Over a century elapsed between the first description of the Huntington's disease phenotype by George Huntington in 1872 and the discovery of the genetic defect underlying the disease in 1993 (Huntington's Disease Collaborative Research Group, 1993). A physician in Long Island, New York, the familial inheritance of the disease was well known to Huntington from the family histories passed down to him by his grandfather and father. Huntington's disease is now known to be an autosomal dominantly inherited neurodegenerative disorder characterized by the adult onset and progressive development of behavioral abnormalities, cognitive impairment, and involuntary choreiform movements, with a typical duration of 15–20 years. The genetic abnormality in Huntington's disease is a CAG repeat expansion in a gene encoding a 350 kDa protein of unknown function, termed "huntingtin" (Huntington's Disease Collaborative Research Group, 1993). It is thought to be a true dominant disorder since homozygous patients do not seem to differ from heterozygote carriers in either age of onset, duration, or severity of the disease (Durr *et al*., 1999). Despite its identification, the definitive role of mutant huntingtin in neuronal degeneration remains unknown. As discussed below, the insidious progression of motor and behavioral disturbances in Huntington's disease reflects the selective pattern of cell loss in the brain and the specific neurotransmitter pathways affected. The reason for the preferential vulnerability of striatal neurons in Huntington's disease is still enigmatic, and cannot be simply explained in terms of the distribution of abnormal huntingtin since the gene mutation is expressed throughout the body. However, experimental evidence suggests that the pathogenesis of cell death in Huntington's disease is linked to a gain of function of mutant huntingtin. In addition, studies in both human Huntington's disease brain and transgenic mouse model of Huntington's disease have identified widespread neuronal intranuclear and cytoplasmic aggregations of mutant huntingtin that may be linked to the disease process. In the following review we have collated the experimental information available to date to give insight into the link between the Huntington's disease gene mutation and selective neuronal dysfunction and death in this disease.

II. Neuropathological Features and Motor Dysfunction in Huntington's Disease

A. Pathological Changes in Huntington's Disease Brain

The typical neuropathological features of Huntington's disease are progressive caudal to rostral degeneration of the caudate-putamen (Vonsattel and DiFiglia, 1998). Patients are graded at postmortem according to the extent of gross and microscopic measures of neuropathological severity, grades ranging from 0 to 4 with increasing severity and extent of striatal involvement (Vonsattel *et al*., 1985). Briefly, grade 0 brains exhibit 30–40% neuronal loss in the head of the caudate, with no visible signs of reactive gliosis. In contrast, in grade 4 more than 95% of striatal neurons are lost, the striatum is severely atrophic with marked gliosis, and about 50% of end-stage

cases show cell loss in the nucleus accumbens. Most Huntington's disease cases reach grade 3 or 4 by the time of death, by which stage nonstriatal regions are also involved, in particular the globus pallidus, cortex, and, to a lesser extent, thalamus, subthalamic nucleus, substantia nigra, white matter, and cerebellum (Sotrel *et al*., 1991; Braak and Braak, 1992; Vonsattel and DiFiglia, 1998). Fibrillary astrogliosis occurs in the striatum, but has not been reported in other affected areas, and no inflammatory responses are involved (Myers *et al*., 1991). In cases of juvenile onset Huntington's disease cerebellar atrophy is particularly prevalent.

The striatal cells most susceptible to degeneration in Huntington's disease are medium spiny projection neurons (Beal, 1994a). Spiny neurons, which constitute 80% of striatal neurons, are the principal input and output neurons of the striatum. All contain the inhibitory neurotransmitter γ-aminobutyric acid (GABA), while subsets also contain enkephalin (ENK), Substance P (SP), dynorphin, or calbindin. The other major class of striatal neurons are aspiny interneurons. Nicotinamide adenine dinucleotide phosphate diaphorase (NADPH-d), neuropeptide Y (NPY), somatostatin, and nitric oxide synthase (NOS) typically colocalize in medium-sized aspiny neurons, and some also contain cholecystokinin or the calcium-binding protein parvalbumin. In Huntington's disease striatum, spiny projection neurons containing SP or ENK degenerate earliest in the course of the disease, whereas aspiny interneurons and the larger cholinergic interneurons are relatively spared (Ferrante *et al*., 1987; Beal *et al*., 1988). There is also some hierarchy in the vulnerability of different spiny neuron subpopulations; ENK-immunoreactive neurons projecting to the external segment of the globus pallidus (GPe) degenerate prior to SP-containing neurons projecting to the internal segment (GPi) (Reiner *et al*., 1988; Richfield *et al*., 1995; Sapp *et al*., 1995). Spiny neurons also undergo morphological changes in the course of the disease process in Huntington's disease, including recurving of the dendrites, altered shape and size of the spines, and increased density of spines.

