect mostly the association neocortical areas, with a relative sparing of primary neocortical regions, subcortical structures, and cerebellum at least until the later stages of the disease (Duara *et al*., 1986; Kumar *et al*., 1991; DeCarli *et al*., 1992; Grady and Rapoport, 1992; Pietrini *et al*., 1996; Mega *et al*., 1999).

Grouping AD patients into those with mild, moderate, and severe dementia using the Mini-Mental State Exam (MMSE; Folstein *et al*., 1975) score has shown differences in cerebral metabolism as a function of dementia severity. Representative examples of brain PET scan examinations from AD patients in the different stages of dementia severity are shown in Fig. 18.1 (see color insert). Such cohort comparisons suggest that the first reductions in brain glucose utilization in mildly demented patients with AD relative to that seen in healthy elderly subjects typically appear in parietal and temporal neocortical association areas. As the disease progresses, resting state metabolism is reduced in additional neocortical regions, including frontal and occipital lobes until, in the most severe stages, only areas of sensorimotor and primary visual and auditory cortices and subcortical structures show some relative preservation of glucose metabolism (Duara *et al*., 1986; Kumar *et al*., 1991; Grady and Rapoport, 1992).

2. The Distribution of Metabolic Reductions is Heterogenous

Within this general framework of progression of the metabolic impairment, the regional distribution of metabolic lesions may differ markedly in individual patients. For example, some patients may show a greater involvement of the left cerebral hemisphere, whereas others may show a larger involvement of the right hemisphere. Some subjects may have a greater impairment of the frontal and temporal lobes and others of the posterior cortical regions (Haxby *et al*., 1988). This hetero-

geneous distribution of metabolic reductions allows for the determination of right/left asymmetry indices and anterior/posterior ratios that can be related to the distribution of the neuropsychological and behavioral impairment shown by individual AD patients (Haxby *et al*., 1985, 1988, 1990; Haxby, 1990; Grady *et al*., 1990). Interhemispheric metabolic asymmetries are greater in patients with AD than in healthy elderly people (Haxby *et al*., 1985; Duara *et al*., 1986; Waldemar *et al*., 1994). Further, these metabolic asymmetries appear to be stable over time, indicating that the pathological process maintains a relatively more selective effect on the same brain regions across the different stages of dementia progression (Grady *et al*., 1986, 1988; Haxby *et al*., 1988, 1990). In a study conducted in our laboratory (Grady *et al*., 1990), a principal component analysis applied to cerebral metabolic data from a large sample of mildly to moderately demented patients with AD revealed four subgroups characterized by distinct patterns of cerebral metabolic abnormalities (Fig. 18.2, see color insert).

The most common pattern involved metabolic reductions in superior and inferior parietal lobules and in the posterior medial temporal regions. In a second group, rCMRglc was reduced in orbitofrontal and anterior cingulate areas, with a relative sparing of parietal regions. Metabolic reductions primarily affected the left hemisphere in a third group of patients, and the fourth group had reduced metabolism in frontal, temporal, and parietal cortical areas. These subgroup differences in brain metabolic abnormalities were subsequently verified in 24 patients with postmortem histopathological confirmation of AD, indicating that the clinical, neuropsychological, and neurophysiological heterogeneity observed in AD patients is not the consequence of clinical misdiagnosis or of concomitant additional neuropathological abnormalities (Strassburger *et al*., 1996) but rather an intrinsic characteristic of the disease process itself.

In the study from Grady *et al*. (1990), each patient subgroup had a characteristic neuropsychological and behavioral profile that corresponded to the distribution of the metabolic deficits. Specifically, the group of patients showing reduced metabolism in orbitofrontal cortex, a brain region known to be important in the regulation of behavior including the modulation of aggressive response (Pietrini *et al*., 2000c), showed increased agitation, anger outbursts, inappropriate social behavior, and personality changes (Grady *et al*., 1990). Patients in Group 3, who had greater left hemisphere hypometabolism, showed more impaired verbal memory, verbal fluency, and calculating abilities than Group 1 patients (who had parietal and temporal deficits), but had better visuoperceptual performance and drawing skills. In agreement with these findings, another study that focused on the relation between intrahemispheric variability of metabolic lesion distribution and neuropsychological profiles, demonstrated that patients with greater parietal than frontal hypometabolism had greater impairment of verbal comprehension, calculations, visuospatial construction, and immediate visuospatial memory span, whereas patients with disproportionate frontal hypometabolism were more impaired on verbal fluency and attention (Haxby *et al*., 1988).

Additional independent studies in patients with AD have demonstrated regional differences in the distribution of brain metabolic abnormalities in the frontal and temporal lobes associated with specific behavioral disturbances, such as depression, agitation, disinhibition, delusions, and hallucinations (Sultzer, 1996), apathy (Craig *et al*., 1996), or delusional misidentification syndrome (Mentis *et al*., 1995).

3. Metabolic Reductions in Neocortical Areas May Precede and Predict Nonmemory Cognitive Impairment

Longitudinal studies that combined clinical, neuropsychological, and PET scan examinations have indicated that some patients in the very early stages of AD, who complain only of isolated amnesia, express abnormal patterns of glucose metabolism in neocortical areas that precede and predict the subsequent development of nonmemory cognitive impairments (Grady *et al*., 1988; Haxby *et al*., 1990). For instance, patients with memory impairment and predominant left hemisphere hypometabolism are subsequentely more likely to develop greater language impairment, while those with disproportionate right hemisphere hypometabolism will tend to show greater impairment of visuoconstructive abilities (Haxby *et al*., 1985). These metabolic alterations can be detected as much as 18–24 months prior to the clinical appearance of the cognitive signs, suggesting that compensatory mechanisms in the brain, likely related to the redundancy in neuronal connections, may maintain cognitive skills within a relatively normal range for quite a long time.

4. Interregional Functional/Metabolic Correlations Are Altered in Alzheimer's Disease

In addition to these regional metabolic abnormalities, patients with AD also have a decreased number of metabolic correlations in functional activity between the association neocortical areas as compared to age-matched healthy individuals. The loss of significant metabolic correlations involves particularly the correlations between homologous regions in the right and left hemispheres and the correlations between frontal and parietal cortical areas (Horwitz *et al*., 1987). These findings suggest that a disruption of the normal functional connectivity between brain regions accompanies the dementing neuropathological process (Horwitz *et al*., 1987). As we will discuss later, in some patients with AD such a disruption in functional/metabolic interregional correlations may be detected even before significant glucose metabolic reductions in any cortical region become evident (Pietrini *et al*., 1993a; Azari *et al*., 1993). Thus, determination of the patterns of interregional metabolic correlations may provide a sensitive method for identifying subtle functional changes in brain activity that can aid in early detection and in characterizing the neural systems preferentially affected throughout the clinical course of AD (Pietrini *et al*., 1993a; Alexander and Moeller, 1994; Azari and Pietrini, 1995).

5. Metabolic Reductions in Temporal and Parietal Cortex Can Be Found in Other Dementing Disorders

While metabolic reductions in the neocortical association areas of the parietal and temporal lobes are a typical finding

in patients with AD, they are not necessarily specific for AD. A pattern of parietal and temporal cortex hypometabolism was found in a patient initially diagnosed as having dementia of the Alzheimer type and then Parkinson's disease with dementia but who was found to have only Parkinson's disease on postmortem histopathological examination. The metabolic changes observed were similar in magnitude and regional distribution to what is seen in patients with probable AD (Schapiro *et al*., 1993). This may indicate that glucose metabolic reductions in parietal and temporal neocortical areas in patients with AD are related to the dementia state rather than being a specific characteristic of the disease. Indeed, glucose hypometabolism in parietal and/or temporal cortical regions has been demonstrated in some patients with Parkinson's disease (Kuhl *et al*., 1984; Arahata *et al*., 1999), normal pressure hydrocephalus (Friedland, 1989), and Creutzfeldt–Jakob disease (Friedland *et al*., 1984). Some mild reductions in glucose metabolism in temporal cortical areas appear also to be present in patients with sleep apnea syndrome, a disorder of breathing during sleep that is associated with cognitive disturbances, as compared to healthy control individuals. The degree of reduction in glucose utilization is strongly related to the severity of the breathing disorder and of the cognitive impairment (Pietrini *et al*., 1998).

6. Clinical Subgroups in Alzheimer's Disease: The Visual Variant

As discussed above, AD is characterized by some degree of clinical and neuropsychological heterogeneity that corresponds to a heterogenous distribution of brain metabolic alterations as revealed by *in vivo* PET examinations. Despite their distinctive features, however, these clinical subgroups commonly share disturbances of memory function as the presenting complaint at onset of the disease (Foster *et al*., 1983; Haxby *et al*., 1985; Mayeux *et al*., 1985; Martin *et al*., 1986; Grady *et al*., 1990). This seems to imply that the disease process originates in common brain structures in these subgroups but then progresses to involve different cortical regions, resulting in distinct sets of neuropathological and clinical features, such as those characterized by prominent language or visuospatial deficits (Foster *et al*., 1983; Haxby *et al*., 1985; Grady *et al*., 1990). Indeed, impariment of episodic memory appears to be a constant accompanying clinical feature also in the case of patients with focal cortical syndromes who later are shown to have AD (De Renzi, 1986; Mesulam, 1987).

In a relatively rare clinical subtype of AD, however, the onset of the disease is characterized by prominent disturbances of visual and visuospatial functions, which are not accompanied by any memory complaints. The first activities to be impaired usually are those requiring visuospatial processing, including driving and reading. As patients progressively lose their ability to judge the relative distance among objects, simple actions such as keeping the proper distance from other vehicles, parking between cars, or even driving in a straight line become increasingly difficult (Furey-Kurkjian *et al*., 1996; Pietrini *et al*., 1996). Similarly, these individuals lose the ability to keep track of a printed line so that reading books or newspapers is affected as well. These cognitive difficulties stand in isolation and in sharp contrast to the relative preservation of other cognitive domains, including memory function and personality (Furey-Kurkjian *et al*., 1996). Thus, for instance, while driving is impaired because of their visual difficulties, these subjects retain a normal capability to perform all the actions required to operate their cars in the proper sequence. This appears to be different from what is seen in patients with more typical AD, whose driving may be impaired because they cannot remember aspects of the task or become confused in unfamiliar environments.

Because of the purely visual nature of their complaints, it is common for individuals with this visual variant of AD to seek repeated ophthalmological evaluations, which fail to detect a lesion of the peripheral visual system that can explain their disturbances (Pietrini *et al*., 1996; Galton *et al*., 2000). Only several months after the appearance of the first disturbances when, with worsening of the disease, visual dysfunction progresses to include alexia, poor hand–eye coordination, visual agnosia, and Bálint's syndrome (oculomotor apraxia, optic ataxia, visual inattention, and simultagnosia), and even more so when additional nonvisual cognitive difficulties also begin to appear, is the possibility of a neurodegenerative process taken into account (Pietrini *et al*., 1996). Thus, while visual functions also may become impaired in patients with typical AD, the peculiarity of this atypical subgroup is that visual and visuospatial deficits appear as the first salient clinical symptoms and remain prominent until the end stage of disease (Pietrini *et al*., 1993b, 1996; Galton *et al*., 2000). On the other hand, memory, personality, behavior, critical judgment, moral restraints, and insight into their condition, which are consistently affected to some degree in patients with typical AD, remain relatively preserved until the most advanced stages of dementia (Pietrini *et al*., 1993b, 1996).

These distinctive features shown by patients with the visual variant of AD compared to patients with the typical form of AD on clinical and neuropsychological testing are accompanied by differential patterns of brain metabolic changes as measured by PET scan examinations. Relative to heathy control subjects, both the typical and the visual variant groups of AD patients revealed reduced glucose utilization at rest (eyes/ears covered) bilaterally in parietal neocortical association areas (Pietrini *et al*., 1996). The patients with typical AD showed additional metabolic reductions in limbic, temporal, and frontal cortical regions and relative preservation of visual and primary sensory areas. In contrast, the visual variant patients had greater metabolic deficits than the typical AD patients in parietal and occipital cortices (including primary visual cortex) with a relative sparing of inferior temporal, frontal, and limbic regions (Fig. 18.3, see color insert). This distinctive pattern of the regional distribution of brain metabolic impairment remains relatively stable as the disease progresses (Pietrini *et al*., 1993b).

Consistent with the *in vivo* metabolic measures obtained by PET, the postmortem distribution of histopathology in two of the visual variant patients that had come to autopsy from our group showed greater Alzheimer-like neuropathology in the posterior occipital association and primary visual cortex compared to reference values from a group of severity-matched demented patients with typical AD (Pietrini *et al*., 1997b). A similar prevalent distribution of senile plaques and neurofibrillary tangles in the occipitoparietal and posterior cingulate

regions with relative sparing of the temporal, frontal, and limbic regions has been described in a group of autopsy-confirmed AD patients with visual symptoms (Hof *et al*., 1990, 1993, 1997). A recent clinical, neuroradiological, and postmortem study demonstrated severe bilateral reduction in occipital lobe perfusion (as measured by single photon emission computed tomography, SPECT), posterior brain atrophy, and severe neuropathological involvement of occipital visual cortex at autopsy in a patient with AD who had a more than 3-year history of isolated and progressive visual difficulties prior to the appearance of additional cognitive complaints (Galton *et al*., 2000). Together, the clinical and neuropsychological features and the brain metabolic and histological findings in these patients with AD and early and prominent visual dysfunction indicate that a different underlying neuronal vulnerability to the disease process may occur in this clinical variant of AD. This visual variant, along with other atypical presentations of AD, such as progressive biparietal syndrome, provides evidence in support of the heterogeneity of the neuropathological process in AD and raises the question about the mechanisms that may underlie the expression of these different phenotypes. The progress in molecular pathology and genetic studies likely will lead to the understanding of the differential neuronal sensitivity to neuropathological processes and explain the heterogeneity of disease development (Galton *et al*., 2000).

7. Decreased Brain Glucose Utilization in Alzheimer's Disease Reflects Neuronal Dysfunction

Dementia in AD is accompanied by a 30–40% cell loss which leads to brain atrophy. Given that an increased partial volume effect secondary to atrophy may artifactually decrease *in vivo* metabolic measures by PET, for many years it has been debated whether glucose metabolic reductions in the brain of AD patients were true indices of impaired neural activity or simply the result of tissue loss. To address this issue, we employed high-resolution segmented structural magnetic resonance images to correct rCMRglc measures for the atrophy-related partial volume effects in a group of mildy to severely demented patients with AD and age-matched healthy controls (Ibáñez *et al*., 1998). The results demonstrated that rCMRglc reductions per gram of brain tissue in parietal, frontal, and temporal cortex remained significantly lower in the patients with AD than in controls after correction for partial volume effects (Fig. 18.4). Thus, rCMRglc reductions observed in AD represent a true biochemical index of neuronal synaptic dysfunction in the affected brain regions and are not an artifact due to the loss of tissue.

B. Stimulation Studies in the Assessment of the Neural Correlates of Cognitive Dysfunction in Patients with Alzheimer's Disease

The combination of sensory or neuropsychological stimulation paradigms with functional brain imaging methodologies has made it possible to determine the neurophysiological activity of the brain systems involved in distinct cognitive functions and the changes that occur in association with the development of the neuropathological process in patients with AD at different stages of dementia severity. Further, one can evaluate the effects of the pharmacological modulation of specific neurotransmitter systems on brain metabolic and cognitive functions by comparing behavioral performance and brain activity in response to a neuropsychological task prior to and during the administration of a selective neurotransmitter enhancer or suppressor (Furey *et al*., 1997, 2000).

The great majority of these functional brain studies has been conducted using the PET–$H_2{}^{15}O$ technique to measure rCBF, which, as rCMRglc, represents a reliable index of neuronal

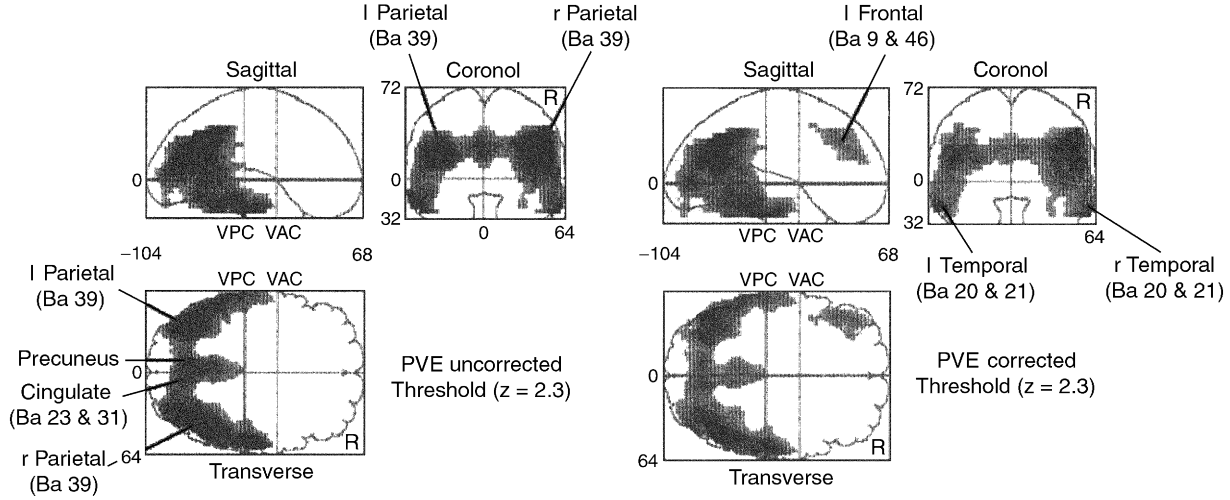

FIG. 18.4. Comparison of glucose metabolism between control subjects and AD patients before and after partial volume (atrophy) correction. Statistical parametric maps of orthogonal projections for significant voxels are shown. The intercommissural line is set to 0 mm. The anterior commissure (VAC) and the posterior commissure (VPC) are represented in the sagittal and transverse projections. The projections are presented with a z threshold of 2.3 for uncorrected (left) and partial volume effect (PVE)-corrected (right) values. No area with significant reduction in metabolism became normal after correction. Further, reductions in glucose metabolism in a left frontal area of AD patients became significant only after correction. Ba, Brodmann areas; l, left; r, right (adapted from Ibáñez *et al*., 1998).

synaptic activity (Jueptner and Weiller, 1995). Unlike PET–rCMRglc exams, though, which require approximately 1 hr to be completed and allow for no more than two scans in the same PET session (Duara *et al*., 1990, 1992; Kessler *et al*., 1991; Pietrini *et al*., 1997a, 1999b, 2000a), rCBF determinations last from 1 to 4 min so that several scans can be repeated sequentially only a few minutes apart, while subjects are at rest or engage in a variety of cognitive activities (Grady *et al*., 1993; Mentis *et al*., 1996, 1998). In general, these studies are conducted by contrasting brain functional responses during a certain stimulation condition with a baseline or control condition to determine those brain regions that show a significantly increased or decreased rCBF from baseline during a specific cognitive or sensory stimulation paradigm.

1. Studies with Cognitive Probes

Several studies have sought to investigate the brain functional responsiveness in patients with AD in comparison with matched healthy control subjects during the performance of distinct cognitive tasks, including memory, language, and visual abilities. In Table 18.1 are reported the experimental designs and major findings from rCMRglc and rCBF studies in AD patients performed with the use of cognitive probes.

In a study conducted in our laboratory, Grady and colleagues (1993) used PET–rCBF to determine how the brain functional response in AD patients with mild to moderate dementia differed from healthy elderly controls on a visual discrimination task that involved the perceptual matching of faces as compared to a sensorimotor control task. The rCBF during the control task (which required pressing a button alternately with right and left thumbs in response to a nonsensical visual stimulus) was subtracted from the rCBF during the face-matching task (subjects had to indicate whether the right or the left face matched the target by pressing the button in the corresponding hand) to obtain the mean difference rCBF value associated with the perceptual task. Response accuracy was similar in the two groups, although the AD patients had significantly slower reaction times. Significant rCBF increases occurred in equivalent occipitotemporal and occipitoparietal visual cortical regions in the AD patients and the control group. Further, despite the fact that rCBF in occipitotemporal regions during the control task was significantly lower in the AD patients than in the control subjects, the mean increment rCBF did not differ between the two groups (Grady *et al*., 1993). These findings suggest that the ability to recruit visual association areas during the performance of a visual perceptual discrimination task is preserved despite the presence of reduced rCBF in the baseline state in the mild stages of dementia in patients with AD (Rapoport and Grady, 1993).

Functional studies in young healthy individuals have shown that face matching is a complex cognitive task that relies on a widely distributed set of brain regions important for object perception and attentional processing that extends from occipital and occipitotemporal areas through frontal association cortical areas (Haxby *et al*., 1994). In addition, individual differences in task performance during the perceptual matching of faces are associated with a differential modulation of the functional interactions among the cortical and subcortical brain regions implicated in object perception and attentional processing (Alexander *et al*., 1999). In patients with AD, these functional regional interactions may be altered by the neuropathological process even in the early stages of the disease and prior to more evident changes in brain responsiveness. Horwitz and colleagues (1995) applied network path analysis to the same face-matching PET–rCBF data reported in the above study by Grady *et al*., (1993) to determine whether the patterns of brain functional regional interactions during the perceptual task differed between the AD patients and healthy controls. Indeed, the results indicated that although the AD patients had the same performance accuracy and mean rCBF increase in occipital visual association areas as controls (Table 18.1), they appeared to use a different network of brain regions while performing the face-matching task (Horwitz *et al*., 1995).

In a study by Becker *et al*. (1996), rCBF was assessed with PET during the performance of auditory–verbal memory tasks in a group of seven AD patients and seven healthy controls. They found that the AD group activated brain regions important for auditory and verbal memory processing to a greater extent than the healthy elderly subjects and, further, that additional brain regions were activated in the AD patients during the cognitive task conditions compared to that seen in the elderly controls. The results of this study and those of Horwitz and colleagues (1995) support the idea that networks important for cognitive functions are altered by the neuropathological process in AD and that the brain may compensate for the effects of neurodegeneration through a functional reorganization of neurocognitive resources.

2. Studies with Sensory Stimulation Paradigms

The *in vivo* assessment of the brain metabolic activity underlying distinct cognitive functions in patients with AD is limited to individuals with mild or mild to moderate levels of dementia severity, as all of the above neuropsychological paradigms require that subjects perform and actively engage in a given memory, language, or visuospatial task. Unfortunately, with worsening of dementia, patients lose their ability to perform even simple cognitive tasks, making the interpretation of the functional data questionable (i.e., AD subjects may not activate a certain brain region found activated in controls because that region is dysfunctional or simply because they did not engage in the task). Further, their compliance with the PET experimental procedure, which requires some restriction of movement, progressively diminishes during the scanning session. In an effort to overcome these limitations and thus be able to investigate brain functional activity across the whole range of dementia severity, including patients in the very advanced stages, we have developed some passive sensory stimulation paradigms that do not require any active participation on the patient's side.

We employed the double injection PET–FDG technique (Brooks *et al*., 1987), which allows for two rCMRglc measures to be performed sequentially during the same PET scan session, to determine the brain functional metabolic response elicited by audiovisual stimulation (presentation of a color movie) as compared to a resting state (i.e., eyes closed, ears occluded, no sensory stimulation) condition. The study was conducted in a group of 15 patients with AD who ranged from the mild to severe stage of dementia and 14 healthy

TABLE 18.1 Functional Brain Imaging Studies in Alzheimer's Disease

Reference	Subjects	Procedure	Results and comments
Duara *et al.*, 1987	7 healthy subjects (2M/5F; mean age 69; range 52–80 years) and 5 AD patients (3M/2F; mean age 69 years; range 52–80 years); careful medical screening	18-FDG i.v. bolus PET; PETT V (FWHM 15 mm); resting state (quiet and darkened environment) compared to picture viewing task condition	The variability of CMRglc measures can be reduced by performing studies during behaviour activation in normal and demented subjects; i.e., a specific behavioral state would be expected to induce more comparable levels of functional activity in the same or in different individuals.
Miller *et al.*, 1987	7 AD patients (68 ± 6 years) and 7 controls (67 ± 8 years); careful medical screening	11C-2-DG i.v. bolus PET; PETT VI; recognition memory task	AD patients were unable to recognize repeated items above a chance level. An abnormal temporal lobe metabolic response was associated with impairment on the memory task: all AD patients demonstrated a right temporal lobe asymmetry, while five of seven controls showed a left one.
Mubrin *et al.*, 1989	26 AD patients (6M/20F; 76 ± 8 years)	^{133}Xe by inhalation, Cerebrograph 32B, (low resolution, planar imaging) was used to assess the effect of pyritinol during mental activation [Word Pair Learning and Recall test (WPLR)] on cognitive disturbance and rCBF	Before treatment, during mental activation, AD patients showed a larger area of CBF increase associated with a poorer WPLR performance. After placebo, the mean hemispheric blood flow at rest remained unchanged, but a diminished number of activated areas was found in the placebo group with a significant increase in WPLR performance. After pyritinol, the resting blood flow level was unchanged, while during activation, a smaller number of activated areas was found in the drug group, which showed a better performance than the placebo group.
Duara *et al.*, 1990	(1) 26 young (33 ± 9 years) and 30 elderly healthy subjects (64 ± 9 years); 17 AD patients (74 ± 9 years) (2) 3 young (42 ± 6 years) and 19 elderly healthy subjects (63 ± 10 years); 21 AD patients (69 ± 9 years) (3) 8 young (38 ± 7 years) and 12 elderly healthy subjects (65 ± 11 years); 6 AD patients (60 ± 11 years)	18-FDG i.v. bolus PET; PETT V (FWHM 15 mm); (1) picture preference task (2) reading memory task (3) verbal fluency task	(1) AD patients showed rCMRglc increases in primary and association visual cortex, similar to elderly normals. (2) During the task, left superior parietal regions, already hypometabolic at rest, were less activated. (3) AD patients demonstrated no rCMRglc increases, but only significant decreases in the right and left occipital regions.
Buchsbaum *et al.*, 1991	6 AD patients (4M/2F; mean age 71; range 65–74 years) and 6 age-matched healthy controls (3M/3F; mean age 69 ± 5 years); careful medical screening	18-FDG i.v. bolus PET; NeuroECAT (FWHM 7.6 mm); olfactory match-to-sample task	Patients had lower metabolic rates in the anterior portion of the medial temporal cortex; this rCMRglc difference was greater during the olfactory memory task.
Kessler *et al.*, 1991	21 ''possible'' AD patients (6 M/15 F; 65 ± 7 years) and 9 age-matched healthy controls (6 M/3F; 62 ± 7 years); careful medical and neuropsychological screening	18-FDG i.v. bolus PET; Scanditronix PC384; a continuous visual recognition task with different degrees of difficulty	The visual task induced significant increase in global CMRglc. CMRglc increase was significantly larger in controls (+21%) than in AD patients (+6%); increases were mainly in visual cortex.
Duara *et al.*, 1992	20 AD patients (6M/14F; 69 ± 9 years) and 14 controls (9M/5F; 61 ± 11 years)	18-FDG i.v. bolus PET; PETT V (FWHM 15 mm); reading memory task versus a resting state condition	No significant difference in the degree of rCMRglc change was found between the AD patients and normal controls. Thus the task did not allow for a better discrimination of AD patients from normal controls on the basis of regional metabolic deficits, despite that the mean global CMRglc change in normals was about 33% greater than in the AD subjects.

(*continues*)

TABLE 18.1 (*Continued*)

Reference	Subjects	Procedure	Results and comments
Grady *et al.*, 1993	7 "possible" AD male patients (64 ± 7 years) and 8 age-matched healthy male controls (65 ± 9 years); careful medical screening	15-Oxygen water i.v. bolus PET; Scanditronix PC1024-7B (FWHM 6.5 mm); a face matching task versus a sensorimotor control task	The pattern of rCBF response to the face-matching task found in controls was seen also in mildly to moderately demented AD patients. Both groups showed bilateral increases in occipitotemporal and occipitoparietal extrastriate cortex, despite lower rCBF in these regions during the sensorimotor control task in the AD group.
Herholz *et al.*, 1993	43 AD patients (19M/24F; 68 ± 7 years) and 8 controls (6M/2F; 61 ± 9 years); careful medical screening	18-FDG PET; resting state versus continuous visual recognition task	Global increase in glucose metabolism was significantly greater in normals than in AD patients. Task-related activation was found in visual cortex, temporo-parietal regions, and cerebellum.
Riddle *et al.*, 1993	10 "possible" AD patients (72 ± 12 years) and 9 healthy controls (69 ± 11 years)	99mTc-exametazime SPECT (Multi-X810) during a verbal memory task	Performance on recognition was worse and more variable in patients than controls. During the recognition task, controls had greater CBF increases in left dorsolateral frontal cortex and anterior cingulate.
Kessler *et al.*, 1996	35 AD patients divided into two groups of 17 patients (68 ± 8 years) and 18 patients (65 ± 8 years)	18-FDG i.v. bolus; Siemens CTI, ECAT EXACT (FWHM 5 mm); resting state versus a continuous auditory recognition task (first group); or versus continuous visual recognition task (second group)	Comparison of task versus resting conditions showed significant rCMRglc increases only in thalamus and cerebellum in the first group and in occipital regions in the second one.
Mentis *et al.*, 1996a,b	10 AD patients (5M/5F; 72 ± 7 years) and 12 controls (7M/5F; 64 ± 12 years)	15-Oxygen water i.v. bolus PET; Scanditronix PC2048-15B; monochromatic red flashing lights administered at different frequencies	The rCBF responses in striate (at 7 and 14 Hz) and in bilateral middle temporal neocortical association areas (at 1 Hz) were signficantly greater in the control subjects than in AD patients.
Becker *et al.*, 1996	7 AD patients (2M/5F; 69 ± 11 years) and 7 age-matched healthy controls (2M/5F; 66 ± 8 years)	15-Oxygen water i.v. bolus PET; Siemens 951/31 PET; auditory–verbal memory task	Performance of automatic cognitive operations activated a similar pattern of cortical activity in both groups. Increasing task demand showed in the AD patients a specific activation of dorsolateral prefrontal cortex and parietal temporal borders, demonstrating that the AD brain retains a significant degree of functional plasticity.
Buck *et al.*, 1997	29 AD patients and 17 age-matched healthy controls	HMPAO-SPECT; cued reaction time task	The cognitive profile associated with AD included both spatial- (right superior parietal lobe hypoperfusion) and object-based (left inferior parietal lobe hypoperfusion) attentional impairments.
Hock *et al.*, 1997	8 healthy subjects (60 ± 15 years) and 10 AD patients (63 ± 13 years)	Near-infrared spectroscopy (NIRO 500, Hamamatsu Photonics K.K.) to assess Hb oxygenation in the frontal and parietal cortex during a verbal fluency task	Elderly subjects showed increases in hemoglobin oxygenation in both parietal and frontal regions, while AD patients had decreases in parietal and increases in frontal cortical regions. In AD patients, a marked reduction in rCBF and hemoglobin oxygenation may accompany cognitive activation, probably mainly in degenerating brain areas, such as the parietal cortex.
Pietrini *et al.*, 1997a	16 healthy subjects with trisomy 21 (Down syndrome): 8 younger (35 ± 2 years) and 8 older (50 ± 7 years) adults; careful medical screening	18-FDG i.v. bolus PET; Scanditronix PC2048-15B (FWHM = 6 mm); resting state condition (eyes patched, ears plugged, minimal room noise) versus a passive audiovisual stimulation paradigm	No significant differences in rCMRglc at rest between the two groups. In contrast, during audiovisual stimulation older nondemented subjects with Down syndrome showed significantly lower rates of rCMRglc than young subjects in parietal and temporal neocortical areas. The differential increases in rCMRglc could reflect an intrinsic functional limitation of the brain to respond to increased neural stimulation in older Down syndrome subjects prior to the onset of dementia, as a result of the effects of the pathological process in the preclinical stages of AD.
Cardebat *et al.*, 1998	17 AD patients (9M/6F; 66 ± 8 years) and 20 healthy controls (7M/13F; 64 ± 5 years)	^{133}Xe SPECT; Tomomatic 64 Medimatic;	No significant rCBF differences between the two groups in the memory versus listening to words comparison. A significant correlation between memory

		verbal episodic memory activation task (rest, passive listening, and memorizing)	performance and rCBF was found in the right lateral frontal cortex in AD patients only.
Mentis *et al.*, 1998	10 mildly demented ASD patients (3M/7F; 69 ± 5 years) and 11 severely demented AD patients (5M/6F; 73 ± 12 years) were compared to 19 healthy controls (11M/8F; 65 ± 11 years)	15-Oxygen water i.v. bolus PET; Scanditronix PC2048-15B; flashing monochromatic red lights at different frequencies	Functional failure was shown in brain regions that had normal function at rest and that typically show modest (frontal and extrastriate cortex, Brodmann's areas 18/19) or minimal (striate cortex) AD neuropathology. Stimuli that resulted in large changes in rCBF in controls were necessary to elicit functional failure in mildly demented patients, whereas stimuli resulting in intermediate and small changes in rCBF were sufficient to elicit failure in patients with moderate to severe dementia.
Woodard *et al.*, 1998	6 healthy older subjects (3M/3F; 70 ± 8 years) and 6 mildly demented AD patients (3M/3F; 69 ± 7 years)	15-Oxygen water i.v. bolus PET; Siemens 951 or 921; word rehearsal task versus a reading control task	Performance accuracy did not differ significantly between the two groups. During task, controls revealed prominent activation of dorsolateral prefrontal cortex (Brodmann's areas 46/9), middle frontal gyrus, precuneus, and precentral gyrus, whereas AD patients demonstrated additional involvement of left dorsolateral prefrontal cortex, left inferior parietal lobule, and left medial frontal gyrus.
Backman *et al.*, 1999	8 AD patients (3M/5F; 63 ± 4 years) and 8 healthy controls (4M/4F; 60 ± 7 years)	15-Oxygen water PET (GEMS PC2048-15B) during verbal episodic retrievial	AD patients showed a marked performance deficit in cued recall. During task, both groups showed increased rCBF in bilateral orbital and dorsolateral prefrontal cortex, left precuneus and right cerebellum, and reduced rCBF in left temporal regions. Healthy elderly subjects only activated the left parietal cortex and left hippocampus, while AD patients showed higher rCBF in the left orbital prefrontal cortex and left cerebellum than controls.
Johannsen *et al.*, 1999	16 AD patients (6M/10F; 68 ± 5 years) with mild to moderate dementia and 16 healthy age-matched control subjects (7M/9F; 65 ± 7 years)	15-Oxygen water PET; ECAT Exact HR-47 PET-camera; visual sustained and divided attention tasks	Compared to the healthy elderly subjects, activations in the right medial, superior, and inferior frontal gyri, and the right middle temporal and left lingual gyri were significantly lower in the AD patients; these differences became statistically greater during the divided attention task.
Saykin *et al.*, 1999	Mildly demented AD patients and healthy controls	Functional MRI BOLD; auditory stimulation tasks requiring semantic or phonological decisions	On the semantic task, inferior and middle frontal gyri were activated in both groups, but AD patients recruited locally expanded foci and other remote regions, suggesting functional compensation.
Smith *et al.*, 1999	26 healthy women were sudivided into a high-risk group ($N=14$, 52 ± 5 years) and a low-risk group ($N=12$, 53 ± 6 years) that differed only in their risk for developing AD (evaluated by positive family history or presence of APOE ϵ_4)	Functional MRI scan (1.5-T Siemens Magnetom Vision Scanner); visual naming and letter fluency tasks	The high-risk group showed areas of significantly reduced activation in the mid- and posterior inferotemporal regions bilaterally during both tasks, as compared to the low-risk group.
Pietrini *et al.*, 1999b	15 AD patients (70 ± 10 years); careful medical screening	18-FDG i.v. bolus; two sequential scans; Scanditronix PC2048-15B PET scanner; a resting state condition (eyes patched, ears plugged, minimal room noise) versus an audiovisual stimulation (watching and listening to a movie)	rCMRglc in the parietal neocortical areas correlated with dementia severity at rest and during audiovisual stimulation; in contrast metabolism in the visual and auditory regions was correlated with dementia severity during stimulation but not at rest.
Pietrini *et al.*, 2000a	15 AD patients (70 ± 10 years), 14 matched healthy subjects; careful medical screening	18-FDG i.v. bolus; two sequential scans; Scanditronix PC2048-15B PET scanner; same experimental paradigm as above (Pietrini *et al.*, 1999b)	Brain metabolic/functional response to stimulation in primary and association visual cortical areas was within the normal control values in the mildly demented AD patients but progressively declined with worsening of dementia up to point where no response could be elicited any longer.

elderly control subjects (Pietrini *et al*., 1999b, 2000a). As a group, the AD patients showed rCMRglc increases in response to the audiovisual stimulation paradigm in similar visual and auditory cortical brain regions as the healthy controls. Compared to controls, the AD patients also showed higher metabolism during stimulation than at rest in additional brain regions, including in the neocortical association areas of the parietal lobes, despite the fact that these areas were hypometabolic at rest. This suggests that more cortical networks may have been recruited in an attempt to compensate for the failure of others (Grady *et al*. 1993).

Consistent with the findings of the rCBF study by Grady *et al*. (1993) examined above, the subgroup of AD patients with mild dementia had rCMRglc increases in visual and auditory brain regions that did not differ significantly from those in healthy controls (i.e., they were within 2 standard deviations); in contrast, the patients with moderate to severe dementia showed significantly diminished rCMRglc responses. Further, in the AD patient group, the decline in the magnitude of metabolic response in primary and association visual cortical regions was highly correlated with dementia severity: virtually no metabolic response to audiovisual stimulation could be elicited in the severely demented patients (Fig. 18.5). The inability of the brain at this late stage of disease to respond to audiovisual stimulation implies a loss or otherwise severe dysfunction of its synaptic elements and neurotransmitter integrity, as shown by biopsy and postmortem studies (DeKosky and Scheff, 1990; Rapoport, 1999).

In addition to the metabolic increments in visual and auditory cortical areas, significant rCMRglc reductions in frontal and limbic regions during audiovisual stimulation were seen in the healthy controls but not in the AD patients (Pietrini *et al*., 2000a). Reductions in brain activity relative to baseline

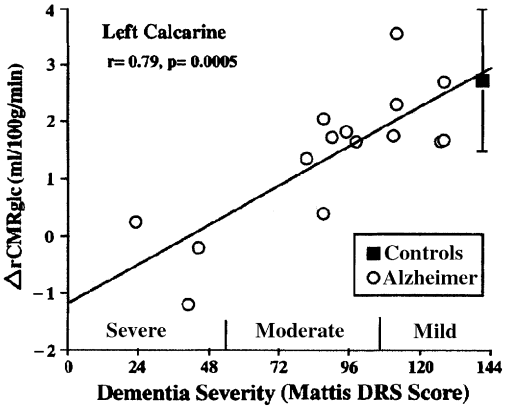

FIG. 18.5. Relation between dementia severity and brain metabolic response to audiovisual stimulation in patients with AD. The abscissa reports dementia severity, measured by the Mattis Dementia Rating Scale (DRS) score (maximum normal score 144). Regional differences in absolute rCMRglc in mg per 100 g of brain tissue per minute between audiovisual stimulation and the resting state for the AD patients are reported on the ordinate. The mean ± SD bar for controls is shown on the right. Mildly demented patients had rCMRglc increases in visual cortical areas within two standard deviations from the control mean. Brain metabolic response to audiovisual stimulation progressively declines with worsening dementia and is almost null in the severe stage of disease (from Pietrini *et al*., 2000a).

in areas not directly involved in a task have been shown in other sensory and cognitive activation studies in healthy subjects (Seitz and Roland, 1992; Haxby *et al*., 1994) and have been interpreted as regional depression of synaptic activity in relation to cross-model inhibition during selective attentional processing. The absence of such regional metabolic reductions in the AD patient group may reflect disruption of corticocortical connectivity (Morrison *et al*., 1990; Azari *et al*., 1992), consistent with the results of Horwitz *et al*. (1995) discussed above and with the neuropathological evidence that large pyramidal neurons with long intracortical and intercortical axons are most affected in the neocortex of patients with AD.

To examine the relation between dementia severity and brain synaptic efficiency in response to neural stimulations of increasing intensity, Mentis *et al*. (1996, 1998) in our laboratory employed PET–$H_2{}^{15}O$ to measure rCBF during the passive presentation of a graded visual stimulus. In this paradigm, goggles were used to present flashing red lights that alternated between left and right eyes to a group of healthy elderly controls and AD patients with mild and moderate-to-severe dementia. The flash frequency of the lights was parametrically increased from 0 (i.e., eyes open in darkness) to 1, 2, 4, 7, and 14 Hz, so that a stimulus–rCBF response curve could be obtained for the distinct primary and association visual cortical areas involved in the processing of these stimuli (Mentis *et al*., 1996, 1998). In the healthy control subjects, rCBF response to increasing flash frequency included a biphasic rising (with a peak at 7 Hz) and then falling in striate visual cortex, a linear increase in visual association cortical regions and a linear decrease in frontal cortical regions (Fig. 18.6). The AD patients showed similar curves but they had significantly smaller rCBF responses than controls at one or more levels of stimulation in many cortical regions (see example in Fig. 18.6). Specifically, in the mildly demented patients, abnormal brain responses were elicited only at the frequency producing the greatest changes in the healthy controls, whereas in the patients in the more advanced stage of dementia, a functional failure was evident also with stimuli that induced moderate rCBF changes in the controls (Mentis *et al*., 1998). Thus, despite the fact that rCBF at rest and rCBF changes at low frequency were not different from those in controls, patients with AD showed a severity-related decrease in the brain's ability to respond to incremental neural stimulation.

Together, results from the above studies by Pietrini *et al*., (2000a) and Mentis *et al*. (1996, 1998), along with those of Grady *et al*. (1993), demonstrate that synaptic viability and thus functional responsiveness in the brain are relatively maintained in the mild and to a lesser extent in the moderate stage of dementia in patients with AD, whereas they are greatly impaired in the later phases. Biopsy and postmortem studies of the density and size of synaptic elements in the brain of AD patients suggest stages of loss that may correspond to two stages of responsiveness in life (DeKosky and Scheff, 1990; Rapoport, 1999). In the first stage, the initial loss of presynaptic terminals is compensated by the relative enlargement of the remaining presynaptic terminals so that the net contact area between pre- and postsynaptic elements remains in the normal range. In the second stage, this hypertrophic mechanism is no longer sufficient to compensate for the additional presynaptic dropout, producing a net decrease in the total synaptic

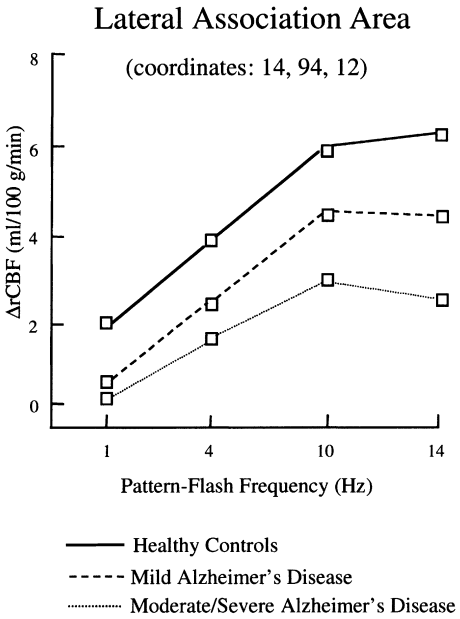

FIG. 18.6. Mean rCBF changes in response to graded neural stimulation induced by a flashing red light at different frequencies in a representative local maxima of the lateral visual association cortical area in healthy controls and in AD patients with mild and with moderate-to-severe dementia. Coordinates are according to the Tailarach and Tournoux atlas (1988). $^{*}P < 0.05$; $^{**}P < 0.001$ (from Mentis *et al*., 1998, modified).

contact area (Terry *et al*., 1991; DeKosky and Scheff, 1990; Rapoport, 1999). These results agree with other postmortem evidence that early neurofibrillary changes in pyramidal cortical neurons in the AD brain are associated with selective downregulation of mitochondrial gene expression (mRNA levels) for enzymes involved with mitochondrial oxidative phosphorylation. Such a downregulation may represent a "physiological" response to the decrease in energy demand associated with the reduced synaptic activity (Rapoport, 1999). In the later stage of the disease, in contrast, higher degrees of neurofibrillary tangle accumulation and cell death are accompanied by a general reduction in gene transcription (Chandrasekaran *et al*., 1996).

The greatly diminished synaptic efficiency observed in the later stage of AD could have a role in the lack of response to pharmacological treatment shown by patients with advanced dementia. Indeed, as available treatments for AD aim at increasing neurotransmitters in the synaptic cleft, viable synapses are needed for them to be effective (Pietrini *et al*., 2000a).

C. Functional Brain Studies in the Diagnosis of Alzheimer's Disease

1. Differential Diagnosis

From a clinical standpoint, the *in vivo* brain metabolic measurements obtained by PET may aid in the differential diagnosis of neurodegenerative diseases by demonstrating relatively distinctive patterns of changes in cerebral glucose utilization and blood flow among the different forms of progressive dementia. Although the distribution of metabolic changes in the brain is heterogeneous and may vary from patient to patient, as we discussed previously, dysfunction of parietal and temporal cortical regions is usually present in the early phase of AD. Further, with progression of dementia, additional metabolic impairments appear in other association regions, including the neocortical areas of the frontal and occipital lobes.

As reduced glucose metabolism and blood flow in several neocortical association areas, including those in the parietal and temporal lobes, can be observed also in other dementing disorders, it becomes important to consider ways for improving the diagnostic specificity and sensitivity of PET measures for AD (Azari and Pietrini, 1995; Small and Leiter, 1998). Integrating information obtained from laboratory and clinical examinations, together with relevant risk factors, may significantly enhance the ability to diagnose AD earlier and with a high degree of accuracy. For example, such an integrated approach has the potential to shorten time to diagnosis by several months or even years in patients with subtle cognitive complaints, thereby allowing for earlier, and potentially more effective, therapeutic interventions (Small and Leiter, 1998).

2. Early Detection

The patterns of abnormal changes in cerebral glucose metabolism and blood flow described in the previous sections of this paper have been reported in individuals who already met established research criteria for the diagnosis of "*possible*" or "*probable*" AD (McKhann *et al*., 1984). That is, significant cognitive impairment or dementia in these subjects was already evident on clinical examination.

In the past few years, several research groups have developed new experimental strategies aimed at detecting subtle alterations in brain metabolic function that could be employed for the preclinical identification of subjects who are likely to develop dementia. To pursue this finality, different experimental approaches can be used in various combinations.

The longitudinal evaluation of healthy individuals who have an established genetic risk for AD is a valuable strategy for identifying brain metabolic dysfunction predictive of development of dementia. Small *et al*. (1995) examined brain glucose metabolism at rest in subjects with mild memory complaints who had family history of AD and showed that those with the APOE ϵ4 allele had lower rCMRglc in the parietal areas than the subjects without APOE ϵ4. In a subsequent study, the same authors found that individuals with a single copy of the APOE ϵ4 allele, followed over 2 years, showed greater declines in glucose metabolism from baseline than noncarriers of the ϵ4 allele (Small *et al*., 2000). Further, they found that the baseline metabolic abnormalities predicted cognitive decline after the 2-year period of follow-up.

Reiman *et al*. (1996) showed altered patterns of resting glucose utilization in posterior cingulate, parietal, temporal, and prefrontal regions in cognitively normal subjects (without memory complaints) with a family history of AD and who were homozygous for the APOE ϵ4 allele. Studies of yet clinically unaffected family members in families with mutations on chro-

mosome 14 or mutations in the amyloid precursor protein (APP) gene have also shown evidence of resting state hypometabolism in parietotemporal brain regions (Kennedy *et al*., 1995).

Individuals with Down syndrome (or trisomy 21), who have a 100% risk for the development of AD pathology (Holland and Oliver, 1995), represent a unique human population for investigating brain function in the preclinical stages of AD and during the transition to dementia (Schapiro *et al*., 1992). All subjects with Down syndrome over 40 years of age show some neuropathological and neurochemical abnormalities postmortem that are indistinguishable from those observed in AD (Holland and Oliver, 1995). Further, up to 75–90% of individuals with Down syndrome develop dementia after 60 years of age.

In a longitudinal study of nondemented and otherwise healthy adults with Down syndrome examined at yearly intervals for up to 12 years, we showed that measures of cognitive abilities and brain metabolism at rest remained normal and stable until the onset of dementia. After the clinical diagnosis of dementia, both cognitive functions and parietotemporal glucose metabolism began to rapidly decline. These findings suggested that neurons maintain the ability to produce energy and perform biochemical activities essential for their survival until a threshold level of AD-like neuropathology is reached and a profound disruption of both cognitive and metabolic brain functions is triggered (Dani *et al*., 1996). However, the accumulation of AD-like neuropathology in the years preceding clinical onset of dementia is likely to impair the neuronal capability to respond to increased functional demands on the brain. Indeed, cerebral metabolic response to the same passive audiovisual stimulation paradigm described above (Pietrini *et al*., 1999b, 2000a) was impaired in parietal and temporal cortical areas of older nondemented Down subjects as compared to young control Down subjects (Pietrini *et al*., 1997a). Thus, despite normal biochemical activities and brain glucose utilization at rest, the functional damage associated with the progressive development of pathology prevents neurons in the parietal and temporal cortical areas, the first and most affected regions in the brains of patients with AD, from responding normally when the neuronal ''workload'' is maximized (Pietrini *et al*., 1997a).

In agreement with data from activation studies in AD patients (Pietrini *et al*., 1999b, 2000a; Mentis *et al*., 1996, 1998; Smith *et al*., 1999), these results indicate that stimulation paradigms with functional brain imaging methodologies may offer greater sensitivity than resting studies to the earliest effects of AD, acting as a neurophysiological stress test for dementia.

The use of sophisticated statistical methods can further enhance our ability to identify subtle metabolic changes to aid in early detection and to relate patterns of cerebral metabolic dysfunction to clinical manifestations (Alexander and Moeller, 1994; Azari *et al*., 1993; Azari and Pietrini, 1995; Pietrini *et al*., 1993a). Rather than relying on *t*-test comparisons of mean metabolic values to demonstrate significant differences between two subject groups (e.g., healthy controls and patients with AD), these analytical methods can uncover subtle abnormalities in the patterns of metabolic and functional correlations among different brain regions, and can be applied to study individual patients (Azari and Pietrini, 1995; Pietrini *et al*., 1993a). Using a multivariate discriminant function method, we identified an AD-like pattern of brain metabolic interregional correlations at rest in a nondemented subject with a family history of autosomal dominant AD, one year before conventional methods of analysis could demonstrate any cerebral metabolic reduction or cognitive decline in comparison to a group of healthy control subjects (Fig. 18.7A, see color insert, and 18.7B; Pietrini *et al*., 1993a).

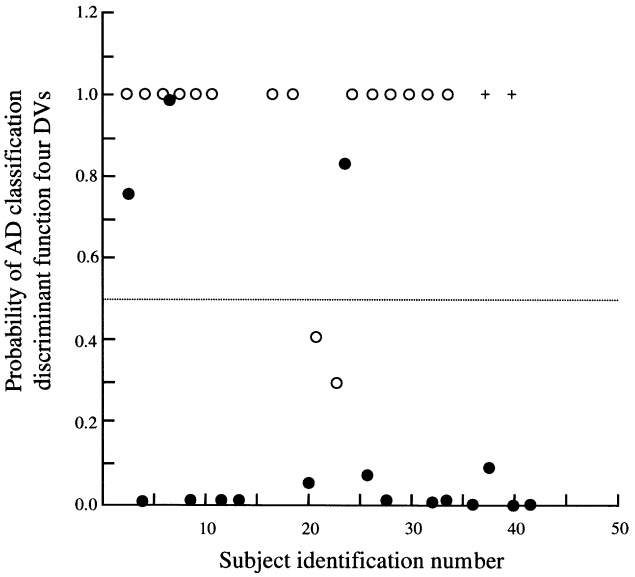

FIG. 18.7B. Probability of being classified as an AD patient based on a discriminant function analysis of rCMRglc data for patients with AD (open circles), healthy control subjects (filled circles), and the subject at risk (crosses). The vertical axis indicates the probability of being classified as AD obtained by applying a jackknife procedure to the discriminant analysis function. The great separation between the healthy control and the AD patient groups can be appreciated from the graph. Note that the at-risk subject was classified as having a 100% probability of being an AD patient at both times, despite the lack of any significant group-mean rCMRglc abnormality at time 1. PET scanning parameters are the same as in Fig. 1 (from Pietrini *et al*., 1993a).

In conclusion, the development of functional brain imaging methodologies has made it possible to evaluate, *in vivo*, the neurometabolic consequences of AD throughout its clinical course, from the earliest to the end stages of disease. In addition to PET studies of glucose metabolism and blood flow at rest, the combination of experimental paradigms which include sensory or cognitive stimulation as well as pharmacological modulation of neurotransmitter systems (Furey *et al*., 1997, 2000) with increasingly more sophisticated data analytic techniques is likely to further enhance our ability to detect subtle alterations in brain function in the earliest, presymptomatic phases of AD. Studying the preclinical and early phases of this disease in individuals with increased genetic risk may greatly advance our understanding of the neurobiological mechanisms involved in AD, individual differences in the progression of distinct clinical subtypes, and which individuals might benefit most from preventive or curative treatments as they become available.

Cholinergic Basal Forebrain Systems in the Primate Central Nervous System: Anatomy, Connectivity, Neurochemistry, Aging, Dementia, and Experimental Therapeutics

The cholinergic basal forebrain is composed of a collection of magnocellular hyperchromic neurons located within the septal/diagonal band complex and nucleus basalis of Meynert. These neurons provide the major cholinergic innervation to the hippocampus and neocortical mantle. Empirical investigations since the 1980s have established a role for the cholinergic basal forebrain in higher order cognitive processes, although its exact role in attentional versus memory processes remains an area of debate. The fact that the cholinergic basal forebrain degenerates in dementing illnesses such as Alzheimer's disease (AD) underscores the importance for understanding the structural and functional aspects of this region. Further, the cholinergic basal forebrain system is intimately linked with trophic factor systems as these neurons contain the appropriate receptors for, and are exquisitely sensitive to, neurotrophins such as nerve growth factor (NGF) and brain-derived neurotrophic factor. This chapter focuses on the neuroanatomical and neurochemical organization of the primate cholinergic basal forebrain, with special reference where appropriate to the organizational properties of the human brain and its relation to aging and dementia. The importance of understanding human cholinergic basal forebrain function is featured as this region displays a unique species-specific organization, especially as it pertains to its relationships with peptidergic systems and the expression of the estrogen receptor within the primate cholinergic basal forebrain as compared to nonprimates. Whether these species differences underlie the vulnerability of cholinergic basal forebrain neurons in diseases of higher order cognitive function remains a mystery. Finally, experimental therapeutic strategies aimed at augmenting the survival of cholinergic basal forebrain neurons, including NGF administration or fetal cholinergic grafting, are discussed.

I. Introduction

A heterogeneous collection of telencephalic structures located on the medial and ventral regions of the cerebral hemispheres collectively make up the basal forebrain in the primate brain. These structures lack a true cortical organization, despite their location on the surface of the brain. They can best be described as having a ''corticoid'' architecture. This area is complex and contains structures such as the septal area and the vertical and the horizontal limbs of the diagonal band of Broca, as well as the region termed the substantia innominata (Beccari, 1911), which is the most anatomically complicated. Historically, this later region has been termed the nucleus of the ansa lenticularis (Meynert, 1872) and later renamed the nucleus basalis (Kölliker, 1896). Although this nomenclature is the commonly most used, other terms have been applied to this region (see Mesulam *et al*., 1983a). Part of the difficulty in understanding this region is the complexity of its chemoanatomical projections. These regions have a diversity of cells containing different neurotransmitters, morphology, and projection patterns (see de Lacalle and Saper, 1997, for review). Among the great diversity of neuronal populations within the basal forebrain (e.g., calbindin, GABAergic, NADPH-d/nitrous oxide, and galaninergic cells), the cholinergic corticopetal projection neurons have received particular attention due to their reduction in Alzheimer's disease (AD) and their intimate relationship with the neurotrophic substance nerve growth factor (NGF) and its high (trkA) and low ($p75^{NTR}$) affinity receptors.

A large body of evidence has accumulated over the years indicating that NGF is involved in the survival and maintenance of the cholinergic neurons of the basal forebrain by an interaction with its receptors (see Mufson *et al*., 1997a; Mufson and Kordower, 1999, for reviews). In fact, virtually all choline acetyltransferase (ChAT)-immunopositive basal forebrain neurons composing the cholinergic subgroups termed Ch1-4 by Mesulam and colleagues (1983b) contain the protein and gene for trkA and $p75^{NTR}$ (Kordower *et al*., 1988; Mufson *et al*., 1989a,b; Sobreviela *et al*., 1994; Gibbs and Pfaff, 1992; Kordower *et al*., 1994b; Mufson *et al*., 1996, 1997a,b) and transport NGF retrogradely (Mufson *et al*., 1994, 1995). Both NGF receptors are excellent markers for cholinergic neurons of the basal forebrain. These NGF receptors have not been revealed within the other brain stem cholinergic cell groups (Schwab *et al*., 1979; Mufson *et al*., 1989a,b; Mesulam and Geula, 1988). The use of genetically engineered cells that secrete NGF has been proposed as a treatment approach for slowing of the progression of cholinergic basal forebrain neuron degeneration in AD (Tuszynski *et al*., 1990a,b, 1991, 1996, 1999; Kordower *et al*., 1994b). This chapter focuses primarily on the ascending cholinergic projection neurons of the basal forebrain and, to a lesser degree, the mesopontine magnocellular cholinergic cell groups. In contrast, we will only mention briefly the intrinsic cholinergic interneurons located within the striatum, the various cholinergic motor neurons, the cerebellum, or brain stem reticular formation. Furthermore, we will not concentrate on the cortical cholinergic interneurons that have been reported only in the rodent (Wainer *et al*., 1993). This review surveys the central cholinergic projection neurons in the primate brain and their relation to development, aging, disease, and therapeutics. For a more complete historical discussion of the definition of the basal forebrain cholinergic system, the reader is refered to the review by de Lacalle and Saper (1997).

II. Embryogenesis of Magnocellular Basal Forebrain

Although many studies have examined the cytoarchitecture, chemoarchitecture, and connections of the cholinergic basal forebrain, there have been relatively few studies examining the development of this system. Initial studies were performed using tritiated thymidine either alone or combined with choline acetyltransferase immunohistochemistry in rats (Bayer, 1985; Semba and Fibiger, 1988). These studies revealed that cholinergic basal forebrain neurons in rats are generated along a caudal to rostral gradient between gestational days 12 and 17. In mice, ChAT immunohistochemistry alone has been used to identify cholinergic basal forebrain neurons. Using this technique, Schambra and co-workers (1989) found immunoreactive cholinergic basal forebrain neurons on days, 14 and 15 of mouse gestation. It needs to be realized, however, that immunohistochemistry does not reveal the genesis of cells just the time at which the cholinergic phenotype is expressed. Thus, it remains possible that these cells were born at an earlier time point but did not express cholinergic markers until embryonic day 14 of gestation.

III. Embryogenesis of the Cholinergic Basal Forebrain in Monkey

In nonhuman primates, the development of the rhesus monkey magnocellular basal forebrain complex was studied using the archival collection of tritiated thymidine-labeled sections from the collection of Dr. P. Rakic (Kordower and Rakic, 1990). When radiolabeled magnocellular neurons are charted, an early burst of neurogenesis is seen at embryonic day 30 of the rhesus monkey 165-day gestation period followed by a short quiescent period (Figs. 19.1 and 19.2). Then, in a manner similar to that seen in rats, the development of the basal forebrain is completed across a caudal to rostral gradient between embryonic days 36 and 45, with peak neurogenesis seen between embryonic days 40 and 42. In this regard, the posterior subdivision develops completely between embryonic days 33 and 36. The intermediate subdivision displays peak neurogenesis between embryonic days 36 and 40, and development of this region is completed by embryonic day 43. The anterior division of the magnocellular basal forebrain, including the septal diagonal band complex, develops last, between embryonic days 35 and 45, with peak neurogenesis seen between embryonic days 40 and 43. In contrast to the caudal to rostral gradient of development, a neurogenic gradient is not observed in the radial direction. The development of the magnocellular basal forebrain between embryonic days 30 and 45 makes this cluster of neurons among the earliest developing cells within the telencephalon. Like other cortically projecting cells located in the thalamus and those giving rise to corticocortical connections, this early development puts these cells in a strategic position to potently influence the development of their target neurons located within the cortical mantle that are generated later in gestation.

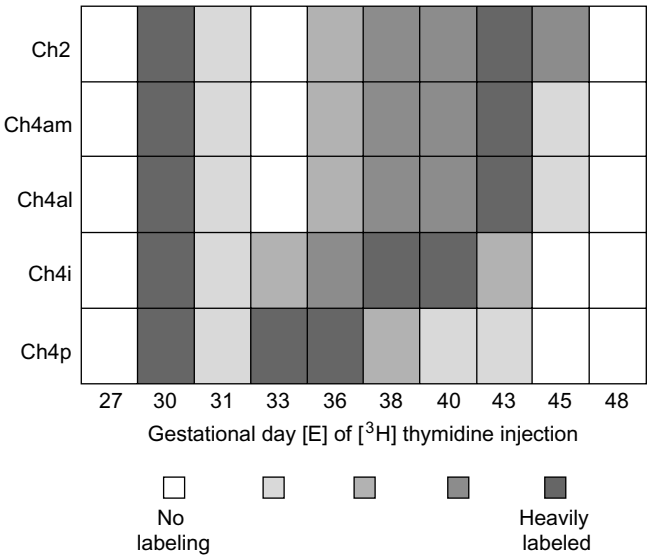

FIG. 19.1. Summary schematic illustrating the developmental tempo for each subregion of the basal forebrain. Black represents abundant neurogenesis whereas white represents little or no neurogenesis. From Kordower and Rakic (1990), with permission.

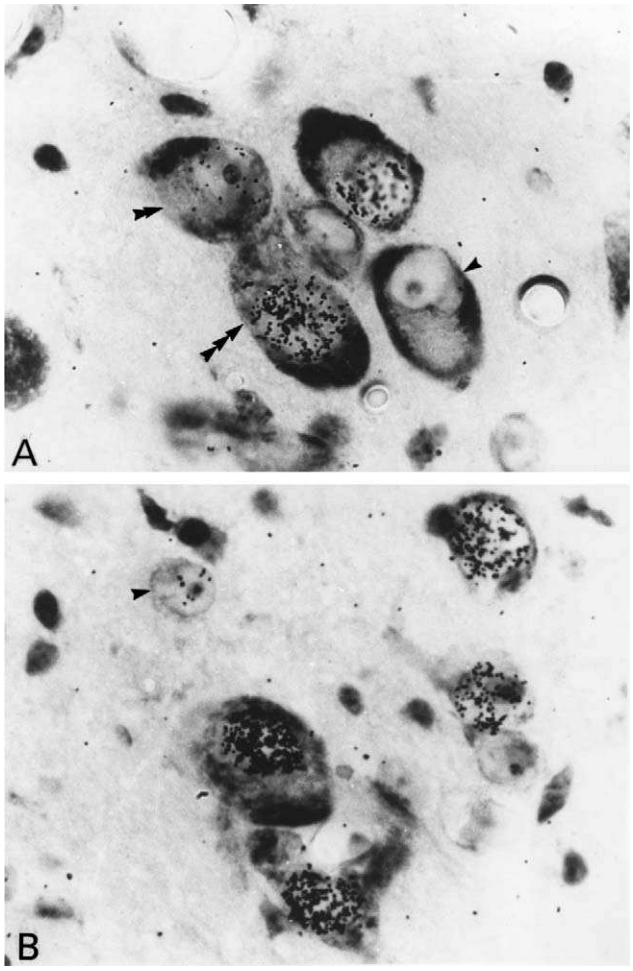

FIG. 19.2. (A) High-power photomicrographs demonstrating typical [^{3}H]thymidine-labeling profiles in the nucleus basalis. In this region, unlabeled (one arrowhead), lightly labeled (double arrowhead), and heavily labeled (triple arrowhead) magnocellular basal forebrain neurons can be observed. (B) Labeled neurons within the Ch4 region. The arrow points to a lightly labeled parvicellular neuron, which, due to its small size, would be excluded from the data analysis (A, B: 400X). From Kordower and Rakic (1990), with permission.