Surviving neostriatal neurons are generally morphologically normal, although some are reduced in size and contain elevated levels of the oxidative damage marker lipofuscin. A subpopulation of ''neostriatal dark neurons'' has also been described by Vonsattel *et al*. (1985), scattered between the zones of atrophic and healthy cells. Interestingly, markers of apoptotic cell death have been detected in these neostriatal dark neurons (for example, granulation of the cytoplasm and condensation of nuclear chromatin and labeling by TdT-mediated dUTP-biotin nick end-labelling [TUNEL]; Vonsattel and DiFiglia, 1998).

B. Motor Dysfunction

The motor defects typical of Huntington's disease result from the disruption of basal ganglia-thalamocortical pathways which regulate movement control. The neostriatum (caudate nucleus and putamen) receives excitatory glutamatergic inputs from the entire neocortex, the first step in the anatomical loop responsible for the initiation and execution of movement. Processed signals are transmitted via basal ganglia output nuclei (GPi, the substantia nigra pars reticulata, SNr, and ventral pallidum) to the thalamus, which in turn sends excitatory projections to areas of the frontal cortex associated with motor planning and execution (Albin *et al*., 1989; Alexander and Crutcher, 1990; Graybiel *et al*., 1994). The GABAergic basal ganglia output projections to the thalamus maintain a tonic inhibition of their target nuclei, which is modulated by two opposing pathways (direct and indirect) which integrate the input and output compartments within the basal ganglia (Fig. 49.1). It is an imbalance in the relative contributions of these two regulatory pathways that triggers, and dictates the nature of, the motor dysfunction in Huntington's disease. In the direct (monosynaptic) pathway, activation of striatal efferents containing GABA and SP projecting directly to the GPi results in disinhibition of thalamic activity. In contrast, in the indirect (polysynaptic) pathway striatal efferents containing GABA and enkephalin project to the GPe which sends purely GABAergic projections to the subthalamic nucleus. From here, excitatory efferents (probably glutamatergic) project to the basal ganglia output nuclei (SNr and GPi). The GPe projection generally exerts a tonic inhibition on the subthalamic nucleus. Activation of GABA/ENKergic striatal efferents tends to suppress activation of GPe neurons, causing disinhibiton of the subthalamic nucleus and hence an increase in the excitatory innervation of the basal ganglia output nuclei. This leads to an increased inhibitory input to the target thalamic nuclei. Thus, cortical function is differentially modulated depending on which basal ganglia pathway, and therefore which thalamocortical pathway, is activated (Albin *et al*., 1989; Alexander and Crutcher, 1990). In Huntington's disease there is preferential loss of the GABA/ENK-containing neurons comprising the indirect pathway. ''Disinhibition'' of the thalamus results, which is manifest in Huntington's disease patients by the development of involuntary choreic movements. The later onset of a rigid akinetic state in some Huntington's disease patients is thought to result from the additional loss of striatal GABA/SP-containing efferents projecting directly to the GPi (Albin *et al*., 1990).

III. Mutant Huntingtin Protein in Huntington's Disease

The genetic defect in Huntington's disease is an expansion of an unstable CAG repeat encoding polyglutamines (Q_n) at the 5′ end of a gene on chromosome 4, *IT15* (''interesting transcript 15''), now termed *huntingtin (HD*) (Huntington's Disease Collaborative Research Group, 1993). Similar trinucleotide mutations in different genes are responsible for at least seven other neurodegenerative disorders: the spinocerebellar ataxias (SCA1, SCA2, SCA3 [Machado-Joseph disease], SCA6, and SCA7), dentatorubral-pallidoluysian atrophy, and spinal bulbar muscular atrophy (Ross, 1995; Zoghbi, 1997). While the genes affected in these disorders have now been identified, only in spinal bulbar muscular atrophy is the function of the affected protein known (androgen receptor). All the glutamine repeat diseases involve neuronal loss and gliosis. However, while gene expression is widespread throughout the body, cell death occurs in specific regions of the brain and spinal cord. How these genetic defects lead to progressive, selective neurodegeneration, remains elusive. The gene product in Huntington's disease, huntingtin protein, is a 348 kDa protein containing 3144 amino acids. Normal, unaffected indi-

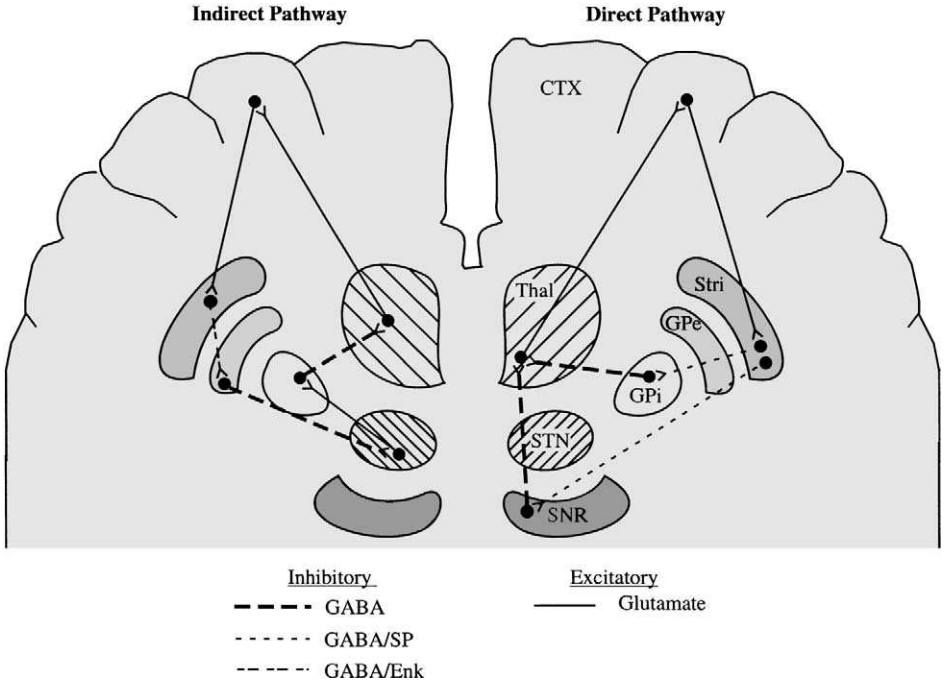

FIG. 49.1. Corticofugal pathways controlling movement. A representative diagram showing the major neurotransmitter systems involved in the direct (right) and indirect (left) basal ganglia output pathways. Activation of the indirect pathway increases the inhibitory input to thalamic nuclei, resulting in reduced excitatory output to the cortex. In contrast, activation of GABA/SP-containing striatal efferents in the direct pathway results in inhibition of the GPi and SNR projection to the thalamus, effectively releasing the thalamus from pallidal inhibition. As a result, the excitatory output to the cortex increases. Choreic movements in Huntington's disease are thought to result from reduced activity of the indirect pathway, due to loss of GABA/Enkephalinergic neurons (Albin *et al*., 1989; Andrews and Brooks, 1998). CTX, cerebral cortex; GPe, globus pallidus, external segment; GPi, globus pallidus, internal segment; Thal, Thalamus; SNR, substantia nigra pars reticulata; STN, subthalamic nucleus; Stri, striatum.