IV. Embryogenesis of the Cholinergic Basal Forebrain in Humans

In humans, the genesis of the cholinergic basal forebrain can only be established using morphological criteria for the presence of magnocellular neurons and the presence of phenotypic markers for this cell population. Thus the birthdating of these cells employing these techniques must be regarded as indirect. Using Nissl and acetylcholinesterase-stained material (Kracun and Rösner, 1986; Kostovic, 1986), the genesis of human cholinergic basal forebrain neurons has been established to be between weeks 9 and 15 of gestation. This early development in the first trimester is similar to what has been seen in nonhuman primates (Kordower and Rakic, 1986) and differs from what is seen in rodents in which this region develops relatively late in gestation (Bayer, 1985; Semba and Fibiger, 1988). This time window of human basal forebrain development is partially confirmed by our group, which examined the development of the human brain using immunohistochemical probes directed against either the low-affinity p75^{NTR} receptor or the high-affinity tropomycin-related kinase (trk) receptor, two receptors known to extensively colocalize with cholinergic basal forebrain neurons in primates (Hefti *et al*., 1986; Kordower *et al*., 1988; 1989b,c; Mufson *et al*., 1989a; see Mufson *et al*., 1997b, for review). Using these tools, we found that the cholinergic basal forebrain expresses both markers in their normal cytoarchitectonic position within the septal/diagonal band complex (Ch1–2; Fig. 19.3) and throughout the nucleus basalis (Ch4; Fig.19.4) by embryonic week 14, the earliest specimen available for analysis. At embryonic week 14, trk-immunoreactive neurons are scattered lightly throughout the Ch1–Ch4 subfields. In addition to the localization of these cells within the classic cholinergic basal forebrain subfields, trk-immunoreactive interstitial neurons are distributed in the external and internal medullary laminae of the globus pallidus, as well as within the internal capsule. The intensity of trk staining, as well as the number of stained neurons, increases appreciably between embryonic weeks 20 and 22. The general pattern of staining for low-affinity p75^{NTR}-immunoreactive neurons is generally the same as that observed for trk immunoreactivity. However, the intensity of staining and the number of trk-immunoreactive perikarya are greater relative to p75^{NTR}-immunoreactive neurons. The discordance between these two basal forebrain markers appears greatest early in gestation, whereas similar staining patterns are seen later in development.

V. Anatomy of Adult Cholinergic Basal Forebrain Subgroups

Initial studies used both the nonspecific cholinergic marker acetylcholinesterase (AChE) and the synthesizing enzyme for acetycholine, choline acetyltransferase, to delimit the location of the primate central cholinergic neurons (Mesulam and Van Hoesen, 1976; Mesulam *et al*., 1983a; Mufson *et al*., 1989a; Mesulam and Geula, 1988). Although various nomenclatures have been applied to the area of the primate basal forebrain [see earlier discussion; we will mainly employ the Ch nomenclature proposed by Mesulam and co-workers (1983a, 1984, 1986; Mufson *et al*., 1989a)] to designate the ascending cholinergic subgroups in the monkey and human brain. These histochemical investigations revealed a continuum of cholinergic neurons within the basal forebrain extending from the olfactory tubercle to the level of the lateral geniculate body (Fig. 19.5). The length of the basal forebrain is approximately 15–19 mm (Zaborszky *et al*., 1999). The cholinergic basal forebrain can be divided into four subdivisions: The cholinergic neurons of the medial septum (Ch1) lie along the midline of the septum and also along the outer edge of the nucleus (Figs. 19.6 and 19.7). The cells are relatively small (25–30×25–30 μm) and generally ovoid and many are embedded within the fibers of the precommissural fornix (Mesulam *et al*., 1983a). Approximately 10% of the Ch1 neurons are cholinergic and most contain both AChE and ChAT (Mesulam *et al*., 1983b; 1986; Mufson *et al*., 1989a). There are very few cholinergic neurons in the monkey and human Ch1 (Figs. 19.6 and 19.7; see Mesulam *et al*., 1983b, 1984; Mufson *et al*., 1989a; de Lacalle and Saper, 1997). The dorsal boundary of the vertical limb of the diagonal band (Ch2) is defined less clearly in the primate (Mesulam *et al*., 1983a, 1986) as compared to the rodent where Ch2 can be divided from Ch1 by a line drawn between the two limbs of anterior commissure (Mesulam *et al*., 1983a; Rye *et al*., 1984). This region appears as a boomerang-shaped structure that lies along the ventral lateral border of Ch1 in rat (Mesulam *et al*., 1983a) and, to a lesser degree, in the primate (Mesulam *et al*., 1986). These Ch2 neurons are somewhat larger ($20–25 \times 30$–40 μm) in the primate and are embedded within the vertical limb of the diagonal band of Broca. These neurons are mostly fusiform in shape, with their long axis parallel to the diagonal band fibers (Mesulam *et al*., 1986). Sections dual stained for ChAT and thionine indicate that approximately 70% of the perikarya in this subfield are cholinergic. At the medial edge of the olfactory tubercle the Ch2 adjoins the nucleus of the horizontal limb of the diagonal band (Ch3), which lies dorsal to the olfactory tubercle. The Ch3 cell group has the most diffuse boundaries in the primate brain (Fig. 19.8; Mesulam *et al*., 1983a, 1986; Mufson *et al*., 1989a). It extends between the septal-preoptic region medially and the amygdaloid region laterally. Very few (approximately 1–2%) of these fusiform-shaped, medium-sized ($15–20 \times 40$–50 μm) neurons contain cholinergic markers (Mesulam *et al*., 1983a, 1986; Mufson *et al*., 1989a,b). The largest group of cholinergic neurons of the basal forebrain is found within nucleus basalis (Ch4; Figs. 19.6, 19.9, 19.10, and 19.11). These neurons constitute the Ch4 sector. The Ch4 subgroup extends from the rostral aspect of the anterior commissure to the lateral geniculate nucleus and comes into close contact with many different structures. Throughout most of its rostral–caudal extent, this region is always in juxtaposition to the globus pallidus (Mesulam *et al*., 1983a, 1986; Mesulam and Geula, 1988; Mufson *et al*., 1989a, 1997a,b). These ChAT-positive neurons are relatively large ($40–50 \times 60$–70 μm) and range in shape from fusiform to complex multipolar cells. Approximately 90% of the perikarya in the nucleus basalis are ChAT positive. Topographically, ChAT-positive perikarya constituting Ch4 can be separated into anterior (Ch4a), intermediate (Ch4i), and posterior (Ch4p) subfields. Moreover, the anterior portion can be divided into medial (Ch4am) and lateral (Ch4al) sectors, whereas the intermediate subfield is divided by the ansa peduncularis into dorsal (Ch4id) and ventral (Ch4iv) regions (Figs. 19.9 and 19.11). The posterior subfield (Ch4p) is located caudal to the ansa peduncularis and extends up to the level of the lateral geniculate nucleus. The total number of cholinergic neurons located within the nucleus basalis using modern sterological counting techniques is approximately 210,000 in a single hemisphere (Gilmore *et al*., 1999). At each level, the Ch4 group has not

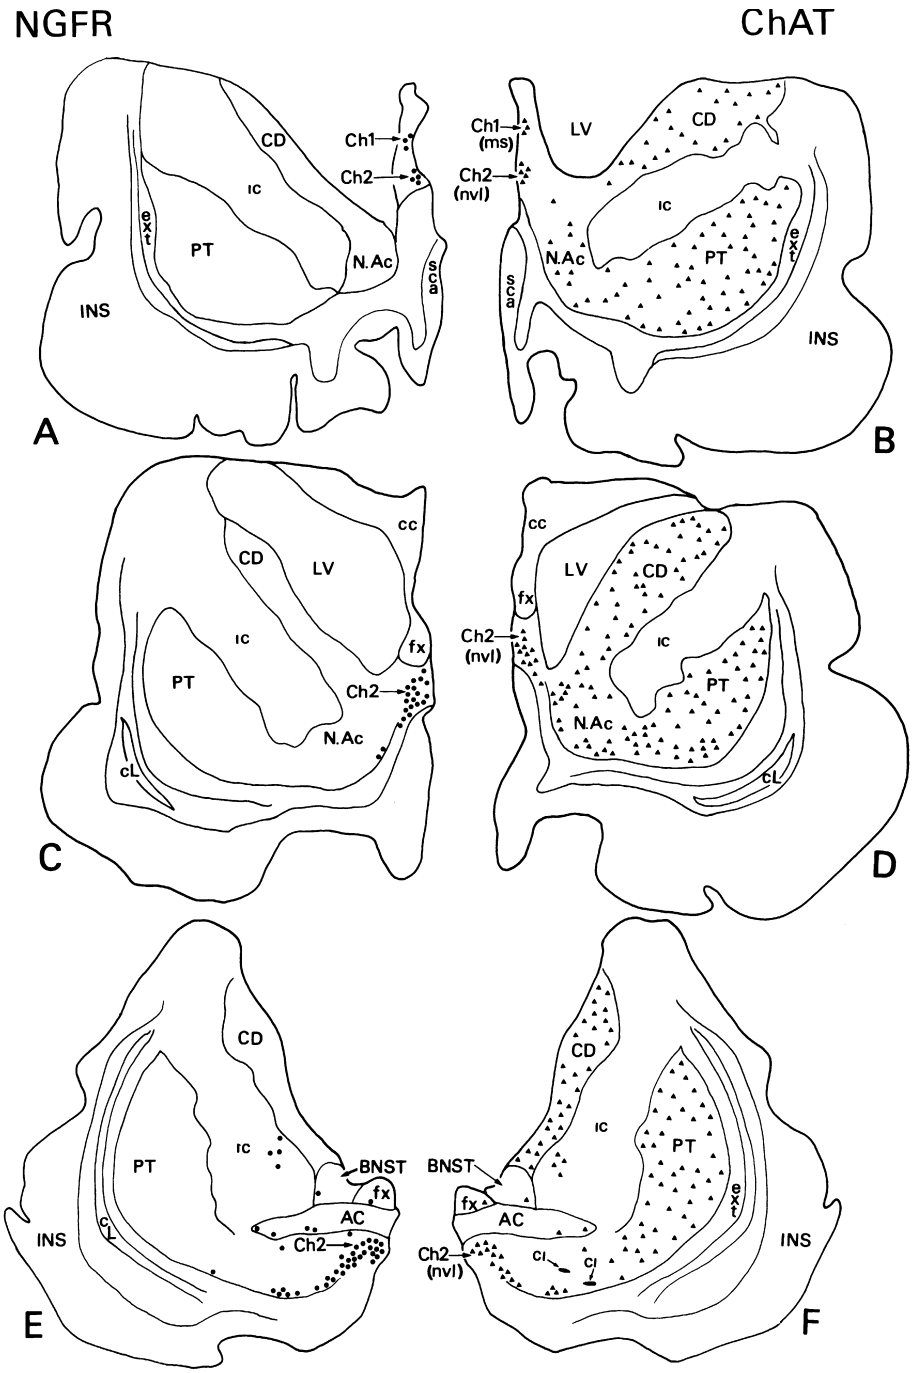

FIG. 19.5. Distribution of $p75^{NTR}$-immunoreactive (black dots) and ChAT-containing (triangles) neurons within the normal, aged human basal forebrain. Note the concordance of the distribution of these markers within the basal forebrain and the lack of such concordance within the striatum. Each section is separated by 720 mm. The distribution of $p75^{NTR}$ -containing neurons was mapped from the brain of a 77-year-old normal male patient. ChAT-containing neurons were mapped from a 78-year-old normal female patient. Each section was matched for level. Curved arrow indicates interstitial elements of the basal forebrain. The blacked-in areas in F indicate islands of Calleja. From Mufson *et al.* (1989b), with permission.

only a compact but also an interstitial component consisting of perikarya, which penetrate nearby fiber bundles, including the anterior commissure, internal capsule, internal and external medullary lamainae of the globus pallidus, stria terminalis, inferior thalamic peduncle, and the ansa lenticularis (Mesulam *et al.*, 1983a, 1986; Saper and Chelimsky, 1984; Satoh and Fibiger, 1985; Kordower *et al.*, 1988; Mufson *et al.*, 1989a,b). These are considered interstitial components of the Ch4 group rather than independent interstitial nuclei of the individual fiber bundles (Fig. 19.12).

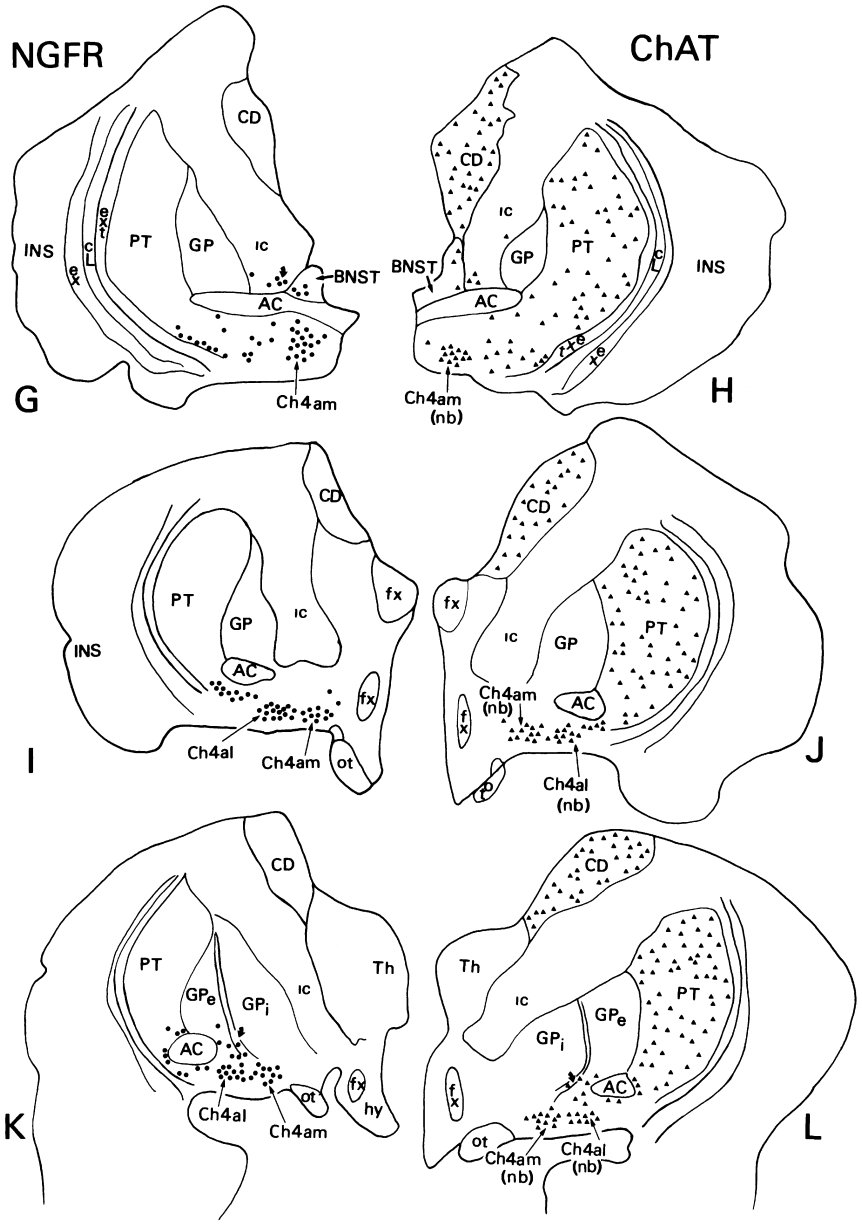

FIG. 19.5. (*Continued*)

VI. Anatomy of Thalamic and Brain Stem Cholinergic Subgroups

Within the upper brain stem, a continuous band of ChAT-containing neurons extends from the rostral midbrain to the midpontine levels (Fig. 19.13; Mesulam *et al*., 1983a, 1986; Satoh and Fibiger, 1985; Mufson *et al*., 1989a). These perikarya can be subdivided into two major fields: Ch5 and Ch6. The cholinergic neurons of Ch5 remain mostly within the pedunculopontine nucleus (PPN) of Olszewski and Baxter (1982) and are analogous to the Ch5 group identified in rodents (Mesulam *et al*., 1983a). This anterior sector of this region appears just lateral to the substantia nigra. More caudally, this subgroup displays its maximum extent within the region of the pedunculopontine nucleus, they are relatively large (75–80 × 40–45 μm), and range in shape from multipolar to fusiform. At the level of the PPN this sector exhibits a compact lateral component, which abuts on the lateral lemniscus, and a more diffuse medial portion, which is interdigitated with the superior cerebellar peduncle, the medial longitudinal fasciculus, and the central tegmental tract (Fig. 19.13). Some Ch5 neurons extend into the region of the cuneiform nucleus and more caudally into the parabrachial region. Moreover, the main portion of the parabrachial area is devoid of ChAT (see de Lacalle and Saper, 1997, for details). As the Ch5 sector gradually disappears at the level of the midpons, the more caudal Ch6 subgroup occupies a lateral position in the periventricular gray, at a location that corresponds to the doral tegmental nucleus (see de Lacalle and Saper, 1997). These cholinergic neurons are relatively smaller than Ch6 (40–45 × 50–55 μm).

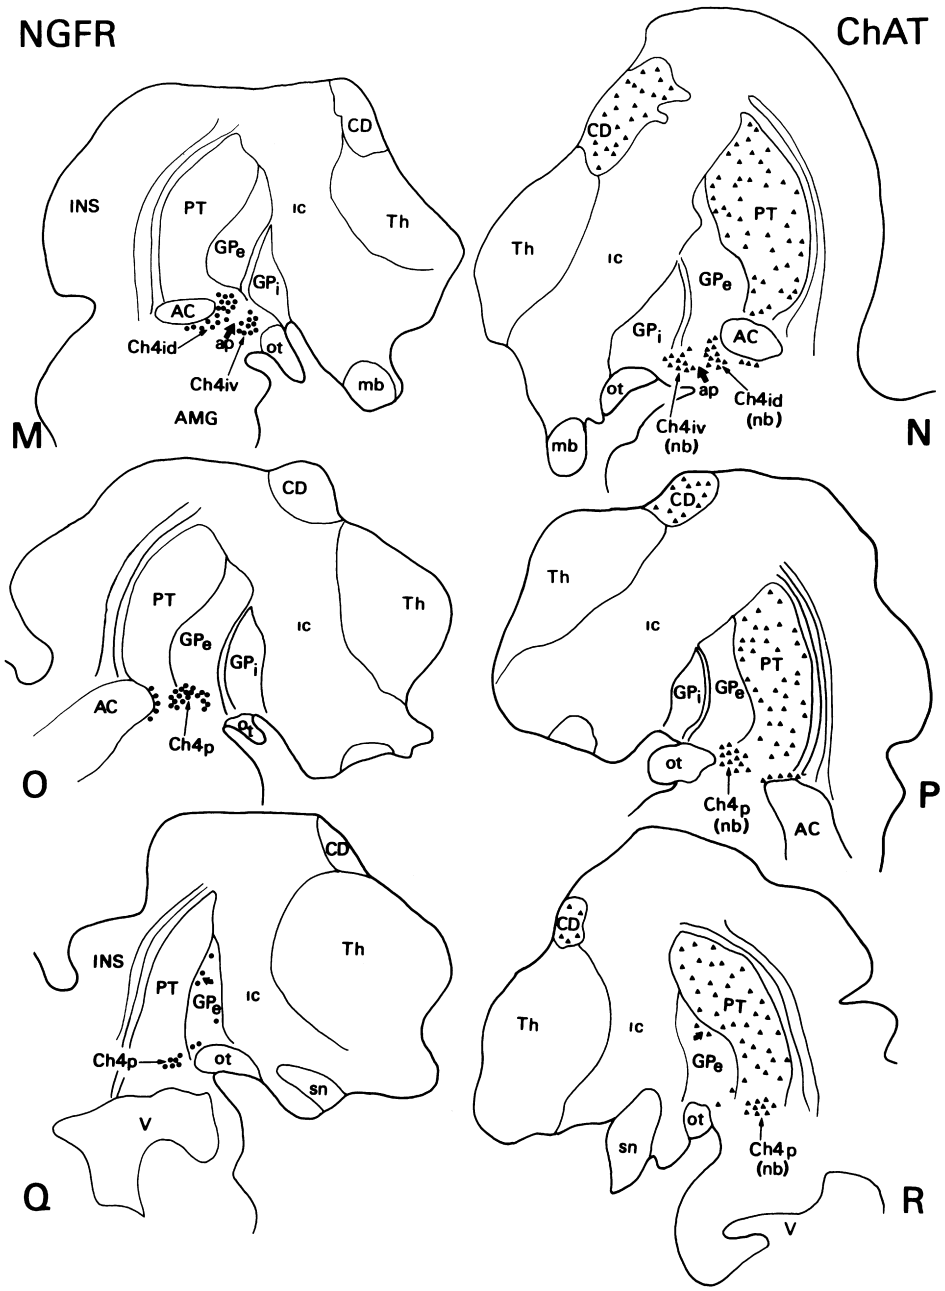

FIG. 19.5. (*Continued*)

Cholinergic markers are confined to 90% of the larger neurons in this region (Mesulam *et al*., 1986). The medial habenula, which is a component of the epithalamus, contains densely packed cholinergic neurons termed the Ch7 subgroup. These cholinergic neurons are oval shaped and $30 \times 35\,\mu m$ in size (Fig. 19.14; Wainer *et al*., 1993). A compact cell group lies along the lateral margin of the mesopontine region just ventral to the brachium of the inferior colliculus termed the parabigeminal nucleus, called Ch8. ChAT immunohistochemical preparations revealed that approximately 80–90% of the perikarya of this region are cholinergic (Mufson *et al*., 1986). A summary schematic diagram of the central cholinergic projections neurons (Ch1–8) is shown in Fig. 19.14.

VII. Other Cholinergic Regions

This section briefly reviews the regions containing cholinergic neurons that are outside the Ch1–8 ascending projection systems. These include the striatal complex interneurons, cranial nerve nuclei, reticular neurons, lateral hypothalamus, and scattered small intercortical cells seen in rodents (see Wainer *et al*., 1993). The latter has been reported in primates (Mesulam *et al*., 1986; Mufson *et al*., 1989a,b). The striatal complex may be subdivided into four major sectors: the caudate, the putamen, the nucleus basalis, and the olfactory tubercle. Each of these regions contains ChAT-immunoreactive neurons. ChAT-positive neurons are larger ($35–40 \times 50\,\mu m$) and less

densely packed than those of the olfactory tubercle (Figs. 19.5, 19.9, and 19.13). In addition, the islands of Calleja also contain numerous cholinergic neurons, although the granule cells do not contain ChAT (Mesulam *et al*., 1986). The striatum and olfactory tubercle display the high (trkA) but not the low ($p75^{NTR}$) affinity NGF receptor staining in the monkey and human (Kordower *et al*., 1994c; Mufson *et al*., 1997a). Interestingly, the interpeduncular nucleus contains an extensive array of ChAT-positive fibers but lacks cholinergic neurons (Mufson *et al*., 1987) (Fig. 19.15).

VIII. Neurotrophin Receptor Expression and Cholinergic Basal Forebrain Neurons

A. Historical Overview

The classic research of Levi-Montalcini (for review, see Levi-Montalcini and Angeletti, 1954; Thoenen and Barde, 1980) first demonstrated that NGF was an important trophic substance in the development and maintenance of noradrenergic peripheral sympathetic neurons. Investigations of mammalian brain have demonstrated the responsiveness of cholinergic neurons to NGF. For example, NGF increases ChAT levels in cultured septal and striatal cholinergic perikarya (Hefti *et al*., 1986; Martinez-Serrano *et al*., 1995). Intraventricular injections of NGF in neonatal rats increase ChAT activity in the basal forebrain, hippocampus, cortex, and striatum (Gnahn *et al*., 1983). In addition, evidence has been accumulating

that NGF may modulate regenerative events within the primate cholinergic basal forebrain. For example, administration of NGF or transplantation of NGF rescues medial septal neurons that undergo degeneration after transection of the fimbria-fornix system in primates (Tuszynski *et al.*, 1990a,b; Kordower *et al.*, 1994b). Early studies using ^{125}I-labeled NGF infused into rat hippocampus resulted in retrograde transport of this injectate to cholinergic perikarya located within the medial septum and vertical limb nucleus of the diagonal band continuum, but not to catecholaminergic neurons of the locus coeruleus or substantia nigra (Schwaab *et al.*, 1979). Cortical injections of iodinated NGF produce exclusive retrograde labeling of neurons located within the nucleus basalis (Seiler and Schwaab, 1984). These studies further supported the view that NGF may serve as a trophic factor for cholinergic basal forebrain neurons. Converging lines of evidence have supported the suggestion that NGF modulates the development, survival, and maintenance of cholinergic basal forebrain neurons in mammals, including primates (Kordower *et al.*, 1994b). There are high levels of NGF protein (Hayashi *et al.*, 1990) and mRNA (Hayashi *et al.*, 1993) in the developing primate brain. In the adult brain, the highest levels of NGF are found in the projection zones of the basal forebrain, including the cerebral cortex, hippocampus, and olfactory bulb (Conner *et al.*, 1992; Conner and Varon, 1992). Radiolabeled NGF-binding sites are found in the human basal forebrain (Strada *et al.*, 1992), and autoradiographic investigations have reported that perikarya that bind ^{125}I-labeled NGF codistribute with cholinergic basal forebrain neurons (Richardson *et al.*, 1986). In fact, NGF immunoreactivity was observed within the cholinergic basal forebrain neurons of monkeys and humans, suggesting that it is transported from the cortex retrogradely (Mufson *et al.*, 1994, 1995).

B. NGF Receptors within Cholinergic Subgroups

1. Overview of NGF Receptors

Localization of receptors that specifically bind, internalize, and transport NGF retrogradely to the cholinergic basal fore-

brain consumer neurons to induce signal transduction have been under investigation for many years. Since the mid-1990s, evidence has accumulated demonstrating that NGF recognizes at least two classes of cell surface receptors: (1) a fast-dissociating, low-affinity NGF receptor and (2) a slow-dissociating, high-affinity NGF receptor (Figure 19.1). The low-affinity receptor is a transmembrane glycoprotein of molecular weight 75 kDa (Bothwell, 1991). Because this receptor binds to virtually all members of the NGF family (Bothwell, 1991), it has been termed the p75 neurotrophin receptor (p75^{NTR}). In the classic retrograde model of NGF/p75^{NTR} interactions, it was hypothesized that this complex is internalized and transported retrogradely to cholinergic basal forebrain neurons where signal transduction occurs (Schwabb *et al*., 1977). Although studies using molecular biologic methods indicate that the physiological actions of NGF requires complexing to its high-affinity receptor (trkA), several important actions for p75^{NTR} have been suggested, such as presentation or recruitment of NGF to the trkA receptor (Jing *et al*., 1993), signaling through a G-protein-mediated mechanism, and a relationship with molecules capable of signaling or providing substrates for the high-affinity receptor, trkA (Parada *et al*., 1992; see Mufson and Kordower, 1997, for review). The trkA receptor is a 140-kDa transmembrane glycoprotein with a cytoplasmic protein kinase domain (see Bothwell, 1991, for review). The trkA receptor is essential for NGF signal transduction and mediates its biological effects (Chao, 1992). Although it was at first controversial whether coexpression of both the low-affinity p75^{NTR} and the high-affinity trkA receptor was necessary for the biological activity of NGF (see Mufson and Kordower, 1997, for review), it is now clear that the trkA receptor alone is sufficient to mediate cellular responses to NGF (Riccio *et al*., 1997) within the cholinergic basal forebrain neurons. TrkA, like most kinase growth factor receptors, signals through receptor oligomerization (Heldin, 1995) and can active gene expression (Riccio *et al*., 1997).

2. Colocalization of trkA and p75^{NTR} within the Primate Cholinergic Basal Forebrain

Immunocytochemical and *in situ* hybridization experiments have determined that trkA and p75^{NTR} are contained within the cholinergic basal forebrain neurons in the monkey and the human (Figs. 19.10 and 19.16; Hefti, 1983; Hefti *et al*., 1986; Kordower *et al*., 1988, 1989b,c; Schatteman *et al*., 1988; Hefti and Mash, 1989; Mufson *et al*., 1989a, 1996, 1997b; Strada *et al*., 1992; Gibbs and Pfaff, 1994; Boissière *et al*., 1997). In the adult and aged monkey using an antibody that reacts primarily with the trkA receptor (Steininger *et al*., 1993; Kordower *et al*., 1994a), an extensive, but incomplete colocalization between trk- and p75^{NTR}-immunoreactive neurons was found within the basal forebrain (Kordower *et al*.,

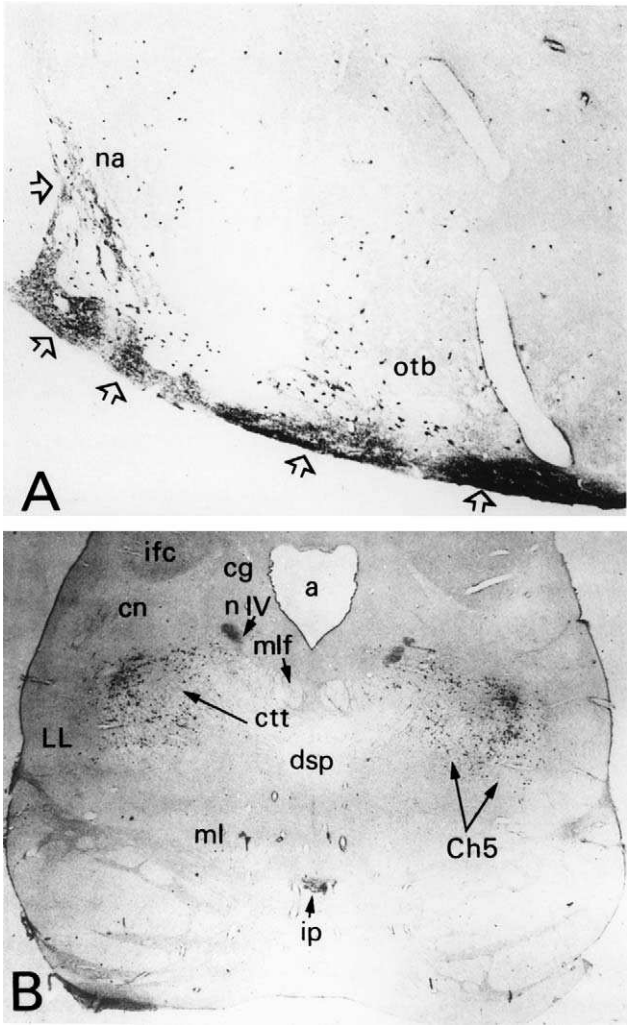

FIG. 19.13. (A) Choline acetyltransferase immunohistochemical stain of the ventral striatum. Open arrowheads point to the islands of Calleja where the neuropil give a positive ChAT reaction. ChAT-positive perikarya are concentrated more densely in the nucleus accumbens and the olfactory tubercle, especially in the spatial relationship to the islands of Calleja. Magnification 33X. FIG. 19.14. Schematic diagram showing the trajectory of the central cholinergic projections system Ch1–8 (see text for details).

1994a). In addition to dual-labeled perikarya, many basal forebrain neurons only expressed trk immunoreactivity. Conversely, a few basal forebrain neurons expressed only $p75^{NTR}$. Colocalization experiments revealed that between 68 and 73% of all basal forebrain neurons (septal/diagonal band complex and nucleus basalis) colocalized trk and $p75^{NTR}$. In contrast, between 23 and 28% of basal forebrain neurons expressed only the trk receptor whereas approximately 4% of the basal forebrain neurons expressed only the $p75^{NTR}$. Although there was some individual variability, a similar degree of trk/$p75^{NTR}$ colocalization was observed in all subdivisions of the basal forebrain. Separate quantitation of double-labeled neurons was performed for hippocampal projecting septal/diagonal band (Ch1/Ch2) neurons and the cortical and amygdaloid projecting neurons of the nucleus basalis (Ch4) subfields. Between 42 and 75% of the neurons within the septal diagonal band complex colocalized trk and $p75^{NTR}$, whereas 66–76% of neurons within the nucleus basalis subfield also displayed both trk and $p75^{NTR}$ immunoreactivity. This nonhuman

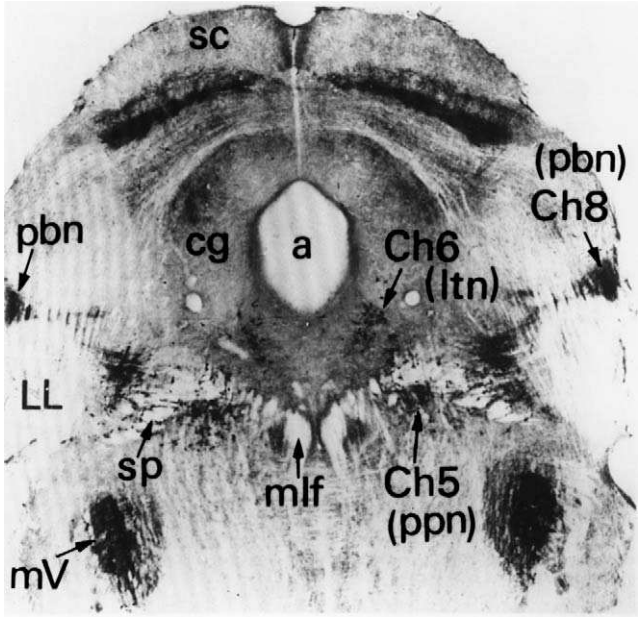

FIG. 19.15. Section stained for the immunohistochemical demonstration of ChAT-like immunoreactivity. Heavy ChAT staining is seen in the region of the parabigeminal nucleus (Ch8), as well as within the pedunculopontine nucleus (Ch5), lateral dorsal tegmental nucleus (Ch6), in the motor nucleus of the fifth cranial nerve, and in the intermediate layers of the superior colliculus. a, cerebral aqueduct; cg, central gray matter; Ch5, cholinergic cell group 5; Ch6, cholinergic cell group 6; Ch8, cholinergic cell group 8; LL, lateral lemniscus; ltn, lateral dorsal tegmental nucleus; mlf, medial longitudinal fasciculus; mV, motor nucleus of the fifth cranial nerve; pbn, parabigeminal nucleus; ppn, pedunculopontine nucleus; sc, superior colliculus; sp, superior cerebellar peduncle. Magnification 27X. From Mufson *et al.*, (1986), with pernission.

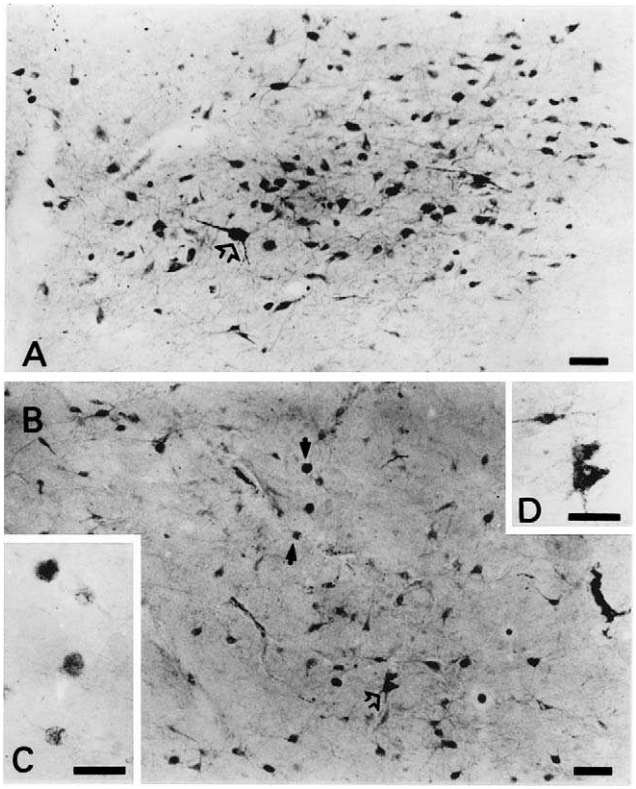

FIG. 19.16. Comparison of trkA immunostaining within the anteromedial portion of the nucleus basalis in an aged control (A) and an AD (B) case. Note in A that virtually all neurons are trkA positive. Open arrow points to the same trkA-positive perikarya shown in Fig. 19.1A. In AD (B), many neurons are shrunken (black arrows) and express decreased trkA immunoreactivity (C). Open arrow in B points to the cluster of trkA neurons shown in D, demonstrating that some neurons appear healthy and continue to express moderate immunoreactivity for trkA in AD. Bars: 100 (A and B) and 50 (C and D) μm. From Mufson *et al*. (1997a), with permission.

primate study also revealed that there was no age-related changes in the degree of colocalization. In humans, various reports using postmortem samples reported that all $p75^{NTR}$ containing cells with the basal forebrain were cholinergic based on the fact that they stained positive for the indirect cholinergic marker AChE (Mesulam *et al*., 1983a). An extensive topographic colocalization study of ChAT and $p75^{NTR}$ revealed that virtually all (>95%) of $p75^{NTR}$-containing cholinergic basal forebrain neurons contain ChAT and AChE within the Ch4 (nucleus basalis) where only about 10% colocalized these markers in Ch1 and 70% in Ch2 (Mesulam *et al*., 1983a; Mufson *et al*., 1989a). Ch3 is virtually nonexistent in the human and therefore was not included in this study. Mesulam *et al*. (1988) supported this finding by showing a topographic overlap between the distribution of ChAT and $p75^{NTR}$ positive neurons in the nucleus basalis. Neither of these neurotrophin markers has been shown to colocalize with ChAT containing neurons in the other brain stem cholinergic subfields. Monoclonal antibodies raised against extra- and intracellular domains of the trkA receptor have been shown to stain the magnocellular neurons of the Ch4 in humans (Fig. 19.16; Mufson *et al*., 1997a; Sendera *et al*., 2000). Studies using mRNA probes for trkA have also revealed a strong codistribution between genes for trkA and $p75^{NTR}$ in the human Ch4 (Mufson *et al*., 1995, 1999; Boissière *et al*., 1997).

IX. m2 Muscarinic Acetylcholine Receptor Neurons within the Primate Cholinergic Basal Forebrain

Several muscarinic receptor subtypes have been identified by differential affinities for antagonists, and it is now established that five distinct genes (m1–m5) encode highly related muscarinic receptor subtypes (Bonner *et al*., 1987; Hulme *et al*., 1990). It is often assumed that m2 is the gene product that functions as a presynaptic autoreceptor to inhibit ACh release (Mash *et al*., 1985, Mash and Potter, 1986; Pohorecki *et al*., 1988; Levey *et al*., 1991) and, like ''M2'' radioligand-binding sites, m2-immunoreactive protein is reduced in AD brain (Flynn *et al*., 1995). However, only a subset of cholinergic neurons coexpress the m2 protein within the rodent basal forebrain (Levey *et al*., 1995), suggesting that these neurons are not the only source of the m2 receptor protein seen in the hippocampus, cortex, and other terminal zones. In support of this concept, lesions of the rodent septohippocampal and monkey nucleus basalis cortical projection systems result in little, if any, decrease in m2 receptor protein in the hippocampus and cortex, respectively (Wall *et al*., 1994; Levey *et al*., 1995; Mufson *et al*., 1997b; Mrzljak *et al*., 1998). In humans, using an m2-specific monoclonal antibody (Levey *et al*., 1995), we found that m2 receptor protein is expressed primarily in noncholinergic multipolar neurons located mainly outside the main aggregate of cholinergic nucleus basalis (Ch1–4) subfields (Mufson *et al*., 1998). Despite this nonoverlap of cell populations, there was a virtually complete overlap between the distribution of cholinergic neurons and m2 neuropil staining in the human (Figs. 19.17–19.19; Mufson *et al*., 1998). Double-labeled sections from the septal/diagonal band complex revealed that m2 is detected in only 14% of ChAT-labeled neurons, whereas only 13% of m2-stained neurons colocalize ChAT. Within the nucleus basalis, ChAT is found in 35% of the m2-labeled neurons, whereas only 6% of ChAT-stained perikarya are double-labeled for m2. A similar distribution of m2 receptor cells was seen in the monkey basal forebrain (Mrzljak *et al*., 1993, 1998). Colocalization of m2-positive/ChAT-immunonegative neurons and the cholinergic inhibitory neuropeptide galanin was not observed, although galaninergic fibers coursed in close apposition to m2-immunoreactive cells. This suggests that galaninergic fibers may modulate m2 receptor activity within the basal forebrain of humans. Cell counts demonstrated that 90% of ChAT-immunolabeled striatal neurons express the m2 receptor. Despite the extensive reduction in cholinerigc basal forebrain neurons, cell counts of the relative number of m2-immunoreactive neurons within the nucleus basalis complex from aged controls and AD patients revealed that the m2 neurons are spared (Fig. 19.20; Mufson *et al*., 1998). Finally, these findings suggest that most m2 receptors in the cholinergic basal forebrain are located on noncholinergic small neurons and, therefore, are not the major source of m2 receptors seen in the cortex. There is, however, a population

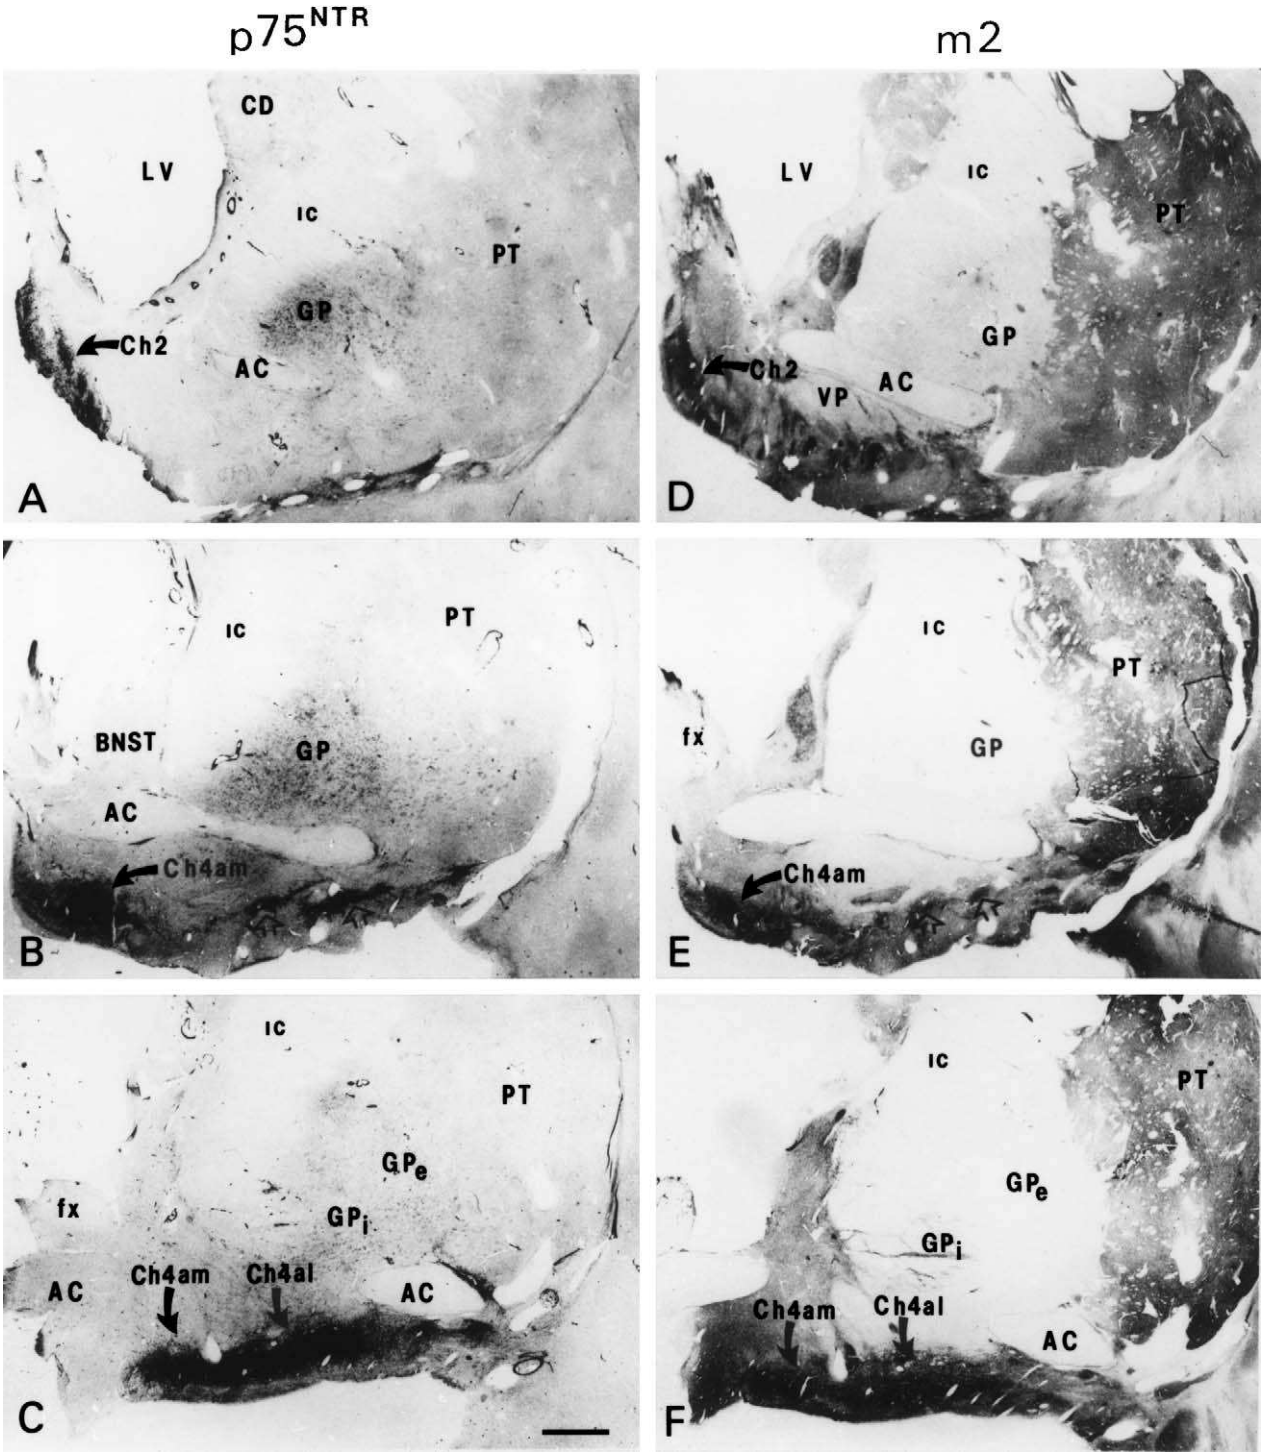

FIG. 19.17. Low-magnification photomicrographs of adjacent stained sections comparing the distribution of cholinergic (A–C) and m2 (D–F) immunoreactivity within the aged normal human basal forebrain. Cholinergic profiles were visualized by using an antibody against the low-affinity p75 neurotrophin receptor ($p75^{NTR}$; see text for details). There was a virtual complete overlap between the distribution of $p75^{NTR}$ and m2 neuropil staining within the diagonal band (Ch2) and the anteromedial (Ch4am) and anterolateral (Ch4al) subfields of the basal forebrain. In contrast, only m2 immunoreactivity was seen in the caudate (CD) and putamen (PT), as well as the bed nucleus of the stria terminals (BNST). AC, anterior commissure; fx, fornix; GR, globus pallidus; GPe, globus pallidus external; GPi, globus pallidus internal; ic, internal capsule; LV, lateral ventricle. Scale bar: 3 mm. From Mufson *et al*. (1998), with permission.

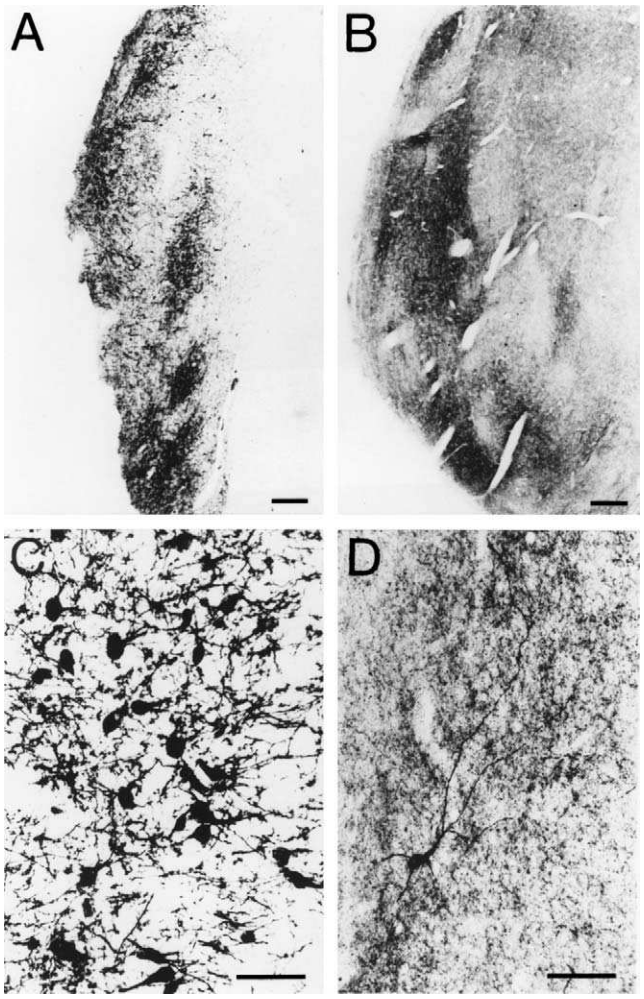

FIG. 19.18. (A and B) High-power photomicrographs of the diagonal band region shown in Figs. 19.1A and 19.1D immunostained for $p75^{NTR}$ and m2, respectively. In A, note that the cholinergic marker distinguishes the medial and lateral divisions of the diagonal band more clearly. (C) Photomicrograph of numerous $p75^{NTR}$-immunostained cholinergic diagonal band neurons and processes. (D) In contrast, very few m2 neurons were seen embedded within the immunoreactive neuropil of the diagonal band. Note the extensive dendritic process emanating from the m2 neuron. Scale bars: 500 (A and B) and 100 (C and D) μm. From Mufson *et al.* (1998), with permission.

of m2-immunoreactive small interneurons scattered throughout the cortex in both monkeys and humans (Mufson *et al.*, 1997b; Mrzljak *et al.*, 1998).

X. Relationship of Noncholinergic to ChAT-Contain ing Neurons within the Primate Cholinergic Basal Forebrain

A. Overview

In addition to the magnocellular cholinergic neurons located within the Ch4 subfields, there are many smaller noncholinergic perikarya (see de Lacalle and Saper, 1997). In the rhesus monkey the novel neuropeptide galanin coexists with ChAT in large neurons throughout the cholinergic basal forebrain (Kordower and Mufson, 1990; Kordower and Rakic, 1990; Walker *et al.*, 1991; Kordower *et al.*, 1992). Other perikarya stained for somatostatin, neuropeptide Y (NPY), enkephalin, or neurotensin interdigitate with cholinergic neurons in limited areas of the basal forebrain. De Lacalle and Saper (1997) indicate that these neuronal types are concentrated most heavily in the anterior and intermediate aspects of the nucleus basalis. However, these cells are relatively small interneurons that are not cholinergic. Within the various subregions of the monkey basal forebrain there are reports of fibers and/or putative terminals that display several peptides, including enkephalin (Haber and Elde, 1982; Candy *et al.*, 1985; Haber and Watson, 1985), NPY (Smith *et al.*, 1985; E. J. Mufson, personal observation), proopiomelanocortic peptides (Candy *et al.*, 1985), somatostatin (Fig. 19.21; Candy *et al.*, 1985; Mufson *et al.*, 1988a; Desjardins and Parent, 1992), substance P, cholecystokinin, vasoactive intestinal polypeptide, and oxytocin (Candy *et al.*, 1985). These observations suggest that peptidergic neurons can modulate the actions of cholinergic neurons within the basal forebrain.

1. Galanin Species Differences

Galanin is a 29 amino acid peptide that is cleaved from a 123 amino acid precursor, preprogalanin (Tatemoto *et al.*, 1983). Galanin inhibits acetycholine release in the ventral hippocampus (Fisone *et al.*, 1987). Galanin protein and mRNA have been shown to be widely distributed throughout the mammalian central nervous system and, in particular, galanin is intimately associated with basal forebrain cholinergic neurons (Melander and Staines, 1986; Chan-Palay, 1988; Kordower and Mufson, 1990; Walker *et al.*, 1991; Kordower *et al.*, 1992; Bowser *et al.*, 1997). Several studies have demonstrated that the distribution of galanin protein varies within the basal forebrain across a variety of mammalian species. For example, immunohistochemical investigations in rats have shown that galanin immunoreactivity exists within cholinergic neurons of the medial septal/vertical limb of the diagonal band complex, but not within the nucleus basalis (Melander *et al.*, 1986). In Old and New World primates, galanin protein colocalizes with virtually all magnocellular cholinergic neurons within each basal forebrain subfield (Melander *et al.*, 1986; Melander and Staines, 1986; Walker *et al.*, 1991; Kordower and Mufson, 1990; Kordower *et al.*, 1992). In contrast, neither galanin protein nor mRNA exists within the magnocellular cholinergic basal forebrain neurons in lesser or greater apes and humans, although a small population of parvicellular neurons within this region does express galanin (Figs. 19.22 and 19.23; Chan-Palay, 1988; Kordower and Mufson, 1990; Walker *et al.*, 1991; Kordower *et al.*, 1992; Mufson *et al.*, 1993; Benzing *et al.*, 1993). These observations are in conflict with others who have indicated that galanin immunostaining occurs in the different subfields of the human basal forebrain (Kowall and Beal, 1989; Vogels *et al.*, 1989; Gentleman *et al.*, 1989). The few neurons that do express galanin consist of a small population of parvicellular neurons within these regions that do not express either the protein or mRNA for galanin (Chan-Palay, 1988; Kordower and Mufson, 1990; Walker *et al.*, 1991; Kordower *et al.*, 1992; Mufson *et al.*, 1993; Benzing *et al.*, 1993).

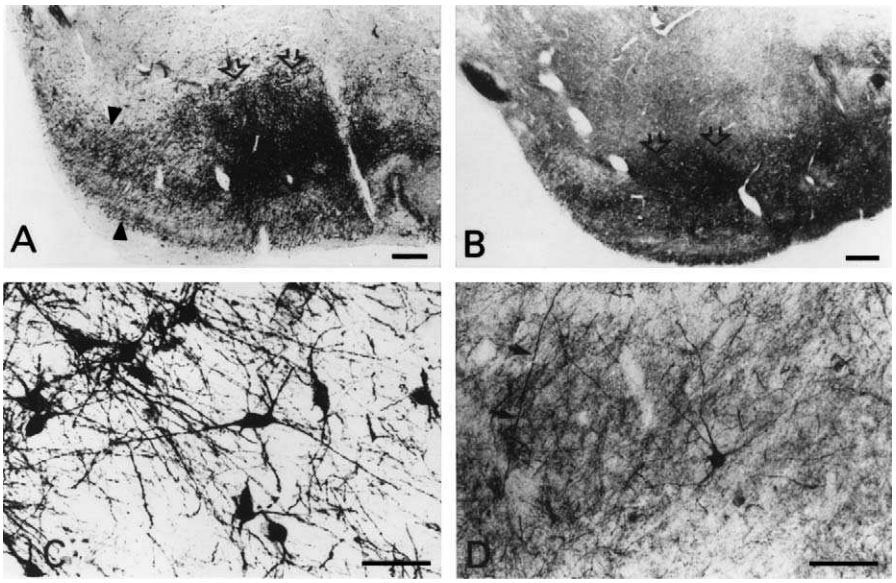

FIG. 19.19. (A and B) High-power photomicrographs of the anterior medial region of the nucleus basalis shown in Figs. 19.2B and 19.2E immunostained for $p75^{NTR}$ and m2, respectively. Arrows in A and B indicate the overlap between cholinergic and m2 staining in this region. Arrowheads in A indicate the caudal extension of the diagonal band nucleus. (C) Photomicrograph of numerous $p75^{NTR}$-immunostained cholinergic nucleus basalis neurons. Note their magnocellular appearance and extensive dendritic processes. (D) In contrast, very few m2 neurons were seen embedded within the immunoreactive neuropil. Arrows in D indicate the location of m2-immunostained fibers. Scale bars: 500 (A and B) and 100 (C and D) μm. From Mufson *et al*. (1998), with permission.

Although human magnocellular basal forebrain neurons do not synthesize galanin, they are innervated by a galanin-immunostained fiber system that courses through the basal forebrain and is closely apposed to the cholinergic perikarya mainly in the anterior portion of the nucleus basalis (Ch4a) (Fig. 19.24; Chan-Palay, 1988; Kordower and Mufson, 1990; Mufson *et al*., 1993). The potential importance of this unique galanin basal forebrain innervation pattern is underscored by observations that this galanin-immunoreactive fiber network is hypertrophied in AD (Chan-Palay, 1988; Mufson *et al*., 1993; Bowser *et al*., 1997). These findings, coupled with experimental evidence indicating that galanin is inhibitory to acetylcholine (Fisone *et al*., 1987), have led to the hypothesis that galanin modulates cholinergic tone within the magnocellular basal forebrain system (Chan-Palay, 1988). More recently, it has been suggested that galanin may exhibit trophic activity (Wynick *et al*., 1998), aiding in the survival of cholinergic neurons in disease states. In general, the distribution of neuroactive substances is organized along a general mammalian plan (Felten and Sladek, 1983). Available data indicate that galanin deviates from this rule.

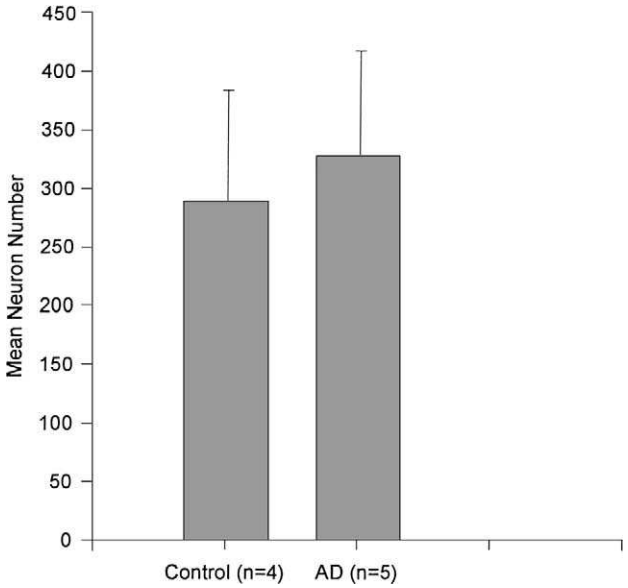

FIG. 19.20. Histogram showing that m2-immunoreactive neurons are not reduced significantly within the nucleus basalis in AD compared with aged controls. From Mufson *et al*. (1998), with permission.

2. Calcium-Binding Proteins

Findings in the squirrel monkey revealed large numbers of (35 μm mean diameter) calbindin-immunoreactive neurons in the septum (Ch1) and within the diagonal band (Ch2; Côté *et al*., 1991). Calbindin-immunoreactive neurons are also scattered within the nucleus basalis (Ch4) with an average diameter of 40 μm. Dual immunohistochemical experiments showed that ChAT and calbindin are colocalized within the basal forebrain of the rhesus monkey (Fig. 19.25; Geula *et al*., 1993; Côté and Parent, 1992). Calbindin and ChAT have been shown within the cholinergic neurons of the human nucleus basalis (Ch4) (Geula *et al*., 1993). de Lacalle and Saper (1997) have also reported that calbindin-immunoreactive neurons are intensely stained in the human nucleus basalis, but only light staining is seen in the nucleus of the diagonal band (Ch2). Geula and colleagues (1993) have shown an age-related

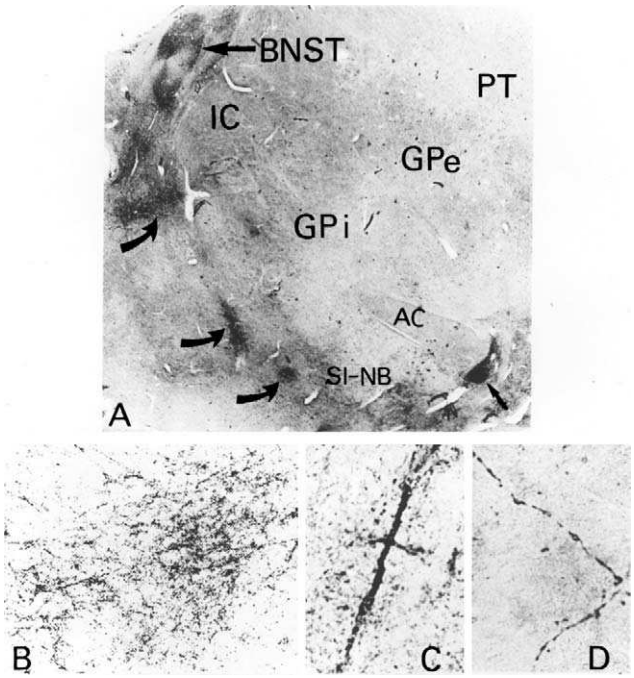

FIG. 19.21. Photomicrographs of tissue stained for somatostatin (SOM) with the S309 antibody. (A) Woolly fibers (curved black arrows) coursing dorsomedially beneath the anterior commissure at the level of the substantia innominata–nucleus basalis complex en route to the bed nucleus of the stria terminalis (large black arrow). Terminal-like staining is located adjacent to the lateral edge of the anterior commissure (small black arrow). Tissue obtained from a 68-year-old female AD case (X10). (B) Terminal-like and fine fiber staining in the substantia innominata–nucleus basalis complex (X30). (C) Wooly fiber in the substantia innominata-nucleus basalis complex (X40). (D) Slender beaded fiber with regularly dispersed varicosities located within the substantia innominata–nucleus basalis complex (X50). Tissue shown in B–D was obtained from a 70-year-old male neurologically normal case. From Mufson *et al*. (1988a), with permission.

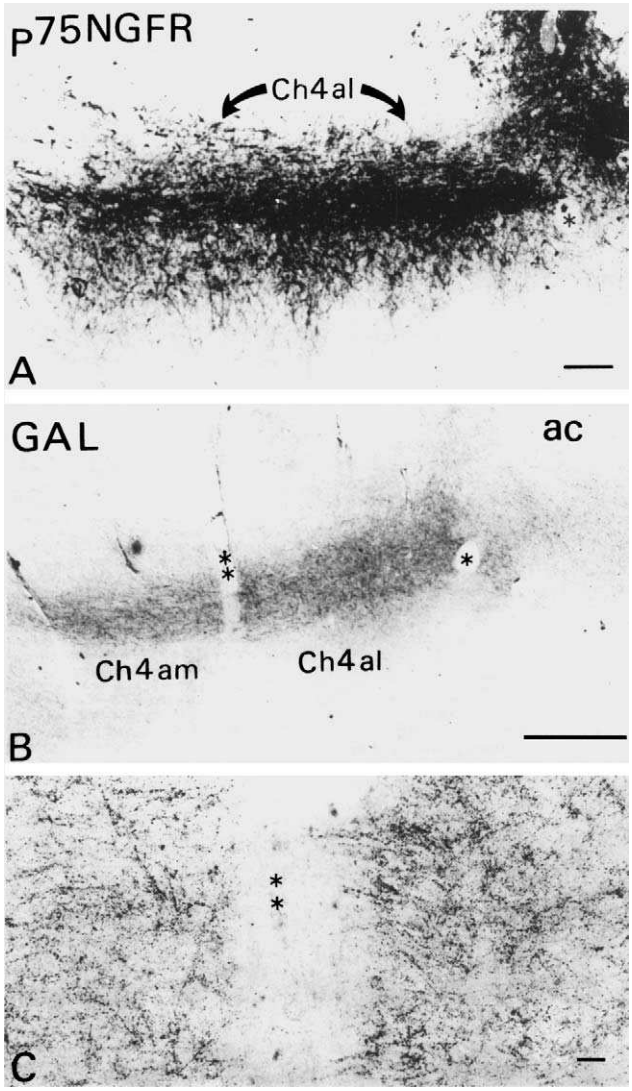

FIG. 19.22. $p75^{NTR}$ and galanin (GAL)-immunoreactivity within the gorilla nucleus basalis. (A) Intense p75 $p75^{NTR}$-immunoreactive perikarya and fiber staining within Ch4al. (B) Adjacent section stained for galanin-immunoreactivity showing only a dense band of immunoreactivity within the anteromedial (Ch4am) and anterolateral (Ch4al) divisions of the nucleus basalis. Single asterisks indicate the same blood vessel in A and B. (C) High-power photomicrograph of galanin-immunoreactive fiber staining within Ch4am and Ch4al subfields of the nucleus basalis. Asterisks in B and C indicate the position of the blood vessel separating Ch4am and Ch4al. ac, anterior commissure. Scale bars: 50 (A), 1000 (B), and 10 (C) μm. From Benzing *et al*. (1993), with permission.

loss of calbindin-containing neurons in the cholinergic basal forebrain in normal humans. They suggested that the loss of pheontypic expression of calbindin may be a potential mechanism for the selective loss of cholinergic neurons in aging and neurodegenerative disorders such as AD.

3. Nicotinamide Adenine Dinucleotide Phosphate Diaphorase (NADPH-d) in the Primate Cholinergic Basal Forebrain

Similar to galanin, several studies indicate major species differences in the expression of NADPH-d, a novel neurotransmitter that may be neurotoxic in the cholinergic basal forebrain (Dawson *et al*., 1991). Studies have shown that NADPH-d staining occurs in as many as 20–30% of the cholinergic basal forebrain neurons in the rat, but virtually none of these neurons contain this enzyme in the rhesus monkey (Geula *et al*., 1993). Similarly, in the human, NADPH-d did not colocalize with ChAT/$p75^{NTR}$ neurons within the nucleus basalis (Ch4). Ellison *et al*. (1987) reported a subset of neurons characterized by the presence of NADPH-d in human Ch4. We have shown that NADPH-d histochemistry revealed intensely stained (type 1; Fig. 19.26a), moderately stained (type 2; Fig. 19.26b), and lightly stained (type 3) (Fig. 19.26c) neurons. Types 1 and 2 are the primary neurons in the aged human, whereas type 3 is the least prevalent. Interestingly, only a few scattered NADPH-d-positive perikarya are interdigitated within the dense aggregates of the cholinergic basal forebrain neurons, although NADPH-d-positive processes course within and around aggregates of these perikarya (Benzing and Mufson, 1995). NADPH-d histochemistry labels neurons containing nitric oxide synthase, the synthesizing for nitric oxide.

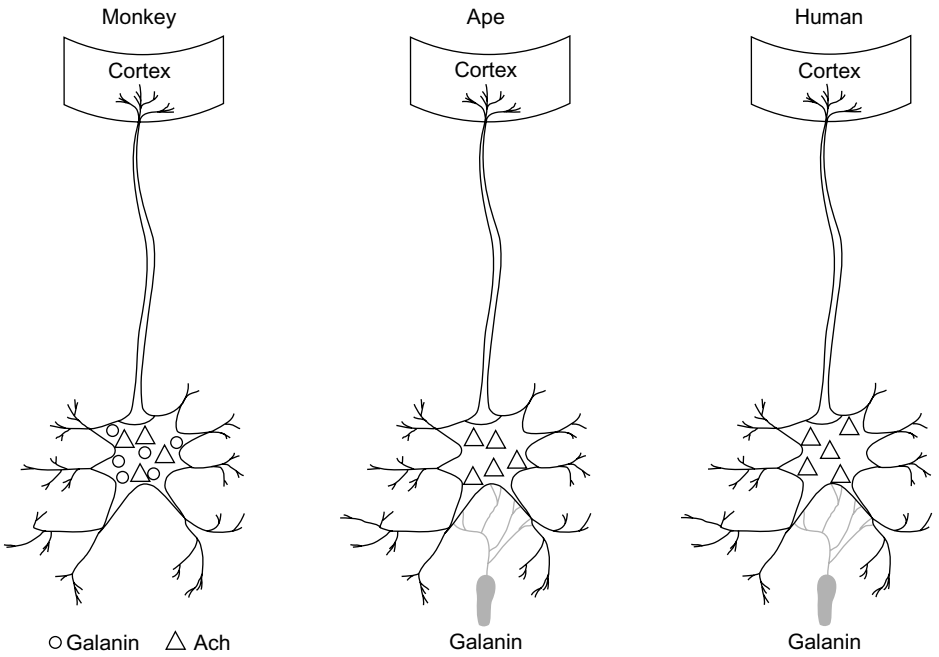

FIG. 19.23. Schematic diagram showing the relation between acetylcholine (Ach) and galanin within neurons of the primate cholinergic basal forebrain. Note that in the monkey, all cholinergic basal forebrain neurons colocalize galanin. In contrast, these neurons are galanin negative in apes and humans. In these species, galanin arises from a population of small interneurons (light gray) as well as in an extraforebrain fiber system (not shown), which terminates on the large cholinergic neurons of the substantia innominata. From Mufson *et al*. (1998), with permission.

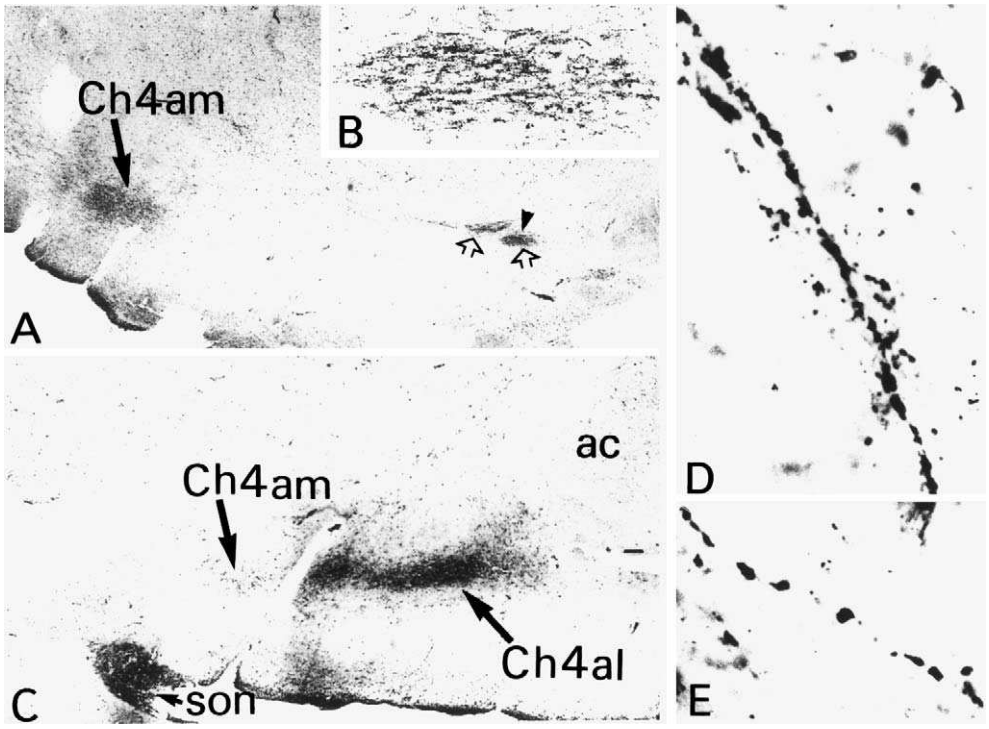

FIG. 19.24. (A) Fibers coursing through the anterior basal forebrain (open arrows) en route to Ch4am. X12. (B) High-power photomicrograph showing the fiber bundle depicted in A (black arrowhead). X94. (C) Dense GAL-immunoreactive ''woolly fiber.'' X350. (D) Thin-beaded fiber found within the fiber plexus seen in B. X131. From Mufson *et al*. (1993), with permission.

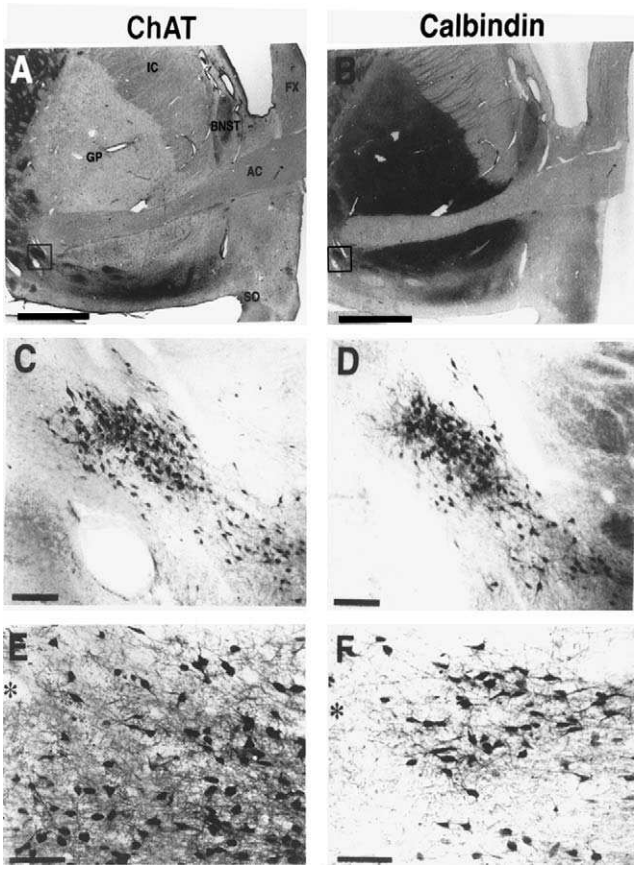

FIG. 19.25. A comparison of the immunocytochemical staining for ChAT and calbindin in the human basal forebrain. These adjacent sections show the overall regional colocalization of these two markers [colocalization at the cellular level was shown by Geula *et* al. (1993)]. Asterisks in E and F mark the same blood vessel. Scale bars: 0.5 cm (A and B) and 300 (E and F) μm. GP, globus pallidus; IC, internal capsule; BNST, bed nucleus of the stria terminalis; AC, anterior commissure; FX, fornix, SO, supraoptic nucleus. From de Lacalle and Saper (1997), with permission.

Quantitative analyses revealed a statistically significant increase in the density of intensely (type 1) and moderately (type 2) but not lightly (type 3) NADPH-d-containing neurons within the nucleus basalis in AD as compared to age-matched controls (Fig. 19.27; Benzing and Mufson, 1995). Increased numbers of NADPH-d-containing neurons suggest that excess nitric oxide production may be neurotoxic to surrounding cholinergic neurons within Ch4 in AD.

NADPH-d is also found in virtually all Ch5 and Ch6 neurons in macaques, baboons (Geula *et al.*, 1993), and humans (Mufson *et al*., 1988b), making it a reliable marker for ChAT neurons. In contrast to calbindin staining in Ch5 and Ch6 in rats, it is not seen in the mesopontine cholinergic system in macaques and baboons (Geula *et al*., 1993). Interestingly, the concurrent visualization of ChAT and NADPH-d displays an extensive overlap in Ch6 in humans (Mesulam *et al*., 1988). In patients with AD, NADPH-d/ChAT dual-stained neurons contain NFTs, suggesting a disconnection between these brain stem neurons and then projection sites in the thalamus (Mufson *et al*., 1988b). Whether the neurotoxic effects of NADPH-d play a role in the formation of NFTs remains to be clarified.

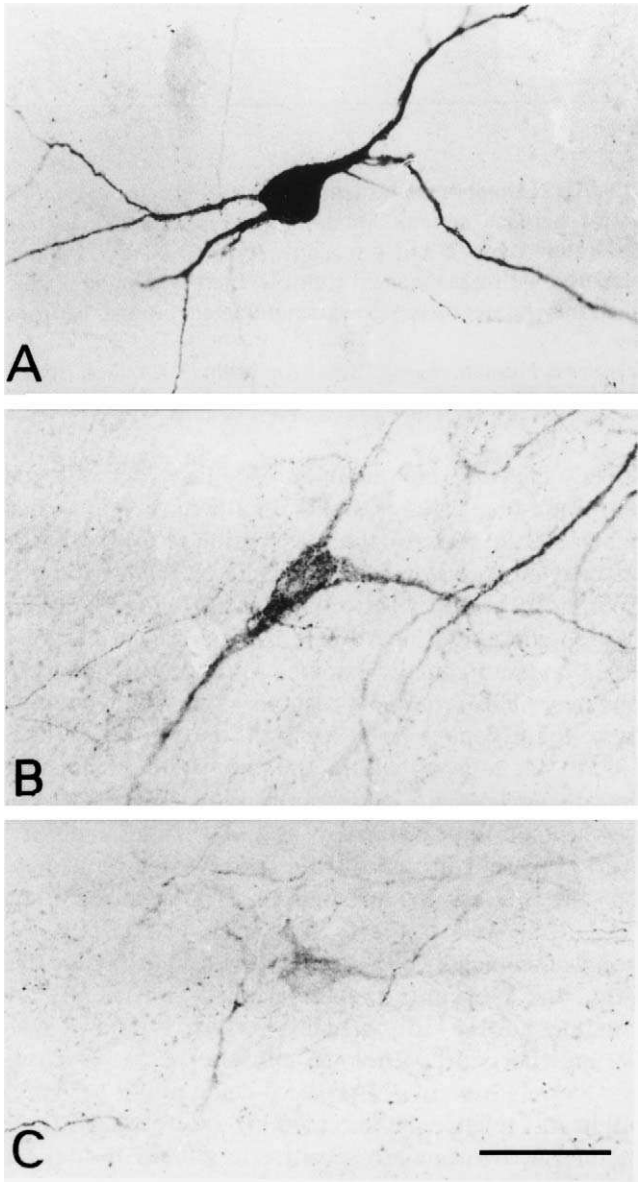

FIG. 19.26. Examples of three types of NADPH-d-positive neurons quantified in the present study: (A) intensely stained (type1) neuron, (B) moderately stained (type 2) neuron, and (C) lightly stained (type 3) NADPH-d neuron. Note Golgi-like appearance of neuron in A. Bar: 30 μm. From Benzing and Mufson (1995), with permission.

4. Estrogen Receptor and the Primate Cholinergic Basal Forebrain

Available data indicate a species difference in the localization of estrogen receptor α (ERα) containing nuclei within the cholinergic basal forebrain between rodents (Simerly *et al*., 1990; Shughrue *et al*., 1992; Gibbs and Pfaff, 1992; Mufson *et al*., 1999) and primates (Blurton-Jones *et al*., 1999; Sendera *et al*., 1999). The presence of estrogen receptors within cholinergic basal forebrain neurons in rodents suggests a potential mechanism by which estrogen could influence their biology and ultimately their behavioral sequela. Numerous

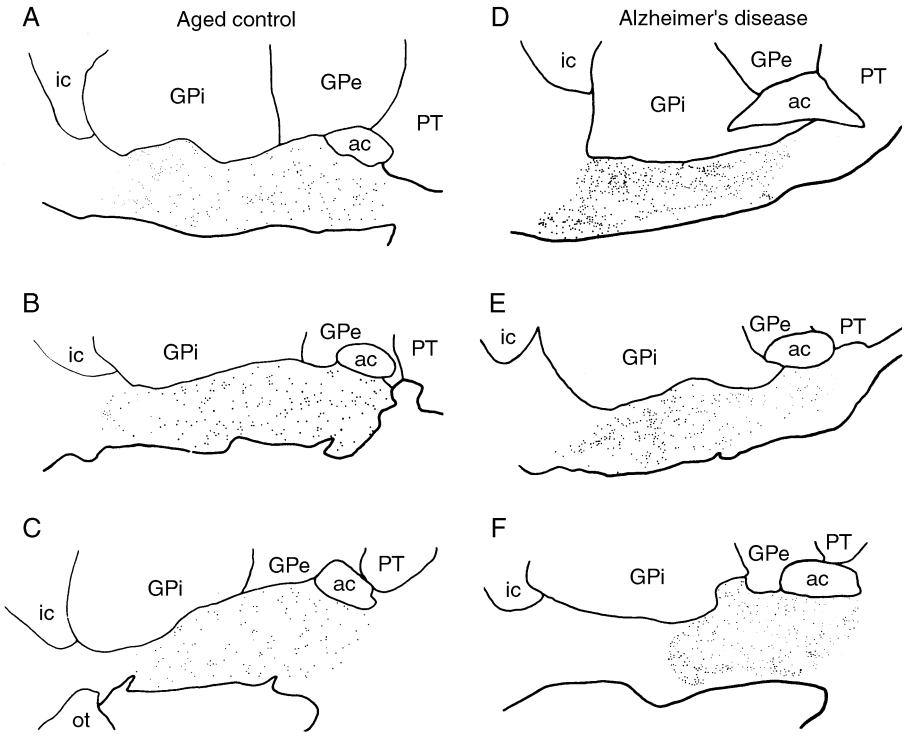

FIG. 19.27. (A–C) Chartings of dark (type 1) and medium (type 2) NADPH-d-positive neurons at three rostral to caudal levels (~1440 μm apart) of SI in an age-matched control (case 4). (D–F) Chartings drawn at similar levels in an AD patient (case 8). Light neurons (type 3) were omitted for clarity as their density did not differ between AD and controls. ac, anterior commissure; ic, internal capsule; GPe, globus pallidus pars external; GPi, globus pallidus pars internal; ot, optic tract; PT, putamen. From Benzing and Mufson (1995), with permission.

histochemical and gene expression studies in the rodent indicate that cholinergic basal forebrain neurons coexpress estrogen receptors (e.g., Toran-Allerand *et al*., 1992; Gibbs and Pfaff, 1992; Shughrue *et al*., 1997; Mufson *et al*., 1999). An evolving literature indicates that the cholinergic basal forebrain is involved in the regulation of cognitive and attentional processes in the normal, aged, and diseased brain (Gibbs, 1994). In fact, epidemiological studies indicate that treatment with the steroid hormone estrogen decreased the risk of AD in postmenopausal women (Tang *et al*., 1996) and enhanced the response to the cholinesterase inhibitor tacrine in these individuals (Schneider *et al*., 1996). Taken together, these biologic and clinical observations suggest that some of the pharmacological effects of estrogen may occur via its interaction with cholinergic basal forebrain neurons, which express the estrogen receptor, at least in the developing (Toran-Allerand *et al*., 1992) and adult (Gibbs and Pfaff, 1992; Gibbs, 1994; Mufson *et al*., 1999) rat. In contrast to the rodent, available immunohistochemical studies indicate that ERα does not colocalize with ChAT, p75, or trkA containing cholinergic basal forebrain neurons in the monkey (Figs. 19.27c and 19.27d; Blurton-Jones *et al*., 1999; Sendera *et al*., 1999) or human (E. J. Mufson *et al*., unpublished observations). By comparison, only a few scattered ERα-positive cholinergic immunonegative neurons were found within the anterior nucleus basalis (Ch4a) in the rhesus monkey (Blurton-Jones *et al*., 1999; Sendera *et al*., 1999). Blurton-Jones *et al*. (1999) reported only rare ERα-labeled nuclei in the horizontal and vertical limbs of the diagonal band. Initial studies in our laboratory in the rhesus monkey have not shown ERα-immunoreactive nuclei within ChAT, calbindin-, or parvalbumin-immunoreactive neurons within the nucleus basalis of the monkey as well (Sendera *et al*., 1999). However, ERα-immunostained nuclei as well as minor cytoplasmic staining were found within other forebrain areas, including the lateral septum (Fig. 19.28, see color insert), amygdala, the bed nucleus of the stria terminalis, subfornical organ, medial, and lateral hypothalamic nuclei, and the amygdalohippocampal transition zone in the rhesus monkey (Blurton-Jones *et al*., 1999; Sendera *et al*., 1999) and human (E. J. Mufson *et al*., unpublished observations; Fig. 19.28). The majority of ChAT-immunostained neurons in the lateral septum were also ERα immunopositive, whereas only about 29% of all ERα-immunoreactive nuclei in the lateral septum were also ChAT stained (Blurton-Jones *et al*., 1999). Further studies are needed to determine the chemical phenotype of ERα-containing neurons within the primate brain and whether these neurons are regulated via genomic or nongenomic mechanisms.

XI. Trajectory of Cholinergic Basal Forebrain Fiber Systems in Primates

A. Cholinergic Fiber Trajectories in the Monkey

Evidence has shown the presence of cholinergic innervation in the olfactory bulb, hippocampus, and amygdala, as well as

the neocortex and paralimbic cortex. These regions have been shown to contain numerous markers indicative of cholinergic innervation, including AChE, ChAT, acetylcholine, $p75^{NTR}$, and trkA receptors, as well as sites for cholinergic agonists (see de Lacalle and Saper, 1997, for review). This cholinergic innervation has been localized primarily to the subfields of the cholinergic basal forebrain, as lesions of this region lead to a considerable decrease in presynaptic cholinergic markers in the hippocampus, neocortex, amygdala, and olfactory bulb (Mufson *et al*., 1983). The trajectories of cholinergic fiber pathways emanating from the cholinergic basal forebrain groups are not well defined in the human, although much more is known in the monkey brain. Most of what is known about the pathways emanating from the cholinergic subfields of the nonhuman primate has been derived from axonal transport studies, enzyme assays, and immunohistochemistry (Mesulam *et al*., 1983b, 1986; Satoh and Fibiger, 1985; Kitt *et al*., 1987; Geula *et al*., 1993). Studies in the monkey reveal that the Ch1–2 system travels within the fornix to connect with the hippocampus. In the rhesus monkey, injections of the tritiated amino acids into the midportion of the Ch4 and surrounding structures were used to define basocortical projection pathways (Kitt *et al*., 1987). This study revealed a medial projection to the cingulate cortex that courses within the cingulum, a lateral projection to the frontal, parietal and insular cortices, and a ventral projection to the temporal cortex and the amygdala that travels within the uncinate fasciculus, although these investigators did not correlate their findings with specific histochemical or immunocytochemical markers to ascertain the cholinergic phenotype of those fiber systems examined.

B. Cholinergic Fiber Trajectories in Human

Human studies of the trajectory of cholinergic basal forebrain pathways have been derived from histochemical investigations obtained from autopsy material. The most obvious cholinergic fiber pathway emanates from Ch1–2 to the hippocampus and courses mainly within the fornix (Fig. 19.14; Green and Mesulam, 1988; de Lacalle *et al*., 1994; Alonso *et al*., 1996). Selden *et al*. (1998) provided unique information on the trajectories of the cholinergic fiber pathways that emanate from the Ch4 cell group to the cerebral cortex using whole hemisphere cryostat-cut human brain sections stained for AChE as well as ChAT and $p75^{NTR}$. These investigators described two well-defined and discrete cholinergic fiber bundles from Ch4 to the cerebral cortex and amygdala, which were designated as the medial and lateral cholinergic pathways. The medial bundle joined the white matter of the gyrus rectus and curved around the rostrum of the corpus callosum to enter the cingulum. These fibers joined with axons of the lateral pathway within the occipital lobe. The lateral fasiculus provided the paraolfactory, cingulate, pericingulate, and retrospinal cortices. Selden and co-workers (1998) divided the lateral pathway into a capsular portion that traveled in the white matter of the external capsule (Fig. 19.29; see also Mufson *et al*., 1989a) and the uncinate fasciculus and perisylvian sector coursing within the claustrum. Divisions of the perisylvian bundle provided the cholinergic innervation of the frontal, parietal, and temporal neocortices (Fig. 19.29). Cholinergic fiber pathways are greatly reduced in patients with AD (Fig. 19.30; Mufson *et al*., 1989b). Magnetic resonance imaging reconstruction of these anatomically defined cholinergic pathways was also observed in the human brain (Selden *et al*., 1998).

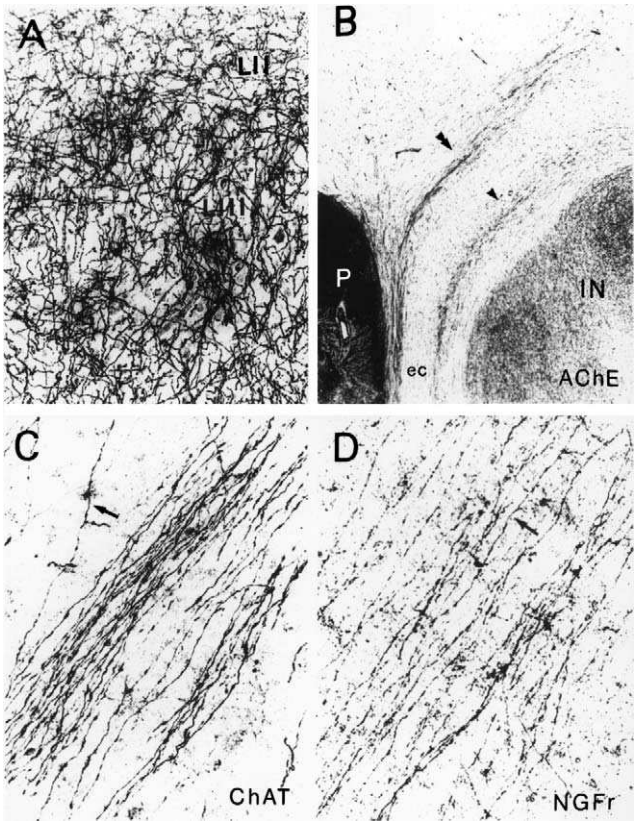

FIG. 19.29. (A) AChE histochemistry in the insula demonstrates a dense network of AChE-rich cholinergic axons. (B) Photomicrograph of the regions of the external capsule and claustrum revealing dense AChE reaction product over the putamen (P) and a thick network of AChE-rich fibers in the insular cortex (IN). The two components of the lateral cholinergic pathway are shown by the arrowhead (perisylvian division) and the double arrowhead (capsular division). The microscopic fields shown in C and D include the part of the capsular division located at the tip of the double arrowhead in B but immunostained in adjacent sections for ChAT (C) and $p75^{NTR}$ (D). The correspondence of the AChE-rich fiber bundle with ChAT- and $p75^{NTR}$-immunoreactive fibers demonstrates that the pathway is definitively cholinergic and that it originates in Ch1–4 cells of the nucleus basalsis. ec, external capsule; LII, LIII, cortical layers II and III; P, putamen. Medial is toward the left and dorsal toward the top. Magnifications: A, X186; B, X11.3; and C and D, X371. From Seiden *et al.* (1999), with permission.

XII. Connectivity of the Primate Cholinergic Basal Forebrain

A. Efferents of the Cholinergic Basal Forebrain

Combined horseradish peroxidase retrograde tracing and acetylcholinesterase (AChE) histochemistry to visualize double-labeled neurons (Mes-ulam and Van Hoesen, 1976; Mesu-

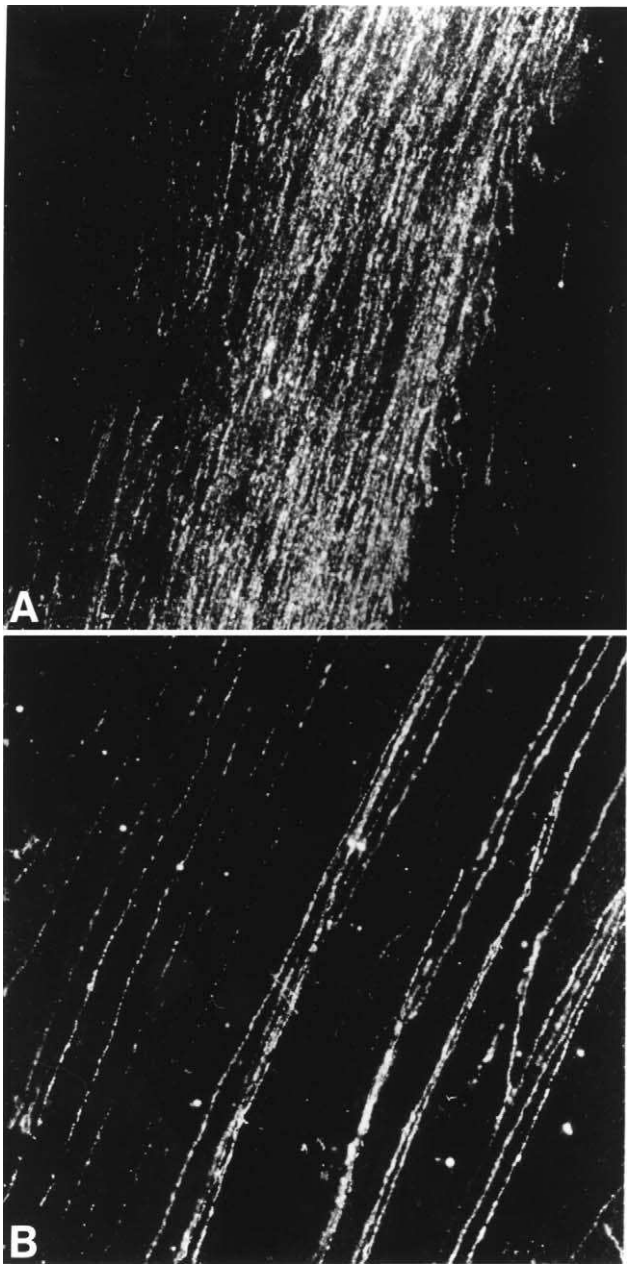

FIG. 19.30. Dark-field photomicrograph of $p75^{NTR}$ receptor-containing fibers coursing within the external capsule of a neurologically normal (A, 4X) and an AD (B, 11X) patient. Note the striking loss of $p75^{NTR}$-containing fibers between the control and the AD patient. B is presented at a magnification higher than that of A to better visualize the few remaining fibers seen in the AD case. From Mufson *et al*. (1989a), with permission.

lam *et al*., 1983b), demonstrated that the various cholinergic basal forebrain subfields project in a topographic fashion to different regions of the neocortical mantle, hippocampus, and amygdala and olfactory bulb of rhesus monkey. These findings have been substantiated in studies using concurrent labeling of neurons containing ChAT and HRP in the monkey (Mesulam *et al*., 1986).

1. Cholinergic Cell Group Medial Septum (Ch1) and Vertical Limb of the Diagonal Band Nucleus (Ch2)

Using the retrograde transport marker horseradish peroxidase, injections into the hippocampal formation with some spread to the parahippocampal area demonstrated cholinergic neurons within Ch1 and Ch2 in the rhesus monkey (Fig. 19.14). In contrast, only 1% were seen in Ch3 (horizontal limb of the diagonal band) and a small number within Ch4am. Others reported that neurons projecting to the hippocampus in the rhesus monkey were located mainly in the medial septum, the diagonal band, and the anteromedial aspect of Ch4. Approximately one-third of the retrogradely labeled neurons are ChAT immunoreactive (Koliatsos *et al*., 1990). Extensive cholinergic/$p75^{NTR}$ fiber labeling has been reported in the aged human hippocampus, presumably originating from cells, of the Ch1 and Ch2 (see also de Lacalle *et al*., 1994).

2. Cholinergic Cell Group Horizontal Limb of the Diagonal Band Nucleus (Ch3)

Projections from the Ch3 group (nucleus of horizontal limb of the diagonal band) are most prominent following injections into the olfactory bulb. Substantial projections of Ch3 were also seen within frontolateral area 12 and the amygdala.

3. Cholinergic Projections to the Cortex from the Nucleus Basalis (Ch4)

Projections of the Ch4 subregions are the most widespread and are directed mostly to the cortical mantle of the cerebral hemispheres. The extensive projections of the Ch4 group exhibit an internal topography. The Ch4am cell group projects mainly to the midprincipal, medial frontal pole, subcallosal gyrus, cingulate, dorsomedial motor, and parietal (area 7) cortices. Lesser but substantial projections of Ch4am are directed to the hypothalamus, hippocampal formation, ventral somatosensory cortex, amygdala, ventrolateral orbital, middle insula, periarcuate, peristriate cortices and parahippocampal region as well as the inferior parietal lobule.

The Ch4al subfield major source of innervation was to the lateral portion of area 12, frontal operculum, frontal operculum (M1), ventral S1, ventral posterior parietal cortex, and the amygdala. Additional retrograde tracer studies have reported a substantial projection from Ch4al to the amygdala (Kordower *et al*., 1989b). Other areas include the ventrolateral orbital cortex, medial, anterior, and posterior portions of the insula, as well as inferior temporal and parahippocampal regions.

These groups displayed many similarities in their projection patterns. Their major projections are to the ventrolateral orbital, insular, periarcuate, peristriate, inferotemporal, and parahippocampal areas, as well as the inferior lobule. Substantial contributions from these regions are also found in the medial frontal pole, dorsomedial motor cortex, and frontoparietal opercular areas, the amygdala, anterior auditory cortex, and the temporal pole.

The Ch4p region exhibits a very restricted distribution pattern. Its principal source of projections is to the auditory association cortex and the superior temporal gyrus, as well as the temporal pole. Additional major projections are also found in the adjacent inferotemporal and posterior insular regions.

4. Cholinergic Cell Groups 5 and 6 of the Brain Stem

The Ch5 and Ch6 sectors are located mostly within the pedunculopontine nucleus of the reticular formation (Ch5) and within the lateral dorsal tegmental nucleus (Ch6) and provide the major cholinergic innervation of the thalamus (Steriade *et al*., 1990; Hoover and Baisden, 1980). Rye *et al*., (1988) confirmed these connections using modern tract tracing procedures and the concurrent visualization of cholinergic markers. Although not confirmed in the primate, a minor projection from these cells to the cerebral cortex has been reported in the rodent (Vincent *et al*., 1983; Saper and Loewy, 1982). A significant descending projection from Ch5 to the brain stem reticular formation has also been described in rodents (Rye *et al*., 1988; Yasui *et al*., 1990), but has not been studied in primates. These connections have been suggested to play a role in coordinating switching from slow wave to rapid eye movement sleep (Rye *et al*., 1988).

5. Cholinergic Cell Groups 7 (Ch7, Medial Habenula) and 8 (Ch8, Parabigeminal Nucleus)

Ch7 projects mainly to the interpeduncular nucleus via the interpeduncluar tract (Fig. 19.14; Mesulam *et al*., 1986, Mufson *et al.*, 1987). The Ch8 region projects mainly to the superior colliculus (Fig. 19.14; Mufson *et al*., 1986). Following horseradish peroxidase–wheat germ agglutinin injections into the superior colliculus, the contralateral Ch8 contained six times as many labeled neurons as the ipsilateral nucleus. Some retrograde labeling was seen in the pedunculopontine (Ch5) and lateral dorsal tegmental nuclei (Ch6). Double labeling with ChAT and retrograde transport revealed that about 80% of retrogradely labeled neurons in the parabigeminal nucleus were also ChAT positive. Further support for the cholinergic nature of Ch8 neurons was derived from autoradiographic experiments that visualized intense labeling over the region corresponding to Ch8. In addition, tissue processed for a ChAT and AChE, as well as muscarine receptors, showed bands of these cholinergic markers in the superficial, intermediate, and deep layers of the superior colliculus (Fig. 19.15). These markers may correspond, at least in part, to the projection field of the cholinergic Ch8 neurons (Mufson *et al*., 1986).

B. Afferents to the Cholinergic Basal Forebrain Complex in Primates

1. Overview

Although it is well established in both the rodent and the monkey that the fornix carries cholinergic fibers from Ch1, very little is know about the neural inputs into the nucleus basalis (Ch4) in the monkey. This information is critical, as extensive pathological alterations have been reported in the Ch4 complex in a number of neuropsychiatric disorders, such as AD (Whitehouse *et al*., 1982; Arendt *et al*., 1985; Kordower *et al*., 1989a), schizophrenia (Stevens, 1982), Parkinson's disease (Whitehouse *et al*., 1983; Mufson *et al*., 1991), and Creutzfeldt–Jakob's disease (Arendt *et al*., 1984). Limited information on the behavioral specialization of the Ch4 complex in primates suggests that these neurons have response contingencies that go beyond simple sensory processing or motor control. In contrast to the neurons of the globus pallidus, which change their firing rate in temporal relationships to push–pull movements of the limbs, which most likely plays a significant role in motor control, the adjacent Ch4 neurons in the macaque respond to the delivery of juice reward (DeLong, 1971). These neurons also respond to the sight and taste of food. The size of the response is influenced by the interest of the food object and by the state of the animal's hunger (Burton *et al*., 1975). These findings indicate that the Ch4 perikarya are responsive to motivational states and that they must be receiving multiple sensory and limbic information that enables them to intergrate the external sensory events with the internal milieu.

C. Afferents of the Cholinergic Basal Forebrain

In 1984, Mesulam and Mufson placed tritiated amino acid injections within cortex and subcortical targets of the rhesus monkey. In contrast to their widespread projections to all parts of the cortex, these neurons receive reciprocal projections from only a few cortical areas. Most of the sensory, motor, and association areas in the frontal, parietal, occipital, and temporal lobes did not reveal projections back to the Ch4 complex. The Ch4 neurons receive their cortical input from the prepyriform cortex, orbital frontal (Fig. 19.31), the anterior insula, the temporal pole, entorhinal cortex (Fig. 19.32), and the medial temporal cortex. We found additional subcortical inputs from the septal nuclei, the nucleus accumbens–ventral pallidum complex, and the hypothalamus. Review of the organization of Ch4 input suggests that this region is in a position to act as a cholinergic relay for transmitting predominantly limbic and paralimbic information to the neocortical surface (Fig. 19.33). It would also appear that cortical areas that do not project into Ch4 may have not have a direct manner of controlling the cholinergic input that they receive. The findings supported and expanded earlier neuroanatomical experiments in the macaque, which demonstrated the presence of Ch4 projections to the amygdala, medial frontopolar cortex, ventromedial hypothalamic nucleus, the magnocellular portion of the dorsomedial nucleus of the thalamus, caudal orbitofrontal cortex, and the peripeduncular nucleus (see de Lacalle and Saper, 1997, for review). However, the apparent limited set of cortical areas that do project into Ch4 probably can control not only the cholinergic innervation that they receive but also cholinergic innervation into the cortex.

XIII. Pathology of Cholinergic Systems in Aging and Alzheimer's Disease

A. Overview

Over the last two decades, the relationship between cholinergic basal forebrain function and cognition, especially age-related cognitive decline, has engendered great scientific interest (e.g., Bartus *et al*., 1982; DeKosky *et al*., 1985). The cholinergic basal forebrain neurons located within the septal/diagonal band complex and the nucleus basalis provide the major cholinergic innervation to the cortex and hippocampus

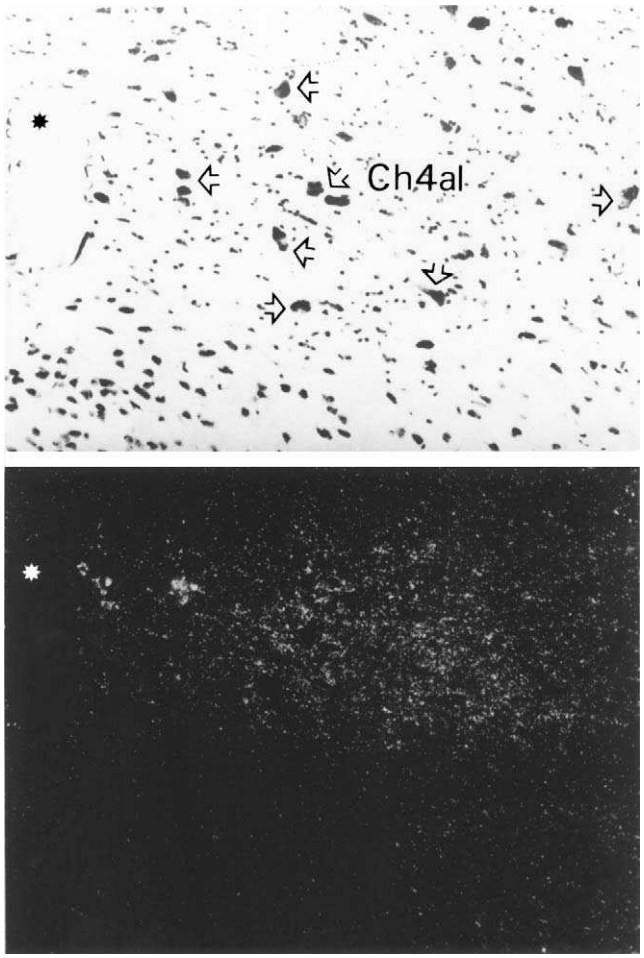

FIG. 19.31. Photomicrographs from orbitofrontal radioisotope-labeled injection. The upper photomicrograph was taken with bright-field illumination. It shows the part of Ch4al that overlies the most caudal portion of the olfactory tubercle. Open arrowheads point to some examples of the large hyperchromic Ch4 neurons. The smaller neurons at the bottom belong to the olfactory tubercle. The lower photomicrograph shows the same area but under dark-field illumination. This makes the silver label stand out as white dots. The label is clearly concentrated in Ch4al and forms dense homogeneous clusters. Because there are no linear streaks of silver grains, this label represents axonal terminals rather than passing fibers. For purposes of orientation, the arteriole in both photomicrographs has been marked with an asterisk. Magnification X266. From Mesulam and Mufson (1984), with permission.

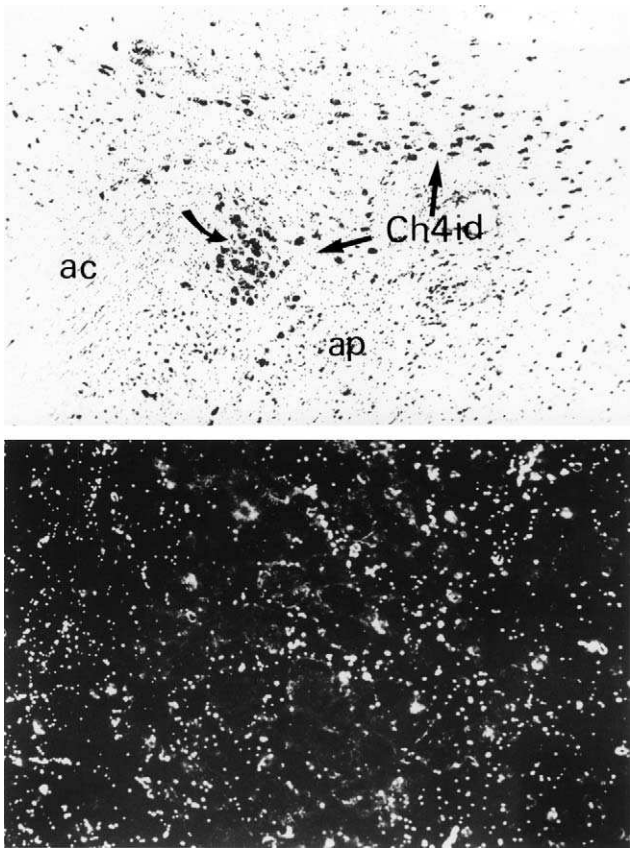

FIG. 19.32. Photomicrographs from an entorhinal radioisotope-labeled injection. (Top) Bright-field illumination shows two islands of Ch4id (straight arrows). The curved arrow points to neurons that have been magnified in the lower photomicrograph. Magnification X70. (Bottom) Dark-field illumination shows the silver grain label as white dots. This label surrounds the Ch4id perikarya indicated by the curved arrow in the top photomicrograph. Magnification X500. From Mesulam and Mufson (1984), with permission.

(Fig. 19.14; Mesulam *et al*., 1983b), respectively. Several reports demonstrated a significant reduction in both cholinergic basal forebrain neurons (Whitehouse *et al*., 1982) and cortical ChAT activity (DeKosky *et al*., 1998) in human aging. Price and co-workers (1991) noted that aged nondemented cases displayed remarkably few neurofibrillary tangles within the cholinergic neurons of the nucleus basalis, whereas mildly demented cases displayed increased tangle density. These data suggest that pathologic abnormalities co-occur with changes in cognition. However, the strongest evidence that the cholinergic basal forebrain system plays a pivotal role in human cognitive function is derived from clinicopathologic studies of this region in patients with AD (e.g., Whitehouse *et al*., 1983; Allen *et al*., 1988; Mufson *et al*., 1989a). Intensive study of the cholinergic basal forebrain system has been fueled by these findings and the observation that cholinergic deficits in AD were thought to occur early in the disorder (Wilcock *et al*., 1982) and correlate with severity (Wilcock *et al*., 1982) and duration (Mufson *et al*., 1989b) of the disease process. The extensive degeneration of cholinergic basal forebrain neurons in AD is accompanied by an increase in the number of NADPH-d neurons (Benzing and Mufson, 1995) and an overexpression of the neuropeptide galanin (Chan-Palay, 1988; Mufson *et al*., 1993), which may further enhance cholinergic basal forebrain dysfunction. However, the relationship of these plastic responses to the loss of cholinergic neurons is not well understood. Furthermore, there is also a vast animal literature linking cholinergic basal forebrain systems to normal and pathological memory function (see Bartus, 1983). Although it is clear that many brain regions degenerate in aging and AD, cholinergic hypofunction was originally thought to be central to its major symptomatology and to correlate with cognitive impairment (Bierer *et al*., 1995).

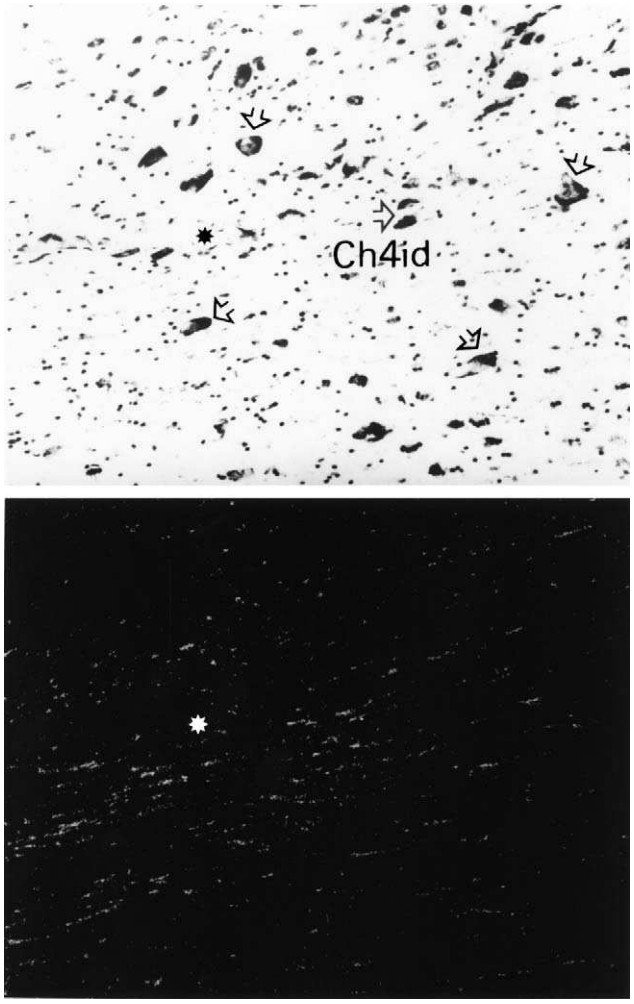

FIG. 19.33. Photomicrographs from Ch4id following a triated amino acid injection site in the midcaudal parahippocampal gyrus. The top photomicrograph was taken with bright-field illumination. Open arrowheads point to some examples of Ch4 neurons. The bottom photomicrograph shows the same area but under dark-field illumination. This makes the silver label stand out as white dots. The great majority of the label forms linear streaks and is undoubtedly within passing fibers. This was the only type of label seen in the Ch4 of this case that was therefore considered negative. In the vast majority of the other negative cases, even this linear labeling was absent from Ch4. For purposes of orientation, the arteriole in both photomicrographs has been marked with an asterisk. X266. From Mesulam and Mufson (1984), with permission.

B. Cholinergic Changes in Subjects with Early AD

1. Cortical ChAT Activity in Early AD

As mentioned previously, a major tenet of AD has been the loss of cholinergic markers, cholinergic basal forebrain cell degeneration, and the loss of ChAT and AChE activity within the cortex in postmortem AD brains (e.g., Davies and Maloney, 1976; Whitehouse *et al*., 1982). Most postmortem studies examining these changes in the basocortical cholinergic system in AD have been derived from end-stage patients with severe dementia. However, whether these deficits in cholinergic markers found in end-stage patients are also seen in subjects with much earlier disease has only been investigated recently. In fact, data derived from two different groups have provided information that changes in the cholinergic system are not severe in cases with mild cognitive impairment without dementia and early AD (Davis *et al*., 1999; Gilmore *et al*., 1999). The first data to demonstrate that cortical cholinergic levels were not altered in patients with early AD were characterized using the clinical dementia rating scale (CDR) (Davis *et al*., 1999). In this postmortem study, ChAT and AChE cortical levels did not differ significantly in subjects with CDR scores of 0 (no AD) to 2 (mild AD) in nine cortical areas. In contrast, significantly lower levels of these enzymes were found in cases with severe dementia (CDR 4–5), (Figs. 19.34 and 19.35). Similar findings have been reported from a cohort of retired Catholic clergy (DeKosky *et al*., 1998). CDR cognitive scores correlated when all groups were included in the analysis. However, when the CDR 5 scores were excluded from the analysis, the ChAT and AChE activity did not correlate significantly with cognitive scores in any cortical region examined. Interestingly, ChAT levels were significantly correlated with the severity of neuropathological lesions of AD [i.e., density of neuritic plaques and neurofibrillary tangles (NFTs)]. In summary, this study confirmed that severe reductions of cortical ChAT levels are found in end-stage but not mild AD patients.

C. Cholinergic Basal Forebrain Neuron Degeneration in Early AD

1. Overview

As indicated earlier, a second major tenet of AD is the loss of basal forebrain cholinergic neurons in end-stage patients (Whitehouse *et al*., 1982; Saper *et al*., 1985). Since the mid-1990s, numerous studies employing various markers have shown that alterations to the basocortical cholinergic system are more complex than originally proposed. For example, the vesicular acetylcholine transporter (VAChT), which is responsible for the accumulation of acetylcholine in synaptic vesicles in cholinergic axon terminals and coexpresses with ChAT within the human cholinergic basal forebrain (Fig. 19.36; Gilmore *et al*., 1999), is not severely altered in AD. In this regard, pharmacological studies of VAChT in postmortem AD tissue or *in vivo* imaging studies using vesamicol and its analogs suggest that VAChT levels remain steady or are minimally decreased coincident with a severe decline in ChAT activity in cortical areas (Ruberg *et al*., 1990). The discordance between ChAT and VAChT in the cortex is particularly surprising in light of the discovery that they are part of a single cholinergic gene locus with shared regulatory elements (for review, see Eiden, 1998). Moreover, evidence from experimental lesions in animals (Sofroniew *et al*., 1990) and from postmortem human studies (Pearson *et al*., 1983; Rinne *et al*., 1987) suggests that many cholinergic neurons shrink after injury or during the pathological process rather than degenerate. Taken together, these observations suggest that cholinergic basal forebrain neurons may be viable, albeit dysregulated, in AD.

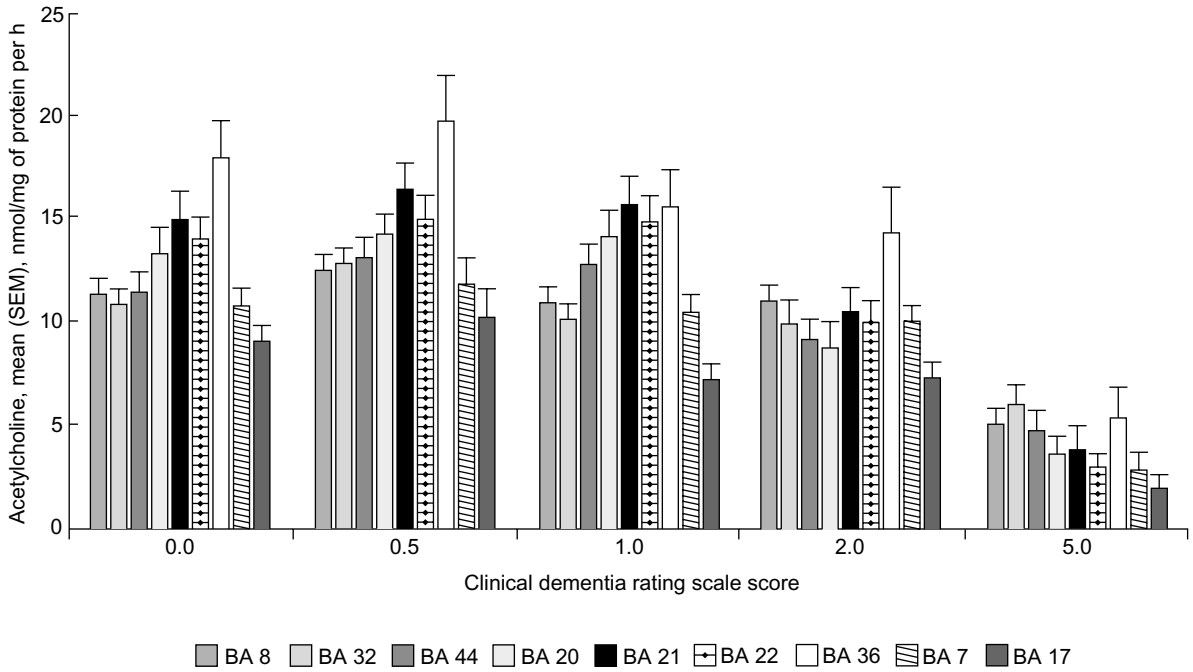

FIG. 19.34. Relative to the group without dementia [(clinical rating (CDR) scale score 0.0)], the activity of choline acetyltransferase (ChAT) was reduced significantly ($P < 0.001$ for all) in the CDR 5.0 group only. BA, Brodmann area. From Davis *et al*. (1999), with permission.

2. Cholinergic (Ch4) Cell Preservation in Early AD

To clarify the extent of cholinergic basal forebrain neuronal degeneration in the early stages of the disease process, we compared the total number of neurons containing ChAT and VAChT within the nucleus basalis of individuals classified clinically as displaying no cognitive impairment (NCI), mild cognitive impairment (MCI), or early AD. These cases are part of a longitudinal study of aging and AD of retired Catholic clergy (Gilmore *et al*., 1999; Mufson *et al*., 1999). Stereologic

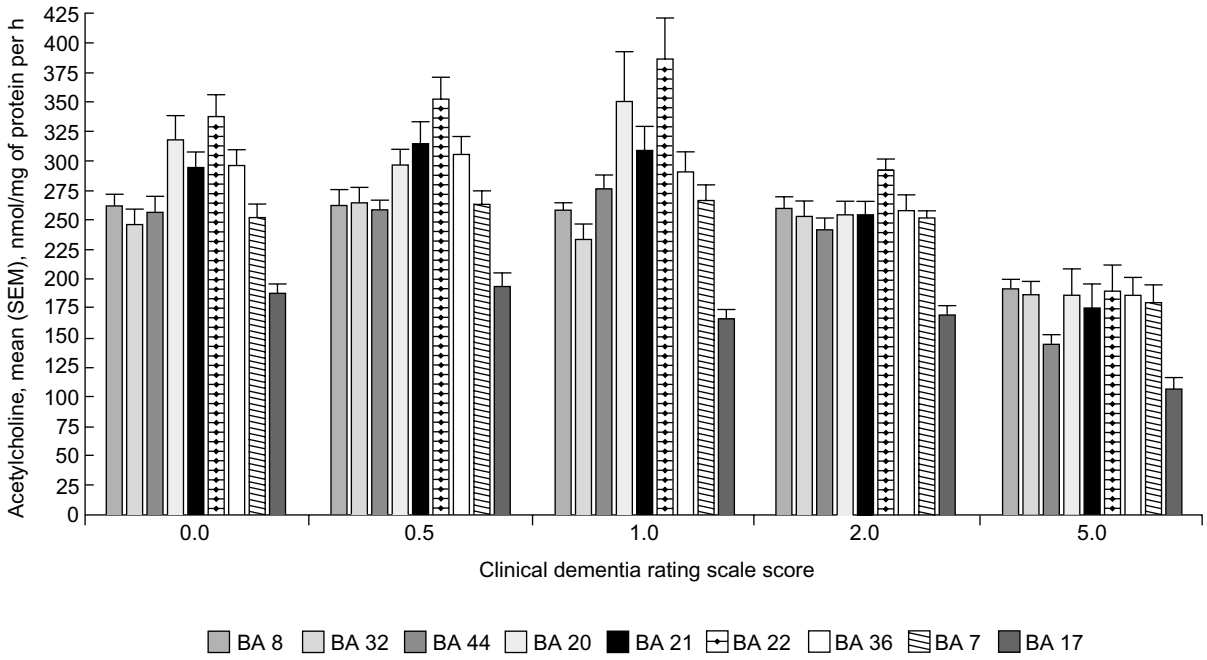

FIG. 19.35. Relative to the group without dementia [clinical rating (CDR) scale score 0.0], the activity of acetylcholinesterase (AChE) was reduced significantly ($P < 0.001$ for all) in the CDR 5.0 group only. BA, Brodmann area. From Davis *et al*. (1999), with permission.

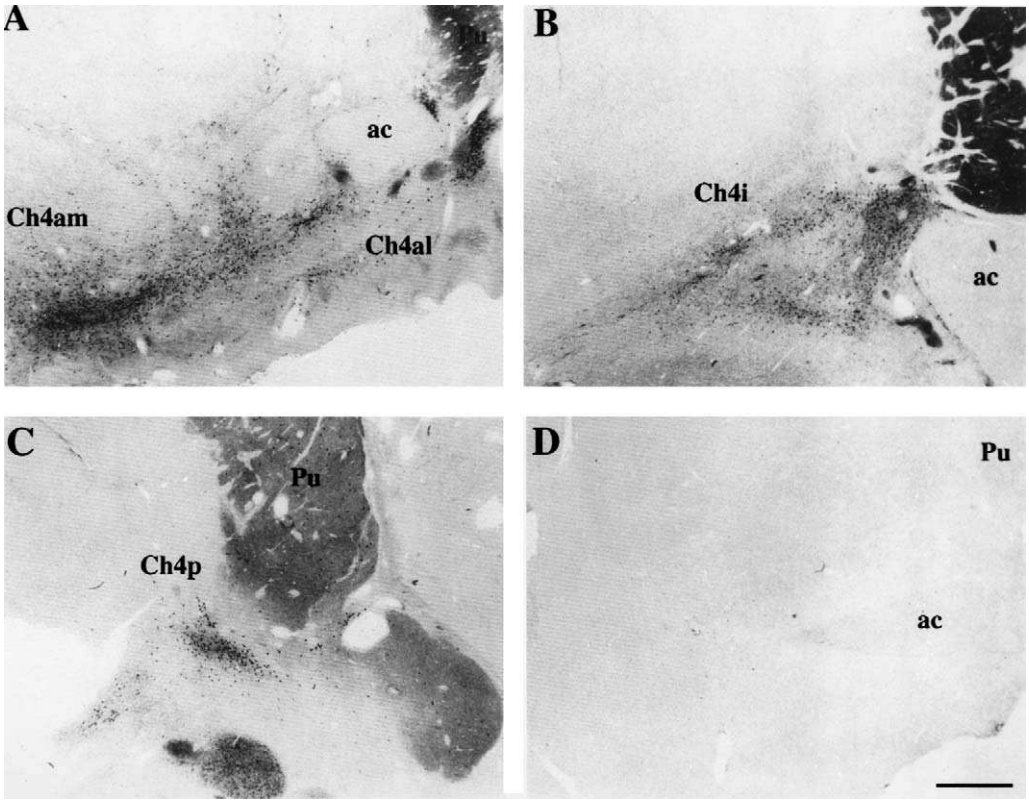

FIG. 19.36. Immunocytochemical localization of vesicular acetylcholine transporter-immunoreactive neuron immunoreactivity in the human nucleus basalis of Meynert. Shown are representative stained sections from rostral (A), intermediate (B), and caudal (C) levels of the basal forebrain from individuals with no cognitive impairment. The subdivisions of the nucleus correspond to those described previously using choline acetyltransferase-immunoreactive neurons to mark the cholinergic neurons (Mesulam and Geula, 1988). Also note the high density of immunoreactivity in the putamen and amygdala. (D) Staining was abolished when the primary antibody was omitted. ac, anterior commissure; Ch4am, anteromedial cell group; Ch4al, anterolateral cell group; Ch4i, intermediate cell group; Ch4p, posterior cell group; Pu, putamen. Scale bar: 2 mm. From Mufson *et al*. (1998), with permission.

counting methods were used to count the number of ChAT- and VAChT-immunoreactive neurons from tissue derived from these three groups (Gilmore *et al*., 1999). Both markers were expressed robustly in nucleus basalis neurons and across all three cognitive groups (Fig. 19.36). On average, there was no significant difference between the number of ChAT (210,000)- and VAChT (174,000)-immunopositive neurons in the nucleus basalis (Ch4) per hemisphere in NCI (see Table 19.1). There was a nonsignificant reduction in the number of cholinergic neurons in Ch4 in AD cases with no decline in MCI cases (Fig. 19.37; Table 19.1). The number of ChAT- and VAChT-immunopositive neurons was shown to significantly correlate with the severity of dementia determined by scores on the Mini-Mental State Examination, but showed no relationship to apolipoprotein E4 (ApoE) allele status, age, gender, education, or postmortem interval when all clinical groups were combined or evaluated separately. These data indicate that ChAT- and VAChT-immunoreactive neurons are relatively preserved in early stages of AD. These findings suggest that nucleus basalis neurons are capable of a compensatory increase in ChAT during the early stages of AD, which is reflected by no apparent loss of cortical ChAT activity early in the disease processes (Davis *et al*., 1999). An important therapeutic implication of these findings is that survival of the basal forebrain cholinergic neurons in early stages of the disease provides an opportunity for interventions aimed at restoring or maintaining function.

TABLE 19.1 ChAT- and VAChT-Immunoreactive Neurons in the Nucleus Basalis of Meynert[a]

Cases	ChAT (mean ± standard deviation)	VAChT (mean ± standard deviation)
NCI	210,540 ± 15,240 (n=6)	174,000 ± 12,773 (n=6)
MCI	167,879 ± 17,903 (n=7)	192,637 ± 34,737 (n=5)
AD	155,585 ± 17,949 (n=9)	149,423 ± 17,615 (n=9)

[a]ChAT, choline acetyltransferase-immunoreactive neurons; VAChT, vesicular acetylcholine transporter-immunoreactive neurons; NCI, no cognitive impairment; MCI, mild cognitive impairment; AD, Alzheimer's disease. From Mufson *et al*. (1998), with permission.

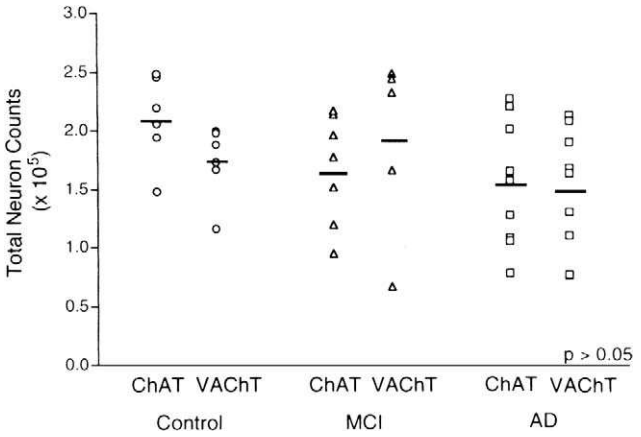

FIG. 19.37. Summary of choline acetyltransferase (ChAT) and vesicular acetylcholine transporter (VAChT) total neuron counts. No cognitive impairment (NCI) cases (O), mild cognitive impairment (MCI) cases (△), and Alzheimer's disease (AD) cases (□). Total neuron counts were estimated in the same NCI, MCI, and AD cases for ChAT and VAChT. There was no significant difference between the number of ChAT- and VAChT- immunopositive neurons for any of the three clinically diagnosed groups. Bars represent the mean. From Mufson *et al.* (1998), with permission.

XIV. Apolipoprotein E Genetics and Cholinergic Basal Forebrain Degeneration

Pathogenetic and biochemcial studies have shed new light on the involvement of the cholinergic basal forebrain system in neurobiology of AD. First, significantly lower levels of cortical and hippocampal ChAT activity and cholinergic basal forebrain neuron loss were found in AD patients with an ApoE ϵ4 genotype (Poirier *et al*., 1994; Poirier, 1994: Soininen *et al*., 1995; Allen *et al*., 1997). ApoE ϵ4 is a known genetic risk factor for AD (Saunders *et al*., 1993). These observations indicate that the ApoE ϵ4 genotype is associated with the function and integrity of the cholinergic basal forebrain system in the brain. Of particular importance are the findings that this genetic susceptibility results in subgroups of AD patients, which respond differentially to anticholinesterase agents such as tacrine (Schneider *et al*., 1996). This suggests that the ApoE ϵ4 carriers are at a greater risk for dysfunction of their ACh synthetic machinery and are therefore less likely to respond to anticholinesterease drugs. Second, it has been shown *in vivo*, that AChE, which is the degrading enzyme for ChAT, accelerates assembly of amyloid-β-peptides into AD-like fibrils (Inestrosa *et al*., 1996). Interestingly, it has been found that cortical ChAT but not AChE activity is reduced with normal aging (DeKosky *et al*., 1985). Taken together, these findings support the suggestions that (1) the presence of acetylcholine (ACh) in the neocortex plays an essential role in normal cognitive function, (2) genetic factors are associated with cholinergic basal forebrain dysfunction, and (3) defects in the cholinergic basal forebrain system potentially provide an important molecular link related to plaque formation.