viduals typically have trinucleotide repeats of 11–34 CAGs. Expansion to 34–39 CAG repeats in one or both alleles confers the possibility of developing Huntington's disease, while the disease is inescapable when CAG repeats in either allele exceed 39. The trinucleotide repeat is polymorphic and undergoes alterations during meiosis, generally fluctuating by ± 1–5 repeats per transmission, although larger increases can occur following paternal transmission (Ross, 1995). The physiological functions of both normal and mutant huntingtin have not yet been determined, although several features of the Huntington's disease phenotype are known to be influenced by CAG repeat length, such as age of onset of the disease (Andrew *et al*., 1993; Duyao *et al*., 1993; MacDonald *et al*., 1999) and the extent of DNA fragmentation in Huntington's disease striatal neurons (Butterworth *et al*., 1998). CAG repeat length has also been correlated with neuropathological severity, although this observation is controversial since the grade of disease at time of death is dependent on a number of factors also influenced by repeat length, including age of onset and disease duration (Furtado *et al*., 1996; Sieradzan and Mann, 1998).

Distribution studies give little insight into the involvement of mutant huntingtin in the regional selectivity of cell loss in the disease, since huntingtin protein is ubiquitously expressed throughout the body. The fact that its distribution shows no apparent selectivity for cerebral regions targeted by the disease process suggests that another property of basal ganglia neurons confers vulnerability to degeneration in Huntington's disease (Strong *et al*., 1993; Sharp *et al*., 1995). However, recent immunohistochemical studies suggest that huntingtin may be differentially distributed at the cellular level within the striatum. Ferrante *et al*. (1997) reported that within the striatum huntingtin immunoreactivity is heterogeneous, the patch compartment showing low levels or no immunoreactivity in neurons and neuropil, while levels are relatively higher in the matrix. Double labeling techniques revealed higher levels of huntingtin expression in medium spiny neurons and colocalization with calbindin, in contrast to little or no colocaliztion of huntingtin with NADPH-d or NOS neurons, suggesting that there is some correlation between huntingtin's cellular location and cell vulnerability. A more recent study (Fusco *et al*., 1999) supports Ferrante and colleagues' observations that huntingtin protein load varies within the striatal population of medium-sized neurons and is not consistently found in all medium spiny projection neurons. Taken with their observations that large striatal cholinergic interneurons which are relatively spared in the disease contain high levels of huntingtin, Fusco and colleagues suggest that the huntingtin mutation is not directly toxic to cells.

At the neuronal level, huntingtin protein is widely expressed throughout cells, with a largely cytoplasmic distribution in perikarya, axons, dendrites, and some nerve terminals, and protein fragments have been identified in neuronal nuclei. Subcellular fractionation studies revealed an association of

huntingtin with synaptic vesicles (DiFiglia *et al*., 1995), while another report suggests association with the microtubules (Gutekunst *et al*., 1995), implicating potential roles in intracellular trafficking and synaptic function. N-terminal fragments of huntingtin form ubiquinated protein aggregates in neuronal nuclei (neuronal intranuclear inclusions) and in dystrophic neurites (cytoplasmic inclusions). These protein aggregates have been identified in both Huntington's disease brain and in the brains of transgenic mice expressing a fragment of human mutant huntingtin (Davies *et al*., 1997; DiFiglia *et al*., 1997; Reddy *et al*., 1998; Hodgson *et al*., 1999). The mechanism of inclusion formation has not yet been detrmined, but Perutz and colleagues (1994) suggest that the expanded polyglutamine stretches in mutant huntingtin lend themselves to the formation of β-pleated sheets held together by hydrogen bonds between amide groups. CAG repeat length appears to be critical for aggregate formation (Scherzinger *et al*., 1997). Similar intranuclear inclusions also occur in other CAG repeat disorders including spinocerebellar ataxia type 3 (Paulson *et al*., 1997) and in transgenic mice expressing merely an expanded CAG repeat (Ordway *et al*., 1997), suggesting that nuclear inclusions are a common product of trinucleotide expansions irrespective of the affected gene.

The toxic function associated with mutated huntingtin appears to be due to gain of a novel function, rather than loss of wild-type huntingtin function, since murine *HD* homolog-null mice die *in utero* while heterozygous knock-out mice show little or no pathology (Duyao *et al*., 1995). Further, Huntington's disease knock-out mice are completely rescued by crossing into knock-in Hdh^{Q50} mice with a mutant polyglutamine expansion (48 CAGs), while mice expressing abnormally low levels of murine huntingtin exhibit developmental abnormalities (White *et al*., 1997). Putative mechanisms of huntingtin dysfunction include altered cellular interactions. These include suggestions that expanded glutamine repeats may allow protein–protein interactions or that polyglutamines might be substrates for transglutaminases (Perutz *et al*., 1994; Cooper *et al*., 1997b). The principal candidates for protein interactors are huntingtin-associated protein-1 (HAP-1) and glyceraldehyde 3-phosphate dehydrogenase (GAPDH) (Li *et al*., 1995; Burke *et al*., 1996). Others include calmodulin, caspase-3, α-adaptin, cystathionine β-synthase, and huntingtin interacting protein (HIP-1) (see Aronin *et al*., 1999). Interestingly, in the case of calmodulin the polyglutamine expansion seems to increase huntingtin's affinity (Bao *et al*., 1996). A potential role for HAP-1 in the pathogenesis of Huntington's disease has largely been discounted on the basis of reports that although it is found only in brain it does not show a preferential striatal distribution, and that HAP-1 does not interact with the mutant stretch in huntingtin (Bertaux *et al*., 1998). GAPDH is a critical glycolytic enzyme, which led to intriguing proposals that an interaction with mutant huntingtin might impair metabolic function. Arguing against this idea, we found that the glycolytic function of GAPDH is not altered in postmortem Huntington's disease brain tissue (Browne *et al*., 1997). However, a recent study in fibroblast preparations showed that GAPDH's glycolytic activity is less responsive to metabolic stress in Huntington's disease patients than in fibroblasts from control subjects and unaffected Huntington's disease family members (Cooper *et al*., 1998). GAPDH also has a number of other functions within the cell which might be altered by an interaction with huntingtin. These include a role as a uracil DNA glycosylase in DNA repair, and binding to a number of proteins including DNA, RNA, ATP, actin, tubulin, amyloid precursor protein, and calcyclin. GAPDH expression is very susceptible to metabolic stress, and a glycolytically inactive form of the enzyme found in the nucleus has been implicated in apoptotic mechanisms in neurons and somatic cells (Saunders *et al*., 1997; Sawa *et al*., 1997). The potential for huntingtin to deleteriously affect GAPDH function is supported by a report that both GAPDH and α-ketoglutarate dehydrogenase are inactivated by fusion proteins containing polyglutamine stretches of pathological length, in reactions catalyzed by transglutaminase (Cooper *et al*., 1997a). Tissue transglutaminases (tTGase) are also implicated in the pathogenesis of trinucleotide repeat disorders including Huntington's disease due to another functional role within neurons and astrocytes, catalyzing Ca^{2+}-dependent cross-linking of glutamine residues with lysine and polyamines in other proteins (Aeschlimann and Paulsson, 1994; Kahlem *et al*., 1996; Lorand, 1996; Cooper *et al*., 1997a,b, 1999).

IV. Huntingtin Aggregates: Toxic, Protective, or Inert?

A great deal of debate surrounds the issue of whether neuronal intranuclear inclusion deposition plays a causative role in the pathogenesis of cell death in Huntington's disease, or is merely a secondary event. There is conflicting evidence about the role of neuronal intranuclear inclusions, although at present the weight of opinion seems to favor a lack of involvement, or even a neuroprotective role. The original thesis that nuclear localization of huntingtin aggregates was essential for pathogenic processes came from observations in the R6/2 transgenic mouse line, that neuronal intranuclear inclusion deposition preceded symptoms and pathology in the mouse phenotype (Mangiarini *et al*., 1996; Davies *et al*., 1997). Expanded CAG repeats have also been shown to induce huntingtin aggregation and cell death in transfected cerebellar granule cell cultures (Moulder *et al*., 1998). In addition, transfection of a human mutant huntingtin fragment into *Drosophila* eye cells induced CAG repeat-dependent photoreceptor degeneration and death, putatively via apoptotic mechanisms (Jackson *et al*., 1998).