XV. Cytoskeletal Abnormalities within the Cholinergic Basal Forebrain in AD

Degeneration of the cholinergic basal forebrain system has been a major tenent in the field of AD. In AD, cholinergic basal forebrain neurons display extensive NFT degeneration. These NFTs are formed by insoluble intracellular polymers of hyperphosporylated tau, the less phosporylated forms of which stabilize the microtubules of the axonal cytoskeleton (Trojanowski *et al*., 1993). To determine the extent to which cholinergic basal forebrain neurons exhibit cytoskeletal lesions, basal forebrain sections from AD and aged controls were dual stained with thioflavin-S or an antibody against paired helical filament (PHF) (Mufson *et al*., 1989b). A few senile plaques were seen scattered in the AD basal forebrain (Fig. 19.15B). Of particular interest is the observation derived from a fluorescence microscopic analysis, which revealed a large number of $p75^{NTR}$/cholinergic-immunoreactive neurons that are invested with differing degrees of neurofibrillary material (Fig. 19.38). Some neurons are thioflavin-S negative or only minimally fluorescent for this amyloid marker. Others are more heavily invested, suggesting a greater involvement in the disease process (Figs. 19.38D and 19.38E). In addition, many NFT-bearing profiles observed in the basal forebrain were ghost tangles, i.e., neurons appeared to be largely devoid of cytoplasm and organelles consisting of neurofibrillary remnants (Fig. 19.38D). This pattern of NFT expression is suggestive of a continuum of degenerative events related to the hyperphosphorylation of tau-like molecules. NFTs observed within the cholinergic basal forebrain neurons were globose in shape and fluoresced as a dense core mass (Fig. 19.38C). This is in contrast to the more wispy appearance of the NFTs observed within the cortex (Fig. 19.38A). These observations potentially represent differences in the pattern of amyloid aggregation between cortical and basal forebrain cell types. The overexpression of tau may play a crucial role in the selective degeneration of cholinergic basal forebrain neurons in AD over time.

XVI. NGF and the Cholinergic Basal Forebrain in Alzheimer's Disease

A. Overview

The trophic factor NGF specifically supports the viability and phenotypic expression of cholinergic basal forebrain neurons. The findings that NGF is synthesized mostly in cholinergic basal forebrain target regions, enhances cholinergic function both *in vitro* (Levi-Montalcini *et al*., 1954; Levi-Montalcini, 1987) and *in vivo* (Hefti *et al*., 1986; Koliatos *et al*., 1990), is specifically transported from the cortex and hippocampus to cholinergic basal forebrain consumer neurons (Connor and Varon, 1992), rescues medial septal cholinergic neurons that undergo degeneration following axotomy in rodents, young monkeys, and aged monkeys (for review, see Tuszynski *et al*., 1999), and prevents cholinergic basal forebrain atrophy and improves cognitive function in aged rats (see Fischer *et al*., 1987), support the contention that cholinergic basal forebrain neurons are exquisitely sensitive to the

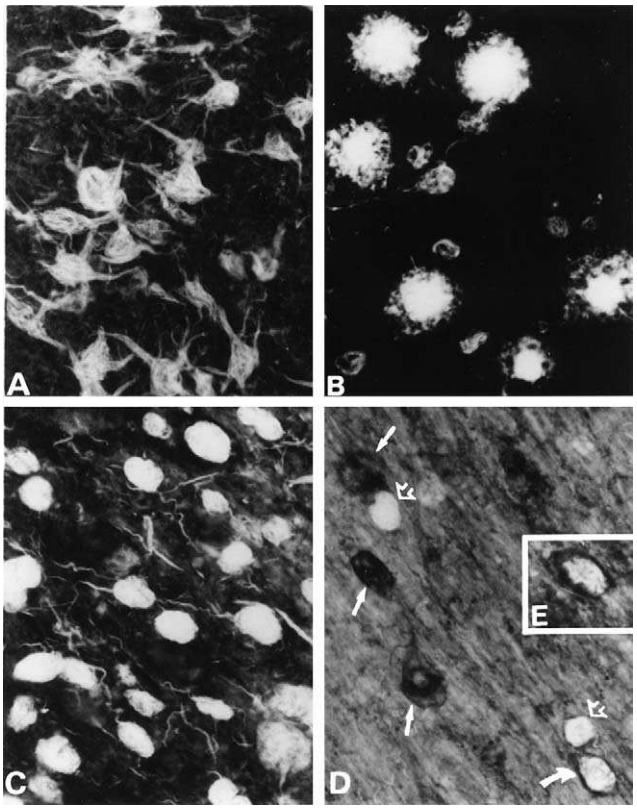

FIG. 19.38. Thioflavin-S-stained sections showing neurofibrillary tangles (NFTs) and neuritic plaques in AD patients. (A) NFTs within layer II of the entorhinal cortex. (B) Neuritic plaques located within the superior temporal cortex. (C) NFTs located within the nucleus basalis (Ch4am). (D) $p75^{NTR}$-immunoreactive nucleus basalis (Ch4al) neurons (DAB chromagen) counterstained with Thioflavin-S. Solid white arrows indicate NGF receptor-containing neurons, open arrows indicate ghost tangles (see text), and curved arrow denotes NFT-bearing NGF receptor-containing neuron. (E) Another example of a NFT-bearing NGF receptor-containing neuron. Note the dark rim of $p75^{NTR}$ immunoreactivity surrounding the fluorescent NFT staining (A–E, 380X; Ch4am, anteromedial division of the cholinergic cell group 4; Ch4al, anterolateral division of the cholinergic cell group 4). From Mufson *et al.* (1989a), with permission.

trophic influences of NGF. Furthermore, mRNA and protein for both high (trk)- and low-affinity (p75) NGF receptors are expressed by cholinergic basal forebrain neurons in monkeys and in young and aged humans (Kordower *et al*., 1988; Mufson *et al*., 1995, 1997b; Blurton-Jones *et al*., 1999) but not in the other cholinergic cell groups. These observations raise the possibility that neurotrophins and their receptors may be used therapeutically in the human to reverse the age-related cognitive decline associated with cholinergic basal forebrain degeneration in AD (Tuszynski *et al*., 1990a; Mufson *et al*., 1997b; Mufson and Kordower, 1999).

The extensive literature linking NGF processes to basal forebrain function led to the initial suggestion that impaired NGF trophic support underlies cholinergic basal forebrain degeneration in AD (Hefti and Weiner, 1983; Mufson *et al*., 1999). Subsequent studies primarily examining NGF message levels in cerebral cortex and the expression of protein and mRNA for the low-affinity $p75^{NTR}$ within the cholinergic basal forebrain failed to support this initial hypothesis (Mufson *et al*., 1997b; Mufson and Kordower, 1999) and enthusiasm for this concept diminished. While cortical NGF synthesis is not impaired in AD (Crutcher *et al*., 1993; Scott *et al*., 1995), it is important to keep in mind that NGF exerts trophic influences on cholinergic basal forebrain neurons via a series of complex events, including NGF synthesis, trkA receptor synthesis and anterograde transport, NGF binding to its high-affinity *trk* receptor, retrograde transport of the NGF/receptor complex from the cerebral cortex and hippocampus to cholinergic basal forebrain neurons, and autophosphorylation of the NGF signal. Failure at any of these steps could result in cholinergic basal forebrain degeneration secondary to impaired NGF trophic support. In this regard the low-affinity receptor may induce apoptotic events (Rabizadeh *et al*., 1998) by acting as a death receptor if the ratio of trkA to $p75^{NTR}$ levels is not in balance. Interestingly, even though there is not a change in cortical NGF levels (Crutcher *et al*., 1993; Scott *et al*., 1995), there is a reduction of retrogradely transported NGF by cholinergic basal forebrain consumer neurons in AD (Mufson *et al*., 1994). In aging, the two receptors most likely remain in equilibrium and continually transport NGF to cholinergic basal forebrain neurons, maintaining their survival and maintenance. By comparison to AD, there is a reduction in trkA protein and mRNA, a stability of $p75^{NTR}$ and cortical NGF. This led us to postulate that a discordance between trkA and $p75^{NTR}$ may result in a cascade of events leading to the degeneration of cholinergic basal forebrain neurons such as the induction of apoptosis (Rabizadeh *et al*., 1998) or the formation of NFTs.

XVII. Cholinergic Basal Forebrain and Experimental Therapeutics

A. Overview

Since the 1980s, numerous studies have established a link between the cholinergic basal forebrain and higher order cognitive function. The question has now arisen as to whether the cholinergic basal forebrain is involved specifically in attentional or memory processes (Voytko, 1996). However, it remains clear that an intact basal forebrain system is required for normal higher order informational processing.

Initial reports demonstrating reduced cholinergic markers within the cortex of AD patients (Davies and Maloney, 1976) led to intense interest in the source of this innervation in the cholinergic basal forebrain system. Cholinergic neurons within this region atrophy and degenerate in AD (Whitehouse *et al*., 1982; Doucette and Ball, 1987; Mufson *et al*., 1989b; Kordower *et al*., 1989a). There are a number of important concerns when considering which system to target with experimental therapeutic strategies. Is this system impaired when the symptoms first appear? Does this system continue to degenerate as the disease progresses? Does failure of this system in animal models mimic what is observed in humans? The answer to these types of questions furthers our interest in targeting the cholinergic basal forebrain with novel therapeutic interventions. The cortical cholinergic deficit has been reported to be present within 1 year of symptom onset and remains the neurotransmitter system that best correlates with the severity

and duration of this illness (Bierer *et al*., 1995). However, it should be noted that nondemented individuals with mild cognitive impairment do not display deficits in cortical cholinergic markers (Davis *et al*., 1999).

An extensive animal literature also indicates that an intact cholinergic basal forebrain is needed for normal cognition (Bartus *et al*., 1982; Dunnett and Fibiger, 1993, Wainer *et al*., 1993). Lesions of the cholinergic basal forebrain system in rodents and monkeys induce long-lasting impairments of trial-dependent and trial-independent memory tasks (Bartus *et al*., 1982; Dunnett and Fibiger, 1993). In addition to lesion studies, pharmacological experiments indicate that an intact cholinergic system is necessary for normal cognition. Administration of cholinergic antagonists to rodents, monkeys, and humans consistently impairs short-term memory (Bartus *et al*., 1982; Dunnett and Fibiger, 1993; Wainer *et al*., 1993). Conversely, administration of cholinergic agonists to aged rodents and aged nonhuman primates enhances cognitive performance (Bartus *et al*., 1982; Dunnett and Fibiger, 1992; Wainer *et al*., 1993). These data support the concept that the cholinergic deficit mediates, in part, the memory deficits seen in AD.

Because the loss of cholinergic neurons induces impairments on tasks of cognition and attention in rodents, monkeys, and humans, neuroprotective drug strategies and neural replacement strategies have been employed experimentally in an attempt to sustain and/or enhance cognitive function on the one hand (neuroprotection) or reverse cognitive deficits on the other (neural replacement). For neuroprotection, the molecule that has received the most empirical attention is the trophic factor NGF. We have already detailed the association of cholinergic basal forebrain neurons with NGF systems. The steroid estrogen has also received a great deal of attention as a possible treatment strategy for the slowing of the onset and risk of AD in women (Tang *et al*., 1996; Kawas *et al*., 1997).

B. Neuroprotection by NGF in Models of Cholinergic Degeneration

As an initial test of the hypothesis that NGF can prevent the degeneration of the cholinergic basal forebrain neurons, three groups virtually simultaneously demonstrated that intraventricular administration of NGF could completely prevent the death of cholinergic basal forebrain neurons that would normally result from transection of the fimbria fornix (Hefti, 1986; Gage *et al*., 1988). In the absence of NGF, control animals receiving fimbria-fornix transection demonstrate a 75% loss of ChAT neurons. In contrast, animals that received injections or continuous infusions of NGF into the ventricular system of the brain at the time of the lesion showed virtually no loss of ChAT labeling in cholinergic basal forebrain neurons. These dramatic findings provided direct evidence for the first time that a single molecule, NGF, was capable of preventing what had heretofore been thought to be an irreversible loss of neurons after injury. Subsequent experiments examined the effects of NGF on the entire population of cholinergic basal forebrain neurons. Like the fimbria-fornix model, studies consistently demonstrated that structural and functional changes seen following lesions of the nucleus basalis, which provides the entire neocortex with cholinergic input, could be reversed by NGF treatment (Liberini *et al*., 1993). NGF was found to influence the entire population of cholinergic basal forebrain neurons in the medial septal region (Ch1), vertical limb of the diagonal band (Ch2), and nucleus basalis (Ch4), cementing its role as an important neurotrophic factor for this neuronal population. In addition to the ability of NGF to reverse lesion-induced deficits, a critical study performed by Fischer and co-workers (1987) revealed that NGF could also prevent age-related *spontaneous* atrophy of cholinergic basal forebrain neurons and the associated cognitive deficits displayed by a subset of aged rats on the Morris water maze. Thus NGF neuronal protection was not merely evident following experimental trauma to neurons, but also exerted a protective effect in the natural biological process of neuronal loss with aging.

As this technology marched toward a clinical trial, follow-up studies virtually identical to the ones performed in rats were carried out in nonhuman primates (Tuszynski *et al*., 1990b, 1991; Koliatsos *et al*., 1990; Kordower *et al*., 1994b). Here too, transection of this projection to the hippocampus resulted in the retrograde degeneration of approximately 75% of cholinergic basal forebrain neurons. However, when monkeys received NGF infusions into the ventricular system, 80–100% of cholinergic neurons were rescued after fornix lesions.

Experiments described in the preceding section set the stage for trials of NGF therapy in AD. However, careful examination of noncognitive processes revealed that unacceptable adverse effects were directly related to the intraventricular NGF delivery. Intracerebral ventricular NGF delivery *floods* the cerebrospinal fluid pathways with NGF, delivering high concentrations into the lateral, third, and fourth ventricles and into the subarachnoid space overlying the cerebral hemispheres, brain stem, and spinal cord. Flooding of the ventricular system with this highly diffusable and potent trophic factor results in hypophagia, sprouting of sympathetic axons around the cerebral vasculature, migration and proliferation of Schwann cells in a thick pial layer that surrounds the brain stem and spinal cord, and dense sprouting of sensory axons into the proliferating Schwann cell layer (see Tuszynski *et al*., 1999, for review). Adult and aged monkeys received 75% of basal forebrain cholinergic neurons, whereas monkeys that received NGF-secreting, autologous genetically modified cell grafts showed an average loss of immunolabeling in only 28% of cholinergic neurons. The grafted monkey with the largest and most accurately targeted NGF-producing transplant showed a loss of only 8% of immunolabeled cholinergic neurons. Critically, monkeys receiving intraparenchymal NGF grafts do not experience weight loss, Schwann cell migration into the central nervous system, or abnormal sprouting of sympathetic and sensory systems. Transgene expression as determined by NGF ELISA protein measurements is maintained for at least 8 months *in vivo* in the primate brain. Thus, gene therapy is an effective means of delivering NGF to the large primate brain, rescuing cholinergic neurons without inducing adverse effects. Animals receiving intraventricular grafts of NGF-producing cells also displayed lethargy and an apparent pain syndrome (Emerich *et al*., 1994; Kordower *et al*., 1994b). Finally, two AD patients received intraventricular NGF infusions in Sweden several years ago, and although reports on these patients are limited (Olson *et al*., 1992), they apparently developed pain syndromes that were likely related to Schwann

cell and sensory axon growth. Some of the clinical and preclinical effects were reversed when NGF treatment was discontinued. However, it is likely that chronic NGF treatment would be needed for patients with AD, making this route of neurotrophin delivery untenable, requiring the development of other site-specific means of NGF delivery.

1. Gene Therapy

a. Overview. Relatively recent advances in molecular biology have introduced gene therapy as a potential means of delivering substances to the nervous system. Gene therapy offers the prospect of providing neurotrophic factors to the brain intraparenchymally in a well-targeted, regionally restricted, long term, and safe manner. Two approaches to gene therapy have been utilized to date in animal models and in human clinical trials: (1) *In vivo* gene therapy refers to the genetic alteration of host cells *in vivo* using viral-derived vectors that insert DNA directly into a targeted brain region, whereas (2) *ex vivo* gene therapy refers to the genetic alteration of dividing cells in the culture dish, followed by the transplantation of these genetically altered host cells into specific nervous system sites (see Tuszynski *et al.*, 1999, for review). In both approaches, the genetically modified cells act as biological "minipumps" that can deliver substances such as NGF to precise brain targets.

b. Ex Vivo Gene Therapy. Gage and co-workers (1988) pioneered gene delivery of NGF using *ex vivo* technology. In these studies, fibroblasts were modified genetically to produce human NGF at a rate of approximately 10 ng of human NGF/10^6 cells/day, whereas nonmodified fibroblasts produced no detectable NGF (Rosenberg *et al.*, 1988). This amount exceeds physiological levels of NGF production in the adult brain by approximately 500-fold. Thus, *in vitro* prior to transplantation to the brain, host cells can be modified genetically to produce large amounts of human NGF. To test the ability of NGF gene therapy to rescue degenerating basal forebrain cholinergic neurons, primary fibroblasts modified genetically to produce and secrete human NGF were transplanted to the rat septal nucleus after fimbria-fornix lesions (Rosenberg *et al.*, 1988). Control animals received identical lesions and grafts of fibroblasts transduced to produce a nonneurotrophic factor gene. Whereas the lesion induced the degeneration of approximately 75% of cholinergic neurons in control animals, rats that received grafts of NGF-producing fibroblasts showed a loss of only 5% of neurons. Thus, the transplantation of genetically modified cells to the brain was an effective means of preventing injury-induced cholinergic neuronal degeneration. In subsequent experiments, rats with spontaneous age-related atrophy of basal forebrain cholinergic neurons and associated deficits in learning and memory received NGF-producing fibroblasts to the nucleus basalis region of the cholinergic basal forebrain. Animals that received NGF-producing cells, but not control, nonmodified fibroblasts, showed reversal of mnemonic deficits and improvement of cholinergic neuronal morphology (Chen and Gage, 1995). Subsequently, other investigators replicated these findings using grafts of other genetically modified cell types (Martinez-Serrano *et al.*, 1995).

To determine whether gene therapy with human NGF was a practical means of protecting neurons in the larger primate brain, the degeneration of basal forebrain cholinergic neurons in adult monkeys was induced by performing unilateral fornix transections. Monkeys then received transplants of autologous fibroblasts modified genetically to produce human NGF (Tuszynski *et al.*, 1996). Control subjects received lesions and non-genetically modified fibroblast grafts. Transplants were placed intraparenchymally, directly into the septal region of degenerating cell bodies. The placement of cells intraparenchymally maximized neurotrophin delivery to degenerating neurons and shielded other potentially NGF-responsive neurons from the neurotrophin exposure encountered by delivery techniques such as intracerebroventricular infusions. One month after the lesion, control-lesioned monkeys showed degeneration of 75% of basal forebrain cholinergic neurons, whereas monkeys that received NGF-secreting, autologous, genetically modified cell grafts showed an average loss of immunolabeling in only 28% of cholinergic neurons. The grafted monkey with the largest and most accurately targeted NGF-producing transplant showed a loss of only 8% of immunolabeled cholinergic neurons. Critically, monkeys receiving intraparenchymal NGF grafts do not experience weight loss, Schwann cell migration into the central nervous system, or abnormal sprouting of sympathetic and sensory systems. Transgene expression as determined by NGF ELISA protein measurements is maintained for at least 8 months *in vivo* in the primate brain. Thus, gene therapy is an effective means of delivering NGF to the large primate brain, rescuing cholinergic neurons without inducing adverse effects.

2. Encapsulated Xenografts

An alternative method to *ex vivo* gene therapy using autologous host cells is *ex vivo* gene therapy using xenografted species different from a cells that are encapsulated in biopolymers to prevent graft rejection (Emerich *et al.*, 1994; Kordower *et al.*, 1994b). The advantage of the encapsulated gene therapy approach is that banks of cells can be maintained that would be available for transplantation on short notice. Further, these cells are retrievable should problems related to the growth factor be encountered by simply removing implanted capsules. To test the ability of encapsulated, genetically modified xenografts to rescue cholinergic neurons, baby hamster kidney (BHK) cells were modified genetically to secrete high levels of human NGF (hNGF); these cells were then implanted into rhesus monkeys to determine whether they would prevent lesion-induced degeneration of cholinergic basal forebrain neurons. Following polymer encapsulation, BHK cells were grafted into the lateral ventricle of four long-tailed macaque monkeys immediately following a unilateral transection/aspiration of the fornix. Three control monkeys received identical grafts, with the exception that BHK cells were not modified genetically to secrete human NGF, thus differing by only the single gene construct (Fig. 19.39). One monkey received a fornix transection only. All monkeys displayed complete transections of the fornix as revealed by a comprehensive loss of AChE-containing fibers within the hippocampus ipsilateral to the lesion. Control monkeys, which were either nonimplanted or received non-NGF-secreting BHK cell implants, did not differ from

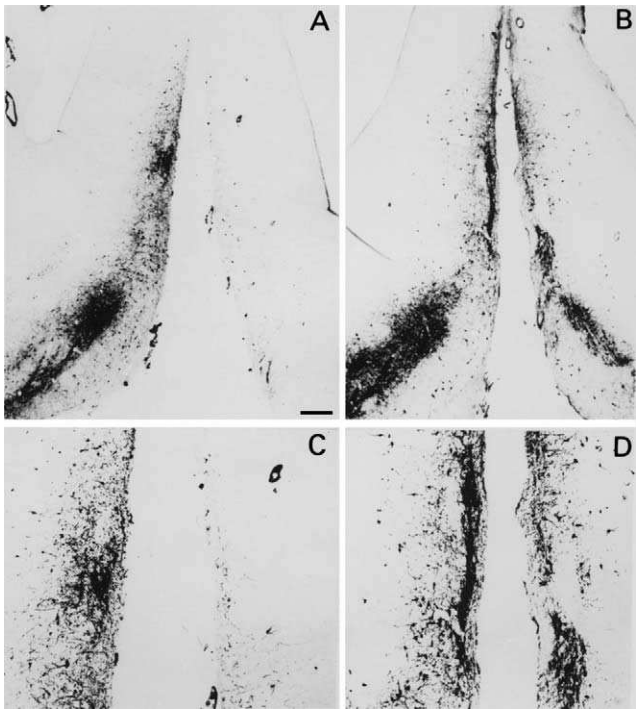

FIG. 19.39. Low (A and B)- and high (C and D)-power photomicrographs of $p75^{NTR}$-immunostained sections through the septal diagonal band complex of young adult long-tailed macaque monkeys that received unilateral fornix transections and intraventricular grafts of encapsulated BHK cells (A and C) or encapsulated BHK cells that had been modified genetically to secrete human NGF (B and D). (A and C) Note the loss of $p75^{NTR}$-immunoreactive neurons ipsilateral to the fornix transection in monkey receiving the fornix transection. (B and D). In contrast, the loss of $p75^{NTR}$-immunoreactive neurons was almost completely prevented in monkeys receiving the same lesion and the same graft with the single addition of the human NGF construct. From Emerich *et al*. (1994), with permission.

each other and displayed extensive losses of ChAT- and p75-immunoreactive neurons within the medial septum (53 and 54%) and vertical limb of the diagonal band (21 and 30%) ipsilateral to the lesion. In contrast, monkeys receiving implants of BHK–hNGF cells exhibited only a modest loss of cholinergic neurons within the septum (19 and 20%) and nucleus of the ventral limb of the diagonal band (7%). Furthermore, only grafts of human NGF-secreting cells induced a dense sprouting of cholinergic fibers within the septum that ramified against the ependymal lining of the ventricle adjacent to the transplant site. Examination of the capsules upon their removal from the animal prior to sacrifice revealed numerous healthy-appearing cells that produced detectable levels of human NGF sufficient to induced differentiation of PC12 cells in culture. These latter findings indicate that genetically modified fibroblasts can secrete biologically relevant levels of human NGF following transplantation into the primate brain.

3. Gene Therapy in Aged Primates

AD is a disease that afflicts the elderly. However, the vast majority of *in vivo* studies attempting to discover therapeutic strategies for AD patients employ young rodents or monkeys. Even rarer are studies employing aged nonhuman primates, a species that exhibits both behavioral and pathological sequelae similar to that seen in AD. To study the effects of cellular delivery of NGF upon degenerating basal forebrain neurons in an aged primate, rhesus monkeys between the ages of 24 and 29 years old received unilateral transections of the fornix. All of these monkeys displayed numerous diffuse plaques in the temporal and limbic cortices. Three aged monkeys received intraventricular transplants of polymer-encapsulated BHK fibroblasts that had been modified genetically to secrete hNGF. The additional three monkeys received identical grafts except that the cells were not modified to secrete hNGF. Monkeys receiving the fornix transection and control grafts displayed extensive reductions in the number of ChAT (57–75%)- and $p75^{NTR}$-immunoreactive (53%) medial septal neurons ipsilateral to the lesion/graft. In contrast, monkeys receiving grafts of encapsulated hNGF-secreting cells displayed only a modest loss of ChAT (0–36%)- and p75 (7–22%)-immunoreactive medial septal neurons (Fig. 19.40). Additionally, all monkeys receiving the hNGF-secreting implants, but none receiving control implants, displayed robust sprouting of cholinergic fibers within the septum ipsilateral to the graft. Just prior to sacrifice, the capsules were retrieved and determined to contain viable BHK cells releasing biologically relevant levels of hNGF. These data demonstrate that hNGF can provide trophic and tropic influences to degenerating cholinergic basal forebrain neurons in aged nonhuman primates, supporting the possibility that human NGF may prevent the degeneration of basal forebrain neurons in AD.

4. Replacement of Cholinergic Neurons by Fetal Grafts

The grafting of embryonic cholinergic neurons to replace those that are lost due to lesions or neural degeneration has been tested preclinically and provided a theoretical framework from which fetal grafting in humans with AD might be considered. Numerous studies have demonstrated that fetal cholinergic grafts survive, provide organotypic cholinergic innervation, and reverse the cognitive deficits seen in rats that are secondary to experimental lesions (fimbria-fornix transections or nucleus basalis lesions) or aging processes. The details of these studies have been reviewed extensively elsewhere (Kordower and Collier, 1999). Fetal cholinergic grafting studies have also been performed in nonhuman primates, and because this chapter focuses on the primate cholinergic basal forebrain system, they will be reviewed here.

Prior to the initiation of clinical trials, especially for behaviors as complex as cognition, we believe that experimental therapeutic strategies should be demonstrated to be safe and effective in nonhuman primate models of the disease. Unlike Parkinson's disease, where MPTP-treated monkeys represent an outstanding animal model, nonhuman primate models for AD are limited. For specifically modeling the cholinergic deficit in AD, lesion studies have been employed. Ridley and coworkers (1991, 1992, 1994) have pioneered the study of cholinergic basal forebrain transplants in monkeys with lesions of the basal forebrain system. Their initial investigations employed bilateral lesions of the fimbria fornix system (Ridley *et al*., 1991). If should be noted that, as detailed later, the

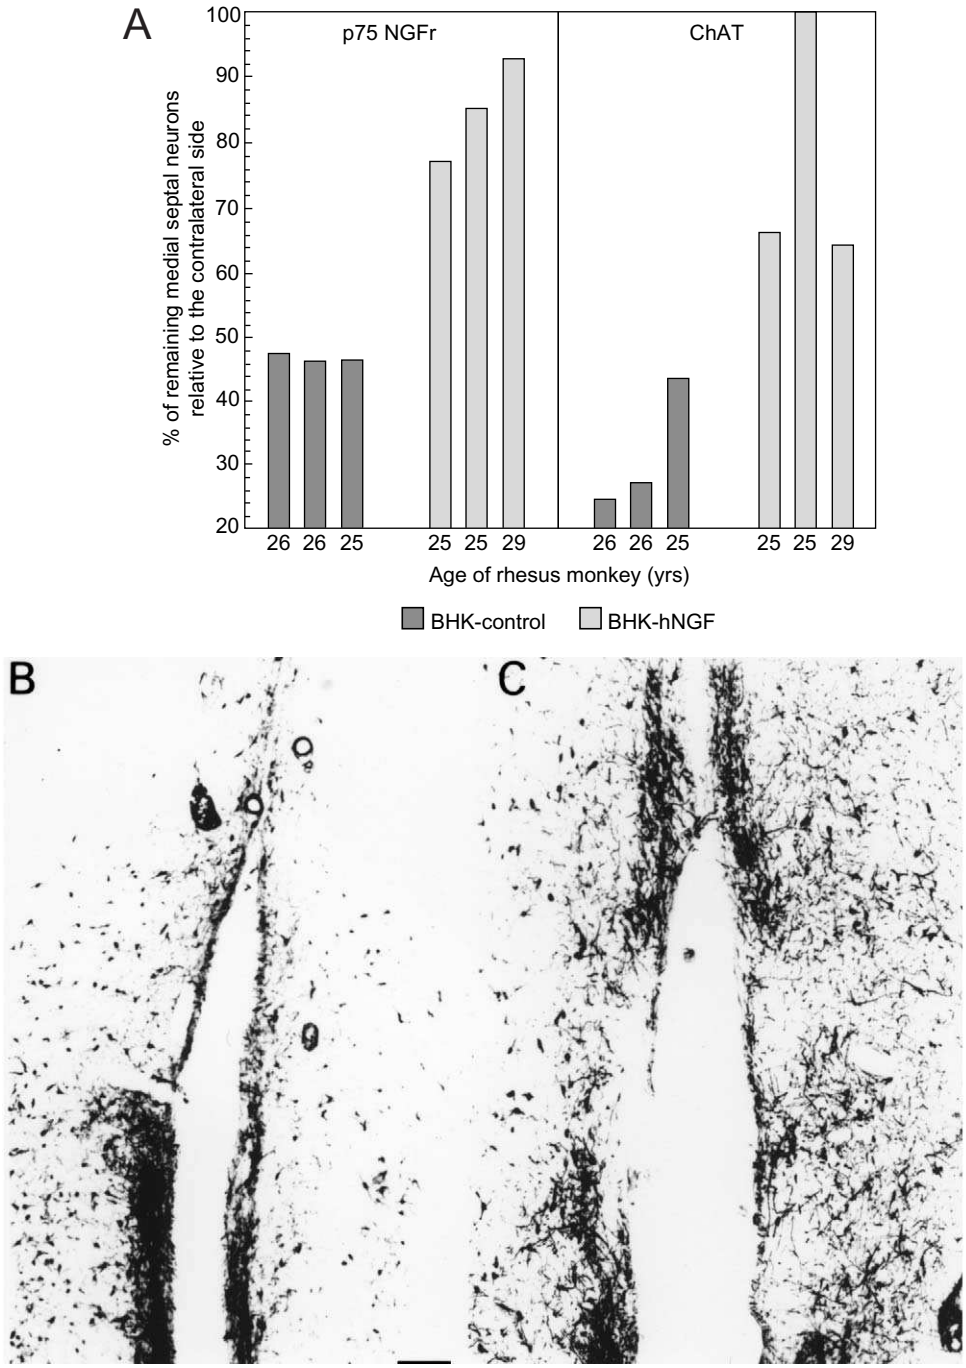

FIG. 19.40. (A) Quantification of the loss of $p75^{NTR}$- and ChAT-immunostained neurons in BHK controls and BHK–hNGF-grafted aged monkeys. (B) $p75^{NTR}$-immunostained section through the medial septum of a monkey receiving a BHK control graft. Note the extensive loss of neurons ipsilateral (right) to the lesion relative to the intact (left) side. (C) Monkeys receiving BHK–hNGF grafts displayed a symmetrical pattern of $p75^{NTR}$-immunoreactive staining within the medial septum with minimal neuronal loss (Bar: 100 μm). From Kordower *et al*. (1994b), with permission.

septohippocampal system is less affected in AD than the basocortical system and thus this lesion paradigm does not mimic the pattern of neural degeneration seen in AD. Still, given the more restricted target zone (hippocampus) and the numerous studies using this model system in rodents, this was a logical choice for initiating these investigations.

In their first study (Ridley *et al*., 1991), marmosets received bilateral transection of the fornix that resulted in impairment in function on a number of cognitive tasks, including visuospatial conditional discriminations, visual conditional discriminations, and nonconditional spatial-response tasks. These monkeys then received bilateral implants of cholinergic-rich fetal basal

forebrain tissue into the hippocampus. These grafts resulted in a significant improvement in function on these tasks 3–9 months posttransplantation. In contrast, lesioned animals receiving fetal hippocampal grafts remained impaired. These fornix-transected/control-grafted animals displayed a severe reduction in acetylcholinesterase staining throughout the dentate gyrus and hippocampus. Staining was largely restored to normal in the host hippocampus and dentate gyrus in monkeys with cholinergic transplants, whereas AChE staining was abnormal in those with noncholinergic grafts.

In a second study (Ridley *et al*., 1992), marmosets with bilateral transections of the fornix were severely impaired on learning visuospatial conditional tasks presented in a Wisconsin general test apparatus. Bilateral transplantation of cholinergic-rich embryonic basal forebrain tissue into the hippocampus led to on this task across a range of task difficulties. Administration of the direct cholinergic agonist pilocarpine to ungrafted animals immediately before testing also reduced this impairment, suggesting that the graft-associated recovery was mediated by acetylcholine release. Again, transection of the fornix produced a marked loss of AChE staining confined to hippocampus and entorhinal cortex relative to controls. In all transplanted animals, densely AChE-staining cellular masses were seen bilaterally in temporal lobe structures, with fiber outgrowth into the surrounding host tissue.

To investigate the potential benefits of fetal cholinergic basal forebrain grafts for AD, their latest study employed a model system that more closely mimics the pattern of degeneration seen in AD (Ridley *et al*., 1994). Rather than study graft effects in the septohippocampal system, these investigators examined the ability of implanted cholinergic basal forebrain neurons to improve memory function in marmosets receiving lesions of the nucleus basalis (Ch4). In this study, three groups of marmosets were trained to perform a series of visual discrimination tasks using a Wisconsin general test apparatus. Two groups then received bilateral lesions of the basal nucleus of Meynert using the excitotoxin *N*-methyl-D-aspartate. Monkeys receiving these lesions were severely impaired on relearning on a visual discrimination test. One lesioned group then received grafts of acetylcholine-rich tissue dissected from the basal forebrain of fetal marmosets. Three months later the marmosets with lesion alone remained impaired on a number of retention and reversal tasks, whereas the transplanted animals were no longer significantly impaired. Histological examination of the brains indicated that all lesioned animals had sustained substantial loss of Ch4 and that the lesion-alone animals showed marked loss of the cholinergic marker AChE in the dorsolateral and parietal cortices. All transplanted animals had surviving graft tissue as visualized by cresyl violet staining, dense AChE staining, and the presence of a limited number of nerve growth factor receptor-immunoreactive neurons in the neocortex. Five of the six cholinergic basal forebrain-transplanted marmosets showed near complete restitution of AChE staining in the frontal and parietal cortices. Examination of individual animal data showed that the one animal without a neuroanatomical recovery did not display a significant behavioral recovery. The performance of the remaining transplanted animals was significantly improved relative to animals with lesion alone. There was a significant positive correlation between the degree of AChE staining and performance on tasks sensitive to frontal lobe damage. These results demonstrate that acetylcholine-rich tissue transplanted into the neocortex of primates with damage to the cholinergic projections to the neocortex can produce substantial restitution of function, provided that an appropriate level of interaction between graft and host tissue is achieved.

For cholinergic basal forebrain grafts to be useful for AD patients, they would have to survive, innervate, and function for a long period of time. We carried out a series of fetal allografts in rhesus monkeys to assess the long-term survival in and innervation in a large primate brain (Kordower and Collier, 1999). Further, we examined whether graft viability was improved following immunosuppression with cyclosporin. Sixteen rhesus monkeys received unilateral lesions of the fornix to denervate the hippocampus of cholinergic afferents. Ten to 14 days later, these monkeys received implants of monkey fetal basal forebrain neurons into the hippocampus. All implants were between 35 and 50 days of gestation. This gestational age was chosen based on neurogenesis of the rhesus monkeys cholinergic basal forebrain (Kordower and Rakic, 1990). Monkeys were sacrificed 3, 9, 12, and 18 months following transplantation. Half of the monkeys received cyclosporin (15 mg/kg, im) daily beginning 1 day prior to the transplants and continuing until sacrifice. Viable grafts of cholinergic basal forebrain neurons were routinely observed. Importantly, large cholinergic basal forebrain grafts were observed in monkeys 12 and 18 months after transplantation (Fig. 19.1). Grafted cholinergic basal forebrain neurons appeared healthy with a magnocellular morphologically. Grafted cholinergic basal forebrain neurons displayed long multiplolar neuritic processes emanating from the cell soma.

Numerous ChAT-, trk-, $p75^{NTR}$-, and galanin-immunoreactive neurons, as well as AChE-containing perikaryon neurons, could be observed within the grafted hippocampus surviving in an organotypic fashion. Since most of these five proteins colocalize in cholinergic basal forebrain neurons, it was not surprising that similar numbers of neurons stained for each marker were seen within animals. Interestingly, an exception to this finding was one monkey with a graft surviving for 18 months, which displayed similar numbers of cholinergic basal forebrain neurons staining for all markers except for a marked diminution of ChAT-immunoreactive cells. Additionally, grafted cholinergic basal forebrain neurons sustained their expression of trk receptors, indicating that they would be responsive to NGF exposure. This is particularly important if fetal cholinergic basal forebrain grafts are supplemented by trophic factor treatment.

Fetal cholinergic basal forebrain neurons were capable of providing extensive innervation to the host hippocampus. Beginning 6–9 months after transplantation, grafts provided innervation in an organotypic pattern which by 12 months was similar in magnitude to the level seen in the normal hippocampus. These data indicate that fetal cholinergic basal forebrain neurons can survive long term following grafting into the primate brain. Qualitative observations indicate that immunosuppression did not enhance graft viability. Thus, fetal cholinergic basal forebrain neurons are capable of providing a long-term, relatively normal, cholinergic reinnervation in young adult lesioned monkeys. These data support the concept that fetal cholinergic basal forebrain grafts may be useful in treating the cholinergic deficit seen in AD.

XVIII. Estrogen as a Treatment for Cholinergic Basal Forebrain Changes in Aging and Alzheimer's Disease

Estrogen replacement in postmenopausal women decreases the risk of developing AD (Tang *et al*., 1996; Kawas *et al*., 1997). At present, very little is known where the putative neuronal action of estrogen occurs within the central nervous system. Based on studies in rodents, a possible site of action may be cholinergic basal forebrain neurons (Luine, 1985; Gibbs, 1994, 1998; Mufson *et al*., 1999), whose neurons consistently degenerate in AD (Whitehouse *et al*., 1982; Mufson *et al*., 1989a). Since the mid-1990s, a large body of data has accumulated, suggesting that estrogen may enhance cholinergic basal forebrain cell survival through interactions with the growth-promoting substance NGF and its high-affinity trkA receptor (Mufson *et al*., 1997a). In fact, several studies have shown that cholinergic basal forebrain neurons contain the trkA receptor in the rat (Sobreviela *et al*., 1994; Holtzman *et al*., 1995), monkey (Kordower *et al*., 1994b), and human (Mufson *et al*., 1997a) brain. In fact, trkA-containing neurons within the cholinergic basal forebrain coexpress ERα in the rat (McMillan *et al*., 1996). In AD, there is a downregulation in protein and message for trkA (Mufson *et al*., 1995, 1997a; Boissière *et al*., 1997) similar to that seen in ovariectomized rats (Gibbs, 1996). However, whether the cholinergic basal forebrain/NGF-responsive neurons within the primate brain also express ER is unclear. This is an important issue as studies have shown species differences in the chemoanatomical phenotype of the mammalian cholinergic basal forebrain among rodents, monkeys, and humans (Benzing *et al*., 1993; Kordower and Mufson, 1990; Kordower *et al*., 1992). Interestingly, available immunohistochemical studies indicate that ERα-positive nuclei do not correspond to ChAT-, $p75^{NTR}$- or trkA-containing cholinergic basal forebrain neurons in the monkey brain (Fig. 19.28; Blurton-Jones *et al*., 1999; Sendera *et al*., 1999). In this regard, preliminary studies in our laboratory have not revealed detectable ERα-immunopositive neurons within the human cholinergic basal forebrain (E. J. Mufson *et al*., unpublished observations). Studies from our laboratory have also failed to reveal ERα within neurons containing calbindin and parvalbumin (Sendera *et al*., 1999). These observations indicate the need for additional studies aimed at understanding the neural basis of estrogen's action within the mammalian forebrain and its role in the regulation of memory and attention. It has been shown that estrogen promotes axonal and dendritic plasticity in the limbic neurons of male and female brain (Woolley *et al*., 1996). In ovariectomized mice the impairment of reactive synaptogenesis within limbic structures is reversed by estrogen replacement (Stone *et al*., 1998). Thus, the age-related postmenopausal estrogen deficiency may suppress the potential for central nervous system neural plasticity (Mesulam, 1999), including cholinergic basal forebrain cortical projection neurons. Findings generated from further investigations of the role that estrogen plays in the central nervous system may lead to novel therapeutic treatments for the prevention of neurologic disorders such as AD.

Glutamate Receptors in Aging and Alzheimer's Disease

The discovery that the stimulation of ionotropic glutamate receptors mediates not only the physiological action of glutamate but also a neurotoxic response provided the impetus for numerous investigations that sought to determine the role of glutamate in the pathophysiology of a number of neurodegenerative diseases, including Alzheimer's disease (AD). To date, nearly 200 articles have been published that specifically focus on the integrity and/or functional properties of the glutamate receptors in aging and AD. This chapter attempts to synthesize the results of these many studies and present them in as unbiased manner as possible. The chapter is divided into four main sections: (i) overview of the glutamate receptors, (ii) glutamate receptors in the aging (rodent) brain, (iii) glutamate receptors in the AD brain, and (iv) current topics of glutamate toxicity in AD. What will become obvious following the reading of this chapter is that data are at times inconsistent, with some investigators reporting that glutamate receptors are highly vulnerable in the aged and AD brain, whereas others state that these receptors are intact or even hyperfunctional. Contributing to these inconsistencies are a host of technical issues. To address this matter, the details of a number of studies (i.e., strain, species, age, brain region investigated, postmortem interval, when applicable) are presented in tabular form (Tables 20.1–20.14). By providing this information, it is our goal that the reader will be able to make some personal assessment of the extent to which technical details, may or may not, confound the biological relevance of the findings. It is also important to bear in mind that much of our knowledge of glutamate receptors in aging and AD has come about through studies employing autoradiographic techniques to investigate the anatomical distribution and density of various ligand-specific binding sites. Although these studies have been of considerable value in defining the role of glutamate in the aging brain and AD, it is clear from our knowledge of the molecular biology of the glutamate receptor that specific techniques are required allowing for the identification of individual glutamate receptor subtypes. Studies employing these latter techniques are currently underway in several laboratories and while much of the data remain unpublished it is clear that these works will play a critical role in the future in defining glutamates participation as an excitotoxic agent in the aging brain and AD.

I. Introduction

For many years it has been known that in Alzheimer's disease (AD), and during normal aging, specific populations of neurons are more susceptible to pathologic insult than others. With this knowledge, investigators have sought to determine those molecular determinants that distinguish vulnerable neurons from those more resistant. While investigating potential mechanisms underlying neuronal vulnerability, it is important to consider that glutamate is likely the most abundant excitatory neurotransmitter in the brain. Importantly, the main physiological role of glutamate is to act at excitatory synapses. However, the response of a cell to glutamate depends on a host of variables, including the abundance and molecular composition of the various glutamate receptors expressed by the cell. In this same context, it is important to bear in mind that the neurotoxic action of glutamate is triggered by the stimulation of many of the same ionotropic receptors that mediate the physiological action of this neurotransmitter (Choi, 1988). Nevertheless, neurons within the same or even different brain region are not equally susceptible to glutamate toxicity. It appears that excitotoxicity follows the abusive stimulation of *N*-methyl-D-aspartate (NMDA) and non-NMDA ionotropic glutamate receptors that are permeable to Ca^{2+}. Although traditionally NMDA receptors have been considered to play the dominant role in the mediation of excitotoxic injury, a growing body of evidence affirms the important contribution of α-amino-3-hydroxy-5-methyl-4-isoaxolepropionate (AMPA)/kainate receptors with high permeability to calcium.

As a result of the putative role of glutamate in the pathophysiology of a number of neurodegenerative diseases, a wealth of studies have emerged in an attempt to define the integrity and/or functional properties of these receptor subtypes during normal aging and in disease. Data that have emerged from these

studies are, at times, highly inconsistent, thus contributing to a number of controversies concerning the role of glutamate during disease and normal aging. To our knowledge, few, if any, comprehensive reviews on this subject exists and as a result we have attempted to compile and present the results of the majority of those studies investigating the role of glutamate, particularly the glutamate receptor, in aging and AD. This work is divided into four parts: (i) overview of the glutamate receptor, (ii) glutamate receptors in the aging brain, (iii) glutamate receptors in the Alzheimer's brain, and (iv) current topics of glutamate toxicity in Alzheimer's disease. This chapter is limited to ionotropic glutamate receptors, and while every effort has been made to include all relevant publications, it is inevitable that some works are overlooked and to those authors whose work was excluded an apology is extended.

II. Overview of the Glutamate Receptors

Glutamate is a dicarboxylic acid that is stored in synaptic vesicles and is released from the nerve terminal following neuronal stimulation. Glutamate fulfills all criteria of a chemical neurotransmitter in the vertebrate central nervous system (CNS) (Fonnum, 1991) and is the most abundant excitatory neurotransmitter present in the mammalian brain. The release of glutamate and its interactions with specific membrane receptors is responsible for many important neurologic functions, including cognition and memory. While glutamate is traditionally considered to function as a rapidly acting neuronal transmitter, it too possesses the potential of producing long-lasting changes in neuronal excitability, such as the appearance of long-term potentiation (LTP) following the stimulation of hippocampal neurons. Under physiological conditions the interaction of glutamate with its receptor is relatively brief, and within a millisecond or less specific uptake mechanisms and/or degradative enzymes begin to clear glutamate from the synaptic cleft. However, if the natural order of these processes is overwhelmed, e.g., by the excessive release of glutamate due to uncontrolled transmitter release following neuronal damage, glutamate then accumulates in persistently high concentrations at the synaptic cleft, resulting in the continuous and protracted binding of glutamate to its receptor, leading to neuronal damage or death. This process, also termed ''excitotoxicity'' (Olney, 1990), is believed to be operative in several acute and chronic neurodegenerative diseases, including AD.

Notably, the responsiveness of a neuron to glutamate depends to a large extent on the repertoire of glutamate receptors expressed by the cell. Historically, the pharmacological profile of glutamate receptors has been delineated based on their ability to be activated selectively and specifically by synthetic agonists. In brief, ionotropic glutamate receptors are divided into a class of NMDA-selective and another class of non-NMDA-selective receptors (for review, see Seeburg, 1993). The latter class is subdivided into kainate and AMPA-sensitive receptors. In addition, in mammalian brain a family of metabotropic receptors exists that differs functionally and pharmacologically from ionotropic receptors. For example, these latter receptor subtypes often are coupled to the G-protein/inositol phosphate (IP)/Ca^{2+} signaling pathway (Nakanishi, 1992). Although the study of metabotropic receptors and their role in neurotoxicity is an emerging area of investigation (Lipartiti *et al*., 1993), this chapter focuses largely on the ionotropic glutamate receptor because functionally they account for the majority of the excitotoxic responses to glutamate.

cDNAs encoding subunits of various ionotropic glutamate receptor subunits have been cloned (Seeburg, 1993). These studies have revealed that ionotropic glutamate receptors are formed from five main families of genes, with each gene encoding an individual subunit of heterooligomeric complexes acting as ligand-gated conveyors of ion fluxes for the receiving cells (reviewed in Seeburg, 1993). One family of genes encodes subunits that form AMPA-selective receptors (GluR1-4 or, alternatively, GluR-A, -B, -C, -D), two families encode kainate-selective subunits (GluR5-7, KA1, and KA2), and two encode NMDA-selective subunits (NMDAR1 and NMDAR2A-D). In addition, all four AMPA receptor subunits occur in two alternatively spliced variants (designated flip and flop) that are encoded by exons 14 and 15 (GluR2) positioned just before the M4 domain (see later). Whereas both spliced variants are expressed in the adult brain, the flip variant predominates in pre- and neonatal rat brains (Sommer *et al*., 1991). Functionally, the flip forms of most subunits densensitize more slowly and to a less extent than the flop forms. GluR2, GluR4, and the kainate receptor subunits all express carboxy-terminal splice variants. In the rat, GluR5 displays four different carboxy-terminals (designated GluR5-1, GluR5-2, GluR5a, and GluR5b), whereas GluR6 and GluR7 each display two splice variants that differ in the carboxy-terminal (GluR6-1, GluR6-2; GluR7a, GluR7b). To date, relatively little is known about the functional differences among the various splice variants of the kainate receptor except for the finding that the GluR7a subunit, when expressed as homomeric receptors in HEK 293 cells, gives rise to significantly larger currents than receptors assembled from the GluR7b subunit (Schiffer *et al*., 1997). The NR1 subunit exists as eight splice variants (designated NR1-1a,b; NR1-2a,b; NR1-3a,b; NR1-4a,b), which assemble to form receptors of distinct functional properties. Information in the cassettes that are spliced into or out of NR1 appears to be vital to the regulation (e.g., phosphorylation) and localization (e.g., synaptic vs nonsynaptic) of the assembled receptor (Durand *et al*., 1993; Ehlers *et al*., 1995). For example, Ehlers *et al*. (1995) have demonstrated that NR1 subunits expressed in transiently transfected cells are localized predominantly either in the cytoplasm or on the cell surface, depending on which splice variant is used. Thus, variants that contain the C1 exon cassette, a 37 amino acid insert in the carboxy-terminal region of NR1, are targeted to the plasma membrane, whereas splice variants that do not contain this exon cassette are found mainly in the cytoplasm. In addition, it is suggested that the presence or absence of specific exon cassettes of NR1 directs whether this receptor subunit will be phosphorylated, a process that appears to be required for clustering of the receptor (Ehlers *et al*., 1995).

Studies on the structure of the glutamate receptor have yielded different results over time with earlier studies favoring a pentamer [similar to nicotinic acetylcholine receptors (nAChRs)] and more recent investigations suggesting a tetrameric structure similar to that of potassium channels (Mano

and Teichburg, 1998). In addition, relatively little is known about the rules that determine which subunits coassemble, although it is generally accepted that a subunit will assemble only with other subunits within its own family. Coexpression studies of selected combinations of these receptor subunits demonstrate that not only do all the GluR subunits participate in the formation of ion channels when coexpressed with another related subunit, but many subunits are capable of forming functional homomeric channels. The latter is particularly true for the AMPA/kainate receptor subunits. In contrast, functional NMDA receptors require coexpression of NMDAR1 and one of four NMDAR2 subunits. Moreover, a number of important channel properties depend to a large extent on the specific NMDAR2 subunit expressed by the cell and its ability to assembly with NMDAR1. For example, studies of transfected HEK293 cells demonstrate that heterodimeric NMDAR1a/NR2A and NMDA1a/NR2B but not NMDAR1a/NR2C result in glutamate-mediated cell death (Anegawa *et al*., 1995). In addition, recombination studies in cell cultures demonstrate that NMDA receptors assembled from NR1 and NR2D subunits show a prolonged decay rate of glutamate-induced ion currents and a lowered threshold for voltage-dependent Mg^{2+} blockade compared to properties of NMDA receptors assembled from NR1 and NR2A or NR2B subunits (Monyer *et al*., 1994). These kinetic properties of NMDA receptors containing the NR2D subunit are thought to result in a hyperexcitable type of NMDA receptor.

The finding that nAChRs are characterized by four transmembrane-spanning domains with both amino-terminal and the carboxy-terminal located extracellularly led investigators to speculate that glutamate receptors would have a similar transmembrane topology. However, contrary to these initial predictions, it has been determined that glutamate receptors have only three transmembrane domains (M1, M3, and M4) plus a cytoplasm-facing reentrant pore loop segment (M2) that contributes to the opening of the ion channel. Thus, GluRs have a large extracellular amino-terminal and an intracellular carboxy-terminal that vary considerably in length between different subunits.

Glutamate receptor mRNAs were the first neurotransmitter receptor RNAs found to be modified by posttranscriptional RNA editing. To date, editing has not been demonstrated for any NMDA subunit RNA, but is recognized to occur at multiple positions for AMPA and kainate receptor RNAs. For example, in primary transcripts of GluR2, GluR5, and GluR6, a glutamine codon in the p loop (i.e., M2 domain) can be edited to arginine at the Q/R site. Nearly 99% of all GluR2 transcripts are edited, whereas the other AMPA subunits (i.e., GluR1,3,4) are not edited. Functionally, homomeric GluR2 subunit channels and heterooligomeric assemblies containing this subunit exhibit different current–voltage relationships than receptors composed without it. Furthermore, the presence of the GluR2 subunit substantially reduces Ca^{2+} conductance through AMPA receptors in response to ligand binding (Hollmann *et al*., 1991). Thus, it would appear that the presence or absence of the GluR2 subunit in non-NMDA receptor assemblies may have a profound influence on the ability of a cell to gate extracellular Ca^{2+} and to maintain intracellular calcium homeostasis. As discussed later, it is hypothesized that the absence of the GluR2 receptor subunit in the AMPA receptor allows Ca^{2+} to enter the cell more readily, resulting in an increase in intracellular calcium and hence progressive neuronal damage as a consequence of ionotropic glutamate receptor stimulation. Editing of the Q/R site in GluR6 transcripts also controls anion permeability (Burnashev *et al*., 1996). In addition, the AMPA receptor subunits GluR2–4 are edited at the R/G site found at the end of the exon that precedes the alternatively spliced flop and flip exons. The extent to which the R/G site is edited is developmentally regulated and depends, in part, on the specific subunit and the flip/flop variant.

III. Glutamate Receptors in the Aging Rodent Brain

The following section is devoted to a review of glutamate receptors in the aging rodent (mice and rats). As one will quickly discern, data are at times discrepant with some authors reporting a decrease in glutamate receptor function, whereas others report that these receptors are unchanged or even hyperexcitable. Contributing to these various findings are a number of factors, including the age and strain of the rodent, the method employed to investigate the glutamate receptor, and the subtype of glutamate receptor, examined (including specific binding sites within a receptor). The various works discussed in this chapter are categorized first according to glutamate subtype (i.e., NMDA, AMPA, kainate receptors) and then to the ligand-specific binding site associated with the receptor. Admittedly, the vast majority of these studies employ ligand-binding techniques and thus are limited in their ability to address important issues related to the molecular composition of the glutamate receptor. Molecular studies, however, are emerging, and the results of these investigations are included immediately following the ligand-binding studies. Whereas ligand binding and molecular studies are highly useful in evaluating the density and to some extent the integrity of the glutamate receptor, they fail to reveal much about the functional status of the receptor. In order to assess various functional properties of the glutamate receptor, most investigations have employed *in vivo* electrophysiological recording techniques. These latter investigations provide valuable information with respect to the functional integrity of the glutamate receptor during normal aging and are presented at the end of this section.

A. NMDA Receptor-Binding Sites

1. Glutamate

Thus far, many studies have investigated the glutamate-binding site in the NMDA receptor in aged rodents with the majority of these investigations reporting a decrease in [^{3}H]glutamate-binding sites (Tamaru *et al*., 1991; Wenk *et al*., 1991; Clark *et al*., 1992; Ingram *et al*., 1992) (Table 20.1). For example, Tamaru *et al.* (1991) observed significant decreases in [^{3}H]glutamate binding in membrane preparations of the hippocampus and neocortex of Fischer 344 rats 7 and 29 months of age compared to 3-month-old rats. Similarly, Wenk *et al.* (1991) observed a significant decrease in glutamate binding in the sensory motor neocortex, parietal-occipital neo-

TABLE 20.1 Glutamate Binding in Aged Rodents

Strain/species	Sex	Age (months)	Region	Change	Reference

cortex, hippocampus, and the caudate nucleus of 24-month-old Fisher 344 rats compared to 5-month-old animals. In interpreting their data, Tamaru *et al.* (1991) speculated that NMDA-bearing neurons in the neocortex and hippocampus of old animals may be vulnerable to excitotoxic injury as the result of excessive increases in extracellular glutamate. That extracellular glutamate may be elevated in the aged rat is supported by the work of Freeman and Gibson (1987), who observed in BALB/c mice a 77% increase in the basal release of glutamate in the striatum and a 94% increase in the hippocampus of 30-month-old mice compared to those 3 months of age. In addition, Matsumoto *et al.* (1982) and Price *et al.* (1981) demonstrated age-related impairments in glutamate uptake mechanisms, which may also contribute to increases in extracellular glutamate. Collectively, these data support the notion that extracellular glutamate levels may increase with age, thereby leading Tamaru and colleagues (1991) to speculate that the age-related reduction in NMDA receptors potentially represents a compensatory response to protect NMDA-bearing neurons from the pathologic consequences of elevated extracellular levels of this excitatory amino acid. However, in consideration of the work of Tamaru *et al*. (1991), it is important to note that while differences in levels of glutamate binding were observed in 7- and 29-month-old rats compared to 3-month-old rats, no decreases in binding were observed in rats 7 and 29 months of age. These data led Nicolle *et al*. (1996) to suggest that the observed differences between groups could, in fact, represent a developmental change rather than an effect of aging.

The hypothesis that deficits in glutamatergic neurotransmission may produce deficits in cognitive performance provided the impetus for a number of investigators to examine the integrity of the NMDA receptor in behaviorally characterized rodents. For example, Clark *et al*. (1992) tested young and aged Fischer 344 on the Morris water maze and divided aged animals into two groups (i.e., achievers and nonachievers) on the basis of their ability to meet selected criterian. Whereas *in vitro* autoradiographic studies demonstrated significantly

higher levels of NMDA binding in nearly every hippocampal subdivision of young rats compared to aged rats, no differences were observed between aged achievers and nonachievers. The failure to detect a correlation between levels of glutamate binding and performance on the water maze may, in part, be explained by the fact that this study focused exclusively on the relationship between hippocampal glutamate binding and spatial memory and did not take into account other neocortical and subcortical brain regions, within which age-related decreases in glutamate binding have also been reported (Clark *et al*., 1992). As stated by Clark and colleagues (1992), additional insights into the brain systems involved in age-related decline in memory must await detailed analyses of the relationship between glutamate binding and spatial memory within these other brain regions. In support of the notion that specific behaviors involve the complex interactions between NMDA receptors and other neuronal systems comes from the work of Ingram *et al*. (1992). Specifically, Ingram and colleagues (1992), similar to Clark *et al*. (1992), observed a marked reduction in NMDA binding in the hippocampus of aged rats (i.e., 23–24 months-old) compared to young animals (i.e., 3–4 months-old) (Ingram *et al*., 1992). However, when Ingram *et al*. (1992) correlated glutamate binding with performance in a shock-motivated 14 unit T maze, they found a positive correlation between errors in the maze and hippocampal [^{3}H]glutamate binding (i.e., rats that made the most errors had the highest level of NMDA receptor binding). In interpreting these data, Ingram *et al*. (1992) suggested that the observed learning impairment may not be specific to hippocampal function. Alternatively, they suggest that brain regions with higher glutamate receptor densities might be more vulnerable to the neurotoxicity of glutamate via a mechanism involving the activation of NMDA receptors and subsequent increases in nitric oxide production. Ingram *et al*. (1992) also pointed out that because cholinergic systems are likely involved in radial maze performance, it is reasonable to consider that NMDA-bearing neurons are, in fact, cholinergic and thus the behavioral deficits may reflect a loss of cholinergic neurons due to glutamate neurotoxicity.

Davis and colleagues (1993) also reported an age-related decline in [^{3}H]glutamate binding in the frontal neocortex of old rats (24 months). Notably, this decrease was ameliorated following a 10-month administration of acetyl-L-carnitine, the ester of the natural compound carnitine. Comparable results with L-carnitine were observed by Castorina *et al*. (1994), who, following treatment for 6 months, demonstrated a significant impediment in the decline in the number of NMDA receptors within the hippocampus, the frontal neocortex, and striatum compared to untreated animals.

In contrast to those studies reporting a decline in glutamate binding, Baudry *et al*. (1981) demonstrated an increase in Na-independent glutamate binding in hippocampal membranes of male Fischer rats 12 and 24 months of age compared to 3-month-old rats. Moreover, binding levels in 24-month-old rats were significantly greater compared to 12-month-old rats. The authors attributed this elevation to an increase in the maximum number of binding sites rather than a change in the affinity of the receptor for glutamate. However, when [^{3}H]glutamate binding was measured with a saturating concentration of calcium, the density of glutamate-binding sites appeared to remain constant throughout all ages examined. The finding that glutamate binding in the absence of calcium increases with age whereas in the presence of calcium it does not suggests that the extent to which calcium stimulates glutamate binding must decrease with age. Functionally, the decreased ability of calcium ions to stimulate [^{3}H]glutamate receptor binding may account for age-related deficits in, for example, LTP (Baudry *et al*., 1981).

Glutamate binding has also been examined in aged mice. For example, Peterson and Cotman (1989) studied [^{3}H]-glutamate binding in two strains of aged mice, C57B1 and BALB/c (3, 10, and 30 months of age). In brief, the authors observed an age-related decrease in binding of glutmate to the NMDA receptor, although the magnitude of the decline was greater in the BALB/c strain than in the C57B1 strain. In explaining their data, they, like Tamaru *et al*. (1991), suggested that an age-related increase in basal glutamate release and a corresponding reduction in glutamate uptake mechanisms (Freeman and Gibson, 1987; Aprikyan and Gekchyan, 1988) may lead to a prolonged elevation of extracellular glutamate and, in turn, the downregulation of the NMDA receptor. Other studies of these same mice strains have likewise shown decreases in glutamate binding (Magnusson and Cotman, 1993b; Magnusson, 1995, 1997).

2. CPP

Despite abundant evidence for a decrease in glutamate binding, investigations of CPP binding (i.e., a potent and selective antagonist of the L-glutamate-binding site) appear somewhat more controversial (Table 20.2). For example, using *in situ* autoradiographic techniques in aged rats (i.e., 21 months old), Miyoshi and colleagues (1991b; Kito *et al*., 1990) found a marked preservation of [^{3}H]CPP-binding sites in the hippocampus and neocortex, regions of the brain where the highest density of binding sites were found. In contrast, both studies reported significant declines in [^{3}H]glycine-binding sites. At the molecular level, the NMDA receptor complex has been shown to consist of an L-glutamate binding site, a strychine-insensitive glycine modulatory site, and a voltage-dependent cation channel. In the neocortex and hippocampus, [^{3}H]CPP- and [^{3}H]glycine-binding sites codistribute and are present at high levels. The finding that [^{3}H]glycine but not [^{3}H]CPP-binding sites are affected with increasing age suggests that the NMDA receptor in the hippocampus and neocortex itself remains unchanged, while the glycine modulatory site is affected.

Additional investigations of [^{3}H]CPP binding demonstrate a 30% decrease in the density of CPP-binding sites in hippocampal membranes of 24-month-old rats compared to those 3 months of age (Bonhaus *et al*., 1990). In contrast, these same investigators observed no significant age-related reductions in the total number of [^{3}H]CPP-binding sites or in the affinity of these binding sites (Bonhaus *et al*., 1990). Notably, a significant increase in protein content was observed in membranes prepared from old rats (3.6 ± 0.2 mg protein/pair hippocampal formations) compared to young rats (2.7 ± 0.2 mg protein/pair hippocampal formations), thus providing a reasonable explanation for the reduction in receptor density (Bonhaus *et al*., 1990). Although it is unclear, the precise mechanism

TABLE 20.2 CPP Binding in Aged Rats

[b]Significant change at intermediate age.

underlying the increase in hippocampal membrane protein, Bonhaus *et al*. (1990) suggested that an increase in nonneuronal elements (i.e., the hypertrophy of hippocampal astrocytes) could be a contributing factor. Hippocampal [^{3}H]CPP binding was also investigated in behaviorally characterized Long–Evans rats (Pelleymounter *et al*., 1990). In brief, hippocampal [^{3}H]CPP binding was reduced approximately 45% in aged animals regardless of whether they were naive or trained in the Morris water maze, thus suggesting that training itself does not affect [^{3}H]CPP binding (Pellymounter *et al*., 1990). However, [^{3}H]CPP did corrrelate significantly with the number of trials to criterion for the aged subjects and was significantly lower in impaired aged rats compared to unimpaired aged coherts and young rats. Collectively, these data led Pellymounter and colleagues (1990) to conclude that a reduction in hippocampal-binding sites, as measured by [^{3}H]CPP binding, may contribute to age-associated cognitive deficits. Consistent with the previous findings, Magnusson (1995) observed a significant decrease in [^{3}H]CPP binding in the majority of neocortical and hippocampal regions of aged C57B1 mice.