The case against a pathogenic role of neuronal intranuclear inclusions is steadily growing. In Huntington's disease postmortem brain, neuronal intranuclear inclusion deposition in the cortex and striatum does not mirror the pattern of cell death in the disease (Ferrante *et al*., 1997; Fusco *et al*., 1999). Neuronal intranuclear inclusions and cytoplasmic inclusions are seen in NADPH-d neurons spared in the disease, but are not found in acetylcholinesterase- and choline acetyltransferase-positive interneurons, suggesting that neuronal intranuclear inclusion formation is not critical for cell death mechanisms. Also, in the majority of Huntington's disease patients huntingtin aggregates are most commonly found in neurites, with the exception of 5–10% of patients with juvenile onset of disease in whom neuronal intranuclear inclusions are prevalent in the cortex and striatum (Aronin *et al*., 1999). In addition, Sawa

et al. (1999) demonstrated in cultured Huntington's disease and control lymphoblasts that stress-induced depolarization is much greater in Huntington's disease mitochondria than in mitochondria from controls, in the absence of any neuronal intranuclear inclusion deposition—suggesting that neuronal intranuclear inclusions are not necessary for cellular dysfunction. They went on to demonstrate that this mitochondrial dysfunction is linked to apoptotic cell death. Furthermore, Saudou and colleagues (1998) recently reported cell-selective neurodegeneration resembling apoptotic cell death in cultured striatal (but not hippocampal) neurons transfected with a human mutant huntingtin fragment, independent of the presence of intranuclear inclusions. Observations that suppression of neuronal intranuclear inclusion deposition resulted in increased cell death in this neuronal population led to the proposal that neuronal intranuclear inclusion deposition may reflect a protective mechanism within cells.

Another study in cultured mouse clonal striatal neurons supports the argument that nuclear aggregates are unnecessary for the cell death mechanism to be activated in Huntington's disease. Kim *et al*. (1999) demonstrated that transfecting mouse clonal cells with either full-length or truncated huntingtin containing mutant CAG repeat lengths induced the formation of both nuclear and cytosolic inclusions, whereas huntingtin with wild-type CAG repeats remained within the cytoplasm. Nuclear inclusions consisted largely of N-terminal cleaved fragments of huntingtin, while cytoplasmic inclusions contained both fragments and intact proteins. Apoptotic features were present in both wild-type and mutant huntingtin transfected cells, but were exacerbated in mutant cells. Findings that inhibiting caspase activity with Z-VAD-FMK increased cell survival, but had no effect on either neuronal intranuclear inclusion or cytoplasmic inclusion number, imply that neuronal death is independent of aggregate formation in this model. This hypothesis was supported by observations that another caspase inhibitor, Z-DEVD-FMK, reduced neuronal intranuclear inclusion and cytoplasmic inclusion number but had no effect on cell survival. The authors also demonstrated that only mutant, and not wild-type, huntingtin underwent cleavage to form N-terminal fragments, which suggests that the polyglutamine domain confers some propensity for cleavage by caspases (Kim *et al*., 1999). In another study, nuclear import and export sequences were inserted into huntingtin fragments in 293T cultured cells to alter their normal distribution within the cells (Hackam *et al*., 1999). Results show that toxicity of mutant huntingtin is unaffected by the intracellular location of huntingtin aggregates. Although neither full-length huntingtin or huntingtin fragments have yet been found in mitochondria, an effect on mitochondrial function cannot be ruled out. For instance, huntingtin may play a role in mitochondrial trafficking, or alternatively neuronal intranuclear inclusions may influence nuclear transcription and thus affect the expression of nuclear-encoded proteins including subunits of mitochondrial complex II. The latter is of particular note since complex II activity is impaired in affected brain areas in Huntington's disease.

Transgenic and knock-in mouse models (discussed in section VI) further support the argument that neuronal intranuclear inclusions are not needed for cell toxicity in Huntington's disease models. Although neuronal intranuclear inclusion deposition precedes behavioral symptoms and neurotransmitter changes in R6/2 mice, there is no direct link between the distribution of neuronal intranuclear inclusion deposition and patterns of cell death or dysfunction in several other mutant Huntington's disease mouse models (Reddy *et al*., 1998; Hodgson *et al*., 1999; Levine *et al*., 1999). In addition, R6/2 transgenic mice also develop neuronal inclusions in many postmitotic peripheral tissues from about 6 weeks of age, including both skeletal and cardiac muscle, kidney, liver, pancreas, and adrenal glands (Sathasivam *et al*., 1999). Peripheral aggregate formation seems to coincide with tissue atrophy, but there is no direct evidence of cell death. It is of interest, therefore, that unlike the brain where the bulk of aggregtes are neuritic, inclusions in skeletal muscle cells are found solely within nuclei. There is also increasing evidence from transgenic mouse models that the mechanism of neuronal death in other polyglutamine repeat disorders is independent of nuclear aggregation of the mutant protein. Lin *et al*. (2000) report that polyglutamine expansion in ataxin-1 causes the downregulation of several neuronal genes involved in signal transduction and calcium homeostasis in SCA-1 mice expressing the transgene. More interestingly, these changes precede any pathological changes in the mice by at least 3 weeks (pathology is evident at 6 weeks). Mutant ataxin-1 also forms intranuclear inclusions in cerebellar Purkinje cells of SCA-1 mice, and in humans, by aggregating with proteosomes and ubiquitin (Cummings *et al*., 1998). However, these inclusions do not appear to be pathogenic, since decreasing the frequency of nuclear inclusion formation (by treating with E6-AP ubiquitin ligase) actually exacerbated the rate and extent of pathology in SCA-1 mice (Cummings *et al*., 1999).

V. Putative Mechanisms of Cell Death

The main question still confounding researchers is how the huntingtin mutation results in selective neuronal cell loss in Huntington's disease. The definitive answer is still elusive, but several hypotheses exist.

A. Bioenergetic Defects

One hypothesis is that the gain of function associated with expanded polyglutamine repeats leads either directly or indirectly to a defect in energy metabolism, potentially via secondary excitotoxicity (Albin and Greenamyre, 1992; Beal, 1994b). Reduced ATP production due to impaired energy metabolism can lead to partial cell depolarization by making neurons more vulnerable to endogenous levels of glutamate. The concomitant increase in Ca^{2+} influx into neurons may trigger further free radical production, exacerbating damage to cellular elements. This hypothesis is supported by findings that normally ambient levels of excitatory amino acids become toxic in the presence of oxidative phosphorylation inhibitors, sodium–potassium pump inhibitors, or potassium-induced partial cell membrane depolarization. Further, excitatory amino acid antagonists such as MK-801 can ameliorate cerebral lesions induced by mitochondrial toxins such as 3-nitropropionic acid (3-NP), 3-acetylpyridine (3-AP), aminooxyactic acid (AOAA), 1-methyl-4-phenylpyridinium (MPP^+), and malo-

nate (Storey *et al*., 1992; Beal, 1996; Schulz *et al*., 1996b). The principal indicator of an energetic involvement in the disease process is the observation of insidious weight loss in Huntington's disease patients despite a sustained caloric intake (O'Brien *et al*., 1990). Subsequently, positron emission tomography (PET) and biochemical studies in postmortem brain have shown selective metabolic defects in brain regions targeted by the disease, and mitochondrial abnormalities in Huntington's disease have been identified in ultrastructural studies of cortical biopsies from juvenile and adult-onset Huntington's disease cases (Goebel *et al*., 1978).