[^{3}H]CPP binding was also examined in rats with an inborn high (HP) or low (LP) learning capacity to perform in a shuttle box (Keller *et al*., 1992). The inborn ability of HP and LP rats has been related to the plasticity of hippocampal circuits. Keller *et al*. (1992) reported that HP rats show an increased number of NMDA receptor-binding sites in the hippocampus compared to control and LP rats. Although the current work does not provide a direct link with the aging brain, it nevertheless provides compelling evidence to suggest that the putative differences in hippocampal synaptic plasticity observed in HP and LP rats may be related to variations in the density of NMDA receptors.

3. MK-801

MK-801 is a noncompetitive NMDA antagonist used to label the activated state of the cation channel of the NMDA receptor complex. To date, considerable evidence indicates that the density of MK-801 binding is decreased in the aged rodent (Tamaru *et al*., 1991; Mitchell and Anderson, 1998; Serra *et al*., 1994) (Table 20.3). For example, Tamaru *et al*. (1991) observed significant reductions in [^{3}H]MK-801 binding in the neocortex and hippocampus of rats 7 and 29 months of age compared to 2-month-old rats. Moreover, Scatchard analysis revealed that the reduction in [^{3}H]MK-801 binding was due to a significant decrease in binding sites with aging, with their affinities being unaltered. However, as stated previously, in the absence of any significant differences in binding between 7- and 29-month-old rats, one must consider whether these differences in [^{3}H]MK-801 binding are more representative of a developmental/maturational change rather than an age-related event.

Age-related decreases in [^{3}H]MK-801 binding have also been reported by a number of additional investigators. For example, while failing to observe any decreases in [^{3}H]MK-801 binding in middle aged (12-month-old) rats compared to young rats (3-month-old), Wardas *et al*. (1997) found significant reductions in binding in old (36-month-old) rats compared to both middle-aged and young rats. Mitchell and Anderson (1998) also observed a significant age-related decrease in ^{3}H-binding in the inner frontal neocortex, entorhinal neocortex, and lateral striatum of 24-month-old rats compared to 6-month-old rats. No differences in binding were observed between 24- and 12-month-old rats or between 12- and 6-month-old animals. Moreover, a number of brain regions did

[e] Significant change at intermediate age.

not undergo any significant age-related change in [^{3}H]MK-801 binding, including the dentate gyrus and CA1 region of the hippocampus.

Le Jeune *et al*. (1996) studied aged Long–Evans rats and grouped them based on their performance in the Morris water maze. In brief, they observed a decrease in [^{125}I]MK-801 binding in 4 of 35 neocortical areas of aged-unimpaired rats (24–25 months old) compared to young rats (6 months old). No changes in binding were observed in aged-impaired rats. Collectively, these data led Le Jeune *et al*. (1996) to conclude that aging itself has little, if any, influence on the expression of the NMDA receptor in the brains of Long–Evans rats.

A number of investigators have also examined MK-801 binding in aged mice with the vast majority reporting age-related decreases in binding (see Muller *et al*., 1994a,b, for reviews). For example, Scheuer *et al*. (1996) examined young (3 months), middle-aged (12 months), and aged (23 months) female Naval Medical Research Institute (NMRI) mice and observed a 19 and 22% decrease in MK801 binding in the forebrain of middle-aged and aged rats, respectively. Scheuer *et al*. (1996) also reported a significant age-related correlation between NMDA receptor density and performance in a passive avoidance acquisition task. In an attempt to provide a biochemical basis by which aging affects NMDA receptor number and cognitive function, Scheuer *et al*. (1996) measured membrane fluidity and found that changes in the fluidity of forebrain membranes correlates inversely with NMDA receptor density. While the authors concluded that their findings do not prove a causal relationship, they are nevertheless compatible with the hypothesis that changes in membrane fluidity, by decreasing the number of NMDA receptors, affects performance in a passive-avoidance task. In an additional study of NMRI mice, Cohen and Müller (1992) observed a 35% reduction in MK-801 binding of mice 20 months of age compared to 3-month old-rats.

Likewise, Magnusson (1995) examined C57B1 mice and observed a decrease in binding in 6/10 neocortical regions, 3/6 hippocampal regions, and the caudate nucleus by 28–30 months of age. Senescence-accelerated mice also showed reduced MK-801 binding in neocortical membranes (Kitamura *et al*., 1992) and in the hippocampus (Nomura *et al*., 1997) compared to normal strain mice.

4. TCP

TCP, like MK-801, binds to the cation channel in the NMDA receptor complex. Both compounds bind to the activated state of the channel, as evidenced by the ability of

TABLE 20.4 TCP Binding in Aged Rodents

			Subcortical regions	Decrease[a,b]	
			Cerebellum	No change	

[a]Significant change at intermediate age.
[b]Changes noted only in certain subregion(s).

glutamate to increase the rate of binding of both TCP and MK-801. Similar to findings with MK-801, Magnusson (1995) observed a significant decline in [^{3}H]TCP binding in six neocortical, one hippocampal, and one subcortical region in C57B1 mice between 3 and 28–30 months of age. Bonhaus *et al*. (1990) also observed a significant decrease (i.e., 30%) in the density of TCP-binding sites in the hippocampus of Fischer 344 rats (Table 20.4). However, as stated previously, the reduction in receptor density may not be due to a decrease in the number of receptors, but rather to an age-related increase in protein content.

5. Glycine

To date, a general agreement exists in the literature regarding a decrease in glycine binding in aged rodent brains. For example, Fischer 344 rats show severe decreases in selective telencephalic regions by 21 months of age (Kito *et al*., 1990; Pelleymounter *et al*., 1990; Miyoshi *et al*., 1991b). Tamaru *et al*. (1991) also observed a 40% decrease in the neocortex and a 27% reduction in the hippocampus of Fisher 344 rats between 2 months of age and 29 months of age. In addition to decreases in [^{3}H]CPP and [^{3}H]TCP binding, Bonhaus *et al*. (1990) observed significant decreases in the density of the glycine-binding site. C57B1 mice also exhibited a significant decrease in [^{3}H]glycine binding, although this binding site appeared to be less affected by aging compared to [^{3}H]MK-801 and [^{3}H]TCP binding both in percentage decline and the number of brain regions affected (Magnusson, 1995) (Table 20.5).

B. AMPA Receptor-Binding Sites

While a substantial number of studies report an age-related reduction in the NMDA receptor, the vast majority of works support the preservation of the AMPA receptor with advanced age (Table 20.6). For example, in aged Fischer 344 rats (i.e., 21 months), Miyoshi *et al*. (1991a) found no significant changes in [^{3}H]AMPA-binding sites in the hippocampus or neocortex compared to young rats (i.e., 2 months of age). These data led the authors to conclude that AMPA-binding sites are not involved in the age-related decline of neuronal functions, especially impairment of learning and memory. Tamaru *et al*. (1991) also stated that AMPA receptors are relatively unaltered by the aging process, despite the finding that [^{3}H]AMPA binding, determined in the presence of KSCN, is decreased in the aged rat. Cimino *et al*. (1992) also reported relatively modest age-related alterations in AMPA binding with decreases

restricted to sites localized in the CA3 region of the hippocampus and in the molecular layer of the dentate gyrus. In contrast, NMDA binding was decreased in many more regions, thus suggesting that NMDA and non-NMDA recognition sites are affected differentially by the aging process (Cimino *et al*., 1992). This latter view is supported by the work of Wardas *et al*. (1997), who observed age-related declines in AMPA binding within only limited regions of the striatum and hippocampus, whereas decreases in NMDA binding were observed throughout most of these regions. The latter data are supportive of the concept that NMDA receptors are more vulnerable to aging than AMPA receptors.

Using *in situ* hybridization methods, Pagliusi *et al*. (1994) observed significant declines in message levels for the AMPA receptor subunits GluR1 and GluR2 in all hippocampal subfields of aged rats (24 months) compared to young controls (2 months). In an attempt to evaluate the potential changes in calcium permeability of the AMPA receptors, Pagliusi *et al*. (1994) determined the ratio of mRNA levels of GluR1, which forms calcium-permeable channels, and of GluR2, which

blocks calcium from passing through the ion channel when part of the assembled receptor. In all regions of the hippocampus, the ratio of GluR1/GluR2 was increased modestly in the aged rat, thus suggesting that glutamate receptors in aged hippocampus may exhibit greater calcium permeability and thus are rendered more vulnerable to cell death as a consequence of altered calcium homeostasis. In contrast, Nicoletti *et al*. (1995) studied Sprague–Dawley rats at 4, 12, and 24 months and found no significant decrease in levels of GluR1, GluR2, GluR3, or GluR4 mRNA. Likewise, protein levels remained unaltered for all subunits except GluR1 for which significant decreases were observed. These data led Nicoletti *et al*. (1995) to conclude that AMPA receptors are influenced only slightly by the aging process. Moreover, the observed decrease in GluR1 protein may be explained by a decrease in the translational efficiency or an increase in protein degradation for the GluR1 subunit.

A number of investigators have also examined the integrity of the AMPA receptor in behaviorally characterized rodents with rather mixed findings. For example, Clark *et al*. (1992) observed significant declines in [^{3}H]AMPA within 8 out of 10 hippocampal subfields of aged rats. On the one hand, no relationship was observed between the density or the distribution of AMPA receptors and performance on the water maze. On the other hand, Nicolle *et al*. (1996) found [^{3}H]AMPA binding to be preserved in the striatum of aged rats whereas regionally selective effects of age were detected in the hippocampus, although limited to the CA1 field. Consistent with the results of Clark *et al*. (1992), this reduction in AMPA binding was not correlated with the cognitive status (Nicolle *et al*., 1996). In contrast to the previous two studies, Le Jeune *et al*. (1996) observed a significant increase in the density of [^{3}H]AMPA binding within most hippocampal subfields of cognitively impaired rats versus young adult rats. No changes in [^{3}H]AMPA bindings were observed in the unimpaired cohort. Although the mechanism underlying the alterations in AMPA binding in the aged impaired rats is unclear, it is hypothesized that this increase may be an attempt to reverse the cognitive deficits, as heightened AMPA receptor signaling is associated with improved cognitive performance (Le Jeune *et al*., 1996).

[^{3}H]AMPA binding has also been studied in mice. For example, using an antibody against the GluR-A (GluR1) glutamate subunit, Bahr *et al*. (1992) observed a significant decrease in immunolabeling in the telencephalon of 25-month-old BALB/c mice compared to 3-month-old mice. Notably, the magnitude of the decrease (i.e., 30%) was comparable to the decrease in [^{3}H] AMPA binding. Scatchard analysis revealed that this latter reduction was due to a decrease in receptor density and not to a change in binding affinity. Moreover, binding to the GABA, dopamine, or serotonin receptor was not reduced significantly in these mice nor were reductions observed in the nerve terminal markers, synaptophysin, and SV2 glycoprotein. Collectively, these data suggest that AMPA receptors in the telecephalon of BALB/c mice are selectively altered by the aging process (Bahr *et al*., 1992). Additional support for age-related alterations in AMPA binding (albeit modest) within the forebrain of mice comes from the work of Magnusson and colleagues. They observed significant reductions in [^{3}H]AMPA binding within 4 of 21 brain regions (Magnusson and Cotman, 1993a) and in a subsequent study within 1 of 21 brain regions (Magnusson, 1997). In contrast, NMDA receptors were altered to a much greater extent, thus underscoring the possibility that NMDA receptors are selectively vulnerable to the aging process.

C. Kainate Receptor-Binding Sites

In an attempt to provide a comprehensive view of the ionotropic glutamate receptor, a number of investigators have examined the kainate receptor in addition to the NMDA and AMPA receptor (Table 20.7). Similar to the findings for NMDA and AMPA receptors, a number of inconsistencies exist with respect to the integrity of the kainate receptor during aging.

TABLE 20.7 Kainate Binding in Aged Rodents

[a]Significant change at intermediate age.
[b]Changes noted only in certain subregion(s).

For example, Tamaru *et al*. (1991) found no significant changes in kainate binding in the hippocampus and neocortex of aged rats. These same investigators observed AMPA receptors to remain relatively unaltered during the aging process while observing marked reductions in the NMDA-sensitive receptor complex. However, Clark *et al*. (1992) reported age-related reductions in NMDA, AMPA, and kainate binding, although the extent to which [^{3}H]kainate binding is reduced is far less than for NMDA or AMPA receptors. Notably, in no instance did binding levels for any of the three glutamate receptor subtypes correlate with the behavioral status of the rat (Clark *et al*., 1992). Nagahara *et al*. (1993) was also unable to demonstrate a strong correlation between [^{3}H]kainate binding and the spatial learning performance of the animal in a Morris water maze, even though the density of [^{3}H]-kainate binding was reduced in several regions of the hippocampus (i.e., CA3, CA1, hilus) and within related cortical areas (i.e., subicular complex, entorhinal cortex, perirhinal cortex).

Le Jeune *et al*. (1996) also observed significant decreases in [^{3}H]kainate binding in 21 of 37 brain regions of aged Fisher 344 rats. However, similar to the results of Clark *et al*. (1992) and Nagahara *et al*. (1993), no correlations were observed between levels of kainate binding and the cognitive status of the rat (i.e., reductions were observed in both impaired and unimpaired groups). In contrast, binding to the NMDA receptor was reduced significantly in the cognitively unimpaired group whereas binding to the AMPA receptor was increased in the impaired cohert (Nagahara *et al*., 1993). Collectively, these data suggest that the three classes of ionotropic glutamate receptors are regulated differentially in impaired and unimpaired rats. Changes in the NMDA and AMPA receptor subtypes may play a more critical role than alterations in kainate-binding sites for the emergence of the behavioral deficits observed in some aged impaired rats. In a more recent investigation, Nicolle *et al*. (1996) observed a significant decrease in [^{3}H]kainate binding in 1 of 7 hippocampal subfields (i.e., CA3) in aged (24–25 months) Long–Evans rats. Moreover, [^{3}H]kainate binding in the CA3 region revealed a significant correlation with spatial learning performance in the aged group. Specifically, rats with the most preserved spatial learning ability had lower values for [^{3}H]kainate binding, thus suggesting a compensatory reduction in receptor binding in a subpopulation of aged rats (Nicolle *et al*., 1996). In contrast, reductions in AMPA binding, although also observed in 1 of 7 hippocampal subfields (i.e., CA1), were not strongly correlated with spatial learning (Nicolle *et al*., 1996). These data reaffirm the concept that age-related alterations in ionotropic receptors differ with respect to the receptor subtype and anatomical region examined.

Magnusson and Cotman (1993b) studied kainate binding in C57Bl and BALB/c mice and observed significant age-related reductions (30 months of age) in the frontal and parietal cortices, caudate nucleus, and stratum lacunosum/moleculare of CA1, as well as the outer two-thirds of the dorsal blade of the dentate molecular layer in both strains of mice. The authors also reported reductions in AMPA and NMDA binding in these same regions, thus suggesting that these brain areas are particularly vulnerable to the effects of aging (Magnusson and Cotman, 1996).

D. Glutamate Receptor Function

In addition to studies that focus primarily on levels of binding of the various ionotropic glutamate receptor subtypes, a number of investigations utilize a host of approaches to assess the functional status of these receptor subtypes in the aged rat. For example, Dawson *et al*. (1989) assessed the functional integrity of intrinsic and extrinsic glutamate-utilizing pathways innervating the frontal neocortex of 6-month-old adult and 24-month-old aged Fisher 344 rats by examining the release, uptake, and content of glutamate in brain slices of frontal cortex. In brief, the stimulated release and high-affinity uptake of glutamate were not altered appreciably in aged rats. These data suggest that glutamate-utilizing neurons in the frontal cortex are functionally intact and are not affected significantly by the aging process. In contrast, glutamate content is decreased signficantly in the frontal cortex, reflecting either an age-related loss of neurons or a metabolic defect in the biochemical pathways that normally produce or utilize glutamate (Dawson *et al*., 1989).

Baskys *et al*. (1990) also utilized brain slices and compared NMDA-induced depolarizations in neocortical neurons of young (4–6 months) and old (24–29 months) Fischer 344 rats. Whereas increasing amounts of NMDA produced membrane depolarizations in cells obtained from both groups, regression analysis revealed significantly reduced sensitivity to NMDA in old neurons compared to young neurons. Moreover, tetanic stimulation induced LTP in the young neocortex but failed to do so in the neocortex of aged rats. Although the authors failed to establish a direct link between decreased responsiveness to NMDA and the failure to establish LTP, such an association is highly tenable. In explaining their data, Baskys *et al*. (1990) stated that the age-related decrease in sensitivity to NMDA is consistent with a reduced number of agonist receptor sites (Peterson and Cotman, 1989; Bonhaus *et al*., 1990; Tamaru *et al*., 1991; Clark *et al*., 1992; Ingram *et al*., 1992).

Gonzales *et al*. (1991) also examined brain slices to determine the functional status of the NMDA receptor in young (3–5 months), middle (12–14 months), and old (24–28 months) Fischer 344 rats. The functional status of NMDA receptors was determined by examining the NMDA-induced inhibition of muscarinic-stimulated phosphoinositide hydrolysis in the hippocampus and the NMDA-stimulated release of [^{3}H]norepinephrine or [^{3}H]dopamine. Briefly, these investigators observed a marked attenuation, in an age-dependent manner, of NMDA-induced inhibition of muscarinic-stimulated phosphoinositide hydrolysis in the hippocampus. Moreover, using hippocampal slices, Gonzales *et al*. (1991) demonstrated that the maximal NMDA-stimulated release of [^{3}H]norepinephrine declines by 30% as the rat matures from an age of 3–5 months to 12–14 months with no additional decrements in the hippocampus of old rats (28 months). In the neocortex, [^{3}H]norepinephrine release was also decreased, although the largest decline occurred between middle and old age. NMDA-stimulated [^{3}H]dopamine release from striatal slices also displayed an age-dependent reduction with maximum declines again observed between middle and old age. Collectively, these data support the notion that NMDA-mediated responses in the neocortex, hippocampus, and striatum are attenuated with increasing age (Gonzales *et al*., 1991).

Additional evidence for an age-related decline in the function of the NMDA receptor comes from the work of Pittaluga *et al*. (1993), who sought to determine whether aging affected the NMDA receptor-mediated enhancement of noradenaline release from rat hippocampal synaptosomes. Briefly, the authors observed that the maximal effects of NMDA on the release of [^{3}H]noradrenaline decreased with age, whereas the apparent affinity did not seem to change significantly. In addition, the authors investigated the age-related changes of the strychnine-insensitive glycine allosteric site, in part, because the NMDA-binding site requires glycine for its activation and glycine has been demonstrated to potentiate the NMDA-induced release of [^{3}H]noradrenalin. Notably, the effects of adding 1 μM glycine increased the effect of 100 μM NMDA by nearly 100% at 3 months and 270% at 24 months. In explaining these data, the authors suggested that the apparent ''superresponsiveness'' of the glycine-binding site may be due to a more efficient removal and/or to impaired release of glycine, as the uptake of the amino acid was increased by 350% in 24-month-old rats versus 3-month-old rats, whereas the K^+-evoked tritium release from synaptosomes prelabeled with [^{3}H]glycine was decreased. Although these latter findings appear to be in contradiction to studies that show glycine binding to be decreased with age (Kito *et al*., 1990; Pelleymounter *et al*., 1990; Bonhaus *et al*., 1990; Miyoshi *et al*., 1991b; Tamaru *et al*., 1991; Magnusson, 1995), it should be considered that these latter studies were limited in their ability to determine whether the glycine-binding site may have undergone a functional ''upregulation'' with age. These latter data are also consistent with the work of Serra *et al*. (1994), who demonstrated an age-dependent increased sensitivity of [^{3}H]MK-801 binding to the stimulatory action of glycine, despite reduced numbers of NMDA-binding sites. This increase in sensitivity of ^{3}H binding to glycine is hypothesized to reflect an increase in NMDA receptor activity to compensate for the decrease in receptor number (Serra *et al*., 1994).

Using *in vitro* slice preparations, Cepeda *et al*. (1996) investigated the age-induced alterations in the interaction of glutamate and dopamine in the neostriatum of rats and cats. They determined that populations of aged neurons from both species displayed qualitative and quantitative alterations in response to an iontophoretic application of NMDA and glutamate. These alterations included a lack of response, unusual responses consisting of depolarizations without action potentials or combinations of prepotentials, and full amplitude action potentials. In addition, the ability of dopamine to modulate responses mediated through the activation of glutamate receptors was reduced in aged animals. Specifically, subpopulations of neurons were either unresponsive to dopamine or required higher iontophoretic current intensities to modulate the glutamate-induced responses. Collectively, these data support the view that with increasing age, the interactions between glutamate and dopamine appear to be compromised in the striatum. Moreover, this compromise may be largely attributed to decreases in NMDA receptor function during aging.

Electrophysiological techniques were similarly employed by Barnes *et al*. (1997) to determine the effects of age on the amplitude of NMDA receptor-mediated synaptic responses in the CA1 region across the life span of the animal. All animals were behaviorally characterized using a Morris water maze to ensure that old animals were in fact memory impaired. Throughout these studies, Barnes *et al*. (1997) measured the presynaptic fiber potential, as well as the NMDA component of synaptic responses at the Schaffer collateral-CA1 synapse. In brief, the authors observed an equivalent age-related decline in the NMDA and non-NMDA receptor-mediated excitatory postsynaptic potentials for a given fiber potential amplitude in the CA1 region (Barnes *et al*., 1997). In interpreting these data, Barnes *et al*. (1997) suggested that these findings are consistent with the hypothesis that there are fewer NMDA receptors per Schaffer collateral during aging (possibly because of a reduction in the number of Schaffer collateral synapses per presynaptic axon). Of importance, in the aged brain those NMDA receptors that remain appear to be functionally normal.

Further support for a functionally intact NMDA receptor in the aged hippocampus comes from the studies of Billard *et al*. (1997). Specifically, *ex vivo* extra- and intracellular electrophysiological recording techniques were used to investigate the effects of aging on the activation of NMDA receptors in the CA1 field of hippocampal slices of Sprague–Dawley rats (Billard *et al*., 1997). In summary, only modest alterations in NMDA activation were observed in the CA1 region of aged rats. Moreover, NMDA receptor-induced synaptic plasticity was not altered in aged animals. While these data appear to be in contradiction to the several reports indicating a decrease in NMDA binding in the aged hippocampus (Bonhaus *et al*., 1990; Pelleymounter *et al*., 1990; Tamaru *et al*., 1991; Wenk *et al*., 1991; Peterson and Cotman, 1989; Cohen and Müller, 1992), it can be argued that the current study focused solely on the CA1 region, whereas the majority of binding studies used homogenates of relatively gross regions of the hippocampus. This raises the possibility that the previously reported decreases in NMDA binding may reflect decrements within hippocampal subfields other than the CA1 region.

Jasek and Griffith (1998) pharmacologically characterized ionotropic excitatory amino acid receptors in an acutely dissociated medial septum/nucleus of diagonal band neurons from young (1–4 months) and aged (24–26 months) male Fischer 344 rats. The authors found that while NMDA-induced currents were relatively maintained during aging, AMPA-induced current densities were increased significantly. Although the increase in AMPA-induced current density provides a possible mechanism for changes in calcium entry during aging, the authors did not investigate if the subunit composition of these receptors, particularly those involved in the gating of calcium (i.e., GluR2), was changed.

Jouvenceau *et al*. (1998) also used *ex vivo* extracellular recording techniques to examine the synaptic responses mediated by NMDA receptor and non-NMDA receptors in the CA1 hippocampal region of 3- to 4-month-old and 25- to 33-month-old Sprague–Dawley rats. In brief, Jouvenceau *et al*. (1998) found that the functional properties of these glutamate receptor subtypes are affected differentially by aging in the CA1 region. Specifically, they observed an age-dependent decrease in the magnitude of non-NMDA receptor-mediated field excitatory postsynaptic potentials (fEPSP) in aged rats, whereas increases were observed in the duration, but not amplitude, of NMDA receptor-mediated fEPSPs. As demonstrated previously, data are supportive of the concept that NMDA and non-NMDA receptors are affected differentially by aging.

IV. Glutamate Receptors in Alzheimer's Disease

The finding that glutamate is a potent excitotoxin provided the impetus for a host of studies investigating the role of this exictatory amino acid in a variety of neurodegenerative diseases, including AD. Similar to work in the aged rodent, the results of studies of AD brains are variable, thus contributing to the many controversies concerning the role of glutamate in the pathogenesis of AD. The following section presents the vast majority of work related to the integrity and/or dysfunction of the glutamate receptor in AD. Like the previous section, the works are subdivided broadly according to receptor subtype (i.e., NMDA, AMPA, kainate) and, when appropriate, according to specific ligand-binding sites.

A. NMDA Receptors

1. Glutamate and Aspartate Binding

Thus far, a number of receptor autoradiographic studies have investigated the levels of glutamate and aspartate binding in the brains of patients with AD, with the majority reporting disease-related decreases (Table 20.8). For example, Greenamyre *et al*. (1985) examined the binding of sodium-independent [^{3}H]glutamate in patients with senile dementia of the Alzheimer's type and observed significant reductions in layers I and II (i.e., 45%) and layers V and VI (i.e., 35%) in the superior temporal neocortex of AD patients compared to controls. Binding was not reduced in the caudate, putamen, claustrum, or nucleus basalis of Meynert. Notably, cortical binding for the $GABA_A$ or muscarinic cholinergic receptors was not reduced, thus supporting the notion that glutamate receptors are uniquely affected in AD. In a subsequent study, Greenamyre *et al*. (1987) found marked reductions in NMDA-sensitive binding sites in all areas of the hippocampus and adjacent parahippocampal cortex in subjects with dementia of the AD type compared to controls. Most profound were the reductions observed in the stratum pyramidale (84%) and stratum moleculare (87%) of the CA1 subfield of the hippocampus of brains. In these latter studies, $GABA_A$ receptors were also reduced, although to a lesser extent than glutamate receptors (i.e., 21–46%), and muscarinic receptors were unchanged. Although these earlier studies provided important evidence for the selective loss of NMDA receptors in AD, they nevertheless were conducted without the advantage of highly specific autoradiographic assays for the NMDA receptor. Moreover, in these latter studies, the majority of, if not all, cases were affected with severe AD pathology, thus making it difficult to discern whether receptor loss contributed to the pathology or simply reflected the loss of glutamate receptor-bearing neurons. Accordingly, in a later study, these same investigators sought to reexamine the status of the glutamate receptor in the hippocampus of AD brains using an assay more specific for the NMDA receptor (Penney *et al*., 1990). In addition, binding was examined in 10 AD brains (ranging from early to late disease), 9 controls, and 6 demented non-AD brains. Overall, binding to the NMDA receptor was reduced 50% in the stratum pyramidale of CA1 and 40% in the CA3 fields of AD patients compared to controls and demented non-AD brains. Binding was not correlated with the number of neurofibrillary tangles, age, postmortem delay, or storage time. Although modest decreases were also observed for kainate, muscarinic, and benzodiazepine receptors, the extent of loss for NMDA receptors was much greater than for the other receptors. Notably, AMPA (i.e., quisqualate) receptors were unchanged. The finding that NMDA receptors were decreased to a greater extent than other receptors was taken as evidence by Penney *et al*. (1990) to be consistent with the hypothesis that these receptors are located on the distal portions of hippocampal neurons where they are more vulnerable to the pathologic consequences of AD.

In support of the findings of Greenamyre and colleagues, Represa *et al*. (1988) investigated the binding density of [^{3}H]glutamate and reported significant reductions in NMDA receptor binding ($>40\%$) in the hippocampus of nondemented elderly compared to younger controls. This reduction was significantly greater in AD brains. Moreover, in AD brains the extent to which NMDA receptor binding was reduced in the CA1 subfield was significantly correlated with the density of neurofibrillary tangles and senile plaques. The authors suggested that this decrease in binding was due to cellular degeneration as well as age and AD-related loss of pyramidal neuron dendritic spines.

In agreement with the preceding studies, Simpson *et al*. (1988) examined the binding of D-[^{3}H]aspartate in AD and control brains. D-[^{3}H]aspartate was employed as a marker of glutamate-releasing nerve terminals. Reductions in D-[^{3}H]aspartate-binding density was observed in the temporal cortex and caudate nucleus in AD subjects. The authors stated that the reduction observed in D-[^{3}H]aspartate binding is consistent with a loss of glutamate-releasing terminals in these regions.

Chalmers *et al*. (1990) also studied the distribution and density of sodium-dependent glutamate uptake sites and receptor subtypes in the frontal cortex of patients with senile dementia of AD and age-matched controls. In agreement with Represa *et al*. (1988), D-[^{3}H]asparate binding to sodium-dependent uptake sites was reduced markedly in SAT brains throughout the frontal cortex compared to controls. In addition, [^{3}H]glutamate binding to NMDA receptors was reduced in layers I and II of the frontal cortex of AD brains compared to controls, although no relationship was observed in the AD brain between numbers of senile plaques and levels of glutamate binding. In considering their data, the authors stated that the loss of [^{3}H]asparate binding is consistent with a marked reduction of glutamatergic terminals in the AD frontal cortex and may reflect the degeneration of excitatory corticocortical association fibers (Represa *et al*., 1988).

Reductions in [^{3}H]glutamate binding to NMDA receptors in the AD hippocampus were also observed by Jansen *et al*. (1990). Specifically, they observed significant reductions in binding to the glutamate site of the NMDA receptor in the CA1 region (52%) and entorhinal neocortex (37%) of the AD brain compared to controls. Significant parallel losses were also observed for the quisqualate, serotonin$_2$, and adenosine A1 binding sites (CA1 region) and benzodiazepine, serotonin$_2$, neurotensin, and opioid receptors (entorhinal neocortex). In contrast, the dentate gyrus molecular layer and CA3 regions showed no significant changes in any NMDA-binding site, although reductions were observed for serotonin$_2$

receptors and binding to opioid and adenosine A1 receptors. Although these studies support a role for the NMDA receptor in AD, they also raise the possibility that changes in multiple receptor subtypes contribute to the symptomatology of AD.

While the vast majority of studies focus on the hippocampus or other brain regions highly vulnerable to the pathologic consequences of AD, Carlson *et al*. (1993) examined the laminar distribution of NMDA-binding sites in the visual cortex. Notably, the number of neurofibrillary tangles increases progressively across primary (area 17), secondary (area 18), and higher-order association visual cortex (areas 19, 20, and 21). These latter observations are consistent with the findings that the dementia in AD results from the loss of the structural and functional integrity of the long corticocortical projection systems. The NMDA receptor complex was detected using [^{3}H]glycine and [^{3}H]glutamate. In area 17 (i.e., primary visual

neocortex), binding to the NMDA receptor was not altered significantly in the AD brain. In contrast, in areas 18 and 19 (i.e., secondary and tertiary association visual cortices), binding to the NMDA receptor was reduced compared to controls. The demonstration that the reduction in NMDA receptor binding parallels the hierarchical pattern of increasing complexity of association visual cortices and with increasing numbers of neurofibrillary tangles in these latter regions is consistent with a role of NMDA receptor-bearing neurons in the pathology of AD (Carlson *et al*., 1993).

D'Aniello *et al*. (1998) examined the levels of free D-aspartate in human brains from AD and control patients. Levels of D-aspartate were found to be reduced in the frontal (43%), parietal (38%), and temporal (35%) cortices, hippocampus (47%), and amygdala (41%). D'Aniello *et al*. (1988) interpreted these data to suggest that decreased levels of D-aspartate could contribute to a lower NMDA receptor function and consequently to the memory deficits seen in AD.

Although a number of studies report reductions of NMDA receptors in AD, still others fail to support a disease-related loss of this receptor subtype. For example, Geddes and Cotman (1986) employed [^{3}H]glutamate to investigate NMDA receptors in the hippocampus of control and AD brains. While no significant changes in the density or distribution of NMDA receptors were observed when comparing AD and control brains, the distribution of NMDA receptors did, however, correlate with the density of AD pathology. These latter data were taken as evidence to suggest that excitotoxic mechanisms may be involved in the pathogenesis of AD. In a second study, Geddes *et al*. (1986) provided further evidence supporting the lack of any change in hippocampal NMDA receptor density in AD patients compared to controls. They do note, however, that in cases displaying major hippocampal neuron loss, reductions in receptor density were observed.

Cowburn *et al*. (1988) also employed [^{3}H]glutamate binding to examine the integrity of NMDA receptors in the caudate, hippocampus, and frontal, temporal, and parietal cortices from control and AD brains and observed no change in binding within any of the regions examined. In contrast, reductions in [^{3}H]asparate binding (40%) were observed in the AD hippocampus compared to controls, thus suggesting a loss of glutamate terminals within this region of the brain. Collectively, these findings led Cowburn and colleagues (1988) to conclude that in AD there is a general integrity of NMDA receptors, at least in the early phases of the disease. However, reductions in [^{3}H]asparate suggest that these receptors may not be appropriately innervated, thus contributing to the learning and memory deficits of AD.

Ulas *et al*. (1992) also employed L-[^{3}H]glutamate and observed a 35% reduction in binding in the CA1 region of AD cases compared to controls. Notably, Ulas *et al*. (1992) demonstrated marked intersubject variability in NMDA receptor binding, with some AD patients showing significant decreases in receptor levels, whereas others displayed no changes or even increased binding. This variability could not be attributed to age, sex, postmortem interval, or even a loss of neurons, thereby leading Ulas and colleagues (1992) to hypothesize that the variability may result from differences in genetic background and/or an accumulation of life experiences that result in distinctive receptor characteristics. Although this hypothesis remains largely untested, it does suggest that the analysis of individual AD cases may prove valuable in determining the role of glutamate in AD. These data also provide a reasonable explanation for discrepant results among the various investigations discussed in this chapter.

Ulas *et al*. (1994) also examined NMDA receptors by *in vitro* quantitative autoradiography in Parkinson's disease and AD patients. Binding to the NMDA receptor by [^{3}H]glutamate was increased in the caudate, the putamen, and the nucleus accumbens in Parkinson's disease, AD, and Parkinson's/AD brains compared to controls. The authors suggest that the increase in NMDA receptors is in response to an insult or insults within the striatothalamocortical circuits, which may contribute to the clinical similarities in AD and PD patients.

2. CPP Binding

As an additional means of assessing the status of the NMDA receptor in AD, several investigators have employed the ligand [^{3}H]CPP, a potent and selective antagonist (Table 20.9). For example, Porter *et al*. (1992) studied the binding of [^{3}H]CPP in synaptic membranes of human brain and found the presence of two distinct binding components for CPP, one of high ($K_d \sim 70$ nM) and the other of low ($K_d \sim 5$ μm) affinity.

[b] AH: anterior hippocampus; PH: posterior hippocampus.

Examination of the medial frontal and medial temporal cortices of AD and control brains revealed that neither of the two components of [^{3}H]CPP binding were changed in either the AD or the control group. Ulas *et al*. (1992) also examined [^{3}H]CPP-binding levels in the hippocampus using autoradiographic techniques. On average, binding levels were unchanged in the AD brain compared to control brains except in the outer layer of the parahippocampal gyrus (anterior portion). In this latter region, [^{3}H]CPP-binding levels in AD brains were below the levels observed in control brains. Notably, the studies of Ulas *et al*. (1992) and Porter *et al*. (1992) reported marked intersubject variability, as discussed in the preceding section. In addition, Porter *et al*. (1993) reinvestigated the binding of [^{3}H]CPP in cortical synaptic membranes of AD and control brains and again found no significant changes in binding in the temporal and frontal cortices in either group. Consistent with their 1992 study, considerable intersubject variation in binding parameters was detected (Porter *et al*., 1992, 1993). The authors speculate that while changes in receptor integrity occur in individual patients, these changes may be obscured because of the large variations among individuals.

3. MK-801 Binding

In addition to [^{3}H]glutamate and [^{3}H]CPP binding, a number of investigators have examined the NMDA receptor in AD brains using MK-801 binding (Table 20.10). This dibenzocycloheptene imine is a noncompetitive antagonist of the NMDA receptor complex and binds with a high affinity to the NMDA receptor-associated ionophore. In brief, Mouradian *et al*. (1988) found no differences in [^{3}H]MK-801 binding between control and AD patients in homogenates of frontal, parietal, temporal, or occipital cortices or in the hippocampus. The authors note, however, that the use of homogenized tissue may obviate their ability to discern changes within discrete brain regions (i.e., CA subfields of the hippocampus). Procter *et al*. (1989a) also investigated the frontal cortex and observed no change in [^{3}H]MK-801 binding when comparing control to AD brain. However, despite the lack of change, Procter *et al*. (1989b) demonstrated that MK-801 binding was increased in the presence of glycine within both control and AD brains, although the magnitude of change was significantly greater in control brain. Because glycine has a modulatory effect on the NMDA receptor, Procter *et al*. (1989b) suggested that these data support the hypothesis that in AD there is an abnormality in glutamatergic transmission rather than a marked decline in receptor density.

Ulas *et al*. (1992) also investigated MK-801 binding (in the presence of glycine and glutamate). However, unlike the previous studies, these authors observed a 34% decrease in [^{3}H]MK-801 binding in the CA1 stratum pyramidale and significant, yet smaller, decreases in the dentate gyrus, parahippocampal gyrus, and subiculum. All total, decreased binding was observed in 5 out of 16 regions of the brain. In contrast, [^{3}H]glutamate binding was reduced only in the CA1 region (see previous discussion). The authors speculated that the relatively selective vulnerability of the channel-associated recognition site may be related to changes in the NMDA receptor complex or alterations in membrane lipids that are known to occur in AD.

Palmer and Burns (1994) examined the redox, polyamine, and glycine modulatory sites using [^{3}H]MK-801 to bind to the NMDA receptor in the superior frontal and superior tem-

poral cortices of AD brains and controls. The polyamine site antagonist, arcaine, inhibited [^{3}H]MK-801 binding in a dose-dependent fashion in control brains. This binding was unchanged in AD. The inhibition of the redox site was also similar in control and AD brains. Moreover, glycine-stimulated [^{3}H]MK-801 binding was unaffected in the AD brain. Collectively, these data indicate that the NMDA receptor and its modulatory redox, polyamine, and glycine subsites are preserved in AD patients. This preservation may in part reflect a combination of compensatory and regenerative changes that occur in the AD brain, particularly during the earlier phases of the disease.

Scheuer *et al*. (1996) examined [^{3}H]MK-801 binding and observed significant reductions in binding in the frontal cortex (20%), but no changes in the parietal cortex when comparing control and AD brain. The reduction in the frontal cortex occurs independent of AD-specific neuropathologic changes and/or alterations in the composition or structure of the neuronal membrane.

4. TCP Binding

As stated previously, TCP, like MK-801, binds to the cation channel in the NMDA receptor complex. In addition, glutamate has been shown to increase the rate of binding of TCP, thus suggesting that it binds to the activated channel (Table 20.11). With this ligand, Maragos *et al*. (1987) examined the distribution of NMDA-binding sites in subjects with AD and observed significant reductions in [^{3}H]TCP binding in the strata pyramidale of CA1/CA2, CA3, and subiculum. Of note, the reductions were greatest in regions of the hippocampus containing significant AD pathology (i.e., CA1 and subiculum) and least in areas displaying less pathology (i.e., CA3). Consistent with these latter observations, no reduction was observed in the molecular layer of the DG. Because this latter region is known to contain high densities of NMDA receptors but is relatively spared of plaques and tangles (at least until the end stage of the disease), Maragos and colleagues (1987) hypothesized that plaque and/or tangle formation in this region may antedate reductions in the glutamate/TCP receptor complex.

Monaghan *et al*. (1987) also studied the density and distribution of [^{3}H]TCP-binding sites in the human hippocampus of control and AD brains. Consistent with work of Maragos *et al*. (1987), AD patients showed significant loss of binding in the CA1 strata pyramidale/radiatum (40%). No change was seen in the molecular layer of the dentate gyrus or strata pyramidale/lucidum of CA3. Collectively, these data support the theory that the reduction of TCP binding in the CA1 region of the hippocampus in AD corresponds to the selective loss of neurons in this region.

Simpson *et al*. (1988) also utilized the binding of [^{3}H]TCP in AD brains to study the NMDA receptor. Binding of [^{3}H]TCP showed a reduction only in the frontal cortex of AD subjects. Binding in the temporal cortex, head of the caudate, and hippocampus were unchanged in AD. Of interest, the temporal cortex and caudate nucleus were also characterized by a loss of glutamate terminals (i.e., [^{3}H]aspartate binding). In explaining these data, Simpson *et al*. (1988) suggested that on the one hand, the loss of [^{3}H]TCP-binding sites in the frontal cortex is indicative of the degeneration of glutamate receptor-bearing cells receiving a glutamatergic innervation. On the other hand, the integrity of these binding sites in the temporal cortex (i.e., a region of frank pathology and cell loss) suggests that if glutamate causes neuronal degeneration, it must do so in a way that spares cells bearing NMDA receptors. Moreover, the demonstration that some regions of the brain are characterized by reductions in [^{3}H]aspartate whereas [^{3}H]TCP is unchanged suggests that a loss of glutamate terminals is not necessarily linked to changes in postsynaptic NMDA receptors.

Ninomiya *et al*. (1990) also studied the binding of [^{3}H]TCP in the frontal cortex of AD and control patients. In AD brains, the total concentration (B_{max}) of binding sites was reduced significantly by 40–50%. [^{3}H]TCP binding exhibited a linear

TABLE 20.11 TCP Binding in Aged Humans

[a]Significant change only in certain layers or subfields.

correlation with NMDA-sensitive [^{3}H]glutamate-binding sites. These data suggest that the primary change in the NMDA receptor–ion channel complex in AD brain is the reduction of its number, possibly reflecting the loss of neurons bearing these receptor complexes. In regions where [^{3}H]TCP-binding sites are spared, they also retained their affinity for glutamate and reactivity to NMDA, L-glutamate, and glycine. These latter data suggest that those receptor complexes spared in AD are functionally normal.

Jansen *et al*. (1990) also examined [^{3}H]TCP binding in the hippocampus of AD and control brains. Reductions were observed in the CA1 field (42%), CA3 field (34%), and entorhinal neocortex (36%). Because the three NMDA-linked sites (i.e., glycine, L-glutamine, and phencyclidine) show congruent changes in AD, the authors suggested that these sites are allosterically linked in this region of the brain.

5. Glycine Binding

The demonstration that glycine enhanced the *in vitro* responses of cortical neurons to NMDA led some to speculate that the NMDA type of glutamate receptor has an agonist (NMDA) site and a strychnine-insensitive glycine-binding site, which show allosteric interactions and together regulate the binding of phencyclidine and related compounds (i.e., TCP, MK-801) to a site in the open ion channel. Because of its putative important role in glutamate receptor functioning, a number of investigators have sought to determine whether binding to the glycine site is disrupted in AD (Table 20.12). For example, Jansen *et al*. (1990) examined [^{3}H]glycine binding in the hippocampus of AD and control brains and observed reductions in the CA1 (44%) and CA3 subfields (34%), as well as the entorhinal neocortex (40%). Del Bel and Slater (1991) also observed significant reductions in [^{3}H]glycine binding in membranes prepared from the frontal cortex of AD brains compared to controls. In contrast, binding in the temporal cortex, hippocampus, and caudate nucleus remained unchanged. Moreover, autoradiograms showed no significant differences between controls and AD in any of the areas examined. These latter data are consistent with the autoradiographic studies of Ulas *et al*. (1992), who, following examination of the AD and control hippocampi, failed to observe significant differences in levels of binding to the glycine modulatory site within any of seven hippocampal subfields. Similar to their results obtained for NMDA-sensitive binding sites, Ulas *et al*. (1992) noted that some AD patients exhibited [^{3}H]glycine binding below the level of binding for any control whereas levels in others were maintained or even increased. This intersubject variability underscores the marked diversity (i.e., stages) of AD subjects and may well help us understand the many conflicting reports on NMDA responses in AD.

6. Immunocytochemistry of the NMDA Receptor

Utilizing immunocytochemical methods, Aronica *et al*. (1998) investigated the localization of glutamate receptor subunits in the hippocampus of AD and control brains. In vulnerable regions of the hippocampus (i.e., CA1), NMDAR1 immunolabeling was reduced, presumably due to cell loss. Notably, of those surviving cells the intensity of staining was comparable to and, in many instances, greater than controls. An increase in NMDAR1 immunolabeling in the hippocampus was also observed by Ikonomovic *et al*. (1999). In the latter study, Ikonomovic *et al*. (1999) examined subjects presenting with a wide range of pathologic severity (i.e., Braak stages I–VI). Whereas small variations in the pattern of immunolabeling were observed in control cases, AD brains were characterized by marked intersubject variability. For example, AD cases with mild to modest AD pathology (i.e., Braak stages I–III) were largely indistinguishable from controls in the overall pattern of immunolabeling. In contrast, in those cases with more severe AD pathology (i.e., Braak stages IV–VI), the intensity of immunolabeling was often more intense than in controls or cases with mild AD pathology. Moreover, in pathologically severe cases, numerous NMDAR1-positive pyramidal cells, particularly in the CA1 and subiculum, were characterized by darkly stained, long, and often tortuous apical dendrites. In contrast to the aforementioned pattern of immunolabeling, a reduction in NMDAR1 immunolabeling was observed within the outer molecular layer (i.e., the termination zone of the perforant pathway). This latter region was also the site of a number of NMDAR1-labeled plaques. The reduction of NMDAR1 immunolabeling within the termination zone of the perforant pathway is consistent with the AD-related loss of

TABLE 20.12 Glycine Binding in Aged Humans

[a]Significant change only in certain layers or subfields.

perforant pathway fibers and concomitant reduction in postsynaptic glutamate receptors. Moreover, the loss of NMDA receptors within the outer molecular layer provides a strong cellular/molecular correlate underlying AD-associated memory impairment.

7. *In Situ* Hybridization of NMDA Receptor

To date, relatively few investigators have studied the expression of selected NMDA receptor subunit mRNAs in AD. For example, Ulas and Cotman (1997) examined the expression of NMDA receptor mRNAs in the hippocampus and entorhinal and perirhinal cortices in AD and control brains and observed significantly reduced levels of NMDAR1 mRNA in layer III of the entorhinal cortex as well as in layers II, III, and IV–VI of the perirhinal cortex. Notably, layer II/III of the entorhinal cortex was affected severely in AD and therefore the reduction in NMDAR1 levels was a predictable corollary to the loss of neurons in this region. However, not all vulnerable sectors of the hippocampus displayed reductions in mRNA levels. For example, the CA1 region was characterized by severe neuronal damage in AD, yet NMDAR1 mRNA levels were not reduced significantly in the AD brain. In contrast, in the granule cell layer of the dentate gyrus (i.e., a region far less affected with AD pathology), substantial, yet nonsignificant, reductions in NMDAR1 mRNA levels were observed. The lack of significance within this latter region can reasonably be attributed to a relatively small sample size as well as considerable intersubject variation in NMDAR1 mRNA levels. Comparable intersubject variations were reported by Mishizen *et al*. (1999) in studies of NMDAR1, NR2A, and NR2B mRNA levels within the hippocampus of control and AD brains. Notably, Ulas and Cotman (1997) found no significant relationship between mRNA levels and postmortem delay, tissue storage, age of the subject, or minimental status. These findings suggested that mRNA levels may be affected by additional factors such as the agonal state. To date, relatively few studies screen individual subjects in order to evaluate the integrity of specific mRNAs. Such prospective analyses may be essential in order to determine whether changes in mRNA levels are indeed disease specific or the result of nonspecified factors possibly related to death but unrelated to the disease process.

B. AMPA Receptors

1. AMPA Binding

To date, a number of investigators have examined the integrity of AMPA receptors in AD (Table 20.13). Similar to studies of the NMDA receptor, the results of these investigations are inconsistent. For example, Chalmers *et al*. (1990) examined levels of [^{3}H]AMPA within the frontal cortex of AD and control brains and observed no significant changes in either group. Moreover, [^{3}H]AMPA binding in the AD frontal cortex was unrelated to senile plaque number. Likewise, Ulas *et al*. (1994) investigated [^{3}H]AMPA binding in the striatum and nucleus accumbens of patients with AD, Parkinson's disease or both and aged-matched controls and observed no changes in binding among the various groups. As discussed in a previous section, binding to the NMDA receptor was increased substantially within the three patient groups. These latter data support a unique role for the NMDA receptor within striatothalamocortical circuits and may in fact represent a compensatory reaction following damage to this circuit.

In contrast, reductions in [H^3]AMPA binding were observed within several brain regions by Dewar *et al*. (1991). Specifically, autoradigraphic studies demonstrated reductions in [^{3}H]AMPA binding in superficial and deep layers of the parahippocampal gyrus, subiculum, and CA1 region. Furthermore, the reduction in binding was correlated with the degree of local neuronal degeneration. Additional confirmation for a reduction in [^{3}H]AMPA binding in AD brains comes from the work of Carlson *et al*. (1993). In their studies of the visual cortex, Carlson *et al*. (1993) observed reductions in [^{3}H]AMPA binding in layer II of area 17, as well as layers III–VI of area 18. No changes were observed within any layer of the higher order visual association cortex area 21. As discussed in a previous

TABLE 20.13 AMPA Binding in Aged Humans

[a]Significant change only in certain layers or subfields.

section, the visual cortex is characterized by hierarchical levels of neuropathologic severity with higher order visual cortex > association cortex > primary visual cortex. Whereas levels of NMDA binding adhered to this hierarchical scheme (i.e., reductions were greatest in regions with most intense pathology), AMPA receptor levels did not parallel the pathology. The authors suggested that these latter data may imply that AMPA receptors do not play a direct role in the AD pathology.

Geddes *et al*. (1992) investigated the density and distribution of [^{3}H]AMPA-binding sites in the hippocampus and parahippocampal gyrus in AD and control brains. On average, binding levels were similar between control and AD brains even in regions of the hippocampus characterized by considerable cell loss (i.e., CA1). Further analyses revealed no correlation between levels of [^{3}H]AMPA binding and neuronal density. Although Geddes *et al*. (1992) observed [^{3}H]AMPA binding to be preserved within the vast majority of hippocampal subfields, a couple exceptions were reported in AD. These included a 20% decrease in the outer molecular layer of the dentate gyrus and a 26% increase in the polymorphic region of the dentate gyrus. Although the mechanism underlying the increase in binding is unclear, Geddes and colleagues (1992) noted that it may reflect a subcortical pathology or seizures as both have been reported to result in the compensatory upregulation of postsynaptic receptors.

2. Immunocytochemistry of AMPA Receptors

As a corollary to receptor autoradiographic studies of AMPA receptors, a few laboratories have sought to examine the integrity of the AMPA receptor in AD using immunocytochemical techniques. For example, Hyman *et al*. (1994) examined the hippocampus and temporal cortex of AD and control brains with antibodies to the GluR1, GluR2/3, and GluR4 subunits of the AMPA receptor. On average, the pattern of staining between control and AD hippocampus was similar except for the pattern of staining for GluR2/3 in the molecular layer of the dentate gyrus. In control brains the staining was homogeneous throughout the depth of the molecular layer. However, in 3 of the 15 AD brains, GluR2/3 immunolabeling appeared more intense in the inner portion of the molecular layer than the outer two-thirds. The authors noted that the increase in staining may represent an upregulation of receptors on deafferented neurons or receptors on the terminals of axons sprouting into this region.

Additional immunohistochemical studies of AMPA receptors come from the work of Armstrong and colleagues (Armstrong *et al*., 1994, Ikonomovic *et al.*, 1995a,b, 1997; Ikonomovic and Armstrong, 1996). Initial studies of the entorhinal cortex revealed GluR2/3-labeled cells distributed abundantly throughout layers II, III, V, and VI (Armstrong *et al*., 1994). In AD, there was a profound loss of GluR2/3 labeling and protein concentration (Armstrong *et al*., 1994; Yasuda *et al*., 1995). However, adjacent Nissl-stained tissue sections revealed substantial cell loss in the entorhinal cortex in AD, thus providing a reasonable explanation for the loss of GluR2/3 protein. In contrast, brains with relatively mild AD pathology revealed a dramatic loss of GluR2/3 immunolabeling but little if any loss of layer II neurons following examination of Nissl-stained tissue sections (Armstrong *et al*., 1994). These latter findings support the notion that a decrease in GluR2/3 immunolabeling within layer II neurons precedes the loss of these cells. In subsequent studies, double-labeling techniques were employed to examine the distribution of GluR2/3 and an anti-tau monoclonal antibody (i.e., MC1) within the entorhinal cortex of cases with varying degrees of AD pathology (Ikonomovic *et al*., 1997). In addition, near adjacent sections were immunolabeled with GluR2/3 and a marker of normal neuronal cytoskeleton (i.e., MAP2). In those cases with relatively mild AD pathology, most layer II entorhinal cortex neurons were double labeled with GluR2/3 and MAP2. Occasionally, MC1-labeled cells were observed, although in no instance were these neurons double labeled with GluR2/3. In cases with moderate AD pathology, layer II neurons exhibited a substantial loss of GluR2/3-labeled neurons, whereas the number of MAP2-labeled neurons remained stable. Notably, the loss of GluR2/3-labeled neurons was accompanied by an increase in the number of MC1-labeled neurons. In no instance were GluR2/3 and MC1 colocalized within the same neurons. In cases with severe AD pathology, virtually no GluR2/3-labeled neurons were observed in the entorhinal cortex. In addition, the number of MAP2-positive cells was diminished greatly. In contrast, MC1-labeled neurons were abundant. That GluR2/3 and MC1 were not observed in the same neuron, together with the observation that the number of GluR2/3-labeled neurons decreases as the number of MC1-positive cells increases, supports the notion that a loss of GluR2/3 immunolabeling precedes the appearance of MC1 immunolabeling (Ikonomovic *et al*., 1997).

As a corollary to studies of the entorhinal cortex, Armstrong and colleagues investigated the anatomical organization of GluR2/3 and GluR1 within the hippocampus of control and AD brains (Ikonomovic *et al*., 1995a,b). Within the dentate gyrus, it is well known that glutamatergic afferents arising from layer II neurons in the entorhinal cortex terminate within the outer two-thirds of the molecular layer on the apical dendrites of granule neurons (Hyman *et al*., 1994). Within this termination zone of the perforant pathway, Ikonomovic *et al*. (1995a) observed dense immunolabeling for the AMPA receptor subunits, with GluR1 displaying a greater intensity than GluR2/3. In a number of pathologically severe AD cases, the intensity of GluR1 and GluR2/3 immunolabeling within the dentate gyrus, particularly the molecular layer, was increased substantially. Because the perforant pathway is known to be disrupted in AD, it was hypothesized that the increase in GluR immunolabeling in the dentate gyrus is compensatory in nature, resulting from the loss of glutamatergic (i.e., perforant) pathway fibers (Armstrong and Ikonomovic, 1996). In support of this hypothesis are studies in rat demonstrating increases in GluR1 and, to a lesser extent, GluR2/3 within the molecular layer of the dentate gyrus following perforant pathway lesions (Mizukami *et al*., 1997a,b).

In CA fields, pyramidal neurons also displayed intense immunolabeling for GluR1 and GluR2/3. As discussed in detail (Ikonomovic *et al*., 1995a), these receptor subunits display a differential distribution on pyramidal neurons with GluR1 largely associated with processes and GluR2/3 with somas. In vulnerable sectors of the AD hippocampus (i.e., CA1, subiculum), a variable reduction in GluR1 and GluR2/

3 immunolabeling was observed that appeared to correlate with the extent of cell loss and neurofibrillary tangles (Ikonomovic *et al*., 1995b). Despite the reduction in labeled cells, the intensity of immunolabeling within the remaining cells was comparable, if not greater, than that observed in controls. Within less vulnerable regions of the hippocampus (i.e., CA2/3), the staining pattern was comparable between control and AD brains, although the intensity of imunolabeling was increased greatly in AD cases, particularly in the stratum lucidum of the CA3 regions (i.e., termination zone of mossy fibers). Collectively, these data support that hippocampal plasticity is preserved even in cases displaying severe AD pathology and suggest a critical role for AMPA receptor subunits in this plasticity and in maintaining hippocampal functioning.

The hippocampus is also the site of intense neuropathology in AD, and therefore Ikonomovic *et al*. (1997) performed a series of double-labeled studies to examine the temporal and spatial relationship between GluR2/3- and MC1-labeled neurons within vulnerable sectors of the AD hippocampus. Similar to studies in the entorhinal cortex, cells double labeled for GluR2/3 and MC1 were never observed in any CA1 subregion (Ikonomovic *et al*., 1997). Collectively, these data support the hypothesis that the GluR2/3 subunit is lost prior to the development of neurofibrillary tangles and therefore suggest that the decrease and/or loss of this receptor subunit may be important in the evolution of neurofibrillary changes via a mechanism involving the increase of intracellular calcium.

In addition to the hippocampus, the basal forebrain is another region of the brain that is particularly vulnerable in AD. Although basal forebrain neurons are a rich source of acetylcholine throughout the neocortex and hippocampus, these neurons are densely innervated by glutamatergic fibers and therefore excitotoxic mechanisms may contribute to their death and degeneration in AD. Immunolabeling studies of basal forebrain cholinergic neurons of nondemented elderly revealed both somata and processes of magnocellular neurons within the posterior nucleus basalis of Meynert to be intensely immunoreactive to GluR1 but not GluR2/3 (Ikonomovic and Armstrong, 1996). In contrast, neurons within the more rostral diagonal band region expressed both GluR1 and GluR2/3. Notably, the posterior aspect of the basal forebrain is more vulnerable to pathologic insult than anterior regions. The fact that GluR2/3 is selectively absent from neurons in the posterior (i.e., vulnerable) nucleus basalis of Meynert is consistent with the notion that glutamate receptors assembled without GluR2 are apt to be more permeable to calcium. This affects the ability of the cell to maintain intracellular calcium homeostasis, a critical step in determining the susceptibility of a cell to glutamate toxicity and for its selective vulnerability. Notably, investigation of the basal forebrain from younger subjects (i.e., 5–55 years of age) revealed intense GluR1 and GluR2/3 immunolabeling within posterior and anterior aspects of the nucleus basalis of Meynert, thus suggesting that the paucity of GluR2/3 labeling observed in older subjects is age related. Functionally, a ''switch'' in subunit composition, such that the assembled receptor no longer contains GluR2/3, has serious implications with respect to the responsiveness of these neurons to glutamate receptor activation via the AMPA receptor.

In addition to the studies of Armstrong and colleagues, Aronica *et al*. (1998) examined the staining pattern of GluR2(4) and GluR1 in the hippocampus of AD and control brains. On average, all projection neurons in the hippocampus were immunolabeled for GluR1 and GluR2(4). Specifically, GluR2(4) was characterized by dense cytoplasmic staining, especially in the neuropil of CA1–4. In addition, intense labeling was observed in CA4 polymorphic neurons, CA3 pyramidal neurons, and pyramidal cell somata and apical dendrites of CA1 and subiculum. In most instances, the staining pattern between controls and AD brains was comparable with the exception of the molecular layer of the dentate gyrus. In this latter region, staining was relatively similar in the inner and outer layers of control brains, whereas in the AD brain the inner layer was stained more intensely compared to the outer layer. There was also a decrease in GluR1 and GluR2(4) immunoreactivity noted in the CA1 field of AD brains possibly due to cell loss. Of note, GluR1 and GluR2(4) immunolabeling was observed in novel juxtaneuronal clusters localized to dystrophic dendrites within the neuropil of the CA1 pyramidal layer. The precise neuropathologic characterization of these latter structures is unknown.

3. I*n Situ* Hybridization of AMPA Receptor

As a corollary to immunohistochemical studies of AMPA receptor subunits, a few investigators have employed *in situ* hybridization methods to examine messenger RNAs for each of the AMPA receptor subunits. In brief, Pellegrini-Giampietro *et al*. (1994) examined the expression of GluR1, GluR2, and GluR3 AMPA receptor subunits in AD and nondemented controls and observed no changes in GluR1 message levels in the AD hippocampus. Because GluR2 and GluR3 displayed relatively low hybridization signals, they could not be quantitated reliably. Of note, considerable intersubject variability was observed with some samples showing marked reductions in GluR1 mRNA within the dentate gyrus, CA1, and CA3 relative to controls whereas others showed no changes. When hybridization densities were correlated with a number of pre- and postmortem variables, a negative correlation was found between GluR1 mRNA levels in the dentate gyrus and storage duration of brain samples. These data led the authors to conclude that all differences in mean expression levels between AD and control samples could be ascribed to storage time. The latter findings underscore the importance of taking into account various pre- and postmortem variables prior to making any conclusions as to mRNA changes in brains of patients with AD or any other neurologic disease. In contrast, García-Ladona *et al*. (1994) reported reductions in GluR1–4 levels within the hippocampus of AD subjects relative to controls. However, the significance of these latter findings is not clear in light of the fact that only four AD subjects were examined and no quantitative data were presented.

In addition to *in situ* hybridization studies, Akbarian *et al*. (1995) employed reverse transcriptase-polymerase chain reaction, restriction endonuclease digestion, gel electrophoresis, and scintillation radiometry to determine the proportions of edited and unedited GluR2 RNA within the frontal neocortex of brains from patients with AD and age-matched controls. As stated previously, the posttranscriptional editing of the transcript of the GluR2 gene results in the substitution of an arginine for glutamine in the second transmembrane region (TMII/

pore loop segment) of the expressed protein. The presence of the positively charged arginine is associated with a reduction in Ca^{2+} permeability of the receptor channel. In brief, Akbarian and colleagues (1995) determined that in the prefrontal neocortex of control patients, <0.1% of all GluR2 RNA molecules were unedited (i.e., contains a CAG codon for glutamine) whereas >99.9% were edited (i.e., contains a CGG codon for arginine). In the prefrontal cortex of AD patients, ~1.0% of all GluR2 RNA molecules were unedited and 99% were edited. Although the near 11-fold increase in unedited GluR2 was highly significant, it remains true that the overwhelming majority of GluR2 molecules exist in the edited form. Nevertheless, Akbarian *et al*. (1995) suggested that disturbances in GluR2 RNA editing leading to excessive Ca^{2+} permeability may contribute to neuronal dysfunction in AD.

C. Kainate Receptors

1. Kainate Binding

To date, a number of investigators have examined kainate (KA)-binding densities within AD brains (Table 20.14). For example, Geddes and Cotman (1986) studied the density and distribution of kainate receptors in the hippocampus of AD and control brains and on average found binding density very similar between the two groups, except in the stratum lucidum where a 30% decrease was observed in the AD brain. In addition, in the inner part of the dentate molecular layer (i.e., supragranular layer), Geddes and Cotman (1986) observed a near 75% expansion of the distribution of KA-binding sites. These latter data are consistent with the notion that the AD brain maintains a considerable degree of plasticity and that the progression of the disease is not simply associated with the ongoing loss of neuronal elements. A significant AD-related loss of KA binding in the stratum lucidum of CA3 (i.e., terminal fields of mossy fibers) was likewise observed by Represa *et al*. (1988). However, in contrast to the findings of Geddes and Cotman (1986), these latter investigators failed to observe any expansion of the distribution of KA-binding sites in the supragranular layer of the dentate gyrus. Rather, within this region a significant loss of KA binding was found (Represa *et al*., 1988). To reconcile these discrepant findings, Represa *et al*. (1988) suggested that it is the severity of the neuropathology rather than any methodological issues that explains these differences. Moreover, Represa and colleagues (1988) contended that their inability to support a significant sprouting response of mossy fibers is consistent with a loss of plasticity in AD [a view contrary to the one held by Geddes and Cotman (1986)]. The authors of this chapter hold the position that neuronal plasticity is an innate property of the brain and plays a significant role in the early and moderate stages of AD. However, these compensatory reserves can be overwhelmed with the progression of the disease and, in most circumstances, are largely lost throughout the terminal (i.e., end stages) of the disease. Thus, while characterizing specific aspects of neuronal plasticity, it is critical that it is done so within the context of neuropathological staging.

TABLE 20.14 Kainate Binding in Humans

Age	Subject	Postmortem (hr)	Ligand	Region	Change in AD	Reference
78±5	Control	8±4	[^{3}H]KA	Parietal cortex	Not significant(ns)	Cowburn *et al.* (1989)
78±10	AD	10±7		Temporal cortex	ns	
				Frontal cortex	ns	
				Hippocampus	ns	
				Caudate	ns	
64.4	Control	15.3	[^{3}H]KA	Hippocampus	Decrease in CA1[a]	Penney *et al.* (1990)
70.9	AD	23.4				
68.3	Non AD-demented	12				
84±2	Control	11–23	[^{3}H]KA	Frontal cortex	Decrease[a]	Chalmers *et al.* (1990)
89±2	AD	3–15				
75±3	Control	10±2	[^{3}H]KA	Hippocampus	Decrease[a]	Dewar *et al.* (1991)
82±3	AD	11±2		Parahippocampus	Decrease

74±4	Parkinson's disease/AD	12±3				

[a] Significant change only in certain layers or subfields.
[b] DGML, dentate gyrus molecular layer.
[c] In some but not all patients.

Additional studies of KA binding were conducted by Cowburn *et al*. (1989) using membrane preparations of human neocortex, hippocampus, and caudate. No changes in either the affinity or the number of KA receptors were observed in any of the regions examined, despite the loss of neocortical and hippocampal glutamatergic terminals. These data led Cowburn *et al*. (1989) to conclude that glutamatergic dysfunction in AD is primarily a result of pyramidal cell deafferentation with a relative sparing of postsynaptic glutamate receptors. That KA receptors are preserved in AD is additionally supported by subsequent studies by Geddes and colleagues (1992) and Ulas *et al*. (1994). In fact, Geddes *et al*. (1992) noted that not only were KA receptors unchanged in the AD hippocampus, but in some individuals (i.e., 3 out of 10), increases in KA binding were observed in the outer half of the dentate gyrus. Further evidence for an increase in KA binding comes from the work of Chalmers *et al*. (1990), who observed a 70% increase in KA receptor binding density in the deep layers of the frontal neocortex compared to controls. No changes were observed in the superficial layers of the neocortex. The increases in KA binding were interpreted as representative of a regenerative change in the AD brain in response to the loss of glutamatergic afferents.

In contrast to the findings described previously, Penney *et al*. (1990) observed significant decreases in [^{3}H]KA binding in the stratum pyramidale of CA1 and the prosubiculum in AD brains (i.e., areas of severe neuropathology). However, the magnitude of this reduction was less than that observed for NMDA and AMPA receptor, possibly reflecting a differential distribution of these receptor subtypes on pyramidal cell dendrites. Dewar *et al*. (1991) also compared kainate binding in normal and AD subjects and observed in the AD brain reductions in [^{3}H]KA binding in the superficial and deep layers of the parahippocampal gyrus as well as the subiculum. Notably, NMDA and AMPA binding were variably affected in these latter regions, again possibly reflecting the localization of these three binding sites on neuronal elements, which are differentially susceptible to AD-mediated neuronal degeneration. Specifically, it is hypothesized that those binding sites localized to more distal dendritic locations will undergo a greater degree of loss as distal dendrites and spines of pyramidal neurons are thought to be affected early in AD. In addition, Aronica *et al*. (1998) confirmed that KA receptors are localized to the somatodendritic components of pyramidal neurons utilizing immunohistochemical techniques.

V. Current Topics of Glutamate Toxicity in Alzheimer's Disease

A. Balanced Actions of Excitatory and Inhibitory Systems

The role of Ca^{2+} and perturbed intracellular Ca^{2+} homeostasis ($[Ca^{2+}]_i$) has been implicated in the pathogenesis of a number of acute and chronic neurodegenerative disorders, including AD (Khachaturian, 1989; Mattson, 1992). Glutamate-related excitotoxicity is believed to account, at least in part, for the selective neuronal death within brain regions vulnerable to AD pathology (e.g., hippocampus, entorhinal neocortex) (Greenamyre and Young, 1989). The function and activity of large pyramidal neurons within these latter regions are regulated through a delicate balance between their presynaptic excitatory (i.e., glutamatergic, cholinergic) and inhibitory (i.e., GABAergic) neurotransmitter systems. This regulation largely depends on the distribution, density, and molecular composition of synaptic sites involving glutamatergic (i.e., NMDA, AMPA/kainate), cholinergic (i.e., muscarinic), and GABAergic (i.e., GABA) receptors. Notably, the balanced interaction between excitatory and inhibitory systems ensures normal physiological function of pyramidal neurons. However, the disturbed balance between these two opposing neurotransmitter systems may initiate a process of neuronal degeneration and lead to excitotoxic cell death (Mattson and Kater, 1989). Specifically, whereas individual excitatory effects of glutamatergic and cholinergic inputs may not be damaging to a cell, the additive effects of these two systems may be sufficient to cross a threshold level for the induction of excitotoxic neurodegeneration. Similarly, a disease-related hypofunction of the GABAergic inhibitory system, resulting in the dysinhibition of neurons, may significantly disturb the normal neurotransmitter balance, resulting in cells that are exposed to the damaging effects of glutamate overstimulation. Each one of these two scenarios may result in an increased flow of Ca^{2+} into a cell, which, if sustained for a prolonged period of time, disturbs $[Ca^{2+}]_i$ homeostasis and endangers cell viability. These Ca^{2+}-related events form the basis of excitotoxic cell damage (Siesjö *et al*., 1989; Mattson, 1992).

B. Glutamate Activation of Calcium-Permeable Ion Channels

Glutamate-dependent disturbances of $[Ca^{2+}]_i$ have been implicated in excitotoxic neuronal death (Choi, 1985, 1987). Figures 20.1–20.4 (see color insert) illustrate the interactions of numerous intra- and extracellular mechanisms that may participate in the regulation of $[Ca^{2+}]_i$ homeostasis. Whereas undisturbed functioning of these mechanisms is crucial for proper development, synaptogenesis, and the participation of a cell in neuronal networks, their malfunctioning may lead to a number of pathologic changes and ultimately cell death. As shown in Fig. 20.1 (see color insert), glutamate-gated Ca^{2+}-permeable receptor channels in the plasma membrane represent the main entry routes for Ca^{2+} into the cell. Whereas NMDA receptors, a class of highly Ca^{2+}-permeable ionotropic glutamate receptors, have been traditionally regarded as mediators of excitotoxic neurodegeneration, increasing attention has been given to the role that Ca^{2+}-permeable non-NMDA (i.e., AMPA/kainate) receptors may play in excitotoxic cell damage (Lu *et al*., 1996). As stated in Section I, Ca^{2+} permeability of AMPA receptor channels is largely regulated by a single gene encoding an individual receptor subunit (i.e., GluR2) (Burnashev *et al*., 1992; Jonas and Burnashev, 1995; Swanson *et al*., 1997). Specifically, the presence of an edited form of the GluR2 subunit in the AMPA receptor complex diminishes Ca^{2+} flow through the receptor-associated ion channel. The disease-related, downregulation of the GluR2 subunit has been demonstrated to participate in a number of neurodegenerative conditions, including global ischemia and limbic seizures (see Pellegrini-Giampietro *et al*., 1997). In addition, loss of the GluR2 subunit may account for the selec-

tive neuronal degeneration in vulnerable regions of AD brains (Armstrong *et al*., 1994; Ikonomovic and Armstrong, 1996; Ikonomovic *et al*., 1997). These observations have led to formulation of the ''GluR2 hypothesis'' of excitotoxic neurodegeneration (Pellegrini-Giampietro *et al*., 1997).

In addition to ionotropic glutamate receptor channels, Ca^{2+} may enter a cell through voltage-dependent Ca^{2+} channels (VDCC) and a class of metabotropic glutamate receptors (mGluR) linked to IP3 production, which induces the release of Ca^{2+} from its intracellular stores (Fig. 20.1). Because glutamate can activate multiple receptor classes, it is important to note that it is the additive effect of receptor activation and the net $[Ca^{2+}]_i$ accumulation, rather than the type of channels through which Ca^{2+} enters a cell, that is a critical determinant of excitotoxic cell injury (Lu *et al*., 1996).

C. Neuroprotective Actions of Neurotrophins

Damaging effects of sustained $[Ca^{2+}]_i$ elevations are normally countered by protective mechanisms, including those regulated by neurotrophic factors. Neurotrophic factors (nerve growth factor, basic fibroblast growth factor, and brain-derived neurotrophic factor) can protect neurons from glutamate-mediated excitotoxicity manifested through disturbed $[Ca^{2+}]_i$ and oxidative stress (Mattson *et al*., 1989, 1993a,b). By stabilizing $[Ca^{2+}]_i$, nerve growth factor and brain-derived neurotrophic factor can protect cultured neocortical neurons from damage caused, for example, by hypoglycemia (Cheng and Mattson, 1991). Protective effects of neurotrophic factors can be achieved through several mechanisms involving regulation of gene expression (Fig. 20.2, see color insert). These mechanisms include (1) increasing the expression of antioxidant enzymes (Nistico *et al*., 1992; Mattson *et al*., 1995), (2) suppressing the expression of highly Ca^{2+}-permeable glutamate receptors (Mattson *et al*., 1993c), and (3) increasing the expression of Ca^{2+}-binding proteins (Collazo *et al*., 1992). The ability of a cell to counter potentially damaging $[Ca^{2+}]_i$ increases depends partially on their normal expression of Ca^{2+}-binding proteins. Cells containing certain Ca^{2+}-binding proteins are expected to have greater Ca^{2+}-buffering capacity and to be more resistant to degenerative changes. Wernyj and colleagues (1999) demonstrated that the stable expression of the Ca^{2+}-binding protein calbindin in glial cells attenuated rises in $[Ca^{2+}]_i$ caused by either calcium ionophore or amyloid-β peptide (Aβ), resulting in increased cell survival and suppression of apoptotic cell death. Similarly, neurons overexpressing calbindin have been shown to significantly suppress Aβ-induced elevations in $[Ca^{2+}]_i$ and reactive oxygen species (Guo *et al*., 1998). These effects were potentiated by the mutant presenilin-1gene (PS-1). It should be noted that in addition to APP gene mutations, mutations in presenilin genes can also lead to early onset AD (for review, see Hardy, 1997). Notably, hippocampal neurons of mice expressing mutant PS-1 were more susceptible to Aβ toxicity (Guo *et al*., 1999).

D. Role of Apolipoprotein E

In addition to PS-1 mutations, additional factors affect Aβ toxicity. The apolipoprotein E (ApoE) genotype is one of them (for review, see Strittmatter and Roses, 1995). Inheritance of multiple allele 4 (ApoE4) copies is considered a risk for the familial form of AD (Corder *et al*., 1993). In contrast, ApoE3 (and ApoE2) may have a protective role. By binding to normal tau, they may prevent its hyperphosphorylation and aggregation into neurofibrillary tangles (Strittmatter *et al*., 1994). A positive correlation exists between the presence of ApoE4 allele and increased amounts of both amyloid deposits and neurofibrillary pathology in AD patients (Berr *et al*., 1994; Ohm *et al*., 1995; Nagy *et al*., 1995). It was proposed that binding of ApoE to Aβ is isoform specific (Strittmatter *et al*., 1994). The ApoE4 isoform was reported to enhance Aβ fibril formation more efficiently than ApoE3 (Sanan *et al*., 1994; Wisniewski *et al*., 1994). An *in vitro* study of cultured smooth muscle cells (Mazur-Kolecka *et al*., 1995) showed that both ApoE4 and ApoE3 can induce intracellular accumulation of Aβ, although ApoE3 had a less stable effect. In contrast to these reports, a study using conditioned media from ApoE3- or ApoE4-transfected HEK-293 cells showed substantially higher levels of ApoE3 binding to Aβ (LaDu *et al*., 1994). Richey *et al.* (1995), however, found no significant differences between binding characteristics of ApoE4 and ApoE3 to either senile plaques (Aβ-mediated) or neurofibrillary tangles (tau-mediated). Although the relationship of ApoE4 to glutamate toxicity remains unclear, it is important to consider that any factor that enhances Aβ formation may, directly or indirectly, contribute to the pathologic consequences of glutamate receptor-mediated neurodegeneration (see next section).

E. Role of Aβ and APP in Excitotoxic Cell Injury

In addition to the overstimulation of Ca^{2+}-permeable glutamate receptors, the effects of Aβ are also known to produce $[Ca^{2+}]_i$-destabilizing effects (Mattson *et al*., 1992, 1993d; Mattson, 1994). In AD brains, excessive accumulation of Aβ, a metabolic product of the amyloid precursor protein APP (Neve *et al*., 1990), is one of the neuropathological hallmarks of the disease (Selkoe, 1991, 1994). APP can be metabolized through the α-secretase pathway (α-secretase), resulting in the production of large amino-terminal fragments of secreted APP (APPs, or sAPPα), or through the β-secretase pathway (β-secretase), releasing both a carboxy-terminal-truncated form of APP (sAPPβ) and intact Aβ fragments (Golde *et al*., 1992) (Fig. 20.3, see color insert). Each of these metabolic products of APP has specific cellular effects (for review, see Mattson, 1997). Physiologically, the α-secretase represents a major secretory pathway of APP metabolism (Esch *et al*., 1990). Furthermore, neuronal APP mainly undergoes intracellular metabolic processing, resulting in secretion of only a small amount of Aβ (Shoji *et al*., 1992). In contrast, the aberrant β-secretase is considered a major APP-processing pathway in AD, resulting in abundant deposits of Aβ within the brain parenchyma. APPs have been shown to protect cells from excitotoxic damage through mechanisms of both reducing $[Ca^{2+}]_i$ and preventing its rise (Mattson *et al*., 1993e; Schubert and Behl, 1993). As demonstrated in cultured hippocampal neurons, one of the mechanisms by which APPs may reduce $[Ca^{2+}]_i$ is by their ability to activate high-conductance potassium channels (Furukawa *et al*., 1996a). In addition to its ability to regulate $[Ca^{2+}]_i$, APPs can attenuate glutamate-induced excitotoxicity through regulation (i.e., increased acti-

vation) of a glutamate transporter system that is responsible for clearing glutamate from the extracellular space (Masliah, 1997). This is important because decreased levels of glutamate transporter activity have been found to correlate with the extent of neuropathology in AD brains (Scott *et al*., 1995; Masliah *et al*., 1996). In brains of transgenic mice, human APP increased the uptake of glutamate/aspartate (Masliah *et al*., 1998). These results were also corroborated in an *in vitro* system of cultured astrocytes (Masliah *et al*., 1998). In contrast to the glutamate transporter-related neuroprotective effects of APPs, *in vitro* studies demonstrated that Aβ is responsible for oxidative damage of the astroglial glutamate-uptake system (Harris *et al*., 1996; Butterfield, 1997). Whereas Aβ-induced impairment of glutamate transporter can be attenuated by sAPPα (Mattson *et al*., 1999), it remains unclear whether this impairment in AD results from (1) increased Aβ production or (2) a consequent formation of functionally impaired sAPPβ . It is also of importance to note that sAPPβ is less potent than sAPPα in attenuating glutamate-evoked $[Ca^{2+}]_i$ disturbances (Furukawa *et al*., 1996b). In addition to its ability to both suppress glutamate-induced elevation of $[Ca^{2+}]_i$ and protect neurons against glutamate overstimulation, sAPPα has been shown by whole-cell patch-clamp techniques to selectively suppress NMDA currents in hippocampal neurons (Furukawa and Mattson, 1998), providing yet another mechanism of neuronal protection against excitotoxicity. Following initial reports of neurotoxic effects of Aβ (Yankner *et al*., 1989, 1990), a substantial body of research supported the relationship between Aβ and excitotoxic neuronal injury. While APPs have been mainly viewed as $[Ca^{2+}]_i$ stabilizing and neuroprotective, Aβ can destabilize $[Ca^{2+}]_i$ homeostasis and increase neuronal vulnerability to excitotoxic (Koh *et al*., 1990; Mattson *et al*., 1992, 1993f) or hypoglycemic damage (Copani *et al*., 1991). Of importance, Mattson and colleagues (1993g) demonstrated that $[Ca^{2+}]_i$ increases in cultured neurons directly correlated with increased time of exposure to Aβ as well as Aβ aggregation. Aβ may carry out this effect in several ways. As illustrated in Fig. 20.4, $[Ca^{2+}]_i$-destabilizing mechanisms of Aβ may involve either activation of existing Ca^{2+}-permeable receptors and channels or formation of *de novo* ion channels in the membrane. For example, Mattson and colleagues have proposed that Aβ, when accumulated at the cell surface, is capable of modifying the response of membrane-associated mechanisms responsible for either influx (glutamate receptors, voltage dependent calcium channels) or removal (Ca^{2+} pump, Na^+/Ca^{2+} exchanger) of Ca^{2+} (see Mattson, 1994). In support of this notion, Furukawa and colleagues (1994; Furukawa and Mattson, 1995) suggested that $[Ca^{2+}]_i$ increases can be related to binding of Aβ to the cell membrane and opening of nonselective ion channels. Furthermore, Weiss *et al.* (1994) provided additional evidence that Ca^{2+} influx through Ca^{2+}-permeable channels may be one of the mechanisms Aβ induces neuronal degeneration. This notion, however, was not corroborated by experiments applying Aβ and Ca^{2+} channel blockers in the primary culture of hippocampal neurons (Whitson and Appel, 1995). For a detailed review of studies examining ionic effects associated with APP and its metabolites (e.g., Aβ), see Fraser *et al.* (1997). Finally, an alternative mechanism of Aβ-mediated disturbance of $[Ca^{2+}]_i$ homeostasis was described by Arispe *et al.* (1993, 1994). These authors reported that Aβ incorporates into the cell membrane where it forms *de novo* Ca^{2+} channels (for review, see Pollard *et al*., 1995).

F. Free Radical Formation and Oxidative Stress

Providing additional support of the protective effect neurotrophic factors have against excitotoxic damage, an *in vitro* study by Mattson and colleagues (1993g; Mark *et al*., 1997a) demonstrated that Aβ-induced $[Ca^{2+}]_i$ disturbances and oxidative stress can be significantly attenuated by brain-derived neurotrophic factor. As stated previously, neurotrophic factors can also protect neurons from the toxic effects of free radicals (Mattson *et al*., 1993a). A substantial amount of evidence shows that free radical formation and oxidative stress are some of the mechanisms responsible for Aβ-mediated cell damage (Goodman and Mattson, 1994; Hensley *et al*., 1994; Behl *et al*., 1994; Klegeris and McGeer, 1997; Butterfield, 1997; Mark *et al*., 1997b). Specifically, Aβ can induce oxidative as well as excitotoxic cell injury, whereas these effects are also attenuated by APPs (Goodman and Mattson, 1994; Mattson and Pedersen, 1998). In a study involving rat neocortical synaptosomes, Keller *et al*. (1997) demonstrated that Aβ can induce impairment of glucose and glutamate transport, as well as mitochondrial dysfunction, all of which are oxidative stress mediated. Furthermore, the effect Aβ has on nonneuronal cells (*e.g*., microglia) may also contribute to excitotoxic neuronal damage. For example, Klegeris and McGeer (1997) showed that Aβ stimulates macrophages to produce glutamate and free oxygen radicals. These studies demonstrate that the neurotoxic effects of Aβ, either directly or indirectly, involve free radical damage and may be responsible for selective neuronal death in AD (for review, see Mark *et al*., 1996).

G. Cytoskeletal Alterations and Formation of AD-like Neurofibrillary Changes

Glutamate-related excitotoxicity is also known to induce AD-like cytoskeletal alterations. For example, the *in vitro* exposure of human neocortical neurons to excitotoxins (i.e., glutamate, aspartate) resulted in the induction of paired helical filament (PHF) formation (De Boni and Crapper-McLachlan, 1985). Furthermore, a number of more recent *in vitro* studies supported the notion that glutamate-mediated Ca^{2+} influx into cells can cause antigenic changes (i.e., increased immunoreactivity to tau and ubiquitin) similar to those observed in neurofibrillary tangles of AD brains (Mattson, 1990; Mattson *et al*., 1991; Sindou *et al*., 1992; Sautière *et al*., 1992; Hugon *et al*., 1995; Couratier *et al*., 1995, 1996). Neurofibrillary tangles consist of PHFs in which the microtubule-associated protein, tau, is aberrantly hyperphosphorylated (Grundke-Iqbal *et al*., 1986). Because activation of glutamate receptors can result in protein phosphorylation (Sholz and Palfrey, 1991), it is hypothesized that glutamate-induced Ca^{2+} influx may activate specific protein kinases, or deactivate phosphatases, to result in tau hyperphosphorylation. Specifically, it has been proposed that the mechanism responsible for conversion of normal tau into hyperphosphorylated tau (PHF-tau) may involve dysfunction of protein kinases and/or phosphatases

that are able to phosphorylate and dephosphorylate, respectively, tau protein (for review, see Iqbal *et al*., 1994; Trojanowski and Lee, 1995). A double-labeling study of AD brains (Ikonomovic *et al*., 1997), using a marker of early cytoskeletal changes (i.e., monoclonal antibody MC1), supports the concept that glutamate-induced loss of $[Ca^{2+}]_i$ homeostasis may be responsible for neurofibrillary tangle formation in vulnerable neuronal populations of AD brains (i.e., hippocampus, entorhinal neocortex).

VI. Summary

As summarized in this chapter, a number of investigators have examined the structural and functional integrity of the glutamate receptor in the aged brain and in subjects with AD. While the results of these many studies are far from uniform, a number of trends do emerge. With respect to investigations of the aged rodent brain, the majority of works support the view that NMDA receptor binding is reduced with increasing age. Notably, these reductions are observed regardless of the ligand employed to visualize the NMDA receptor (i.e., [^{3}H]glutamate, -CPP, -MK801, -TCP, -glycine). Similarly, several investigations supported the notion that kainate receptor binding is reduced in the aged rodent brain. In contrast, far less convincing evidence is provided in support of an age-related reduction in AMPA binding. Collectively, these data support the view that glutamate receptors are affected differentially by the aging process. However, not all investigations are in agreement with the majority opinion, thus raising a number of controversies concerning the participation of glutamate in the senescent brain. Contributing to the various inconsistencies in data are a host of technical issues, including strain or species, age, sex, brain region examined, and method employed to visualize the glutamate receptor subtype. For example, binding studies utilizing brain homogenates often run the risk of obscuring discrete (i.e., laminar) differences in binding due to the large size of the brain sample. The interpretation of a number of studies is likewise influenced by age of the animal. For example, while some investigations observed differences in the binding properties of receptors when comparing rodents of young and intermediate ages, no such differences were observed when comparing rodents of intermediate and old ages. Such findings raise the distinct possibility that alterations in binding properties may be related more to a maturational process than an aging one.

A number of investigators also examined the structural and functional integrity of the glutamate receptor in behaviorally characterized rodents. If, in fact, the dysfunction of glutamate neurotransmission participates in age-related declines in cognition, one would predict a positive correlation between deficits in, for example, glutamate receptor binding and poor performance in a given behavioral paradigm. Despite this prediction, deficits in glutamate receptor binding failed, in most instances, to correlate with the extent of cognitive impairment. These findings are somewhat surprising in light of considerable evidence linking the glutamate neurotransmitter system to various aspects of learning and memory, including LTP. To explain these findings, one must consider whether the brain region examined is intimately involved in the execution of the behavioral task under investigation. Moreover, it is equally important to keep in mind that glutamate receptors are expressed by cells utilizing a number of other neurotransmitters. For example, work in our laboratory demonstrates that cholinergic neurons in the basal forebrain express high levels of specific AMPA receptor subunits. The dysfunction of basal forebrain cholinergic neurons is known to result in poor performance in the Morris water maze. Given the fact that, for example, glutamatergic/cholinergic systems are so intimately linked, it may be difficult to attribute behavioral performance and/or the lack thereof to deficits in one neurotransmitter system. Rather, a specific behavior is more likely to result from the net contribution of multiple neurotransmitter systems. This latter concept is supported by a number of electrophysiological studies demonstrating, for example, age-related reductions in NMDA-stimulated dopamine and/or noradrenaline release.

The brain is also known to maintain a number of neuroplastic reserves capable of compensating for deficits in one or another neurotransmitter systems following injury, disease, and/or normal aging. Work from our laboratory provides extensive documentation in support of the plasticity of the glutamate receptor following surgical deafferentation in the rodent brain as well as in the AD brain. That other neurotransmitter systems are undergoing parallel compensatory alterations is highly tenable and may also serve to obviate the behavioral deficits resulting from the dysfunction of a single (e.g. glutamate) neurotransmitter system.

In the AD brain, an argument could also be made for deficits in glutamate receptor binding/function, although the data are somewhat less compelling than for the rodent brain. For example, in the AD brain the outcome appears to depend to a large extent on the subtype of the glutamate receptor, the ligand-binding site, and the brain region examined. Although similar to the rodent brain, the NMDA receptor in the AD brain appears to be more vulnerable than AMPA or kainate receptors, there are numerous exceptions to this rule. Contributing to various discrepant findings are a number of technical issues common to the rodent studies, as well as a number of additional factors unique to studies of postmortem human brain. Notably, a common theme throughout many of the studies is the concept of intersubject variability. Obvious contributors to this variability include postmortem interval, storage time of the tissue sample, and pathologic severity. Studies (Wolfe *et al*., personal communication) demonstrate that specific AMPA and NMDA receptor subunits are highly vulnerable to postmortem degradation whereas others are relatively resistant. For example, GluR1, GluR2/3, GluR4, and NMDAR1 exhibit marked preservation following postmortem times in excess of 18 hr, whereas NR2A and NR2B show evidence of proteolytic breakdown within the first couple of hours postmortem. In addition, Pellegrini-Giampietro *et al.* (1994) found that all differences in mean expression levels of specific mRNA transcripts between AD and control samples could be ascribed to storage time. Finally, relatively few studies of the AD brain took into account pathologic severity, yet for those who did, inconsistencies abound with respect to correlations between glutamate receptor binding and numbers of plaques and neurofibrillary tangles. Notably, the vast majority of studies examined patients with end-stage AD, thus negating any possibility of observing alterations in glutamate receptor

binding and/or function during the early (i.e., incipient) stages of the disease. As stated earlier, it is the belief of the authors that glutamate receptors undergo marked plasticity during the early phases of the disease likely in an attempt to compensate for the loss of glutamatergic innervation. In contrast, during the terminal stages of the disease these receptors are more prone to undergo neurodegenerative changes as reflected in the loss of receptor density. Whereas this loss in receptor density most likely parallels the death of neurons, no study has yet employed sterological methods to assay cell number and glutamate receptor density. The latter is critical in determining whether the loss of glutamate receptors precedes neuronal cell death or occurs concomitant with the loss of neurons. Ikonomovic *et al.* (1997) employed double-immunolabeling techniques and demonstrated that there is a loss of GluR2/3 prior to the appearance of a marker highly specific for neurofibrillary tangles (i.e., MC1) in layer II of the entorhinal neocortex and CA1 region of the hippocampus.

In considering other factors contributing to intersubject variability, one should also take into account the agonal state of the patient. The agonal state is known to contribute significantly to the stability of a number of protein and mRNA species, yet is largely discounted as a potentially confounding variable in the vast majority of studies.

Finally, in interpreting results presented in this chapter it is important to recognize that an overwhelming number of these studies rely on traditional binding methods to assay glutamate receptor levels and/or function. While these studies provide much needed information with respect to the glutamate receptor in the aged and AD brain, it is clear from our knowledge of the molecular biology of the glutamate receptor that additional techniques are needed that allow for the visualization of subunit specific mRNAs and proteins. The functional properties of the glutamate receptor, including its ability to gate calcium, are highly dependent on the subunit composition of the assembled receptor. It is our hypothesis that glutamate receptors in the aging brain and in AD undergo changes in their subunit composition, which in turn either protects the neuron or makes them more vulnerable to the pathologic consequences of glutamate receptor activation. Moreover, the vulnerability of a neuron to glutamate is enhanced significantly if a cell is in a state of disequilibrium with respect to intracellular calcium levels. Thus, factors that may contribute to the increased influx of calcium into a cell (e.g., the presence of Aβ) and/or impede the flow of calcium from the cell (i.e., impaired Na^+/Ca^{2+} exchanger) will enhance glutamate receptor-mediated toxicity. It is important to note that many of the mechanisms involved in the removal of calcium from the cell are highly energy dependent, thereby supporting the notion that any process that compromises glucose/energy metabolism may contribute to the pathologic consequences of glutamate receptor activation.

Tau Phosphorylation

I. Introduction

The emergence of molecular biology and genetics in neurobiology allows for new classifications of neurodegenerative disorders. Among them, one is based on the nature of abnormal protein aggregates. For instance, it is possible to distinguish α-synucleopathies (Lewy body disease, multiple system atrophy, Parkinson's disease), tauopathies [e.g., Alzheimer's disease (AD) and related disorders with neurofibrillary tangles (NFT), Pick's disease], and poly-Glu inclusions (e.g., ataxia, Huntington's disease) (Goedert *et al*., 1998). This new classification emphasizes the role of these proteins or their modifications in the physiopathological process. This chapter focuses on tauopathies that include many dementing neurodegenerative disorders exhibiting intracellular inclusions made of phosphorylated microtubule-associated tau proteins (Delacourte and Buée, 1997; Goedert, 1998).

Neurodegenerative disorders are characterized by neuronal loss and intraneuronal accumulations of fibrillary materials. Neuropathologists distinguish several intracellular inclusions such as Hirano bodies, Lewy bodies, Pick bodies, and NFT. Hyperphosphorylated microtubule-associated tau proteins are the main components of the aggregated filaments found in NFT and Pick bodies. These tau aggregates are consistently found in AD (Brion *et al.*, 1985), amyotrophic lateral sclerosis/parkinsonism–dementia complex of Guam (ALS/PDC) (Joachim *et al*., 1987; Buée-Scherrer *et al*., 1995), progressive supranuclear palsy (PSP) (Pollock *et al*., 1986; Hauw *et al*., 1990), and Pick's disease (Pollock *et al*., 1986; Hof *et al*., 1994a). They have been described in patients with myotonic dystrophy (Kiuchi *et al*., 1991; Vermersch *et al*., 1996) and in other rare conditions. They are also seen in normal aging (Delaère *et al*., 1989).

We will first describe what is known about tau structure at the gene and protein levels. We will then discuss tau phosphorylation among neurodegenerative disorders focusing on AD, as most of our knowledge on tau proteins derives from data obtained in AD. Finally, we will discuss how the study of modified tau proteins in these disorders allows for a better understanding of the disease process and how tau phosphorylation may be possibly considered as a biological marker of tauopathies.

II. Tau Proteins

A. Structure and Roles

Tau proteins belong to the microtubule-associated family (Weingarten *et al*., 1975) and are involved in microtubule assembly and stabilization. In human, they are found in neurons, although nonneuronal cells also have trace amounts (Gu *et al*., 1996).

In the adult brain, six tau isoforms are produced from a single gene, located on chromosome 17q21, by alternative mRNA splicing (Fig. 21.1). Exons 2, 3, and 10 are alternatively spliced and allow for six combinations ($2-3-10-$; $2+3-10-$; $2+3+10-$; $2-3-10+$; $2+3-10+$; $2+3+\ 10+$) (Goedert *et al*., 1989a,b; Kosik *et al*., 1989).

At the protein level, tau proteins constitute a family of six isoforms ranging from 352 to 441 amino acids with molecular masses ranging from 45 to 65 kDa when run on SDS–PAGE (Fig. 21.1A). The tau variants differ from each other by the presence or absence of 29 or 58 amino acid inserts located in the amino-terminal part and a 31 amino acid repeat located in the carboxy-terminal part. In absence of the latter, which is encoded by exon 10, the spliced products give rise to three tau isoforms with three repeats (3R). The three other tau isoforms contain this 31 amino acid repeat and thus have four repeats (4R). These repeats and their adjacent domains constitute the microtubule-binding domains of tau (Lee *et al*., 1988, 1989; Goedert *et al*., 1989a). In normal cerebral cortex, 3R-tau isoforms are slightly more predominant than 4R-tau isoforms (Goedert *et al*., 1989a). Furthermore, the two tau isoforms with the 58 amino acid insert are weakly expressed (Hong *et al*., 1998; Mailliot *et al*., 1998a). Finally, tau isoforms may be distributed differentially in neuronal subpopulations. For instance, 4R-tau isoforms are not detected by *in situ* hybridization in granular cells of the dentate gyrus (Goedert *et al*., 1989a). These variations indicate that the different domains of tau are likely to be involved in various physiological functions.

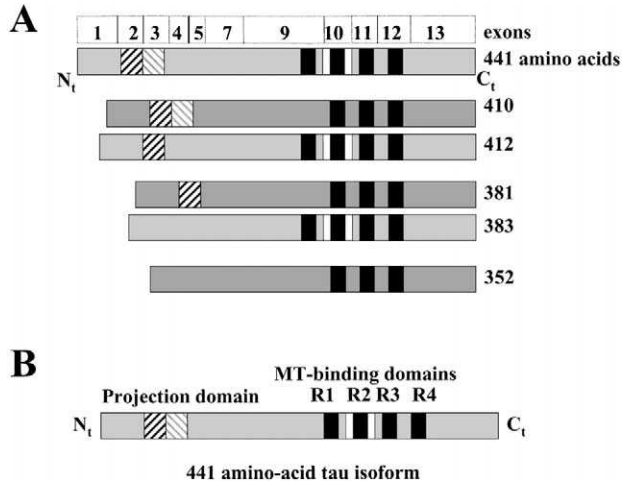

FIG. 21.1. (A) Schematic representation of the six brain tau isoforms (ranging from 352 to 441 amino acids). Constitutive and cassette exons code for different tau regions. Alternative splicing of the exons 2, 3, and 10 allows the six combinations (2−3−10−; 2+3−10−; 2+3+10−; 2−3−10+; 2+3−10+; 2+3+10+). They differ from each other by the addition of one or two 29 amino acid inserts [encoded by exons 2 (dark hatched box) and 3 (light hatched box)] in the amino-terminal domain in combination with either three (R1, R3, and R4) or four (R1–R4) microtubule-binding domains [referred to as 3R (light gray) and 4R (dark gray), respectively]. The fourth microtubule-binding domain (R2) is encoded by exon 10 (white box). (B) Protein domains of the longest brain tau isoform. The amino-terminal region is highly acidic and is referred to as the projection domain. The four repeat domains (R1–R4) constitute the microtubule-binding domains in the carboxy midpart of tau protein.

The two 29 amino acid sequences encoded by exons 2 and 3 are highly acidic and give different lengths to the amino-terminal part of tau proteins. They are referred to as the projection domain as this amino-terminal part projects from the microtubule surface and interacts with other cytoskeletal elements, cytoplasmic organelles, and plasma membrane (Fig. 21.1) (Delacourte and Buée, 1997; Mandelkow and Mandelkow, 1998).

As indicated earlier, the carboxy-terminal part of tau proteins is characterized by the presence of three or four microtubule-binding domains (Fig. 21.1). These repetitive domains are the repeats encoded by exons 9–12. The 3R or 4R is made of a highly conserved 18 amino acid repeat separated from each other by less conserved 13 or 14 amino acid interrepeat domains. It has been demonstrated that adult 4R tau isoforms are more efficient at promoting microtubule assembly than 3R tau isoforms. Data indicate that a heptapeptide (K_{224}KVAVVR$_{230}$) located in the proline-rich region has a high microtubule-binding activity in combination with the repeats regions (Fig. 21.2) (Goode *et al*., 1997). However, microtubule assembly also depends partially on the phosphorylation state of tau proteins: phosphorylated tau proteins are less effective than nonphosphorylated tau on microtubule polymerization.

B. Tau Phosphorylation and Physiology

1. Phosphorylation Sites

There are 80 putative Ser or Thr phosphorylation sites on the longest human brain tau isoform (441 amino acids), and tau proteins can be phosphorylated at multiple sites, some of which regulate their microtubule-binding properties. The phosphorylation sites can be divided in two classes: Ser/Thr-Pro and non-Ser/Thr-Pro sites. The first class includes sites mostly located in both regions flanking the microtubule-binding domains, whereas the second one includes sites all along the tau molecule.

Using phosphorylation-dependent monoclonal antibodies against tau, mass spectrometry, and sequencing, at least 30 Ser/Thr sites have been found to be phosphorylated (Table 21.1; Fig. 21.3) (Hasegawa *et al*., 1992; Morishima-Kawashima *et al*., 1995; Lovestone and Reynolds, 1997; Roder *et al*., 1997; Hanger *et al*., 1998; Johnson and Hartigan, 1998). All of these sites are localized outside the microtubule-binding domains with the exception of Ser262 (R1), Ser285 (R1-R2 IR), Ser305 (R2-R3 IR), Ser324 (R3), Ser352 (R4), and Ser356 (R4) (Goedert *et al*., 1989a,b; Seubert *et al*., 1995; Roder *et al*., 1997). Most of these phosphorylation sites are on Ser-Pro and Thr-Pro motives. A number of sites on non-Ser/Thr-Pro sites have also been identified. The different states of tau phosphorylation result from the activity of specific kinases and phosphatases.

2. Kinases

Most of the kinases involved in phosphorylation of the first class of tau sites are part of the proline-directed protein kinases

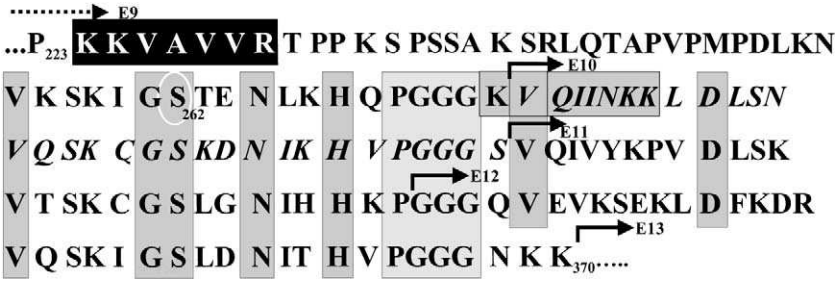

FIG. 21.2. Partial sequence of the 441 amino acid tau isoform (Pro223-Lys370), including microtubule-binding domains. Consensus sequences among the four microtubule-binding domains are in gray. Other major sequences with microtubule-binding properties are the heptapeptide in exon 9 (white characters/black box), R1–R2 inter-repeat (gray characters/gray box), and the phosphorylation site Ser262 (circle). The sequence encoded by exon 10 is in italic. The beginning of sequences encoded by exons 10, 11, 12, and 13 is indicated by an arrow.

[a]Ser/Thr sites are numbered according to the longest human tau isoform (441 amino acids). Ser/Thr sites followed by a proline are indicated by a P after the numbering. Antibodies that label phosphorylated sites are in columns 2 (abnormal phosphorylation, in bold face) and 3. The (+) signs indicate that this kinase phosphorylates tau on this particular site. CaMKII, calcium/calmodulin protein kinase II; CKI/CKII, casein kinases I and II; GSK3, glycogen synthase kinase 3; MAPK, mitogen-activated protein kinases; MARK, microtubule affinity regulating kinases; PhK, phosphorylase kinase; SAPK, stress-activated protein kinases.

(PDPK), which include mitogen-activated protein (MAP) kinases [erk1/2 and stress-activated protein kinases (SAPK)] (Drewes *et al*., 1992; Roder *et al*., 1997; Goedert *et al*., 1997), glycogen synthase kinase 3 (GSK3) (Hanger *et al*., 1992), and cyclin-dependent kinases, including cdc2 and cdk5 (Baumann *et al*., 1993). The second class includes non-Ser/Thr-Pro sites and can be phosphorylated by many other protein kinases, including microtubule affinity-regulating kinase (MARK) (Drewes *et al*., 1997), Ca^{2+}/calmodulin-dependent protein kinase II (CaMPK II) (Baudier and Cole, 1987), cyclic AMP-

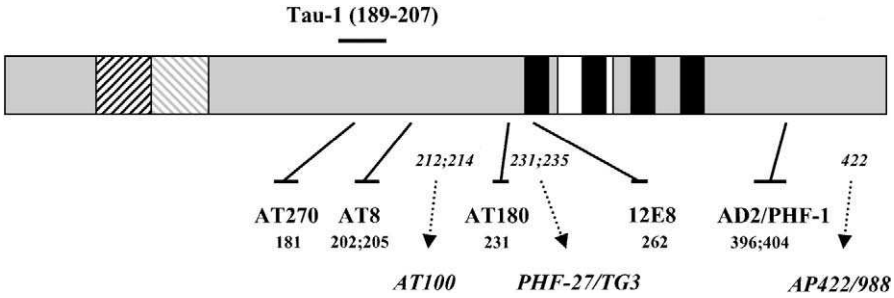

FIG. 21.3. Binding sites of anti-tau antibodies. The different well-known antibodies and their binding sites are represented on the schematic map of the 441 amino acid tau isoform (color codes are similar to those described in Fig. 21.1). With the exception of Tau-1, which recognizes the dephosphorylated 189–207 amino acid sequence, all antibodies bind to phosphorylated epitopes. Antibodies that recognize abnormal tau phosphorylation are in italic.

dependent kinase (PKA) (Litersky and Johnson, 1992), casein kinase II (Greenwood *et al*., 1994), and phosphorylase K (Paudel, 1997) (Table 21.1).

Numerous kinases, proline directed and non-proline directed, have to be used in tandem in order to obtain a complete phosphorylation of recombinant tau, which may be positively modulated at the substrate level by non-PDPK-catalyzed phosphorylations (Singh *et al*., 1996; Mandelkow and Mandelkow, 1998).

3. Phosphatases

Tau proteins from brain tissue or neuroblastoma cells are dephosphorylated rapidly by endogenous phosphatases (Matsuo *et al*., 1994; Buée-Scherrer *et al*., 1996a; Sontag *et al*., 1996; Soulié *et al*., 1996), such as Ser/Thr phosphatase proteins 1, 2A, 2B (calcineurin), and 2C, which are present in the brain (Cohen, 1997). Purified phosphatase proteins 1, 2A, and 2B can dephosphorylate tau proteins (Goedert *et al*., 1992a; Fleming and Johnson, 1995; Goedert *et al*., 1995). Like kinases, phosphatases have many direct or indirect physiological effects and counterbalance the action of kinases. Phosphatases acting on tau are regulated developmentally and may be associated with microtubules (Dudek and Johnson, 1995). For instance, protein phosphatase 1 is targeted to microtubules by tau proteins (Liao *et al*., 1998).

4. Phosphorylation Regulates Different Roles of Tau Proteins

a. Tau Phosphorylation and Microtubule Assembly. Tau proteins bind microtubules through their microtubule-binding domains. However, microtubule assembly depends partially on the phosphorylation state of tau proteins: phosphorylated tau proteins are less effective than nonphosphorylated tau on microtubule polymerization (Lindwall and Cole, 1984; Drubin and Kirschner, 1986). Phosphorylation of Ser262 alone reduces the affinity of tau for microtubules *in vitro* dramatically (Biernat *et al*., 1993). Nevertheless, this site alone, which is present in fetal tau and adult tau, as well as in hyperphosphorylated tau proteins found in NFT, is insufficient to eliminate tau binding to microtubules (Seubert *et al*., 1995). The proline-rich, amino-terminal region of tau proteins is highly phosphorylated, and hyperphosphorylation may also compete for ionic interactions that are important for structural–functional interactions between proline-rich and repeat regions (Goode *et al*., 1997). Thus, phosphorylation outside the microtubule-binding domains can strongly influence tubulin assembly by modifying tau-microtubule affinity.

b. Tau Phosphorylation in Development and Cell Sorting. Phosphorylation of tau proteins is regulated developmentally (Pope *et al*., 1993; Mawal-Dewan *et al*., 1994; Dudek and Johnson, 1995; Rösner *et al*., 1995; Saito *et al*., 1995). It is high in fetal and decreases with age due to phosphatase activation (Mawal-Dewan *et al*., 1994; Rösner *et al*., 1995). Also, there is likely an independent regulation of multiple phosphorylation sites within subcellular domains of developing neurons (Szendrei *et al*., 1993; Rebhan *et al*., 1995; Black *et al*., 1996; Kempf *et al*., 1996). However, compared to other MAPs, tau proteins are preferentially axonal (Litman *et al*., 1993, 1994). It was also shown that microtubules play a crucial role in axonal sorting of tau mRNA (Litman *et al*., 1994; Behar *et al*., 1995). Thus, both tau phosphorylation and microtubules may be involved in tau trafficking and cell sorting (nuclear, axonal, or somatodendritic) (Litman *et al*., 1993, 1994; Hirokawa *et al*., 1996).

In summary, these observations show that tau proteins are found in all cell compartments, but in different phosphorylation states. Phosphorylation seems to affect several sites simultaneously. Furthermore, within the same compartment, variability in the degree of phosphorylation is observed during development, due to the expression of several adult isoforms, and because the ratio between kinases and phosphatases is modified during development (Pope *et al*., 1993; Mawal-Dewan *et al*., 1994; Dudek and Johnson, 1995; Buée-Scherrer *et al*., 1996a). Phosphorylation, in combination with the type of isoform, can modulate the properties of tau proteins. In turn, tau proteins provide the microtubule with its own identity and physical characters (rigidity, length, stability, interactive capacity with other organelles). Therefore, by regulating microtubule assembly, tau proteins play a role in modulating the functional organization of the neuron, particularly in axonal morphology, growth, and cell polarity.

III. Tau Phosphorylation and Pathology

Phosphorylation is a key posttranslational modification in tau metabolism. However, in pathological conditions, hyper-

phosphorylation occurs and modifies tau biochemical properties, in that tau proteins become longer and stiffer (Hagestedt *et al*., 1989). In neurodegenerative disorders, hyperphosphorylated tau proteins are found aggregated into filamentous neuronal inclusions.

A. Nonhereditary Disorders

1. Sporadic Alzheimer's Disease

In AD, these filaments are named paired helical filaments (PHF). The major antigenic components of PHF are tau proteins (Brion *et al*., 1985), and several groups have reported phosphorylation as the major modification in these proteins (Grundke-Iqbal *et al*., 1986; Ihara *et al*., 1986, Flament and Delacourte, 1989; Greenberg *et al*., 1992). Their biochemical characterization by immunoblotting reveals the presence of a triplet of proteins (tau 55, 64, and 69) also referred to as A68, or PHF-tau (Delacourte *et al*., 1990; Lee *et al*., 1991; Goedert *et al*., 1992b; Greenberg *et al*., 1992). However, a 72 to 74 kDa component is also present in only very low amounts (Fig. 21.4A) (Mulot *et al*., 1994; Sergeant *et al*., 1997a). Using PHF-tau preparations, Goedert and colleagues (1992b) showed that dephosphorylated PHF-tau proteins have a more similar electrophoretic mobility than the six recombinant tau isoforms. The following scheme is now well established (Fig. 21.5): tau 55 results from the phosphorylation of the fetal isoform (2−, 3−, 10−), tau 64 from the phosphorylation of tau variants with one cassette exon (2+, 3−, 10− and/or 2−, 3−, 10+), and tau 69 from the phosphorylation of tau variants with two cassette exons (2+, 3+, 10− and/or 2+, 3−, 10+). Phosphorylation of the longest tau isoform (2+, 3+, 10+) induces the formation of the additional hyperphosphorylated tau 74 variant (Sergeant *et al*., 1995, 1997a; Mailliot *et al*., 1998a).

After death, native tau proteins from brain tissue are dephosphorylated rapidly by endogenous phosphatases, whereas PHF-tau are not (Matsuo *et al*., 1994; Mawal-Dewan *et al*., 1994; Buée-Scherrer *et al*., 1996a). Thus, in autopsy-derived materials, tau phosphorylation is a good marker of a pathological process. In this regard, tau proteins may be divided into four states: dephosphorylated, phosphorylated, hyperphosphorylated, and abnormally phosphorylated, which reflect their differences in both autopsy- and biopsy-derived materials (Table 21.2). Indeed, despite the fact that many phosphorylation sites are common to aggregated tau proteins, referred to as PHF-tau in AD, and native tau obtained from biopsy-derived materials, there are biochemical differences that distinguish them and support the concept of ''pathological tau.'' First, two-dimensional immunoblot analysis reveals that PHF-tau are more acidic than native tau (Sergeant *et al*., 1995). Second, the main difference between biopsy and postmortem tissues is that PHF-tau are aggregated, whereas tau from biopsies are not. Therefore, insoluble polymers of tau are present exclusively in AD brain extracts, which are visualized as ''smears'' on Western blots. Third, hyperphosphorylation generates differences that can be visualized by a few phosphorylation-dependent antibodies such as AT100 (Matsuo *et al*., 1994), AP422 (Hasegawa *et al*., 1996), 988 (Bussière *et al*., 1999), PHF-27 (Hoffmann *et al*., 1997), or the TG/MC antibodies (i.e., TG3) (Vincent *et al*., 1996) (Table 21.2; Fig. 21.3).

Altogether, these results show that the main feature of pathological tau is their aggregation into polymers that constitute neurofibrillary lesions. In addition, and possibly in association with the aggregation process, specific abnormal phosphorylation sites are also present on PHF-tau. Both this abnormal tau phosphorylation and the tau hyperphosphorylation (Table 21.2) are the ones that are analyzed in the next paragraphs. We do not consider normal tau phosphorylation, which is found only in biopsy-derived materials, as all neuropathological analyses are performed on autopsy-derived materials with more than 3 hr postmortem delays.

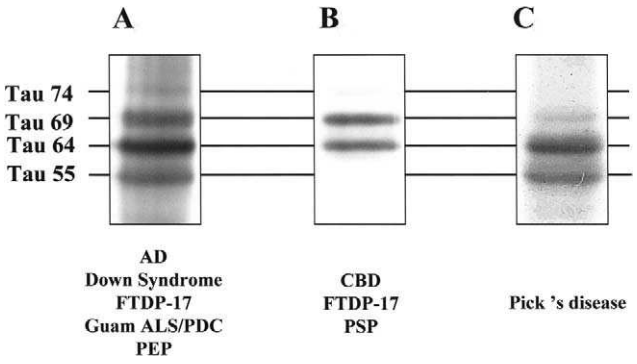

FIG. 21.4. Typical Western blots using the phosphorylation-dependent monoclonal antibody AD2 exhibiting the electrophoretic tau profiles encountered in tauopathies: the triplet tau 55, 64, and 69 and the minor 74 kDa tau variant (A), the tau doublet 64 and 69 and the minor 74 kDa variant (B), and the other doublet tau 55 and 64 and the minor 69 kDa tau variant (C). PEP, postencaphalitic parkinsonism.

2. Corticobasal Degeneration and Progressive Supranuclear Palsy

Tau aggregation is also observed in NFT in corticobasal degeneration (CBD) and progressive supranuclear palsy (see Chapter 13). However, in PSP and CBD, tau aggregates are characterized biochemically by a doublet (tau 64 and 69) and a minor variant at 74 kDa (Fig. 21.4B) (Flament *et al*., 1991; Ksiezak-Reding *et al*., 1994; Vermersch *et al*., 1994; Buée-Scherrer *et al*., 1996b; Feany and Dickson, 1996). In recent studies, tau isoforms with a sequence encoded by exon 10 were found in CBD and PSP, whereas tau isoforms without exon 10 were not detected. These data suggested that only phosphorylated tau isoforms with four microtubule-binding domains aggregate into filaments in CBD and PSP, (Fig. 21.6) (Mailliot *et al*., 1998a; Sergeant *et al*., 1999). The specific pathological tau epitopes found in AD are also observed on aggregated tau proteins in PSP and CBD, as visualized by antibodies AT100 (Schmidt *et al*., 1996; Mailliot *et al*., 1998a; Sergeant *et al*., 1999) and 988 (Bussière *et al*., 1999).

3. Pick's Disease

In Pick's disease, intraneuronal tau aggregates assemble into characteristic spherical Pick bodies (see Chapter 12). Tau from Pick bodies correspond to another doublet (tau 55 and 64) with a minor variant at 69 kDa (Fig. 21.4C) (Delacourte *et al*., 1996). The 55 and 64- kDa doublet is characteristic of Pick's disease because it is different from the AD profile or the CBD/

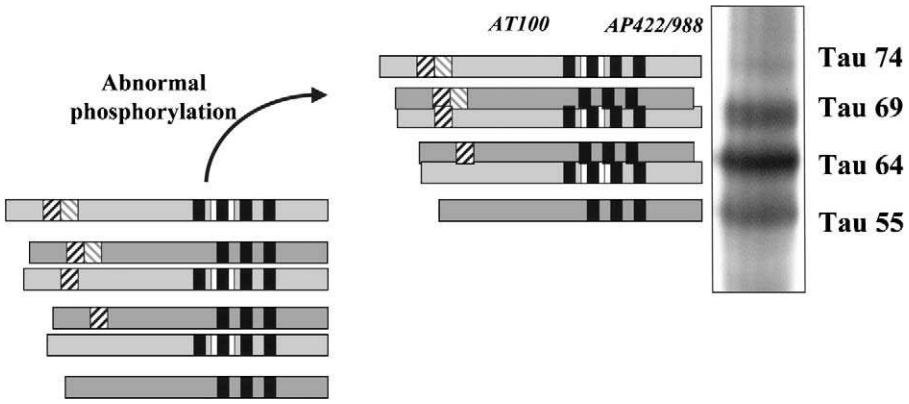

FIG. 21.5. Schematic representation of abnormal phosphorylation of the six brain tau isoforms in AD leading to higher molecular weight tau variants (tau 55, 64, and 69 and the minor tau 74 variant). It should be noted that the two tau isoforms with the 58 amino acid insert are expressed more weakly than the others. Tau 55 results from the phosphorylation of the shortest isoform (2−, 3−, 10−), tau 64 from the phosphorylation of tau variants with one cassette exon (2+, 3−, 10− and 2−, 3−, 10+), and tau 69 from the phosphorylation of tau variants with two cassette exons (2+, 3+, 10− and 2+, 3−, 10+). Phosphorylation of the longest tau isoform (2+, 3+, 10+) induces the formation of the additional hyperphosphorylated tau 74 variant. The color codes are similar to those used in Fig. 21.1. (Right) A typical immunoblot using the phosphorylation-dependent monoclonal antibody AD2, which recognizes phosphorylated Ser396 and 404, allowing the visualization of the AD-type electrophoretic profile (tau 55, 64, and 69 and the minor tau 74 variant). Antibodies AT100 and AP422/988 also labeled the tau triplet.

TABLE 21.2 Relative Tau Immunoreactivity among Neurodegenerative Disorders Using Phosphorylaltion-Dependent Antibodies

	AD2/PHF-1	12E8	AT100	988/AP422
AD	+++	+++	+ ++	+++
CBD/PSP	++	++	++	++
Pick	++	−	++	++
Biopsy-C	+	+	−	−
Autopsy-C	−	−	−	−

[a] +++, strong immunoreactivity; ++, medium immunoreactivity; +, immunoreactivity; −, lack of staining. Biopsy-C; biopsy-derived control materials; autopsy-C, autopsy-derived control materials.

PSP profile (Fig. 21.4) (Buée-Scherrer *et al*., 1996b; Mailliot *et al*., 1998a). The characteristic electrophoretic pattern of pathological tau in Pick's disease is well correlated with the presence of Pick bodies (Delacourte *et al*., 1996). As indicated previously, these neuronal cells do not contain tau isoforms with exon 10 (Goedert *et al*., 1989a). Interestingly, Pick bodies and the tau doublet tau 55 and 64 are not labeled with immunological probes directed against the sequence encoded by exon 10 (Sergeant *et al*., 1997b; Delacourte *et al*., 1998a; Mailliot *et al*., 1998a), suggesting that only 3R-tau isoforms aggregate into Pick bodies (Fig. 21.7). Moreover, Pick bodies and the Pick's disease tau doublet could not be detected by the monoclonal antibody 12E8 raised against the phosphorylated residue Ser 262 (Probst *et al*., 1996; Mailliot *et al*., 1998a),

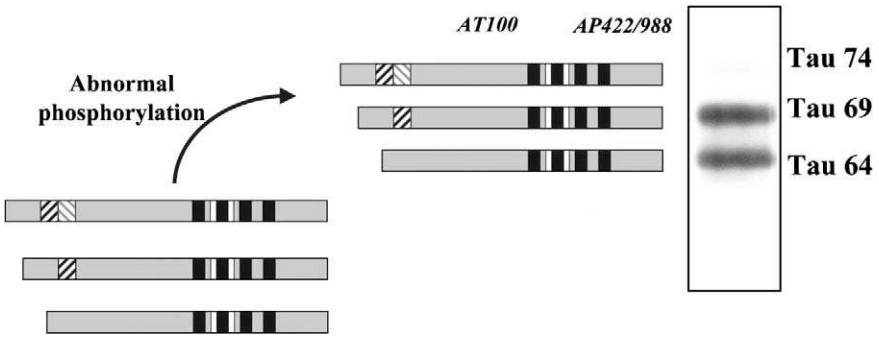

FIG. 21.6. Schematic representation of abnormal phosphorylation of the three brain 4R-tau isoforms in CBD and PSP leading to higher molecular weight tau variants (tau 64 and 69 and the minor tau 74 variant). Tau 64 results from the phosphorylation of the tau isoform with one cassette exon (2−, 3−, 10+) and tau 69 from the phosphorylation of the tau isoform with two cassette exons (2+, 3−, 10+). Phosphorylation of the longest tau isoform (2+, 3+, 10+), which is expressed weakly, induces the formation of the additional hyperphosphorylated tau 74 variant. The color codes are similar to those used in Fig. 21.1. (Right) A typical immunoblot using the phosphorylation-dependent monoclonal antibody AD2, which recognizes phosphorylated Ser396 and 404, allowing the visualization of the CBD/PSP-type electrophoretic profile (tau55, 64, and 69 and the minor tau 74 variant). Antibodies AT100 and AP422/988 also labeled the tau doublet.

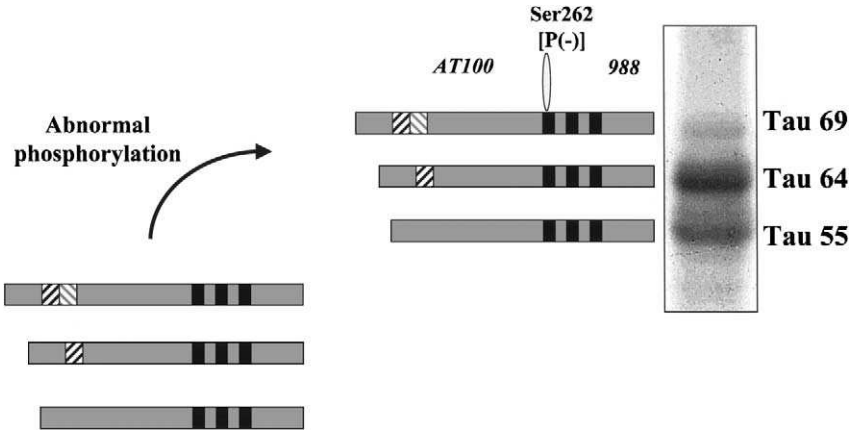

FIG. 21.7. Schematic representation of abnormal phosphorylation of the three brain 3R-tau isoforms in Pick's disease leading to higher molecular weight tau variants (tau 55 and 64 and the minor tau 69 variant). Tau 55 results from the phosphorylation of the shortest isoform (2−, 3−, 10−) and tau 64 from the phosphorylation of the tau isoform (2+, 3−, 10−). Phosphorylation of the weakly expressed tau isoform with two cassette exons (2+, 3+, 10+) induces the formation of the additional hyperphosphorylated tau 69 variant. The color codes are similar to those used in Fig. 21.1. (Right) A typical immunoblot using the phosphorylation-dependent monoclonal antibody AD2, which recognizes phosphorylated Ser396 and 404, allowing the visualization of the Pick-type electrophoretic profile (tau 55 and 64, and the minor tau 69 variant). Antibodies AT100 and 988 also labeled the tau doublet, whereas the 12E8 antibody, which recognizes phosphorylated Ser262, does not label it.

whereas in cells transfected with 3R tau isoforms, this site was found phosphorylated (Mailliot *et al*., 1998a). These data suggested that either Pick bodies bearing cells do not express kinases phosphorylating at Ser 262 or these kinases and tau proteins are not expressed in the same cell compartments. However, specific antibodies to pathological tau, including AT100 and 988, labeled the Pick's disease tau doublet (Sergeant *et al*., 1997b; Bussière *et al*., 1999).

Thus, particular sets of tau isoforms that aggregate in one given neurodegenerative disorder may lead to a specific electrophoretic tau profile (Delacourte *et al*., 1998a; Mailliot *et al*., 1998a). The abnormal phosphorylation visualized in AD using specific immunological tools, including AT100 and 988, is also observed on aggregated tau isoforms found in other neurodegenerative disorders. These data indicate that abnormal tau phosphorylation is a good biochemical marker of the neurofibrillary degeneration processes. This observation is still valuable in hereditary disorders as demonstrated in the following paragraphs.

B. Examples of Hereditary Disorders

1. Myotonic Dystrophy

Myotonic dystrophy (MD) is a slowly progressive multisystemic disorder characterized principally by myotonia and muscular atrophy. Impairment of intellectual and cognitive function in MD has also been reported (Jaspert *et al*., 1995). Myotonic dystrophy is an autosomal dominant defect in which the molecular basis is an unstable CTG trinucleotide repeat in the 3′-untranslated region of a gene encoding a putative serine/threonine protein kinase (myotonic dystrophy protein kinase: DMPK) located on chromosome 19 (Groenen and Wieringa, 1998).

Typically, neuropathological observations of the brain in MD show reduced brain weight, minor abnormalities in gyral architecture, and, microscopically, a disordered cortical cellular arrangement with neurons also present in subcortical white matter and intracytoplasmic inclusion bodies in cortical and subcortical structures (Ono *et al*., 1987). The presence of abnormally frequent NFT has also been reported in the temporal lobe, especially in the hippocampal cortex from patients with MD (Kiuchi *et al*., 1991). By immunoblotting, phosphorylated tau proteins are also detected in the hippocampus, the entorhinal cortex, and in most of the temporal areas. The amounts of pathological tau proteins are higher in the most severely affected MD cases but are always lower than in AD brain homogenates. Their profile differs from the characteristic triplet of AD, with low amounts of the tau 64 and 69 variants but high amounts of the tau 55 variant (Vermersch *et al*., 1996). The interesting observation about this pathology is the possible link between the genetic dysfunction of the Ser/Thr protein kinase and the presence of pathological tau protein. These observations demonstrate that changes in kinase expression can provoke a cascade of pathological events, including the aggregation of one tau isoform in specific brain areas (Vermersch *et al*., 1996).

Different tau electrophoretic profiles are found among neurodegenerative disorders. They are related to a combination of specific tau isoforms and particular phosphorylation sites. Because the myotonin-protein kinase is expressed in subsets of neurons (Balasubramanyam *et al*., 1998), the tau profile in MD may result from the phosphorylation of the shortest tau isoform by the myotonin-protein kinase in these subpopulations of neurons.

2. Frontotemporal Dementia and Parkinsonism Linked to Chromosome 17 (FTDP-17)

Some familial cases with frontotemporal dementia or related disorders, including disinhibition, atypical dementia, parkin-

sonism, and amyotrophy complex, familial progressive subcortical gliosis, and progressive parkinsonism dementia with pallidopontonigral degeneration exhibit a linkage with chromosome 17q21-22 and have been included in a group of pathologies referred to as frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) (Foster *et al*., 1997; Spillantini *et al*., 1998a).

Several mutations have been described on the tau gene in FTDP-17 (Clark *et al*., 1998; Dumanchin *et al*., 1998; Hutton *et al*., 1998; Poorkaj *et al*., 1998; Spillantini *et al*., 1998b; D'Souza *et al*., 1999; Murrell *et al*., 1999; Rizzu *et al*., 1999). Among the families studied, about 10 mismutations are found in coding regions and other mutations affect the splicing region after exon 10 (Table 21.3; Fig. 21.8). The presence of tau-immunoreactive intraneuronal and glial inclusions is a very common neuropathological feature.

The most prominent effect of mutations is a reduced ability of the mutated tau proteins to bind to microtubules. This reduced ability may be related to either a mutation in the microtubule-binding regions or close to a phosphorylation site involved in the regulation of tau binding to microtubules. Finally, other mutations (intronic and exonic close to a splicing site) enhance the formation of tau isoforms with 4R.

Tau isoforms (mutated, overexpressed, etc.) aggregate into filaments. Analysis of these filaments (straight, twisted ribbons, PHF) always reveals that aggregated tau isoforms leads to particular electrophoretic profiles (the doublet tau 64, and 69 and the triplet tau 55, 64 and 69) and are phosphorylated (Goedert *et al*., 1998; Spillantini *et al*., 1998a,b). These data indicate that in hereditary disorders where a tau mutation is involved, hyperphosphorylation of tau proteins still occurs and thus is a good biochemical marker of the fibrillary degeneration process.

TABLE 21.3 Tau Mutations in FTDP-17

Tau mutations	Location	Tau pathology	Reference
K257T	Exon 9	Pick doublet	Unpublished data
1260V	Exon 9	Pick doublet	Unpublished data
G272V	Exon 9	AD triplet	Hutton *et al*. (1998)
N279K	Exon 10	PSP doublet	Clark *et al*. (1998)
ΔK280	Exon 10		Rizzu *et al*. (1999)
L284L	Exon 10	PSP doublet	D'Souza *et al*. (1999)
P301L	Exon 10	PSP doublet	Hutton *et al*. (1998)
P301S	Exon 10	PSP doublet	Bugiani *et al*. (1999)
S305N	Exon 10	PSP doublet	D'Souza *et al*. (1999)
+3	Intronic	PSP doublet	Spillantini *et al*. (1998a,b)

R406W	Exon 13	AD triplet	Hutton *et al*. (1998)

C. Combination of Tau Isoforms and Phosphorylation: A Better Understanding of the Degenerating Process

Tau isoforms with 3R and 4R may be expressed differentially and their aggregation may lead to different biochemical signatures characterized by tau doublets and the tau triplet. First, in hereditary disorders such as FTDP-17, the role of some tau mutations clearly emphasizes these differences of expression. Second, in the absence of mutations, Goedert *et al*. (1989a) showed that neurons do not express 3R and 4R tau isoforms equally (e.g., granule cells of the dentate gyrus), and Delacourte and colleagues (1998a) clearly demonstrated that only 3R tau isoforms are found in Pick bodies bearing cells such as granule cells. Third, tau proteins are found principally in axons. However, in some neurodegenerative disorders, hyperphosphorylated tau proteins accumulate in somatodendritic compartments. As indicated previously, tau trafficking is also phosphorylation dependent. Altogether, these observations indicate that in many tauopathies, different processes, including tau mutations/polymorphisms, aberrant cell trafficking, and cell vulnerability, act to affect tau metabolism leading to degeneration (Fig. 21.9). Whatever these processes might be, they lead to abnormal tau phosphorylation. Thus, it may be interesting to use abnormal tau phosphorylation as a biochemical marker of neurofibrillary degeneration.

IV. Abnormal Tau Phosphorylation as a Biochemical Marker

A. Kinases/Phosphatases Involved in Tau Abnormal Phosphorylation

Because phosphorylation of tau proteins is a common feature of neurodegenerative disorders referred to as tauopathies, a quantitative analysis of this phosphorylation may be useful in defining the degree of neurodegeneration in these disorders. Nevertheless, as described earlier, most of the phosphorylation sites found on pathological tau proteins are also detected in tau proteins obtained from biopsy-derived materials. However, tau proteins are hyperphosphorylated in pathological conditions and exhibit abnormally phosphorylated epitopes as shown by using particular antibodies such as 988, AP422, AT100, PHF-27, and TG3 (Matsuo *et al*., 1994; Hasegawa *et al*., 1996; Hoffmann *et al*., 1997; Jicha *et al*., 1999; Bussière *et al*., 1999). This hyperphosphorylation may lead to tau aggregation and may be related to either an increase in kinase activity or a decrease in phosphatase activity (Trojanowski and Lee, 1995). Many kinases have been involved (Lovestone and Reynolds, 1997). For instance, glycogen synthase kinase 3 (GSK3) is a kinase candidate (Hanger *et al*., 1992; Baum *et al*., 1996). However, these data are controversial as other studies do not support an involvement of GSK3 in tau hyperphosphorylation (Harr *et al*., 1996; Hasegawa *et al*., 1996). Mitotic protein kinases may also play a major role in tau phosphorylation, as many mitosis-specific epitopes are found in NFT (Kondratick and Vandre, 1996; Vincent *et al*., 1996). Stress-activated protein kinases are also of interest (Kyriakis *et al*., 1994; Cuenda *et al*., 1997). All SAP kinases (JNK/SAPK1, p38/SAPK2, SAPK3, SAPK4) have been shown to phosphorylate tau pro-

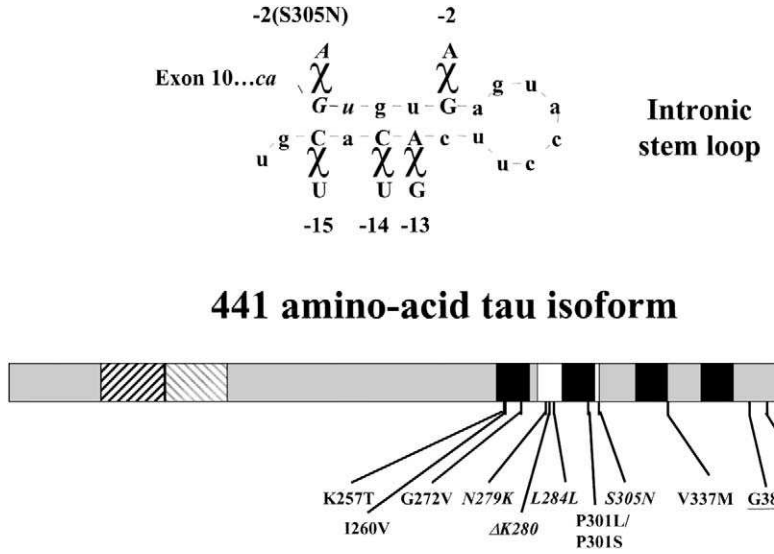

FIG. 21.8. (Top) Nucleotidic sequence of the end of exon 10 (italic black letters) and its 3′ intronic region. All FTDP-17-mutated nucleotides are in capital letters. Mutations are only shown in the stem loop structure. (Bottom) Schematic representation of the longest brain tau isoform and location of FTDP-17 mutations in the coding region. FTDP-17 mutations affecting alternative splicing are in italic, those affecting microtubule-binding domains are in bold, and those outside the microtubule-binding domains are underlined. S305N corresponds to the −2 mutation of the stem-loop structure (see top part of figure).

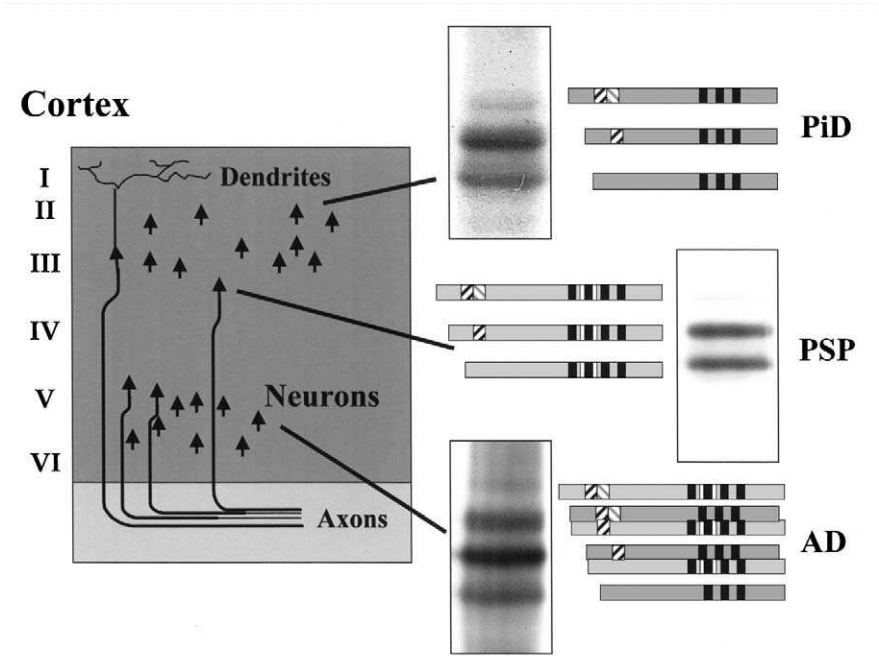

FIG. 21.9 Schematic representation of the laminar distribution of neurons in human isocortex. Because laminar and regional distributions of NFT are different among the dementing conditions, the presence of a pathologic tau triplet or doublet may be specific of a subtype of neurons. Thus, we suggest that different tau isoforms (with or without exon 10) are expressed in subsets of neurons that exhibit different vulnerability in addition to different sets of enzymes (kinases, phosphatases, etc.). Following abnormal phosphorylation, tau isoforms aggregate into filaments and display a particular electrophoretic profile when analyzed by immunoblotting. The color codes for tau isoforms are similar to those used in Fig. 21.1. (Right) A typical immunoblot using the phosphorylation-dependent monoclonal antibody AD2, which recognizes phosphorylated Ser396 and 404, allowing the visualization of the different electrophoretic tau profiles (triplet and doublets). PiD, Pick's disease.

teins *in vitro* (Goedert *et al*., 1997). Altogether, these data suggest that the SAPK family is an interesting candidate for the pathological phosphorylation of tau proteins. Conversely, tau hyperphosphorylation may be related to a decrease in phosphatase activity. Data suggest that phosphatase activities may be decreased in AD brains (Gong *et al*., 1995; Trojanowski and Lee, 1995). Furthermore, phosphatase inhibition in cell models allows the formation of specific AD-type epitopes, such as those recognized by AT100 and AP422/988 antibodies (Caillet-Boudin and Delacourte, 1996; Mailliot *et al*., 1998b).

Actually, the most interesting hypothesis is a sequential phosphorylation of tau proteins in the presence of cofactors (polyanions) leading to conformational changes (Mandelkow and Mandelkow, 1998). Such conclusions are supported by experiments about the AT100 epitope. The appearance of the AT100 epitope on tau proteins is obtained after a sequential phosphorylation of GSK3 in the presence of polyanions (glycosaminoglycans, RNA or lipids) and protein kinase A (Zheng-Fischhöfer *et al*., 1998). Protein kinase A may be a key kinase to obtain abnormal phosphorylation on tau proteins (Jicha *et al*., 1999).

B. Tau Phosphorylation Is a Reliable Marker of Neurofibrillary Degeneration in Aging and AD: Correlates with Cognitive Impairment

Using immunological probes specific of tau phosphorylation sites, it is possible to investigate biochemically NFT in postmortem brain materials from AD patients. There is a strong correlation between the immunohistochemical detection of NFT and the presence of the tau triplet, showing that tau phosphorylation is a reliable and early marker of the degenerating process. Therefore, tau phosphorylation can be used to quantify neurofibrillary degeneration in autopsy-derived brain materials (Flament *et al*., 1990a). Biochemical mappings using immunoblotting and/or ELISA have been performed in several cortical areas of the brain from patients with senile dementia of the Alzheimer type (Vermersch *et al*., 1992a; Holzer *et al*., 1994). Tau phosphorylation is detected in all areas studied, with the exception of some regions such as primary motor and visual cortices (Brodmann areas 4 and 17). The detection is particularly strong in association cortex compared to primary sensory cortex, with the highest levels in temporal neocortical and limbic areas. However, for a given brain area, tau immunoreactivity differs among cases (Vermersch *et al*., 1992a; Holzer *et al*., 1994).

A study of 130 cases ranging from normal aging to severe AD quantified hyperphosphorylated tau by immunoblotting in different cortical areas (Delacourte *et al*., 1998b, 1999). This study shows a sequential progression of neurofibrillary degeneration in cortical brain areas and allows for a classification into 10 stages (S0–S10) (Fig. 21.10). In this scheme, tau hyperphosphorylation is seen consistently in the transentorhinal and entorhinal cortex of nondemented individuals older than 75 years (S1 and S2). In addition, the hippocampus is also frequently affected (S3). This tau phosphorylation is similar to that found in AD brains, with the characteristic tau triplet or PHF-tau (Vermersch *et al*., 1992b; Delacourte *et al*., 1998b; 1999). However, lower amounts of PHF-tau are present in aged controls. In early AD, the neurofibrillary degeneration pathway is highly specific at the beginning of the disease, spreading from the hippocampal formation (S3) to the anterior (S4), inferior (S5), and midtemporal cortex (S6). Then, the disease progresses into association areas of the temporal (superior), parietal, and frontal cortices (S7). Finally, primary motor or sensory areas such as the primary motor cortex (Brodmann area 4) or the primary visual cortex (area 17) are affected (S9a-c). This study shows that neurofibrillary degeneration has to involve almost the entire temporal cortex to induce clear clinical manifestations (Fig. 21.10) (Delacourte *et al*., 1998b, 1999). Comparable data were obtained using a classical immunohistochemical approach on different populations with fewer brain regions investigated (Arnold *et al*., 1991; Dickson *et al*., 1991; Hof *et al*., 1992a; Bouras *et al*., 1993, 1994; Giannakopoulos *et al*., 1994, 1995, 1997; Bierer *et al*., 1995; Duyckaerts *et al*., 1997). Because AD is a disease of the long corticocortical connections, such a hierarchical pathway of neurofibrillary degeneration is not surprising. In fact, these are specifically affected with a well-defined pattern, involving subsets of pyramidal neurons responsible for these connections, which are found mainly in layers III and VI of the neocortex (Morrison and Hof, 1997).

C. Tau Phosphorylation Correlates with Cognitive Impairment in Various Disorders

1. Down Syndrome

Due to the trisomy of chromosome 21, Down syndrome patients have numerous somatic dysfunctions that occur during development. They also develop a variable degree of cognitive impairment, usually leading to dementia. Amyloid deposition is observed in Down syndrome after 15 years, senile plaques are present, followed by neurofibrillary degeneration after 35 years, with tau accumulation (Mann *et al*., 1989; Hof *et al*., 1995). Using immunoblotting, it has been demonstrated that a triplet of pathological tau proteins similar to that found in AD is observed in the neocortex of Down syndrome patients older than 35 years and follows the cognitive impairment (Fig. 21.4A) (Flament *et al*., 1990b). This shows that biochemical dysfunctions linked to tau phosphorylation during Down syndrome are very similar to those found in AD.

2. Parkinsonism

a. Parkinsonism with Dementia. The most characteristic clinical features of Parkinson's disease include resting tremor, expressionless face, rigidity, and slowness in initiating and performing voluntary movements. Approximatively 20% of patients with Parkinson's disease develop dementia (Marder *et al*., 1995), and the cognitive changes evoke a frontal lobe dysfunction that may be a primary event in the disease (Pillon *et al*., 1995; Taylor *et al*., 1986). Neuropathologically, Parkinson's disease is characterized by neuronal loss, especially in substantia nigra and locus coeruleus, and by the presence of intracellular inclusions called Lewy bodies and Lewy neurites (Forno, 1996). Studies suggest that α-synuclein is the major component of Lewy body filaments (Goedert *et al*., 1998). Using immunoblotting, qualitative and quantitative analyses were performed, and tau abnormal phosphorylation

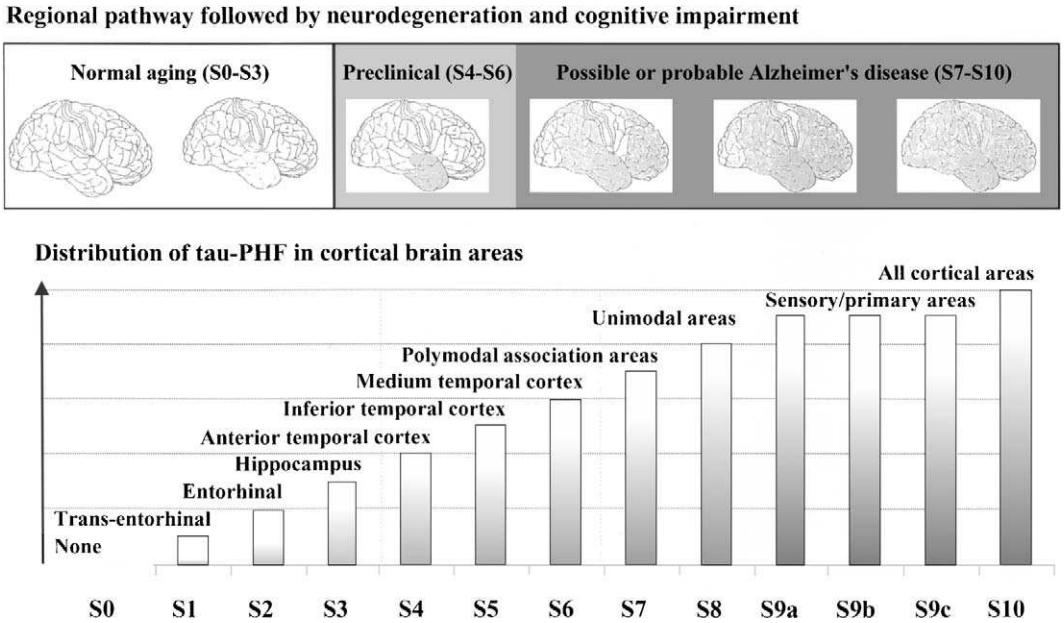

FIG. 21.10. Pathway of neurofibrillary degeneration in aging and Alzheimer's disease (see text). (Top) When PHF-tau are not detected or restricted to the hippocampal formation (S1–S3), subjects are nondemented. When PHF-tau are found in the temporal lobe, AD has began but it could be asymptomatic, as it is the preclinical stage of the disease (S4–S6). When the entire temporal cortex is affected (S7) and later, other brain regions, patients usually exhibit cognitive impairment and are diagnosed with possible or probable AD (S7–S10). (Bottom) PHF-tau distribution is never random. It is stereotyped and hierarchical. It corresponds to 10 brain regions that are successively affected (S1–S10) from the transentorhinal cortex (S1) to all cortical brain areas (S10).

corresponding to a pathological tau triplet similar to that described in AD was found in all demented cases without cortical Lewy bodies (Vermersch *et al*., 1993). The degree of abnormal tau phosphorylation is particularly high in the prefrontal, temporal and entorhinal cortices of Parkinson's disease patients with dementia. Therefore, abnormal tau phosphorylation is found in Parkinson's disease with dementia, but its cortical distribution differs from the pattern seen in AD, with a predominant involvement of prefrontal areas (Vermersch *et al*., 1993). In cases without dementia, tau abnormal phosphorylation is restricted to the hippocampal formation as described in elderly individuals (Vermersch *et al*., 1992b).

b. Postencephalitic Parkinsonism. Some patients who survived the influenza pandemic in the years 1916–1926 later developed postencephalitic parkinsonism (PEP) (Hof *et al*., 1992b; Buée-Scherrer *et al*., 1997). Extrapyramidal symptoms are the major clinical features and affected patients do not exhibit any cognitive changes and are usually neither aphasic nor apraxic. The immunohistochemical analysis of PEP cases demonstrated that NFT are found in variable densities in the hippocampus and entorhinal cortex, in neocortical areas 4, 9, and 20, and in subcortical regions. Higher NFT densities are observed in the hippocampal formation and area 20, compared to areas 4 and 9, and the putamen, indicating that some regions are affected preferentially by the degenerative process (Hof *et al*., 1992b).

Biochemical studies have shown that PEP cases display a tau pathology comparable to AD (Fig. 21.4A). However, the tau 55, 64, and 69 triplet is found in cortical and subcortical brain regions, including primary motor cortex and basal ganglia, in contrast to AD cases where this triplet is mainly restricted to hippocampal formation and association neocortex. Only patients with cognitive impairment display a tau pathology characterized by abnormal phosphorylation in association areas (Buée-Scherrer *et al*., 1997).

c. Guamanian ALS/PDC. The amyotrophic lateral sclerosis/parkinsonism–dementia complex of Guam is a chronic neurodegenerative disorder highly prevalent in the native Chamorro population of Guam island in the western Pacific (Hirano *et al*., 1961) (see Chapter 15). Neuropathologically, Guamanian ALS/PDC shows a severe cortical atrophy and neuronal loss. The neuropathological hallmark of ALS/PDC is the widespread NFT formation (Hirano *et al*., 1961, 1968). Immunohistochemical studies have also revealed that pathological tau proteins are present in NFT of ALS/PDC patients (Hof *et al*., 1994b; Buée-Scherrer *et al*., 1995; Bussière *et al*., 1999). By using immunoblotting and numerous phosphorylation-dependent antibodies, these proteins can be visualized as a triplet tau 55, 64, and 69 (Fig. 21.4A) (Buée-Scherrer *et al*., 1995; Mawal-Dewan *et al*., 1996). According to neuropathological data, and in contrast to AD patients where the tau triplet is found mostly in cortical regions, the Guamanian tau triplet is detected in both cortical and subcortical areas. Finally, Guam ALS/PDC patients are demented only when tau abnormal phosphorylation is found in asssociation areas (Buée-Scherrer *et al*., 1995).

ALS/PDC of Guam and PEP have been linked to external factors such as viruses and toxins that may induce similar neuropathologic changes characterized by the same tau electrophoretic profile. However, it is not known whether tau pathology in Guamanian ALS/PDC is also related to mutations in tau gene in the Chamorro population. Linkage analyses and

genetic studies do not support the involvement of tau as a primary cause for the disease, although it does not rule out the possibility of tau, particularly tau phosphorylation, being involved downstream in the process (Pérez-Tur *et al*., 1999).

d. Progressive Supranuclear Palsy. Progressive supranuclear palsy is a late-onset atypical parkinsonian disorder described by Steele *et al*., in 1964. Dementia is also a common feature at the end stage of the disease (Hauw *et al*., 1990).

The localization of NFT was first described in subcortical structures (Steele *et al*., 1964). Later, the degenerating process was described in cortical areas, with the same features as subcortical NFT (Hauw *et al*., 1990; Hof *et al*., 1992c). These studies demonstrated that the primary motor cortex is affected more severely than neocortical association areas compared to AD (Hauw *et al*., 1990; Hof *et al*., 1992c).

In PSP, the characteristic tau doublet (tau 64 and 69) described in Section III,A,2 was quantified (Vermersch *et al*., 1994). Biochemical mapping performed on several cortical and subcortical areas from PSP brain has revealed that this tau doublet is first detected in the subcortical regions where NFT are found, with neocortical areas being affected later (Vermersch *et al*., 1994). It is interesting to note that abnormal tau phosphorylation in cortical areas is always correlated to dementia. For instance, in a nondemented young PSP patient (33 years-old), abnormally phosphorylated tau proteins were found in both basal ganglia and thalamus, whereas they were absent in all of the other areas studied, including amygdala, hippocampus, and Brodmann's areas 4, 9, 11, 17, 18, 20, and 24 (Vermersch *et al*., 1997). Conversely, the other PSP cases with dementia studied contained large amounts of pathological tau proteins in the neocortex, especially in Brodmann areas 4 and 6 and in subcortical structures (Vermersch *et al*., 1997).

In all dementing disorders, detection of abnormal tau phosphorylation in association cortical areas appears to be always strongly correlated with cognitive impairment and dementia severity.

V. Factors That Modulate Tau Phosphorylation

Tau protein hyperphosphorylation may be modulated by a number of factors, including glucose metabolism, hypoxia, oxidation, and stress.

A. Glucose Metabolism

One of the key enzymes in tau phosphorylation is GSK3β (Hanger *et al*., 1992; Zheng-Fishhoffer *et al*., 1998). It is a protein, serine kinase implicated in the hormonal control of several regulatory proteins including glycogen synthase and the transcription factor c-jun. In AD, some brain regions are not properly supplied in glucose (see Chapters 16, 17, and 63). This hypometabolism may lead to a downregulation of insulin receptors. It is known that insulin and insulin-like growth factor 1 may activate 3-phosphoinositide-dependent protein kinase, which then activates protein kinase B, which in turn inactivates GSK3β (Hong and Lee, 1997). Thus, in case of low glucose concentrations and thus downregulation of insulin receptors, GSK3β is still active and phosphorylates tau proteins. This scheme may explain a first step in the pathology.

B. Ischemia

Ischemia disrupts the neuronal cytoskeleton both by promoting proteolysis of its components and by affecting kinase and phosphatase activities that alter its assembly (Dewar *et al*., 1994; Buée *et al*., 1996). In a reversible model of spinal cord ischemia in rabbits, tau has been found to be dephosphorylated in response to ischemia with a time course that closely matches the installation of permanent paraplegia. In a similar manner, Ca^{2+}/calmodulin-dependent kinase II activity is reduced only in the ischemic region. Thus, dephosphorylation of tau is an early marker of ischemia, as is the rapid loss of Ca^{2+}/calmodulin-dependent kinase II activity (Shackelford and Nelson, 1996). In a canine model of cardiac arrest, the effects of global brain ischemia/reperfusion (Rosenthal *et al*., 1992) on tau proteins were analyzed. Tau proteins are completely dephosphorylated on Ser/Thr-Pro sites, but after resuscitation and 2 hs of reperfusion, there is a full restoration of phosphorylation on Ser/Thr-Pro sites, whereas Ser262 phosphorylation is not restored (Buée *et al*., 1996; Mailliot *et al*., 1998c). Because phosphorylation that detaches tau protein from microtubules (Ser262, Ser214) also protects it against aggregation into PHF (Schneider *et al*., 1999), alterations in phosphorylation or degradation of tau may affect microtubule stability, possibly contributing to the disruption of axonal transport (Dewar and Dawson, 1995; Buée *et al*., 1996; Shackelford and Nelson, 1996; Mailliot *et al*., 1998c).

C. Stress

Stress-activated protein kinases have been involved in tau phosphorylation (Goedert *et al*., 1997; Reynolds *et al*., 1997a,b). They may also explain a number of observations. Cold water stress induces an immediate (30–90 min) two to threefold increase in the phosphorylation of tau proteins in rat brain, without direct involvement of the hypothalamus–pituitary–adrenal axis (Korneyev *et al*., 1995). Heat-shock stress also induces modifications of tau phosphorylation (Papasozomenos, 1996). Furthermore, JNK/SAPK1 and p38 are able to phosphorylate tau proteins (Reynolds *et al*., 1997a,b) and are linked to AD pathology (Mohit *et al*., 1995; Hensley *et al*., 1999).

D. Glycation and Oxidation

Glycation is the reaction between the NH_2 of a side chain of an amino acid and the aldehyde group (CHO) of a carbohydrate. Advanced glycation end-products generate oxygen-free radicals that could activate transcription via nuclear factor-κ B, increase βPP, and cause the release of 4-kDa amyloid peptides similar to Aβ. Therefore, glycated tau could induce oxidative stress, which may contribute to the pathogenesis of AD (Yan *et al*., 1995). In AD, antibodies against glycation products label NFT (Ledesma *et al*., 1994). The most suitable residues for glycation, lysines, which are present in the tubulin-binding motif of tau protein, seem to be preferentially modified compared to lysines in other regions. Among the modified lysines, those located in the sequence comprising residues 318–336 (in the largest human tau isoform) are found to be glycated, as determined by the reaction with an antibody that recognizes a glycated peptide containing this sequence. Because those

lysines are present in a tubulin-binding motif of tau protein, their modification could result in a decreased interaction of tau with tubulin (Ledesma *et al*., 1995). Furthermore, *in vitro* assembly of recombinant tau-derived constructs into PHF depends on intermolecular disulfide bridges formed by the single Cys322. Blocking the SH group, mutating Cys for Ala, or keeping tau in a reducing environment all inhibit assembly. These data imply that the redox potential in neurons is crucial for PHF assembly, independently or in addition to pathological phosphorylation reactions (Schweers *et al*., 1995). The tau regions affected in this oxidation process are those implicated in microtubule binding. It is interesting to note that these regions are also affected by mutations in FTDP-17 and that in all disorders, tau isoforms are found aggregated in a phosphorylated form.

VI. Tau Phosphorylation as Peripheral Marker

As described earlier, tau proteins are the major constituent of NFT, and their biochemical or immunohistochemical detection in the central nervous system is a reliable marker of the degenerative process. Therefore, their presence has been investigated in peripheral tissues and CSF in the hope it could represent a potential diagnostic tool. However, in AD, tau proteins are not found phosphorylated in peripheral tissues, including the olfactory system (Yamagishi and Ishizuka, 1994) and fibroblats (Ingelson *et al*., 1996).

The presence of tau proteins in CSF has been reported in numerous studies using a sandwich ELISA method (Vandermeeren *et al*., 1993), which permits the quantitation of both PHF-tau and total tau proteins (PHF-tau and normal tau). A significant increase in tau concentration has been shown in CSF of patients with AD and other tauopathies compared to control cases. However, this specificity is not sufficient to discriminate between CSF tau concentrations of AD patients and other disorders including vascular dementia and brain trauma (Andreasen *et al*., 1998; Zemlan *et al*., 1999). Regarding AD, an improved discrimination can be obtained by measuring out both Aβ and tau levels (Hulstaert *et al*., 1999).

Data suggest that tau-immunoreactive materials in CSF are mostly made of dephosphorylated and truncated N-terminal tau fragments (Johnson *et al*., 1997).

Altogether, these data indicate that there is an increase in tau protein concentration in CSF in tauopathies, but proteins do not bear the pathological sites of phosphorylation. However, an extensive and accurate analysis of CSF could be helpful in defining the tau protein species present at physiological state and released during the progression of a neurodegenerative disease. Thus, specific immunological probes against tau protein species could be developed and could lead to a sensitive and specific test to diagnosis AD and other neurodegenerative disorders.

VII. Concluding Remarks

In conclusion, among the different neurodegenerative disorders discussed in this chapter, differences in the regional tau distribution are observed. Because laminar and regional distributions of NFT are different among the dementing conditions, the presence of a pathologic tau triplet or doublet may be specific of a subtype of neurons. Thus, we suggest that different tau isoforms (with or without exon 10) are expressed in subsets of neurons that exhibit different vulnerability in addition to different sets of enzymes (kinases, phosphatases, etc.). However, it is also clear that tau mutations/polymorphisms may also emphasize this cell vulnerability by enhancing the expression of particular tau isoforms. Finally, it cannot be ruled out that abnormal tau phosphorylation may affect cell trafficking of tau isoforms and lead to neurofibrillary degeneration. Finally, because abnormal tau phosphorylation is a common feature to all tauopathies, a better understanding of this phosphorylation leading to neuronal degeneration in these dementing illnesses will be of crucial importance to develop strategies aimed at the therapeutic protection of the vulnerable neuronal populations.

Etiology, Genetics, and Pathogenesis of Alzheimer's Disease

I. Amyloid Hypothesis

Alzheimer's disease (AD) is an age-related neurodegenerative disease that causes a global loss of cognitive function and behavioral deficits. Although cholinesterase inhibitors can improve cognitive function slightly (Knopman and Morris, 1997), truly efficacious drugs for AD treatment and/or prevention are not yet available. However, the etiology of AD is beginning to yield to scientific inquiry. Plausible strategies for treatment and/or prevention have been formulated, but await further research. In the United States, AD afflicts four million individuals and imposes an annual tab of $80–100 billion (Hoyert and Rosenberg, 1999). Thus, one can readily appreciate the importance of recent progress in AD research. This chapter summarizes the current understanding of AD etiology and pathogenesis.

AD cases can be classified as ''familial'' or ''sporadic.'' Familial AD occurs in both early-onset (before age 65) and late-onset kindreds. In 1990, a mutation in the amyloid precursor protein (APP) was reported to cause hereditary cerebral hemorrhage with amyloidosis Dutch type (Levy *et al*., 1990). This finding linked amyloid deposition to an APP mutation for the first time and enabled investigators to embrace the idea that plaques were an important cause of neurodegeneration, rather than merely end products of a neurodegenerative process. Later, APP mutations were found to cause AD in a small number of early-onset, autosomal-dominant pedigrees (see Table 22.1).

The neuropathological hallmark of AD is the presence of neuritic plaques in brain parenchyma and cerebral blood vessels. Neuritic plaques consist of a protein core, surrounded by degenerating neurites, astrocytes, and activated macrophages. Alzheimer brain is also characterized by the presence of neurofibrillary tangles (NFT; accumulations of paired helical filaments within neuronal cell bodies), the loss of synapses and neurons, and reduced neurotransmitter concentrations. Cholinergic neurons are especially vulnerable to cell death; these neurons arise in the basal forebrain and terminate in the hippocampus and cerebral cortex. Neurofibrillary tangles consist primarily of ubiquitin and tau, a microtubule-associated protein.

The core protein of plaques is Aβ, a peptide derived from the amyloid precursor protein (APP), which is 39–43 amino acids long (Glenner and Wong, 1984). Plaques also contain numerous other components, including apolipoprotein E (Namba *et al*., 1991), α_1-antichymotrypsin (Abraham *et al*., 1988), serum amyloid P (Coria *et al*., 1988), interleukin-1 (Griffin *et al*., 1995), basic fibroblast growth factor (Gomez-Pinilla *et al*., 1990), α_2-macroglobulin (Bauer *et al*., 1991), low-density lipoprotein-related protein (LRP) (Tooyama *et al*., 1993), and perlecan (a heparin sulfate proteoglycan). Evidence for an inflammatory contribution to AD is provided by the presence of approximately 40 proteins known to play a role in inflammation (McGeer *et al*., 1996). Plaques are enriched in the small molecules, zinc, copper, and iron (Lovell *et al*., 1998).

Within plaques, the primary form of Aβ is Aβ_{42}, a highly-insoluble peptide that readily adopts a β-pleated sheet conformation (Iwatsubo *et al*., 1994, 1995; Fukumoto *et al*., 1996). Aβ molecules assemble into fibrils, which then pack into a highly ordered, crystalline-like lattice known as amyloid. The term ''amyloid'' can be applied to deposits derived from any protein in which a similar arrangement of molecules occurs. In addition to a core protein, all amyloid deposits are marked by the presence of heparan sulfate proteoglycans. ''Diffuse'' plaques are those in which Aβ molecules have not assembled into fibrils. Generally speaking, diffuse plaques are not surrounded by dystrophic neurites, activated microglia, or astrocytes. They occur in greater numbers than neuritic plaques and may be neuritic plaque precursors (Mackenzie, 1994). Neuritic plaque formation also occurs in Down syndrome and, to a lesser extent, in normal aging (Selkoe, 1991).

The ''amyloid hypothesis'' refers to the proposition that events leading to the manifestation of AD originate with the deposition of Aβ in amyloid deposits. Although flawed (or incomplete), this hypothesis is now supported by a large body of experimental work. It is worth noting that amyloid deposition occurs in other disorders such as Down syndrome,

Creutzfeldt–Jacob disease, Gertsmann–Sträussler–Scheinker disease, type II diabetes, familial amyloid polyneuropathy, and multiple myeloma. Aberrant protein deposition is a common theme in neurodegenerative disease (Kaytor and Warren, 2000). In Parkinson's disease, two mutations in the α-synuclein gene that cause early onset disease also accelerate α-synuclein aggregation (Narhi *et al.*, 1999).

Clearly, both environmental and genetic factors contribute to the risk of AD. Evidence from twin studies supports a role for environmental variables in AD (Breitner *et al.*, 1995; Nee and Lippa, 1999). Among the factors suggested to modify the risk for AD are head injury (Molgaard *et al.*, 1990; Roberts *et al.*, 1994), educational attainment (Stern *et al.*, 1992; Cobb *et al.*, 1995; Callahan *et al.*, 1996; Geerlings *et al.*, 1999), depression (Kokmen *et al*, 1996; Chen *et al.*, 1999), smoking (Hebert *et al.*, 1992; Lee, 1994; Hillier and Salib, 1997; Merchant *et al.*, 1999), vitamin E consumption (Vatassery *et al.*, 1999), diabetes (Leibson *et al.*, 1997) and hypertension (Skoog *et al.*, 1998; Behl, 1999). A review of the literature cited earlier will reveal that the legitimacy of many so-called environmental risk factors is open to debate. Stronger, but not conclusive, evidence indicates that estrogen replacement (Birge, 1997; Haskell *et al.*, 1997) and the chronic use of nonsteroidal anti-inflammatory drugs may reduce the risk of AD (McGeer *et al.*, 1996). AD and peripheral vascular disease share several risk factors in common; this indicates that impaired cholesterol metabolism may play a role in AD etiology (McKeon-O'Malley *et al.*, 1998). It remains to be determined whether any environmental factor is sufficient to cause AD in the absence of a permissive genotype.

On the genetic front, the identification of several AD-linked genes has yielded important insights into the etiology of AD, and steady progress continues to be made in this area. Female gender is a risk factor for AD, even when the longer life span of females is taken into account (Letenneur *et al.*, 1999). Almost all individuals with Down syndrome (trisomy 21) develop AD in midlife (Katzmann, 1986), presumably due to the overexpression of the APP gene on chromosome 21. The linkage of specific genes to AD risk is discussed in the following section.

II. Genetic Contributions to the Etiology of AD

To date, seven of the genes linked to AD include: the amyloid precursor protein (Chartier-Harlin *et al.*, 1991; Goate *et al.*, 1991; Murrell *et al.*, 1991), presenilin 1 (PS1) (Sherrington *et al.*, 1995), presenilin 2 (PS2) (Levy-Lahad *et al.*, 1995b), apolipoprotein E (Corder *et al.*, 1993), α_2-macroglobulin (Blacker *et al.*, 1998; Liao *et al.*, 1998), LRP (also known as the α2M receptor) (Kang *et al.*, 1997; Wavrant-DeVriéze *et al.*, 1997; Hollenbach *et al.*, 1998), and tau (Lilius *et al.*, 1999; Bullido *et al.*, 2000). Importantly, four of these proteins are related to each other: APP, ApoE, and α_2-macroglobulin are ligands for LRP.

Preliminary evidence has been presented for the involvement of other genes with AD (see Table 22.2). However, data do not permit firm conclusions to be drawn about other genes at this time. Deterministic mutations (i.e., mutations that can cause AD with 100% penetrance) occur in the genes for the amyloid precursor protein, presenilin 1 and presenilin 2, but these mutations account for only a small percentage of total AD cases. Mutations in APP and the presenilins cause AD by increasing the extracellular load of $A\beta_{42}$ (Scheuner *et al.*, 1996). Polymorphisms in the genes for apolipoprotein

[a]The genes may be associated with AD. Cited references include articles that report the association of a particular gene with AD, or a lack of such an association.

E, α_2-macroglobulin, LRP, and tau are known to increase the risk of AD. A brief description of each of these genes is given.

A. Amyloid Precursor Protein

As indicated earlier, the core protein of neuritic plaques, Aβ, is derived from APP. The APP gene is located at the boundary of 21.q.3 and 21.q22.1 (Kang *et al*., 1987) and is widely expressed in human tissues (Tanzi *et al*., 1988). Ten transcripts can be produced by alternative splicing of 19 exons (Wisniewski *et al*., 1994). However, Aβ cannot be generated by alternative splicing (Lemaire *et al*., 1989). Three major transcripts contain the Aβ sequence, and these encode proteins with 695, 771, or 770 amino acids (APP_{695}, APP_{751}, APP_{770}). The expression of APP_{695} is confined to the brain (Sola *et al*., 1993). APP_{751} and APP_{770} contain a region with 50% homology to a Kunitz protease inhibitor domain.

The APP gene lacks a TATA box and has a high GC content, features characteristic of a housekeeping gene (Salbaum *et al*., 1988). Gene expression produces a protein with the following domains: a signal peptide for transport of APP into the endoplasmic reticulum, a cysteine-rich sequence, a sequence including many negatively charged residues (glutamic acid and aspartic acid), and an uninterrupted stretch of seven threonine residues (Kang *et al*., 987) (see Fig. 22.1). A zinc II-binding site is located between the cysteine-rich domain and the negatively charged region (Bush *et al*., 1993). Two consensus sequences for N-linked glycosylation are located at amino acids 467–469 and 496–498. APP also contains a potential heparin-binding site (Small, 1994). APP is modified by post-translational mechanisms including N- and O-glycosylation (Weidemann *et al*., 1989; Pahlsson *et al*., 1992), sulfation of tyrosine residues (Weidemann *et al*., 1989), and phosphorylation (Oltersdorf *et al*., 1990). APP matures in the endoplasmic reticulum and the Golgi and then becomes inserted into the plasma membrane (Weidemann *et al*., 1989).

APP is a member of a family of highly conserved proteins. Other members of this family include amyloid precursor protein-like protein (APLP1) and APLP2 (Sprecher *et al*., 1993; Wasco *et al*., 1993), but the two latter proteins do not encode Aβ. APP plays a role in many normal functions, including wound healing (Smith *et al*., 1990; Van Nostrand *et al*., 1990), proliferation (Saitoh *et al*., 1989; Ninomiya *et al*., 1993), adhesion (Schubert *et al*., 1989; Breen *et al*., 1991; Chen and Yankner, 1991; Ghiso *et al*., 1992), neurite extension (Araki *et al*., 1991; Milward *et al*., 1992; Small, 1994), survival under stress (Mattson *et al*., 1993; Yamamoto *et al*., 1994), and synaptic plasticity (Mattson, 1994). Processes involved in the production of Aβ from APP are discussed under Section III.

B. Apolipoprotein E

Apolipoprotein E is a 34 kDa (299 residues) protein known primarily for its role in lipid transport (Mahley and Huang, 1999). The gene for ApoE has been mapped to chromosome 19 (Das *et al*., 1985). Three polymorphic alleles, ϵ2, ϵ3, and ϵ4 (corresponding to the proteins ApoE2, ApoE3, and ApoE4), occur at frequencies of 8, 75, and 15%, respectively. ApoE3 has Cys^{112} and Arg^{152}; in ApoE2, Arg^{158} is replaced by cysteine, and in ApoE4 , Cys^{112} is replaced by arginine. In the periphery, ApoE is synthesized primarily in the liver. ApoE cannot penetrate the blood–brain barrier, but is manufactured within the brain by astrocytes (Pitas *et al*., 1987). Apolipoprotein E is a ligand for three cell surface receptors: the low-density lipoprotein (LDL) receptor, the low-density lipoprotein-related protein, and the very-low-density lipoprotein (VLDL) receptor.

The ϵ4 allele of apolipoprotein E increases the risk of AD in a dose-dependent manner and lowers the age at onset (Corder *et al*., 1993). This finding has been confirmed repeatedly in a host of ethnic groups around the world. However, it is clear that apolipoprotein E alone does not cause AD because a proportion of elderly homozygotes are unaffected (Roses *et al*., 1994). Interestingly, the ϵ4 allele has also been shown to increase the risk of cardiovascular disease as well as AD (Lambert *et al*., 2000). Mutations occurring in noncoding regions of the ApoE gene are also associated with AD (see Table 22.3). In

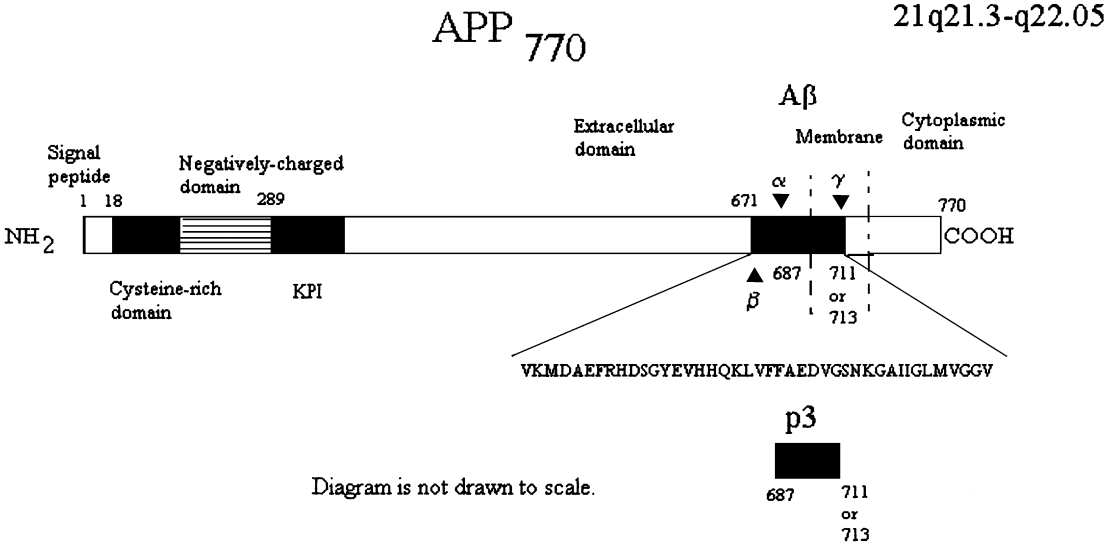

FIG. 22.1. Schematic diagram of APP (not drawn to scale).

TABLE 22.3 Apolipoprotein E Polymorphisms Associated with AD

Polymorphism	Reference
$\epsilon 2/\epsilon 3/\epsilon 4$ polymorphism	The $\epsilon 4$ allele is associated with sporadic and late-onset AD. This finding has been confirmed in more that 100 studies (Corder *et al*., 1993)
APOE*4 Pittsburgh (APOE*4P) (this is a missense mutation, L28P, caused by a T → C substitution in exon 3)	All APOE*4P carriers identified thus far also carry $\epsilon 4$. However, the risk of AD is five-fold greater in $\epsilon 4$ carriers who also carry APOE*4P than in those who bear the $\epsilon 4$ allele alone (Kamboh *et al*., 1999)
Th1/E47 cs polymorphism: G to mutation occurs at −186 bp in relation to the TATA box; this polymorphism is located in a consensus sequence for the transcription factor Th1E47	The presence of at least one T allele increases the risk of AD (Lambert *et al*., 1998)

contrast to the $\epsilon 4$ allele, the $\epsilon 2$ allele decreases the risk of AD (Corder *et al*., 1994; Talbot *et al*., 1994).

C. Presenilin 1 and Presenilin 2

Mutations occurring within the homologous, transmembrane proteins PS1 and PS2 cause early-onset familial AD with 100% penetrance. About 70 such mutations have been identified in PS1, whereas only 5 have been observed in PS2 (see Tables 22.4 and 22.5; Table 22.4 includes only a partial list of all PS1 mutations). Remarkably, mutations in PS1 and PS2 increase the $A\beta_{42}/A\beta_{40}$ ratio, or total $A\beta$ both *in vitro* and *in vivo* (Borchelt *et al*., 1996; Lemere *et al*., 1996; Mann *et al*., 1996; Scheuner *et al*., 1996; Citron *et al*., 1997, 1998; Tomita *et al*., 1997). The presenilins may be γ-secretases, the enzymes that generate final cleavage in the release of $A\beta$ from APP (Wolfe *et al*., 1999).

PS1 and PS2 share a similar pattern of gene expression. Both proteins are expressed primarily within neurons and are localized to the endoplasmic reticulum and Golgi (Kovacs *et al*., 1996; Blanchard *et al*., 1997).

The gene for PS1 is located on chromosome 14q24.3 and encodes a 43 to 45 kDa protein, 467 amino acids long (George-Hyslop *et al*., 1992; Schellenberg *et al*., 1992). The PS2 gene has been mapped to chromosome 1q42.1 and encodes a 53 to 55 kDa protein, 448 amino acids long (Levy-Lahad *et al*., 1995a,b; Takano *et al*., 1997). The presenilins are predicted to contain six (Lehmann *et al*., 1997), seven (Dewji and Singer, 1997), or eight (Li and Greenwald, 1998) transmembrane domains and a large hydrophilic loop. The N-terminal, C-terminal, and the large hydrophilic loop of PS1 protrude from the endoplasmic reticulum membrane into the cytoplasm (Doan *et al*., 1996).

The presenilins are cleaved endoproteolytically to produce N-terminal fragments and C-terminal fragments, with approximate molecular masses of 30 and 20 kDa, respectively (Thinakaran *et al*., 1996). This cleavage occurs at a site within the large hydrophilic loop. N- and C-terminal fragment associate with one another in a 1:1 ratio, forming a stable complex (Capell *et al*., 1998). Measurable quantities of the full-length proteins are difficult to detect by conventional methods, strongly suggesting that the cleavage products are the physiologically relevant entities.

Potential roles for the presenilins have been suggested in protein processing, Notch signaling and development, and apoptosis (Mattson *et al*., 1997, 1998; Guo *et al*., 1998a,b). Mice homozygous for a null mutation in the murine homologue of PS1 (i.e., PS1 knockout mice) die within minutes of birth (Shen *et al*., 1997). These animals exhibit gross skeletal defects, cerebral hemorrhage, and massive neuronal loss. The lethal phenotype of these animals indicates that PS1 plays an essential role in normal development.

D. α_2-Macroglobulin

α_2-Macroglobulin (α2M) is a ''pan-protease'' inhibitor involved in the clearance of proteins from the blood via endocytosis (Borth, 1992). α2M is composed of four identical subunits (180 kDa), each of which contains a 25 residue ''bait region,'' a cytokine-binding domain, and a receptor-binding domain. The bait region contains an internal cyclic thiol ester that is cleaved when a protease binds to α2M. This cleavage provokes a conformational change in α2M that permits it to enclose or ''capture'' the protease and to make its cytokine-binding and receptor-binding domains accessible for ligand binding. Activated α2M binds to its plasma membrane receptor, LRP, to deliver its captured protease. Ligand–LRP complexes are internalized via clathrin-coated pits and are then directed into an endosomal/lysosomal compartment (Kowal *et al*., 1989). There, ligands are released from LRP and degraded; LRP is recycled to the plasma membrane.

The gene for α2M is located on chromosome 12 (Fukushima *et al*., 1988). An AD-linked polymorphism is located in the 5′ splice site of exon 18. Two polymorphisms, occurring in this locale, α2M-2 and α2M-1, specify the presence or absence of a pentanucleotide deletion. Inheritance of a single α2M-2 allele increases the risk of AD three- to fourfold, but does not change the age at onset (Blacker *et al*., 1998). To date, it is not known whether the risk of AD increases with α2M-2 dosage. AD is also associated with a second polymorphic site, Val1000(GTC)/Ile1000(ATC), located near the cyclic thiol ester (Poller *et al*., 1992). AD risk is increased by the presence of a valine residue at this site (Liao *et al*., 1998). The risks conferred by the Val1000(GTC) allele of α2M, and the $\epsilon 4$ allele of ApoE, are independent and additive.

E. Lipoprotein-Related Protein

As described previously, LRP is a plasma membrane receptor for APP, ApoE, and α2M. Importantly, an $A\beta$-serine

protease-α2M pathway is one of several mechanisms by which Aβ is cleared (Qiu *et al.*, 1999). LRP belongs to a family of proteins that includes the LDL receptor, megalin (also known as gp330), the VLDL receptor, and the vitellogenin receptor (Krieger and Herz, 1994).

F. Tau

The diagnosis of AD in postmortem brain requires the presence of both NFT and neuritic plaques. Unlike plaques, NFT are not specific to AD; these entities occur in many neurodegenerative disorders, including supranuclear palsy, dementia pugilistica, corticobasal degeneration, and fronto-temporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) (Goedert *et al.*, 1997). However, NFT density correlates well with dementia severity, whereas plaque density does not (Braak and Braak, 1991).

The primary protein component of NFT is tau (45–60 kDa), a protein that promotes the stabilization of microtubules (Weingarten *et al.*, 1975). In the central nervous system, alternative splicing of the tau gene results in the expression of six isoforms primarily (see Fig. 22.2). A seventh isoform containing a "big tau insert" is expressed prominently in the peripheral nervous system and to a much lesser extent in the central nervous system (Georgieff *et al.*, 1993). Each isoform possesses either three or four microtubule-binding domains (repeat units of 31 amino acids, encoded by exon 10) and 0, 1, or 2 different amino-terminal inserts. Differential expression of tau isoforms occurs during development (Couchie *et al.*, 1988; Kosik *et al.*, 1989). Within NFT, tau is hyperphosphorylated (Grundke-Iqbal *et al.*, 1986), which prevents its binding to microtubules (Bramblett *et al.*, 1993).

The finding made in 1991 that mutations in the amyloid precursor protein gene can cause AD with 100% penetrance focused attention on the role of Aβ in AD. Lately, there has been a resurgence of interest in tau. Tau mutations have been linked to frontotemporal dementia with parkinsonism (FTDP-17; previously known as Pick disease) (Poorkaj *et al.*, 1998a; Hutton *et al.*, 1998; Spillantini *et al.*, 1998; Iijima *et al.*, 1999) and to supranuclear palsy (Chambers *et al.*, 1999). Because plaque deposits are largely absent in FTDP-17 tauopathies, the latter findings indicate that tau aggregation is sufficient for neurodegeneration (Ghetti *et al.*, 1999).

Several groups have searched for AD-linked mutations in the tau gene without success (Crawford *et al.*, 1999; Roks *et al.*, 1999). However, two reports indicate that polymorphisms in the tau gene may increase the risk for AD when found in combination with the ApoE ϵ4 allele (Lilius *et al.*, 1999; Bullido *et al.*, 2000).

III. Pathogenesis

A. Fundamental Questions in AD Research

Most of the current research in AD is designed to address one of the following questions:

What factors regulate the cleavage of Aβ from APP, and Aβ assembly into fibrils?

How does Aβ, alone or in combination with other plaque components, cause neuronal cell death?

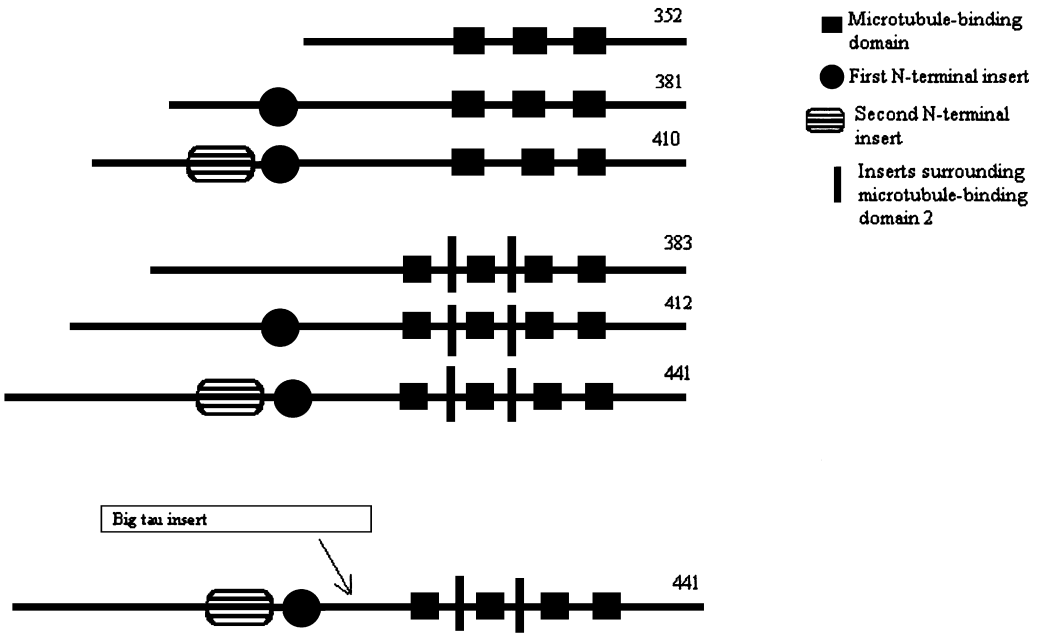

FIG. 22.2. Schematic diagram of tau protein isoforms.

What is the role of inflammation in the maturation of neuritic plaques?

What is the role of tau in AD?

A thorough discussion of last three questions is beyond the scope of this chapter (see Tolnay and Probst, 1999, for a review of the role of tau in AD.) This chapter concentrates, how Aβ is produced from APP, and on Aβ fibrillogenesis.

B. Amyloid, Neuritic Plaques, and Paired Helical Filaments

Within specific brain locale, certain conditions (as yet undefined) permit soluble Aβ molecules to adopt a high degree of β-pleated sheet conformation; this alteration facilitates the rearrangement of Aβ molecules into fibrils. Fibrils pack in cross-β conformation to form amyloid, a highly ordered arrangement of protein molecules that can be detected using Congo Red or Thioflavin S (Kirschner *et al*., 1987). Neuritic plaques, but not diffuse plaques, are visualized using these stains. Fibril stability is critically dependent on the primary structure of the peptide. This is exemplified by the fact that an APP mutation associated with early-onset FAD, $A\beta_{E22Q}$, increases the stability of Aβ fibrils dramatically (Fraser *et al*., 1992).

Within plaques, Aβ molecules differ in length, exhibiting heterogeneity at both amino (Tekirian *et al*., 1998) and carboxyl termini (Jarrett *et al*., 1993a). Plaques contain a mixture of Aβ molecules; $A\beta_{42}$ and $A\beta_{40}$ are the predominant species in extracellular neuritic plaques, whereas the vascular amyloid consists primarily of $A\beta_{39–40}$ (Dickson, 1997). As indicated earlier, a highly amyloidogenic form of Aβ, $A\beta_{42}$, is the initial Aβ species deposited in neuritic plaques (Iwatsubo *et al*., 1995). Diffuse plaques contain $A\beta_{42}$, but not $A\beta_{40}$ (Cummings *et al*., 1996). Plaque enlargement requires a nidus for further protein deposition; $A\beta_{42}$ may serve as a ''seed,'' which permits the deposition of $A\beta_{40}$ (Jarrett *et al*., 1993b). $A\beta_{40}$ constitutes the bulk of the Aβ produced by normal metabolism (Haass *et al*., 1992; Seubert *et al*., 1992).

Neuritic plaques can be surrounded by dystrophic neurites or by neurites containing paired helical filaments (PHF-type neurites). [PHF occurring within neurites are essentially equivalent to those found in neuronal cell bodies. In AD, PHF occur in three locations: within plaques, neurites, or neuronal cell bodies (Braak *et al*., 1986). PHF-type neurites found in the absence of plaques are known as ''neuropil threads'' (Dickson, 1997).] Among dystrophic neurites, diverse neuronal types are represented (Struble *et al*., 1987). In contrast, there is a hierarchy of neuronal types that are susceptible to PHF formation (Price *et al*., 1991). Both dystrophic neurites and PHF-type neurites are recognized by ubiquitin-specific antibodies, but only the latter are recognized by the Alz-50 antibody.

C. Aβ Formation, Aggregation, and Clearance

1. APP Cleavage Sites

APP is cleaved within Aβ at Lys^{687}-Leu^{688} (APP_{770} numbering), by one or more ''α-secretases.'' This cleavage generates a soluble N-terminal fragment ($sAPP_\alpha$) and a membrane-associated C-terminal fragment. Thus, α-secretase-mediated cleavage of APP precludes the production of Aβ. The amino and carboxy termini of Aβ are produced by the actions of ''β-secretase'' and ''γ-secretase,'' respectively. As in the case of α-secretase, β-secretase-mediated cleavage of APP produces an amino-terminal fragment ($sAPP_\beta$) and a membrane-associated C-terminal fragment. The ''p3'' peptide (3 kDa) is created when the C-terminal fragment produced by α-secretase cleavage becomes a substrate for γ-secretase (Haass *et al*., 1993). The p3 sequence may be amyloidogenic (Lalowski *et al*., 1996; Dickson, 1997). The cleavage of APP by γ-secretase is unusual in that it occurs within the transmembrane domain of APP. Aβ and p3 are normal constituents of biological fluids (Shoji *et al*., 1992). Secreted $sAPP_\alpha$ protects cells from toxic insults (Goodman and Mattson, 1994; Furukawa *et al*., 1996). In this regard, it may be much more effective than $sAPP_\beta$ (Barger and Mattson, 1996).

After its synthesis on ribosomes, APP is directed into the endoplasmic reticulum by its signal peptide (Kang *et al*., 1987). During its transit through the constitutive secretory pathway (endoplasmic reticulum, Golgi, and *trans*-Golgi network), APP is phosphorylated on its ectodomain. A small percentage of total holoprotein is inserted into the plasma membrane, where it is subject to cleavage by α- or β-secretases (Selkoe, 1998). Uncleaved holoprotein and the C-terminal fragments remaining in the plasma membrane after α-secretase or β-secretase cleavage (C83 and C99, respectively) are reinternalized via clathrin-coated vesicles. The latter molecules can be recycled to the cell surface or enter an endosomal/lysosomal pathway.

2. α-Secretase-Mediated Cleavage of APP

APP has a hydrophobic sequence near its carboxyl terminus (about 23 residues long), which directs its insertion into the plasma membrane and internal membranes of the endoplasmic reticulum, Golgi, and *trans*-Golgi network (Selkoe, 1998). α-Secretase-mediated cleavage of APP occurs both at the cell surface and within the constitutive secretory pathway. This cleavage does not depend on a specific sequence of amino acids; rather, it cuts APP at a specific distance from the plasma membrane (Maruyama *et al*., 1991).

Total α-secretase activity can be divided into PKC-independent and PKC-dependent components (Buxbaum *et al*., 1994), which represent basal and stimulated α-secretase activity, respectively. PKC-independent regulation of α- secretase activity involves the elevation of intracellular calcium (Buxbaum *et al*., 1994). Several metalloproteases belonging to the ADAM family have been shown to possess α-secretase-like activity; among these are TACE (tumor necrosis $factor_\alpha$ converting enyme, also known as ADAM-17), MDC9, and ADAM-10. ADAM metalloproteases are membrane-anchored proteins that contain a catalytic domain, an autoinhibitory domain, a disintegrin-like domain, a cysteine-rich sequence, and epidermal growth factor-like sequence. TACE, MDC9, and ADAM-10 also possess a consensus sequence (HEXXH) for a zinc-binding domain. TACE mediates most cellular PKC-dependent α-secretase activity (Buxbaum *et al*., 1998; Lammich *et al*., 1999). MDC9 mediates both basal and PKC-induced cleavage of APP_{695} at the α-secretase site, and inhibition of MDC9 increases β-secretase cleavage (Koike *et al*., 1999).

Overexpression of ADAM-10 in HEK 293 cells stimulates both basal and PKC-dependent α-secretase activity (Lammich *et al*., 1999).

3. Cleavage of Aβ from APP

There are several pathways for the production of Aβ_{42} and Aβ_{40}. Aβ_{40} is generated in recycling endosomes following reinternalization from the cell surface (Koo and Squazzo, 1994). Both peptides are produced in the secretory pathway (Chyung *et al*., 1997; Wild-Bode *et al*., 1997), but the primary site for Aβ_{42} production is the endoplasmic reticulum, whereas the primary site for Aβ_{40} production is the *trans*-Golgi network (Hartmann *et al*., 1997). Intracellular production of Aβ may be unique to neurons because nonneuronal cells produce significant amounts of Aβ_{42} and Aβ_{40} only at the cell surface (Hartmann *et al*., 1997).

Four groups independently identified an unusual membrane-bound aspartyl protease as the elusive β-secretase (Hussain *et al*., 1999; Sinha *et al*., 1999; Vassar *et al*., 1999; Yan *et al*., 1999). This enzyme has been named BACE (β-site APP-cleaving enzyme) by one group and Asp2 by another group. Although other proteases, such as cathepsin D, can cleave APP at the β-secretase site, BACE meets all the requirements of a true β-secretase. BACE is located within the Golgi and endosomes and has a pH optimum of 5–5.5.

To date, γ-secretase has not been identified. Because inhibition of γ-secretase activity is a prime therapeutic major therapeutic target, the identity of this enzyme may be known by the time this chapter is published. Clearly, presenilin 1 is implicated in γ-secretase cleavage, either as an essential cofactor or as the enzyme itself (Wolfe *et al*., 1999).

4. Regulation of APP Processing

The regulation of APP processing is extremely complex. It varies across species and also differs between neuronal and nonneuronal cell types. In nonneuronal cell lines or nonhuman cell lines, acetylcholine binding to muscarinic receptor subtypes concurrently increases $sAPP_\alpha$ production and *inhibits* Aβ production (Buxbaum *et al*., 1992; Hung *et al*., 1993; Jacobsen *et al*., 1994). This effect can be mimicked by phorbol ester, indicating the involvement of PKC in signal transduction. However, in cultures of primary human cerebral neurons, PKC activation increases the rate of $sAPP_\alpha$ release and *increases* the production of Aβ (LeBlanc *et al*., 1998). The latter finding, in conjunction with others, indicates that distinct pathways exist for α- and β-secretase-mediated cleavage of APP (Dyrks *et al*., 1994). PKC-induced α-secretase cleavage is regulated by protein phosphorylation, but does not depend on the phosphorylation of APP (Jacobsen *et al*., 1994). The *trans*-Golgi network is the site of regulated, intracellular α-secretase cleavage (Skovronsky *et al*., 2000).

5. Aβ Aggregation

Aβ aggregation is dependent on concentration, pH, and the length of incubation in aqueous media (Burdick *et al*., 1992). Aβ exists in a random conformation at low pH, a β-pleated sheet conformation at pH 4–7, and a random conformation at high pH (Barrow and Zagorski, 1991; Fraser *et al*., 1992). The effect of pH on Aβ conformation indicates that Aβ aggregation is influenced by the ionization state of key residues. Histidine-aspartic acid/glutamic acid salt bridges stabilize β-pleated sheets, facilitating fibril assembly (Fraser *et al*., 1991). Due to the presence of hydrophobic residues at its carboxyl terminus, Aβ_{42} is very insoluble in water at pH 7.4 (Burdick *et al*., 1992).

Aqueous solutions of Aβ exhibit kinetic rather than thermodynamic solubility (Jarrett and Lansbury, 1993). In other words, Aβ will precipitate from apparently soluble solutions, given sufficient time. The rate-limiting step in the formation of amyloid is nucleation, i.e., the formation of a certain sized Aβ oligomer, which can serve as a scaffold for further aggregation (Jarrett and Lansbury, 1992). Lag time, i.e., the time until a solution exhibiting kinetic solubility precipitates, is directly proportional to the size of the Aβ oligomer required for nucleation and inversely proportional to peptide concentration.

Biometals can induce Aβ aggregation *in vitro* (Bush *et al*., 1994). In AD, concentrations of zinc, copper, and iron are likely to be particularly important (for a review, see Atwood *et al*., 1999). Submicromolar copper induces the aggregation of Aβ_{40} at mildly acidic pH values, similar to those that might be encountered during mild acidosis (Atwood *et al*., 1998). Under acidic conditions, nanomolar concentrations of Aβ_{40} form aggregates, which can subsequently be dissociated by chelation or alkalinization. Aβ_{42}, but not Aβ_{40}, is precipitated by copper at pH 7.4.

In vitro, low micromolar concentrations of zinc induce the aggregation of Aβ_{40} at pH 7.4 (Huang *et al*., 1997). This reaction is mediated by dimeric Aβ, potentiated by α-helical-promoting solvents, inhibited by multimeric forms of Aβ, and requires NaCl. At pH 7.4, zinc-induced aggregation of Aβ_{40} is reversible by chelation over the course of several precipitation/solubilization cycles. Aβ aggregation also occurs in acidic solution (pH 5.5), but aggregates formed in this manner cannot be resolubilized by alkalinization (Huang *et al*., 1997). In canine CSF, half-maximal aggregation of endogenous Aβ is produced by zinc concentrations ranging from 120 to 140 μM (Brown *et al*., 1997). The ability of zinc to induce Aβ aggregation is dependent on the presence of a histidine residue at position 13 (Liu *et al*., 1999). Neuronal depolarization can trigger the massive release of zinc in response to pathological events (Howell *et al*., 1984), causing extracellular zinc concentrations to rise dramatically (Tonder *et al*., 1990; Koh *et al*., 1996). Thus, elevated zinc concentrations may facilitate Aβ aggregation *in vivo*.

Aβ aggregates formed in the presence of zinc are more dense and are solubilized less easily than those formed in the presence of copper (Moir *et al*., 1999). Apolipoprotein E inhibits zinc-induced Aβ aggregation, but enhances copper-induced aggregation. Furthermore, the extent to which metal-induced aggregation of Aβ occurs *in vitro* is altered by specific apolipoprotein E isoforms. Zinc- or copper-induced Aβ aggregation is greater in the presence of apolipoprotein E4 than apolipoprotein E3. This is consistent with the increased risk for AD conferred by the ϵ4 allele.

6. Aβ Clearance

Aβ clearance is not well understood, but may be critically important to AD pathogenesis. Pathways for Aβ clearance include, but are not limited to, the following:

In soluble fractions of human and rat brain, maximal clearance of Aβ occurs at pH 4–5 and is mediated by cathepsin D, an aspartyl protease (McDermott and Gibson, 1996, 1997; Hamazaki, 1996a). Because cathepsin D requires a low pH for catalytic activity, Aβ-degradation by cathepsin D must occur in an acidic intracellular compartment. Cathepsin D cleaves a wild-type Aβ sequence 20 times faster than it does a mutant Aβ sequence (a glycine for alanine substitution at position 21) associated with early-onset AD (Hamazaki, 1996b). This suggests that Aβ clearance by cathepsin D may be relevant to AD.

In vitro, Aβ proteolysis by insulin-degrading enzyme occurs at neutral pH (McDermott and Gibson, 1997).

In vivo, microglia cause Aβ degradation by releasing a protease thought to be a member of the disintegrin family (Mentlein *et al*., 1998).

Aβ can be cleared by a serine protease–α2M complex (Narita *et al*., 1997; Qiu *et al*., 1999). Because polymorphisms in the genes for both α2M and LRP are associated with AD, it is tempting to speculate that Aβ might compete with other molecules, such as cholesterol, for lysosomal clearance (Kowal *et al*., 1989).

IV. Therapeutic Strategies

Although AD treatment and prevention are still in the future, many potential therapeutic targets exist, each of which could be implemented via several routes. These include the following:

Inhibition of Aβ_{42} or Aβ_{40} secretion, with or without concomitant stimulation of sAPP$_\alpha$ secretion
Inhibition of Aβ aggregation or fibril formation
Resolubilization of plaques
Limitation of Aβ-induced toxicity
Stimulation of Aβ clearance
Prevention or limitation of brain inflammation
Administration of neurotrophic agents
Inhibition of neurofibrillary tangle formation
Inhibition of β-secretase or γ-secretase

For a fuller discussion of potential therapeutic strategies, see McKeon-O'Malley *et al*. (1998).

V. Summary

Tremendous progress has been made in the area of AD genetics. Several other genes, yet to be unidentified, may have a major impact on AD risk. However, it seems likely that many more genes will be discovered, each of which increases AD risk slightly. A poor combination of genetic risk factors may be sufficient to cause disease or to permit detrimental environmental factors to operate. The fact that four genes, which alter AD risk (APP, ApoE, α2M, and LRP), are related to each other indicates that cholesterol and other lipids may play a role in AD etiology. We speculate that AD may be caused by risk factors leading to sublethal vascular disease. If this speculation is substantiated by further research, it may be possible to implement lifestyle alterations for AD prevention. Presenilin research is likely to bring about many important findings in area of development, as well as in AD.

Inflammation, Free Radicals, Glycation, Metabolism and Apoptosis, and Heavy Metals

I. Roles of Cytokines and Inflammation in Alzheimer's Disease

Studies of the roles of the immune system in Alzheimer's disease (AD) have brought forth many intriguing findings. It is very clear that, at least in the end stages of AD, the profile of cellular and molecular alterations in and surrounding amyloid deposits and degenerating neurons resembles an inflammatory response. Microglia are activated, levels of several different inflammatory cytokines [e.g., tumor necrosis factor (TNF) and interleukin (IL)-1β] and proinflammatory cell adhesion proteins are increased, and the complement cascade is activated. Many of these changes are likely a response to neuronal injury and death and, as such, might either protect or endanger the remaining neurons. For example, microglia produce both neurotoxic compounds, such as nitric oxide and excitotoxins, and neuroprotective agents, such as TNF and transforming growth factor (TGF)-β. In addition, the inflammatory process appears to have quite complex effects on enzymatic processing of the amyloid precursor protein, and deposition and clearance of amyloid β-peptide (Aβ). The development of genetic mouse "models" of AD in which amyloid is deposited in the brain reveals some evidence of an inflammatory response, suggesting that amyloid may be an important trigger of inflammation in AD. Interestingly, studies of presenilin-1 mutant mice are revealing alterations in lymphocyte signaling, suggesting that immune alterations may occur prior to, and possibly contribute to, neuronal degeneration in AD. Initial epidemiological data and clinical trials suggested that increased intake of nonsteroidal anti-inflammatory drugs can decrease the risk for AD, although more recent findings suggest that the antioxidant activity of these drugs may underlie their beneficial effects. A very recent and potentially important finding related to the role of the immune system in AD is the observation that immunization of amyloid precursor protein (APP) mutant mice with aggregated Aβ can suppress amyloid deposition in the brain. Although speculative, the latter findings suggest that a vaccine for AD may be possible.

A. Studies of Brain Tissue from AD Patients Reveal Inflammation-like Alterations in the Brain

The first line of evidence suggesting that inflammation-like processes play a role in the pathogenesis of AD comes from analyses of postmortem brain tissue from AD patients. Histological analyses reveal the presence of several different inflammatory mediators, including proteins involved in the complement cascade and cytokines, in association with amyloid plaques and neurofibrillary tangles. Among the earliest evidence for an inflammatory process in association with amyloid deposition and neuronal degeneration in AD was the work of Eikelenboom and Stam (1982), who described the accumulation of IgG and κ and λ light chains in neuritic plaques. The latter study also documented the presence of the complement factors C1q, C3b, C3c, C3d, and C4 in plaques. Their subsequent studies used immunoenzymatic techniques, and specific antibodies against subunits of individual complement components and activated complement products, to demonstrate complement activation in amyloid plaques (Eikelenboom *et al*., 1989). Further analyses indicated that the cascade does not proceed beyond C3 (Veerhuis *et al*., 1995). Double labeling of brain sections from AD and control patients with thioflavin (which binds to amyloid fibrils) and an antibody against the complement protein C1q demonstrated localization of C1q in plaques containing fibrillar Aβ but not in diffuse plaques (Afagh *et al*., 1996). Many neurons in AD brain were C1q positive, whereas microglia and astrocytes associated with C1q-positive plaques were themselves not C1q-positive. Levels of several acute-phase proteins (α_1-antichymotrypsin, ceruloplasmin, and complement proteins), but not others (haptoglobin, transferrin, and C-reactive protein), were increased in serum of AD patients compared to control patients (Giometto *et al*., 1988). Another study revealed increased levels of several acute-phase proteins in amorphous plaques in cerebral cortex, but not in the cerebellum, of patients with AD (Rozemuller *et al*., 1990).

TNFα levels are elevated in microglia associated with amyloid plaques in the brains of AD patients (Dickson *et al*., 1993), and levels of circulating TNFα are also increased in AD patients (Fillit *et al*., 1991), suggesting a systemic acute-phase-like condition. Increased levels of TGF-β1 are associated with a subset of senile plaques in AD, suggesting that it may play a role in cellular responses to, and/or deposition of, Aβ (van der Wal *et al*., 1993). Levels of TGF-β2 are increased in large neurofibrillary tangle-bearing neurons and in astrocytes of patients with sporadic AD, as well as in patients with mutations in presenilin-1 (Flanders *et al*., 1995). Analyses of cerebral cortical tissue samples from AD patients and age-matched control patients documented significant increases in levels of interleukin-6 (IL-6) and α_2-macroglobulin (Bauer *et al*., 1991; Griffin *et al*., 1998), both of which are also increased in the acute-phase response. Levels of the serine protease inhibitor α_1-antichymotrypsin are increased in association with amyloid plaques in brain tissue from AD patients (Abraham *et al*., 1988).

Cyclooxygenase-2 (COX-2) catalyzes the production of prostaglandins from arachidonic acid and is an important target for anti-inflammatory drugs. COX-2 is upregulated in microglia following brain injury and exposure to lipopolysaccharide but, in contrast to peripheral macrophages, is not induced by TNFα, IL-1β, or IL-6 (Bauer *et al*., 1997). The latter findings suggest that microglia are an important source of prostaglandins and therefore likely play a central role in inflammatory responses in the brain. Levels of mRNA encoding COX-2 were reported to be decreased in brain tissue from AD patients (Chang *et al*., 1996). However, subsequent studies showed that levels of COX-2 immunoreactivity are increased in hippocampal pyramidal neurons of AD patients compared to age-matched controls, and the magnitude of the increase correlates with amyloid plaque density (Ho *et al*., 1999). The latter study also showed that cultured neurons from COX-2-overexpressing transgenic mice are more vulnerable to amyloid β-peptide toxicity than neurons from nontransgenic mice, suggesting that the increased levels of COX-2 in AD could contribute to the neurodegenerative process.

Levels of integrins, proteins upregulated in vascular endothelial cells, and other cell types following injury were shown to be associated with amyloid plaques (Eikelenboom *et al*., 1989, 1994). Immunohistochemical studies have shown that levels of the vitronectin receptor, an integrin, are greatly increased in reactive microglia in both gray and white matter in the brains of AD patients (Akiyama *et al*., 1991). The latter study also showed that levels of vitronectin are increased in neurofibrillary tangle-bearing neurons and senile plaques, suggesting a role for vitronectin in the phagocytosis of damaged cells by microglia in AD. In addition, levels of leukocyte adhesion molecules of the LFA-1 family are increased in microglial cells surrounding amyloid plaques (Rozemuller *et al*., 1989).

Finally, although the vast majority of data obtained in analyses of AD brain tissue suggest that inflammatory cascades involve cells intrinsic to the brain parenchyma, some data suggest a role for peripheral immune cells. For example, Itagaki *et al*. (1988) reported evidence for the presence of leucocyte common antigen positive cells and T-cytotoxic suppressor cells in AD brain tissue.

B. Experimental Studies That Elucidate the Cellular and Molecular Basis of Inflammatory Cascades in AD

By analogy with other tissues and studies of brain injury, it is very likely that a major component of the inflammation-like changes evident in analyses of AD brain tissue is the result of cellular responses to neuronal degeneration and death. Increased levels of oxidative stress (see Section II) may also induce glial activation and cytokine cascades. Experimental cell culture and animal models of AD have shown that Aβ can induce many inflammation-like alterations in glial cells and neurons and that inflammatory mediators can interact with Aβ, and other AD-relevant neurotoxic agents, to either promote or suppress neuronal degeneration. It has been shown that Aβ activates the classical complement pathway (Rogers *et al*., 1992) by interacting with a site within the collagen-like domain of C1q, with Aβ 1–42 being more effective than 1–40 (Jiang *et al*., 1994). The major site at which Aβ 1–42 binds to C1q is within the collagen-like amino acids 14–26 of C1q, a region of interaction of other activators of C1q. Coincubation of Aβ with C1q results in enhanced peptide aggregation (Webster *et al*., 1994). Aβ activates microglia and greatly potentiates microglial activation by interferon-γ (Meda *et al*., 1995). Microglial activation by Aβ may involve binding of receptors for advanced glycation end products expressed in microglia (Mattson and Rydel, 1996). Oxyradicals and excitotoxins produced by activated microglia may promote neuronal degeneration. Studies of transgenic mice expressing mutations in amyloid precursor protein linked to early-onset AD have provided evidence for microglial and astrocyte activation in association with amyloid deposits (Hsiao *et al*., 1996; Chen *et al*., 1998). Thus, data ranging from cell culture studies to animal models to AD patients strongly suggest that amyloid plays a major role in inducing glial activation and inflammatory cytokine cascades (Fig. 23.1).

However, several cytokines produced in inflammatory responses may serve neuroprotective functions. Primary hippocampal neurons treated with TNFα exhibit increased resistance to cell death induced by excitotoxic and oxidative insults, and exposure to Aβ (Cheng *et al*., 1994; Barger *et al*., 1995). Studies of mice lacking TNFα receptors suggest a similar neuroprotective role for TNFα *in vivo* (Bruce *et al*., 1996). The signal transduction pathway that mediates the antiapoptotic and antiexcitotoxic effects of TNFα involves activation of the transcription factor NF-κB, which induces the expression of several neuroprotective proteins, including manganese superoxide dismutase and Bcl-2 (Mattson *et al*., 1997a, 2000; Yu *et al*., 1999). Pretreatment of cultured cortical neurons with TGFβ1 confers resistance to excitotoxicity and Aβ toxicity (Prehn *et al*., 1993; Chao *et al*., 1994). Because of these *in vitro* findings and because TGFβ is localized to sites where neuronal degeneration is occurring in AD brains (see earlier discussion), it is possible that TGFβ serves an important neuroprotective function. However, results generated in transgenic mice clearly indicate that chronic overproduction of TGFβ1 may also promote amyloidogenesis and neurodegeneration through its stimulatory effects on the deposition of extracellular matrix proteins (Finch *et al*., 1993; Wyss-Coray *et al*., 1995).

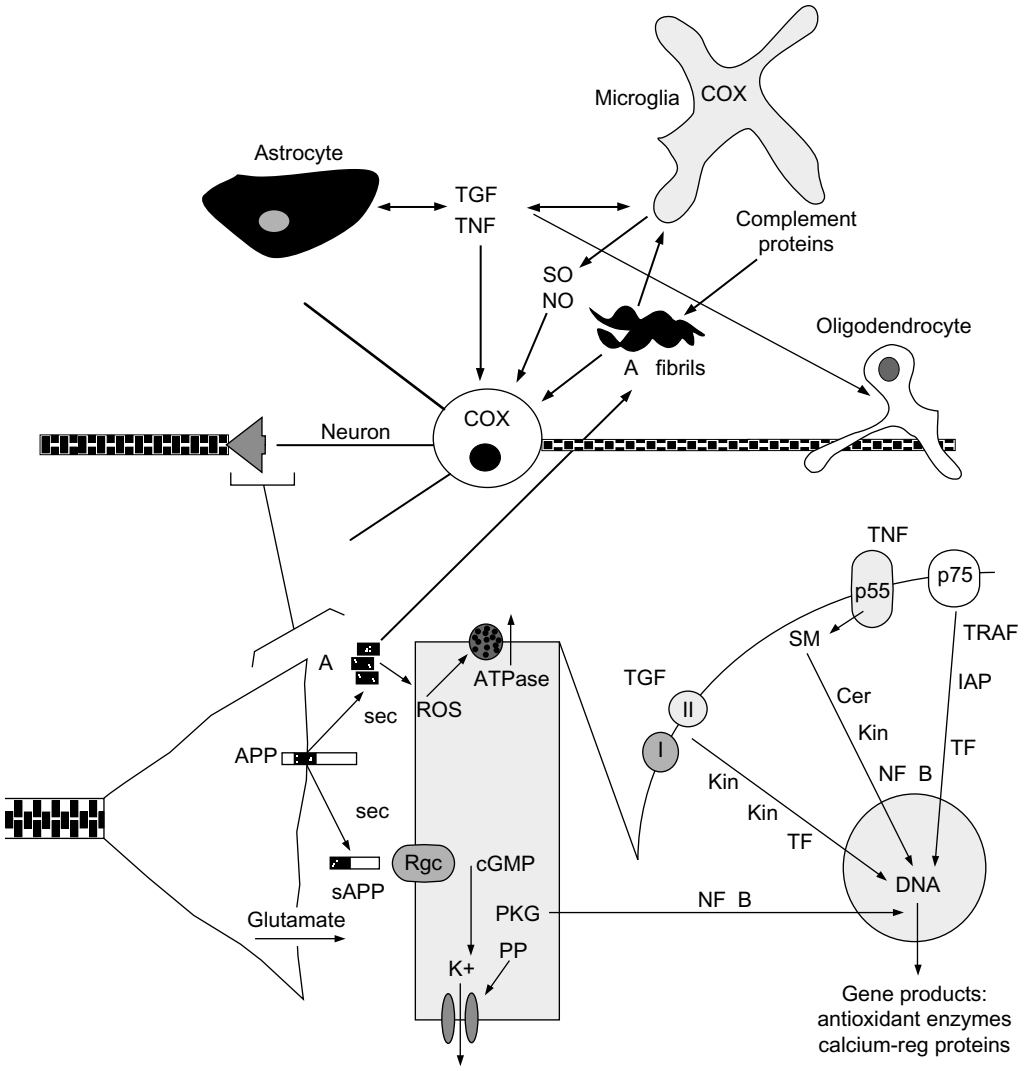

FIG. 23.1. Working model of inflammatory mechanisms that either promote or suppress neuronal degeneration. Neuronal injury and deposition of amyloid β-peptide (Aβ) are likely to trigger inflammatory cascades in AD. Aβ arises from the β-amyloid precursor protein (βAPP); βAPP is transported axonally and may accumulate in membranes of presynaptic terminals (left). Aβ can form aggregates, which induce oxidative stress in neurons and microglial cells, and activate microglia. Alternative enzymatic cleavages of βAPP by α-secretase result in the release of sAPPα from neurons. sAPPα activates a putative receptor guanylate cyclase (GC) in neurons, resulting in cGMP production and activation of cGMP-dependent protein kinase, which then promotes the activation of K^+ channels. cGMP-dependent protein kinase may also induce NF-κB activation, resulting in increased transcription of genes encoding neuroprotective proteins. Activated microglia produce superoxide (via activity of cyclooxygenase; COX) and nitric oxide, which may damage neurons. Cytokines such as TGFβ and TNFα are produced by activated microglia and astrocytes. TGFβ acts on astrocytes and microglia in an autocrine manner to inhibit activation and proliferation, whereas TNFα promotes activation and proliferation of both glial cell types. TGFβ inhibits the proliferation of oligodendrocytes, whereas TNFα may damage oligodendrocytes. Both TGFβ and TNFα increase resistance of neurons to oxidative and excitotoxic insults and may thereby serve a neuroprotective role in AD. TGFβ and TNFα activate specific cell surface receptors, resulting in an intracellular transduction cascade involving kinases (Kin) and transcription factors (TF).

A role for oxygenases in the neurodegenerative process in AD is suggested by studies showing that lipoxygenase inhibitors such as nordihydroguaiaretic acid can protect cultured hippocampal neurons against Aβ toxicity (Goodman *et al*., 1994) and that indomethacin (a cyclooxygenase inhibitor) can suppress microglial activation after infusion of Aβ into the brains of adult rats (Netland *et al*., 1998). However, one concern with such experimental studies, and with the epidemiological and clinical data described later, is that many of the oxygenase inhibitors possess intrinsic antioxidant activity above and beyond their ability to inhibit the oxygenases (Goodman *et al*., 1994). Thus, the beneficial effects of anti-inflammatory drugs may result from their antioxidant actions rather than (or in addition to) their ability to suppress prostanoid production.

Although it is very clear that inflammatory processes play an important role in the pathogenesis of AD after amyloid deposition and neuronal degeneration, it has been suggested that immune alterations may occur prior to amyloid deposition and

TABLE 23.1 Alterations in Lymphocyte Signaling in Presenilin-1 Mutant Knockin Mice

Parameter	Alteration in splenocytes from PS1 mutant mice

	Increased calcium responses to different stimuli
Mitochondrial function	Impaired mitochondrial function and oxyradical levels
Apoptosis	Enhanced spontaneous apoptosis
	Enhanced induced apoptosis
Proliferation	Decreased response to concanavalin A

neuronal degeneration. Mutations in the gene encoding presenilin-1 are responsible for many cases of early onset autosomal dominant AD (Mattson *et al*., 1998). Studies of presenilin-1 mutant knockin mice have shown that an important consequence of the mutations is that calcium regulation is altered in neurons; specifically, presenilin-1 mutations result in enhanced calcium release from ryanodine-sensitive endoplasmic reticulum calcium stores (Guo *et al*., 1999a,b,c). The perturbed calcium regulation endangers neurons such that they are more vulnerable to Aβ, excitotoxicity, and apoptosis. Earlier studies of lymphocytes from patients with sporadic AD and age-matched control patients revealed that calcium signaling is altered in these peripheral immune cells in AD (Eckert *et al*., 1996). Studies have shown that splenocytes from presenilin-1 mutant mice exhibit altered proliferative responses to mitogens, perturbed calcium homeostasis, and increased vulnerability to apoptosis (Table 23.1). The latter alterations were age dependent and occurred prior to any evidence for neurodegenerative changes in the brain. These findings suggest the possibility that alterations in the immune system precede, and possibly contribute to, the neurodegenerative process in AD.

Another type of alteration in AD patients that may contribute to neuronal degeneration and inflammatory processes is dysregulation of the hypothalamus–pituitary–adrenal axis, which manifests increased levels of glucocorticoids and an abnormal dexamethasone suppression response (Raskind *et al*., 1982). Interestingly, studies of amyloid precursor protein mutant transgenic mice have revealed perturbed stress responses associated with hypoglycemia (Pedersen *et al*., 1999). APP mutant mice exhibited severe hypoglycemia and death following food restriction and sustained elevations of plasma glucocorticoid levels and hypoglycemia following restraint stress. These abnormalities were evident in relatively young mice prior to the overt deposition of Aβ, but the presence of diffuse accumulations of Aβ in the hypothalamus suggests a role for soluble forms of the peptide in dysregulation of hypothalamus–pituitary–adrenal function. In light of the fact that inflammatory processes can be modified by the stress response (Elenkov *et al*., 1999), alterations in this neuroendocrine system might modify the disease process in AD patients.

C. Epidemiological and Clinical Data Supporting a Role for Inflammation in AD

Some of the first data implicating an inflammatory response in the pathogenesis of neuronal degeneration and cognitive dysfunction in AD came from epidemiological studies. The results of 15 different studies that examined the relationship of glucocoricoid and nonsteroidal anti-inflammatory drug use and onset or progression of AD have been reviewed (Breitner, 1996). Collectively, epidemiological data make quite a compelling case that the risk for AD is reduced in individuals with a history of chronic treatment with nonsteroidal anti-inflammatory drugs. The possibility that anti-inflammatory drugs might slow the progression of AD is supported by findings of a double-blind, placebo-controlled study in which 100–150 mg of indomethacin/day reduced cognitive decline in patients with mild to moderate AD (Rogers *et al*., 1993). However, a more recent trial of glucocorticoids proved negative (Alzheimer's Consortium Study). The latter result is perhaps not unexpected in light of evidence that glucocorticoids can endanger neurons and increase their vulnerability to Aβ toxicity (Goodman *et al*., 1996). Nevertheless, when taken together with the biochemical, histological, and experimental findings described earlier, epidemiological and clinical data suggest several obvious preventative and therapeutic strategies for AD. The use of nonsteroidal anti-inflammatory drugs, which also possess intrinsic antioxidant actions, seems particularly promising.

II. Free Radicals and the Pathogenesis of AD

Increased oxyradical-mediated damage to cellular proteins, lipids, and nucleic acids occurs in several different age-related neurodegenerative disorders, including AD. Studies of postmortem brain tissue from AD patients have documented increased levels of markers of oxidative stress in association with the two major histopathological lesions: neurofibrillary tangles and deposits of Aβ. Analyses of experimental cell culture and animal models of AD have provided evidence that Aβ induces oxidative stress in neurons, resulting in perturbed energy and ion homeostasis and increased vulnerability to apoptosis and excitotoxicity. Genetic mutations in the APP and presenilins may promote oxidative stress by altering APP processing and disrupting endoplasmic reticulum calcium homeostasis. Experimental and epidemiological data suggest that manipulations that reduce levels of oxidative stress in the brain, such as dietary restriction and administration of vitamin E and estrogen, may reduce risk for AD.

A. Cellular Oxidative Stress Is Increased in Brain Tissue from AD Patients

There is no question that, as in other age-related degenerative diseases (e.g., cardiovascular disease, type 2 diabetes, and cancer), increased levels of cellular oxidative stress play a major role in AD (Mattson, 1997; Markesbery, 1997). Analyses of postmortem tissue from AD patients have revealed increased levels of protein oxidation, membrane lipid peroxidation, and oxidative damage to DNA in association with neuritic plaques and neurofibrillary tangles (C. D. Smith *et al*., 1991; Moccoci *et al*., 1994; Good *et al*., 1996; M. A. Smith *et al*., 1997a; Fu *et al*., 1998). Levels of lipid peroxidation products, including the toxic aldehyde 4-hydroxynonenal, are increased in the cerebrospinal fluid of AD patients relative

to age-matched control patients (Lovell *et al*., 1997), suggesting a widespread increase in cellular oxidative stress in the brain. Further evidence of ongoing oxidative stress in AD brain comes from studies showing that levels of antioxidant enzymes such as catalase, Mn-SOD, and Cu/Zn-SOD are altered in vulnerable brain regions in AD patients compared to corresponding tissues from age-matched control patients (Bruce *et al*., 1997).

B. Experimental Evidence Linking Amyloid Deposition to Oxidative Stress and Neuronal Degeneration in AD

One line of evidence suggesting that increased oxidative stress is a relatively early and pivotal event in the neurodegenerative process in AD comes from analyses of the effects of APP metabolites on cultured neurons (Mattson, 1997, 1998). APP is an axonally transported integral membrane protein, the source of the 40–42 amino acid Aβ that is the major component of amyloid ''plaques'' in the brains of AD patients. Aβ is liberated from APP via two proteolytic cleavages: an initial cleavage at the N terminus of Aβ leaves behind a C-terminal APP fragment, which is then endocytosed and further cleaved at the C terminus of Aβ (Fig. 23.2). Aβ is then released from cells and accumulates in extracellular compartments, initially as diffuse nonfibrillary deposits, which may later transform into classic amyloid fibrils with a β-pleated sheet structure.

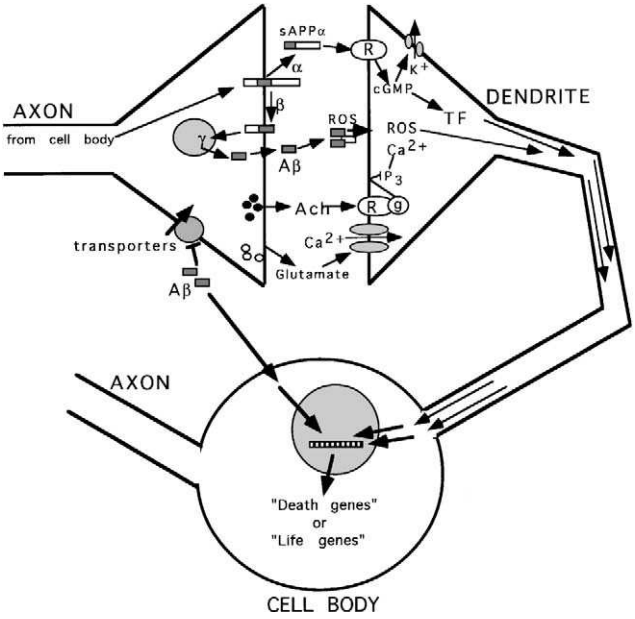

FIG. 23.2. Amyloid precursor protein metabolism and its involvement in synaptic dysfunction and neuronal degeneration in AD. APP is cleaved proteolytically at at least four different sites. α-Secretase cleaves between amino acids 612 and 613, which lies within the Aβ sequence (this cleavage releases sAPPα from the cell surface). β-Secretase cleaves at the N terminus of Aβ (between amino acids 596 and 597), releasing sAPPβ from the cell surface and leaving a C-terminal membrane-associated fragment containing intact Aβ. γ-Secretase cleaves at the C terminus of Aβ at at least two different sites, resulting in the release of intact Aβ1–40 or Aβ1–42. In AD, APP processing is altered in a manner that increases levels of neurotoxic forms of Aβ and decreases levels of neuroprotective sAPPα. See text and Mattson (1997) for further details.

In general, degenerated neurons are associated with fibrillar Aβ deposits, but not with diffuse deposits. Exposure of cultured hippocampal and cortical neurons to Aβ can increase their vulnerability to excitotoxic and metabolic insults (Mattson *et al*., 1992; Cheng and Mattson, 1992; Mark *et al*., 1995b) and can induce apoptosis (Mattson and Begley, 1998; and see Section IV). The mechanism whereby Aβ damages neurons involves, as an initial event, induction of oxidative stress, specifically membrane lipid peroxidation (Goodman and Mattson, 1994; Butterfield *et al*., 1994; Mark *et al*., 1997a). The chemistry underlying the ability of Aβ to induce membrane lipid peroxidation is not established, but appears to occur during the process of transition from soluble to aggregated form and may involve free radical generation by the peptide itself (Hensley *et al*., 1994), possibly catalyzed by metal (Fe^{2+} and or Cu^{2+}) ions (see Section V). Lipid peroxidation is necessary for the neurotoxic actions of Aβ because antioxidants that suppress membrane lipid peroxidation (e.g., vitamin E, propyl gallate, and uric acid) or detoxify 4-hydroxynonenal (e.g., glutathione) protect neurons against Aβ-induced apoptosis and excitotoxicity (Goodman and Mattson, 1994; Mark *et al*., 1995b, 1997a; Keller *et al*., 1998a).

Further studies have elucidated the events subsequent to membrane lipid peroxidation that promote neuronal degeneration (Fig. 23.3). Lipid peroxidation results in production of the aldehyde 4-hydroxynonenal, which, in turn, covalently modifies many different cellular proteins on cysteine, lysine, and histidine residues. Four proteins modified by 4-hydroxynonenal are plasma membrane transporters: the Na^+/K^+-ATPase, the Ca^{2+}-ATPase, the glucose transporter GLUT-3, and the glutamate transporter GLT-1 (Keller *et al*., 1997a; Mark *et al*., 1997a,b; Blanc *et al*., 1998). These transporters play critical roles in the maintenance of cellular ion and energy homeostasis. Accordingly, their modification by 4-hydroxynonenal promotes membrane depolarization and energy (ATP) depletion, thereby rendering neurons vulnerable to excitotoxic and apoptotic cell death. This oxidative stress-mediated cascade of events occurring at the level of the plasma membrane ultimately leads to cellular calcium overload, mitochondrial oxyradical production and dysfunction, and activation of proteases (e.g., caspases and calpains) that contribute to the final destruction of the neuron (Guo *et al*., 1997, 1999a; Keller *et al*., 1998a; Chan and Mattson, 1999). It should also be noted that subtoxic levels of oxidative stress induced by Aβ can disrupt neuronal signaling pathways and may thereby contribute to cognitive dysfunction. For example, Aβ can impair coupling of muscarinic acetylcholine receptors to the GTP-binding protein Gq11 by a mechanism involving membrane lipid peroxidation and 4-hydroxynonenal production (Kelly *et al*., 1996; Blanc *et al*., 1997).

A decrease in the levels of neurotrophic factors and/or impairment of neurotrophic factor signaling pathways has been proposed to contribute to the neurodegenerative process in AD and related disorders (Mattson and Lindvall, 1997). Cell culture studies have directly demonstrated that several different neurotrophic factors, including basic fibroblast growth factor, brain-derived neurotrophic factor, and activity-dependent neurotrophic factor, can protect neurons against oxidative insults, including exposure to Aβ (Mattson *et al*., 1993c, 1995). Interestingly, the secreted form of APP (sAPPα; produced

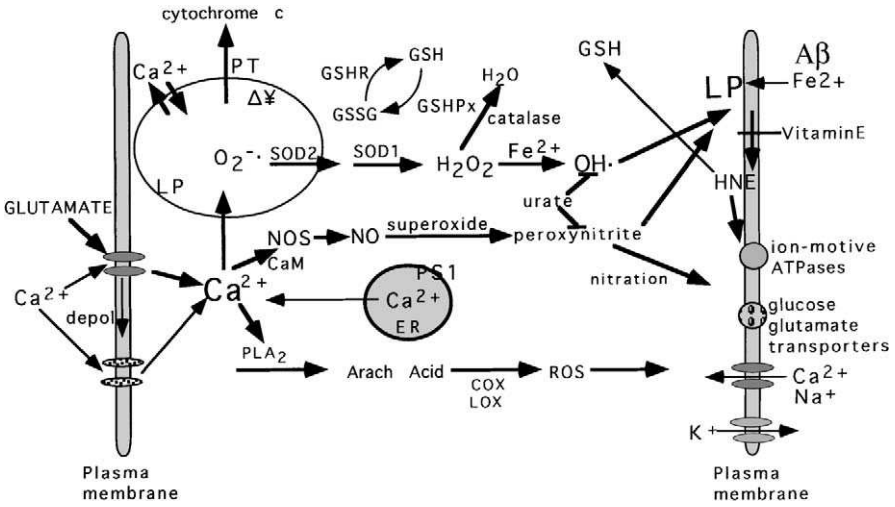

FIG. 23.3. Sources of reactive oxygen species in the brain, mechanisms for their detoxification, and mechanisms of oxidative disruption of neuronal ion homeostasis. The preeminent subcellular source of oxyradicals is mitochondria, wherein $O_2^-\cdot$ is generated during the electron transport process. Superoxide dismutases (SOD) convert $O_2^-\cdot$ to H_2O_2, which, in the presence of Fe^{2+}, generates $OH\cdot$. $O_2^-\cdot$ can also interact with nitric oxide (NO) to form peroxynitrite. Both $OH\cdot$ and peroxynitrite induce membrane lipid peroxidation (LP), which may occur in the plasma membrane, mitochondrial membranes, and endoplasmic reticulum (ER) membranes. Additionally, exogenous agents such as amyloid β-peptide (Aβ) can induce LP. LP liberates 4-hydroxynonenal (HNE), which binds to membrane transporters and ion channels, thereby altering their activities. Impairment of the Na^+/K^+-ATPase, glucose transporter, and glutamate transporters results in membrane depolarization and excessive activation of glutamate receptors, resulting in excitotoxicity. LP also perturbs ion homeostasis in ER and mitochondria, thereby compromising their important Ca^{2+} sequestration functions. It should be noted that not only does MLP lead to an elevation of $[Ca^{2+}]_i$ but, conversely, elevation of $[Ca^{2+}]_i$ promotes MLP by inducing NO and $O_2^-\cdot$ production, as well as by activation of phospholipases, resulting in production of arachidonic acid, which is then acted on by cyclooxygenases (COX) and lipoxygenases (LOX) with resulant generation of reactive oxygen species (ROS). PS1, presenilin-1. Modified from Mattson (1998a).

via anzymatic cleavage of APP in the middle of Aβ) potently protects neurons against Aβ toxicity by a mechanism involving reduced levels of oxidative stress (Goodman and Mattson, 1994; Furukawa *et al*., 1996). Levels of sAPPα have been reported to be decreased in the cerebrospinal fluid of AD patients (Palmert *et al*., 1990) and in neurons expressing presenilin-1 mutations (Ancolio *et al*., 1997). Thus, a decrease in the trophic support of sAPPα may contribute to the increased oxidative stress documented in the brains of AD patients.

C. Role of Oxidative Stress in the Pathogenic Actions of Genetic Aberrancies Linked to Early-Onset AD

Some cases of AD are inherited in an autosomal dominant manner and have an early age of onset (30–50 years of age). Identification of mutations in APP and presenilin-1 as being causally linked to some such cases of familial AD has proven invaluable in producing novel experimental models of AD and in elucidating the molecular and biochemical underpinnings of the neurodegenerative process. Patients with APP and presenilin mutations exhibit brain pathology essentially indistinguishable from that of patients with sporadic AD. Although not yet confirmed, one would presume that (as is the case in sporadic AD patients) oxidative cellular damage is also increased in the brains of familial AD patients. Studies of transgenic mice expressing AD-linked APP and presenilin mutations support a central role for oxidative stress in the pathogenesis of AD. For example, increased levels of membrane lipid peroxidation and protein oxidation occur in association with age-related amyloid accumulation in the brains of APP mutant transgenic mice (Smith *et al*., 1998a). Analyses of cortical tissue from knockin mice expressing the M146V presenile-1 mutation have shown that levels of protein oxidation are increased in older presenile-1 mutant mice (18 months old) compared to age-matched control mice (Fig. 23.4) The mechanism whereby APP mutations lead to increased oxidative stress most likely

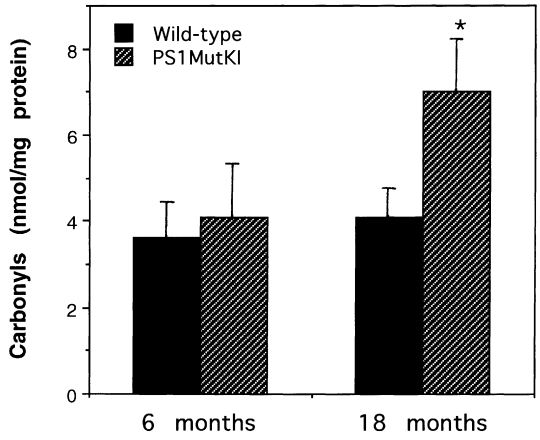

FIG. 23.4. Evidence that levels of protein oxidation are increased in aged PS1 mutant knockin mice. Levels of protein carbonyls were quantified in homogenates of cerebral cortex from 6- and 18-month-old wild-type and PS1 mutant knockin mice. Values are the mean $\pm$SD (four mice/group). $^*p < 0.01$ compared to value for 18-month-old wild-type mice.

involves the altered proteolytic processing scenario described earlier, which results in increased production of neurotoxic forms of Aβ and decreased production of neuroprotective sAPPα (Mattson, 1997).

A series of studies of cultured neurons have elucidated the mechanism whereby presenilin-1 mutations promote oxidative stress and neuronal degeneration. PC12 cells overexpressing mutant presenilin-1 exhibit increased vulnerability to apoptosis, which is associated with an increased production of hydrogen peroxide following exposure to Aβ (Guo *et al*., 1996, 1997). The latter studies further showed that antioxidants can counteract the proapoptotic action of the presenilin-1 mutations. PC12 cells expressing mutant presenilin-1 also exhibit increased mitochondrial oxyradical production following exposure to mitochondrial toxins (Keller *et al*., 1998b). The enhanced oxyradical production in cells expressing mutant presenilin-1 results from a disturbance in cellular calcium homeostasis. Specifically, presenilin-1 mutations result in enhanced calcium release from IP_3- and ryanodine-sensitive endoplasmic reticulum stores (Guo *et al*., 1996, 1997). Accordingly, treatment of neurons expressing mutant presenilin-1 with dantrolene, an agent that blocks calcium release from the endoplasmic reticulum, protects them against the endangering effect of the mutation (Guo *et al*., 1997, 1999a). Hippocampal and cortical neurons in presenilin-1 mutant knockin mice exhibit increased vulnerabilty to excitotoxic and ischemic injury, two insults that damage neurons, in part, via free radical production (Guo *et al*., 1999a; Mattson *et al*., 2000). Analyses of calcium regulation and free radical metabolism in hippocampal neurons from presenilin-1 mutant mice have shown that perturbed calcium homeostasis in the endoplasmic reticulum plays a central role in promoting oxidative stress (Guo *et al*., 1999a,b,c).

Apolipoprotein E, well known for its role in cholesterol metabolism and the pathogenesis of cardiovascular disease, also plays a role in modifying risk for AD. Thus, individuals with the ApoE4 isoform of apolipoprotein E are at increased risk for AD (Strittmatter and Roses, 1996) and exhibit increased levels of markers of oxidative stress (e.g., levels of 4-hydroxynonenal associated with neurofibrillary tangles) (Montine *et al*., 1997) than individuals expressing a different isoform (ApoE2 or ApoE3). Studies have identified a mechanism whereby ApoE4 promotes, whereas ApoE3 and ApoE2 suppress oxidative damage to neurons. Thus, the ApoE isoforms differ in the amount of 4-hydroxynonenal they can bind with ApoE2 binding more than ApoE3, which, in turn, binds more than ApoE4 (Pedersen *et al*., 2000). The latter study further showed that ApoE2 and ApoE3 were much more effective in protecting hippocampal neurons against Aβ toxicity than ApoE4. Thus, the apolipoprotein E genotype appears to affect risk for AD by modifying the antioxidant capacity of the protein.

D. Epidemiological and Experimental Data Suggest That Dietary Restriction and Antioxidants May Reduce Risk for AD

Epidemiological and clinical data support the oxidative stress hypothesis of AD. Increased dietary supplementation with vitamins E and C are associated with reduced risk for AD (Morris *et al*., 1998). In addition, estrogen replacement therapy in postmenopausal women decreases their risk for AD greatly (Tang *et al*., 1996). Experimental studies have shown that estrogen exhibits antioxidant activity and that its ability to suppress membrane lipid peroxidation accounts for its ability to protect neurons against AD-relevant insults, including exposure to Aβ and Fe^{2+} (Goodman *et al*., 1996; Keller and Mattson, 1997). A clinical trial of vitamin E in patients with mild AD resulted in a significant slowing of the progression of the disease (Sano *et al*., 1997). Moreover, the benefit of anti-inflammatory drugs in AD patients may result from their well-established antioxidant activity (see Section I).

Reducing the calorie intake of laboratory rats and mice increases their life span dramatically and reduces the development of age-related cancers and deficits in immune function (Sohal and Weindruch, 1996). Although benefits of dietary restriction on the cardiovascular, immune, and endocrine systems have been demonstrated, its effects on the nervous system are largely unknown. Data suggest that dietary restriction may slow age-related molecular changes in the brain and attenuate age-related deficits in learning and memory ability and motor function in rodents (Finch and Morgan, 1997). In a prospective study of a multiethnic cohort in New York City, it was found that those with the lowest daily calorie intakes had the lowest risk for AD (Mayeux *et al*., 1999). A similarly designed study showed that persons with a low calorie intake have reduced risk for Parkinson's disease (Logroscino *et al*., 1996).

In experimental studies relevant to AD, maintenance of rats on dietary restriction for 2–4 months resulted in resistance of hippocampal neurons to kainate-induced degeneration and associated deficits in learning and memory (Bruce-Keller *et al*., 1999). Interestingly, maintenance of presenilin-1 mutant knockin mice on a calorie-restricted diet (a manipulation known to reduce levels of age-related oxidative stress) results in decreased vulnerability of hippocampal neurons to excitotoxic injury (Zhu *et al*., 1999). In addition, maintenance of mice on dietary restriction increases the resistance of dopaminergic neurons in their substantia nigra to MPTP toxicity in a model of Parkinson's disease (Duan and Mattson, 1999), suggesting that dietary restriction may be of benefit in several different age-related neurodegenerative disorders. The mechanism whereby dietary restriction protects neurons in the brain against aging and disease may involve reduced levels of oxidative stress and a preconditioning response (Lee *et al*., 1999; Yu and Mattson, 1999).

III. Glycation in Aging and AD

Glycation is a process in which monosaccharides such as glucose modify N-terminal amino acid groups, and arginine and lysine residues, of proteins. Glycation is promoted by transition metals and oxyradicals, and glycation, in turn, induces oxidative stress. There is a progressive increase in glycation of many different proteins during aging, and an apparent acceleration of glycation of proteins in the brains of patients with AD. Both the microtubule-associated protein tau (the major component of neurofibrillary tangles) and Aβ (the major component of plaques) have been reported to be heavily glycated. Experimental studies have shown that glycated tau is neuro-

toxic, that glycation enhances amyloid β-peptide induced neuronal damage, and that Aβ can bind to cell surface receptors for advanced glycation end products located on microglia, thereby inducing microglia to produce neurotoxic substances. Protein glycation may contribute to the increased levels of oxidative stress, and synaptic and neuronal degeneration in AD, and therapeutic agents that suppress glycation are therefore being evaluated.

A. Glycation Chemistry

One well-recognized marker of aging is the modification of proteins by sugars, a process called glycation (Brownlee, 1995). The process of protein glycation, which is called the "Maillard reaction," involves the reaction of monosaccharides (e.g., glucose, fructose and hexose-phosphates) with N-terminal amino groups (and side chains of arginine and lysine residues) of proteins (Fig. 23.5). The initial reaction involves reversible formation of Schiff–base adducts, which then form Amadori products. Subsequent oxidation of the Amadori products as catalyzed by Fe^{2+}, Cu^{2+}, or hydroxyl radicals, for example, results in the formation (via reactive intermediates) of protein-bound advanced glycation end products (AGE). AGE may consist of one or more of several cross-links, including pyralline and pentosidine. Importantly, AGE formation is largely irreversible and causes cross-linking of proteins such that they form insoluble deposits. The formation of AGE has been studied extensively as a process that occurs in extracellular matrix proteins such as collagen and has been linked to several age-related diseases, including atherosclerosis and type-2 diabetes (Mullarkey *et al*., 1990; Ceriello, 1999; Sano *et al*., 1999). The following findings suggest an important role for AGE in the cross-linking and deposition of amyloid and cytoskeletal proteins in the brain in AD.

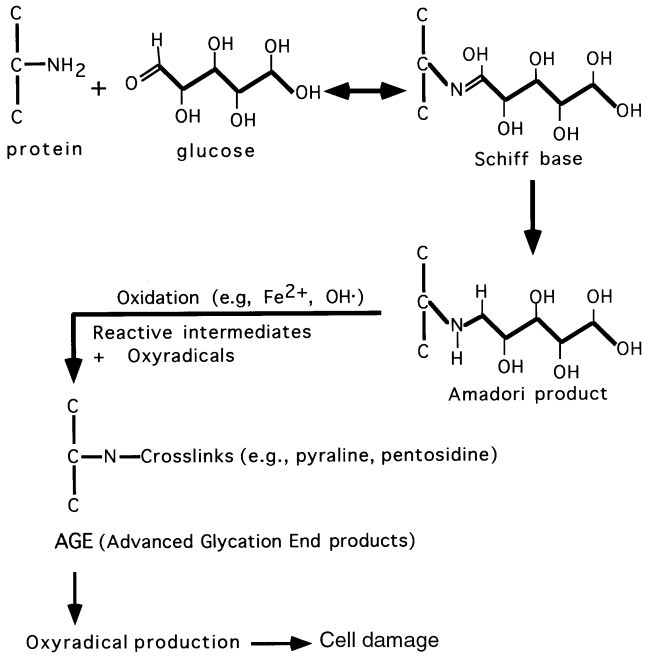

FIG. 23.5. Chemistry of protein glycation.

B. Evidence for Increased Protein Glycation in the Brain in AD

Several findings suggest that protein glycation may contribute to the pathogenesis of AD. As in other organ systems, levels of AGE increase in the brain during aging. Histochemical analyses indicate that AGE products accumulate to particularly high levels in pyramidal neurons of the cerebral cortex and hippocampus (Li *et al*., 1995; Kimura *et al*., 1996), neuronal populations that are selectively vulnerable in AD. Advanced glycation end products are associated with both amyloid plaques and neurofibrillary tangles in postmortem brain tissue from AD patients (Smith *et al*., 1994; Vitek *et al*., 1994). Immunostaining with antibodies that selectively recognize AGE-modified proteins reveals staining associated with extracellular amyloid deposits (both diffuse and senile plaques), as well as in astrocytes (Kimura *et al*., 1995). Ko *et al*. (1999) generated antibodies that selectively recognize Nϵ-carboxymethyl-lysine, a stable AGE known to accumulate during aging. The antibodies labeled PHF-tau on immunoblots, and immunoelectron microscopy demonstrated immunoreactivity with PHF. The patterns of AGE in AD brain are roughly similar to the patterns of oxidative stress (see Section II), suggesting that increased oxidative stress plays a role in AGE formation. The latter possibility would be consistent with the evidence that increased levels of oxidative stress occur at a relatively early stage in the neurodegenerative process. Because AGE may promote further oxidative stress, an amplifying cascade of free radical production and protein glycation and cross-linking may occur.

C. Experimental Evidence Implicating AGE in the Pathogenesis of AD

Two proteins central to the pathogenic process in AD that are modified by AGE are Aβ (Vitek *et al*., 1994), the main component of plaques, and the microtubule-associated protein tau (Yan *et al*., 1995), the major component of neurofibrillary tangles. In light of the well-established ability of glycation to promote protein cross-linking, it seems likely that the modification of amyloid β-peptide and tau by AGE may accelerate their cross-linking and fibril formation. In the case of tau, amino acids within the microtubule-binding domain are glycated (Ledesma *et al*., 1995), whereas amino acids modified in Aβ are unclear. Nonglycated Aβ generates free radicals and induces oxidative stress in neurons (Hensley *et al*., 1994; Goodman and Mattson, 1994), and this process is enhanced by Fe^{2+} (Goodman and Mattson, 1994). Such Aβ-associated free radical production appears to play a key role in peptide aggregation and fibril formation (Dyrks *et al*., 1992; Hensley *et al*., 1994). It is therefore likely that in the presence of Fe^{2+}, radicals arising from Aβ contribute to both glycation of the amyloid and neurotoxicity. Indeed, Aβ induces membrane lipid peroxidation and promotes apoptosis in neurons (Mark *et al*., 1995b; Kruman *et al*., 1997), and glycation of Aβ may enhance its neurotoxic effects (Yan *et al*., 1996). Experimental studies have provided evidence that glycated tau is also capable of inducing oxidative stress in cultured neuronal cells (Yan *et al*., 1995). Thus, protein glycation may contribute to oxidative stress occurring at the cell surface (Aβ) and within neurons (tau).

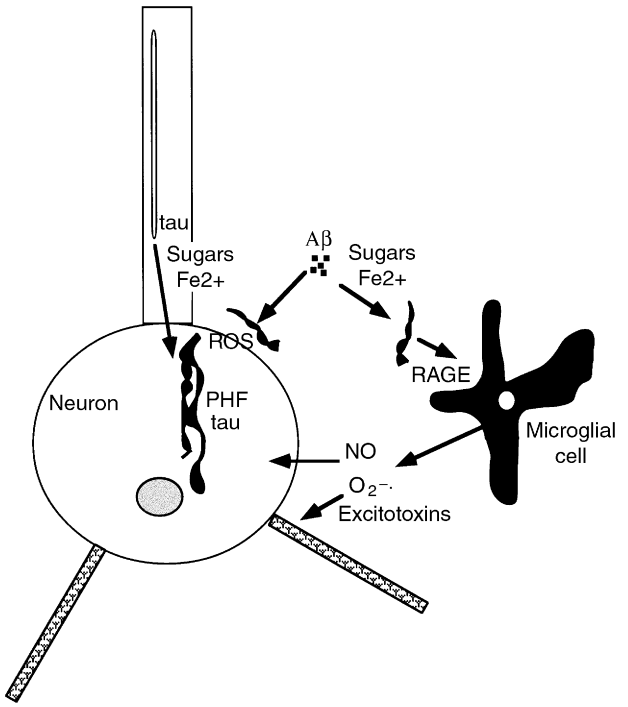

FIG. 23.6. Possible mechanisms whereby glycation contributes to aggregation of amyloid and tau and neuronal degeneration in AD.

One established mechanism whereby AGE can induce oxidative stress is by activating microglia (Vlassara *et al*., 1986, 1988). Microglia express several receptors that can bind glycated proteins, including the scavenger receptor and the (receptor for advanced glycation end products (RAGE) (Schmidt *et al*., 1994; Araki *et al*., 1995). Activation of the receptors induces cytokine production and generation of reactive oxygen species (superoxide and nitric oxide) and excitotoxins, which may have adverse effects on neurons (Fig. 23.6). A role for microglial activation by AGE in the pathogenesis of AD is suggested by the presence of activated microglia in association with amyloid plaques (see Section I) and by the ability of Aβ to activate microglia via a RAGE-mediated mechanism (Yan *et al*., 1996). An indirect, microglia-mediated mechanism of AGE-induced neuronal injury in AD is further suggested by the lack of AGE receptors in neurons. Thus, it is unlikely that RAGE mediates direct neurotoxic effects of glycated proteins. The cytokine cascade induced by glycated proteins may play an important role in inducing an inflammation-like process involving microglial activation. In this regard, increased levels of activation of the transcription factor NF-κB have been documented in cells associated with amyloid deposits in AD brain (Kaltschmidt *et al*., 1997). Whereas activation of NF-κB in neurons can protect them against apoptosis and excitotoxicity (Barger *et al*., 1995; Mattson *et al*., 1997; Yu *et al*., 1999), activation of NF-κB in microglia induces cell activation and cytokine production. However, NF-κB also induces expression of neuroprotective cytokines such as TGF-β, and neurotrophic factors, such as nerve growth factor (NGF) (Heese *et al*., 1998). Therefore, the relative contributions of production of neurotoxic versus neuroprotective agents by microglia remain an important area for future investigations.

Beyond glycation of proteins linked to AD, per se, glycation of other proteins may contribute to AD and related disorders. There is a general increase in protein glycation throughout the body during usual aging, and there are several examples in the literature of proteins subject to glycation that are relevant to the neurodegenerative cascade in AD. Thus, it was shown that glycation of the glucose transporter protein results in impaired glucose transport in erythrocytes (Bilan and Klip, 1990), and impaired glucose transport is believed to be an important early event in the neurodegenerative process in AD (Mark *et al*., 1997b). Similarly, the plasma membrane Na^+/K^+-ATPase can be glycated on residues within its catalytic site, resulting in impaired ATPase activity (Katori *et al*., 1999); experimental findings relevant to AD have shown that Aβ and oxidative stress can impair Na^+/K^+-ATPase activity in hippocampal neurons (Mark *et al*., 1995b).

D. Therapeutic Approaches That Target Glycation

Efforts to develop compounds that inhibit or even reverse protein glycation are being actively pursued. Munch *et al*. (1997) reported that formation of AGE-modified Aβ could be prevented by the AGE inhibitors aminoguanidine, carnosine, and tenilsetam. Other compounds reported to inhibit glycation include aryl and heterocyclic ureido, and aryl and heterocyclic carboxamidophenoxyisobutyric acids (Rahbar *et al*., 1999).

IV. Signaling and Apoptosis in AD

The extended period of time during which neurons die and the morphological features of the cell death in AD are consistent with the process of apoptosis. Analyses of postmortem brain tissue from AD patients have also revealed biochemical changes suggestive of apoptosis, including increased production of ''death proteins'' such as Par-4 and Bax, activation of cysteine proteases called caspases, and release from mitochondria of apoptotic factors such as cytochrome c. Experimental studies have shown that insults relevant to AD (e.g., exposure of neurons to Aβ and oxidative and metabolic insults) induce neuronal apoptosis. Data from analyses of brain tissue from AD patients and experimental models suggest that oxidative stress and disruption of cellular calcium homeostasis are important triggers of neuronal apoptosis in AD. In addition, studies of mice expressing mutant forms of presenilin-1 linked to early-onset inherited AD strongly implicate apoptosis in the neurodegenerative process. Interestingly, findings have shown that apoptotic biochemical cascades can be activated locally in synaptic terminals and neurites of neurons and that degeneration of these regions of neurons (and resultant synaptic dysfunction) may occur prior to cell death. Research is also revealing signaling mechanisms that may normally prevent neuronal apoptosis, and possibly AD. For example, several different neurotrophic factors have been shown to prevent neuronal apoptosis in experimental models of AD. Moreover, antioxidant administration and caloric restriction can protect neurons against insults relevant to AD, suggesting that dietary manipulations may prove effective in preventing and treating AD.

A. Signaling Mechanisms That Regulate Neuronal Survival: Alterations in AD

During brain development, neuroblasts initially proliferate and then cease dividing and differentiate into neurons. Differentiation involves a variety of morphological and biochemical changes, including formation of axons and dendrites, and expression of neurotransmitter receptors and ion channels. During the period of synapse formation, many neurons die by a process called apoptosis or ''programmed cell death.'' Studies of such developmental neuronal death have revealed that whether or not a neuron dies depends on the state of activation of different signal transduction pathways by intercellular signals such as neurotrophic factors and neurotransmitters. Neurotrophic factors are a diverse group of proteins that are produced by neurons and glial cells and act on neurons to promote their survival, growth, and plasticity. Activation of cell surface receptors by neurotrophic factors induces signaling cascades involving multiple kinases, which ultimately result in changes in gene expression and/or protein function. For example, nerve growth factor and brain-derived neurotrophic factor can induce the expression of antioxidant enzymes and can modulate ion channel function in cultured hippocampal neurons (Cheng *et al*., 1993; Mattson *et al*., 1995). Neurotransmitters also influence neuronal survival, growth, and plasticity. One prominent example is the excitatory neurotransmitter glutamate, which has been shown to regulate neurite outgrowth and synaptogenesis in the developing hippocampus (Mattson, 1988) on the one hand, while making a major contribution to neuronal calcium overload and cell death in experimental models of neurodegenerative disorders on the other (Mattson *et al*., 1993a; Doble, 1999). Additional types of intercellular signals that play important roles in regulating neuronal survival and plasticity are cytokines such as TNF and TGF-β (Mattson *et al*., 1996).

Evidence that signaling systems that normally regulate neuronal survival and plasticity are altered in AD is accumulating. Alterations in levels of neurotrophic factors and/or their receptors have been found in studies of postmortem brain tissue from AD patients. For example, NGF levels increase in many of the brain regions innervated by basal forebrain cholinergic neurons, but decrease in the nucleus basalis, suggesting the occurrence of perturbations of NGF signaling (Scott *et al*., 1995). Moreover, there appears to be a defect in retrograde transport of NGF in basal forebrain cholinergic neurons in AD associated with a decrease in expression of the high-affinity NGF receptor (trkA) by the same neurons (Mufson and Kordower, 1997). Thus, the reduced ability to respond to NGF could contribute to the demise of cholinergic neurons in the brains of AD patients. Levels of brain-derived neurotrophic factor were decreased significantly in the hippocampus of AD patients (Phillips *et al*., 1991), whereas levels of the secreted form of APP were decreased in cerebrospinal fluid from AD patients (Palmert *et al*., 1990). It is therefore possible that deficiencies of these factors could contribute to the degeneration of neurons in AD.

Levels of some neurotrophic factors (e.g., basic fibroblast growth factor) and cytokines (e.g., TGF-β and IL-1) are elevated in the vicinity of neuritic plaques (Cummings *et al*., 1993; van der Wal *et al*., 1993; Griffin *et al*., 1995). The influence of these factors on neurons in those locations is not known, although studies of experimental models of AD suggest that neurotrophic factor signaling can prevent neuronal cell death. Thus, several different neurotrophic factors and cytokines, including basic fibroblast growth factor, brain-derived neurotrophic factor, activity-dependent neurotrophic factor, the secreted form of APP, and TNF can protect cultured hippocampal neurons against cell death induced by amyloid β-peptide and oxidative and metabolic insults relevant to the pathogenesis of AD (Cheng and Mattson, 1991; Mattson *et al*., 1993c; Goodman and Mattson, 1994; Guo *et al*., 1999c). Neurotrophic factors and cytokines promote neuron survival by modulating gene expression in a manner that suppresses oxyradical production and stabilizes cellular calcium homeostasis (Mattson and Lindvall, 1997).

A contribution of overactivation of glutamate receptors to the pathogenesis of AD is suggested by studies showing that glutamate receptor activation can induce alterations in the cytoskeleton and the microtubule-associated protein tau similar to those seen in neurofibrillary tangles (Mattson, 1990; Stein-Behrens *et al*., 1994) and that Aβ and oxidative stress render neruons vulnerable to excitotoxicity (Mattson *et al*., 1992). In addition, deficits in neurotrophic factors, such as brain-derived neurotrophic factor and the secreted form of APP, may promote excitotoxic neuronal degeneration in AD because these factors can protect neurons against excitotoxicity in cell culture and *in vivo* (Mattson *et al*., 1993d; Cheng and Mattson, 1994; Smith-Swintosky *et al*., 1994). Moreover, hippocampal and cortical neurons in mice expressing mutations in the presenilin-1 gene linked to early-onset, autosomal-dominant AD exhibit increased vulnerability to excitotoxicity and ischemia (Guo *et al*., 1999a; Mattson *et al*., 2000a). Excessive glutamate receptor activation can induce apoptosis in neurons. Dysregulation of other neurotransmitter systems has also been documented in studies of AD patients. For example, alterations in cholinergic signaling in AD are well established and may contribute to both cognitive dysfunction and neuronal death (Mattson and Pedersen, 1998). Exposure of cultured cortical neurons to Aβ and oxidative insults impairs muscarinic cholinergic signaling in a manner similar to that seen in brain tissue from AD patients (Kelly *et al*., 1996; Blanc *et al*., 1997). Finally, GABA agonists can protect neurons against excitotoxicity (Mattson and Kater, 1989) and Aβ toxicity (Mark *et al*., 1995a), and studies have shown that transgenic mice overexpressing a presenilin-1 mutation exhibit altered hippocampal synaptic plasticity that can be restored to normal by treatment with agents that activate GABA receptors. Thus, altered inhibitory transmission might also contribute to the neurodegenerative process in AD.

B. Aberrant Signaling and Neuronal Apoptosis in AD

Exposure to aggregating forms of Aβ, insufficient neurotrophic factor support, overactivation of glutamate receptors, and metabolic and oxidative stress can each induce neuronal apoptosis in experimental models relevant to AD (Mattson and Furukawa, 1996; Mattson, 1997). Before describing the evidence supporting a role for neuronal apoptosis in AD, several morphological, biochemical, and molecular features that are currently being used to classify the cell death process as

TABLE 23.2 Examples of Criteria Used to Distinguish Apoptosis and Necrosis

Apoptosis	Necrosis
Cell shrinkage	Cell swelling
Membrane blebbing	Loss of membrane integrity
Membrane integrity maintained	Organellar disruption
Exposure of phosphatidylserine on cell surface	
Nuclear DNA condensation and fragmentation	
Maintenance of ATP levels	Decrease in ATP levels
Partial maintenance of ion homeostasis	Loss of ion homeostasis
Mitochondrial membrane permeability transition	
Release of cytochrome c	
Production of Par-4, Bax, and other "death proteins"	Cessation of protein synthesis
Caspase activation