PET studies show marked reductions in glucose metabolism in the basal ganglia and cerebral cortex of symptomatic Huntington's disease patients (Kuhl *et al*., 1985; Kuwert *et al*., 1990; Andrews and Brooks, 1998). Caudate hypometabolism in symptomatic patients has been shown to correlate with clinical test scores for bradykinesia, rigidity, dementia, and functional capacity, while the extent of putaminal hypometabolism correlates with chorea and eye-movement dysfunction, and thalamic hypermetabolism correlates with dystonia scales (Young *et al*., 1986; Berent *et al*., 1988; Kuwert *et al*., 1990). Cortical hypometabolism is also seen in patients suffering psychological disturbances and mood changes, before the onset of motor symptoms (Kuwert *et al*., 1990). More convincing evidence of a causative role for energetic defects comes from observations of striatal hypometabolism prior to the bulk of tissue loss, and in asymptomatic subjects at risk of developing the disease (Grafton *et al*, 1992; Kuwert *et al*., 1993; Antonini *et al*., 1996). Approximately 50% of gene-positive mutation carriers exhibit metabolic defects years before the onset of clinical symptoms (Antonini *et al*., 1996). PET techniques have also demonstrated that the first clinical symptoms of the disease correlate with loss of 30–40% of striatal dopamine D1 and D2 receptors, which are localized on the GABAergic medium spiny projection neurons in the striatum (Andrews *et al*., 1997; Hussey *et al*., 1998). More evidence of metabolic dysfunction in Huntington's disease comes from proton nuclear magnetic resonance (^{1}H NMR) imaging studies which show increased lactate production in the basal ganglia and occipital cortex of Huntington's disease patients (Jenkins *et al*., 1993, 1998). Notably, these lactate defects can be ameliorated by treatment with the metabolic cofactor coenzyme Q_{10} (Koroshetz *et al*., 1997).

Biochemical studies in Huntington's disease postmortem tissue have revealed selective dysfunction of components of the oxidative phosphorylation pathway and the tricarboxylic acid (TCA) cycle in brain regions targeted in the disorder. Activities of complexes II-III and IV are markedly reduced in advanced grade Huntington's disease caudate and putamen, while enzyme activities are unaltered in other brain regions (Gu *et al*., 1996; Browne *et al*., 1997). Complex I activity is also reported to be impaired in muscle from Huntington's disease patients, but has not been shown to be affected in brain (Parker *et al*., 1990; Browne *et al*., 1997; Arenas *et al*., 1998). Pyruvate dehydrogenase activity is decreased in Huntington's disease basal ganglia and hippocampus, while polarographic studies show that striatal oxygen consumption in Huntington's disease patients is lower than in age-matched controls (Butterworth *et al*., 1985). The most profound enzyme defect seen in Huntington's disease to date is the dramatic reduction in activity of the TCA cycle enzyme aconitase in affected brain regions and muscle (> 70%; Tabrizi *et al*., 1999). In addition, mitochondrial toxins, which inhibit succinate dehydrogenase in the TCA cycle and complex II (3-nitropropionic acid and malonate), induce selective striatal lesions in rodents and primates which closely resemble those seen in Huntington's disease (Beal *et al*., 1993, 1994; Wullner *et al*., 1994; Schulz *et al*., 1996a,b). Mitochondrial abnormalities and metabolic defects are also features of other trinucleotide repeat disorders, including SCA1, SCA2, and SCA3, leading to the proposal that energetic dysfunction may play a common role in these disorders, and is directly linked to the polyglutamine defect (Matthew *et al*., 1993; Mastrogiacomo and Kish, 1994; Mastrogiacomo *et al*., 1994; Matsuishi *et al*., 1996).

Further indirect evidence that energetic defects contribute to neurodegenerative processes in Huntington's disease is provided by findings that agents which enhance energy production in the brain exert neuroprotective effects. Preliminary studies in rodent mitochondrial toxin models, and NMR measurements of lactate production in man, suggest that coenzyme Q_{10} and creatine are neuroprotective, putatively via enhancing cerebral energy metabolism (Koroshetz *et al*., 1997; Matthews *et al*., 1998). Coenzyme Q_{10} also has potent antioxidant effects. Oral administration of coenzyme Q_{10} improves symptoms in some other mitochondrial-associated disorders including MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes) and Kearns-Sayre syndrome (reducing cerebrospinal fluid, serum lactate and pyruvate levels, and enhancing mitochondrial enzyme activities in platelets) (Bresolin *et al*., 1988; Ihara *et al*., 1989). We recently showed that oral administration of coenzyme Q_{10} ameliorated elevated lactate levels seen in the cortex of Huntington's disease patients, an effect which was reversible on withdrawal of coenzyme Q_{10} (Koroshetz *et al*., 1997). Furthermore, coenyme Q_{10} attenuates neurotoxicity induced by the mitochondrial toxins MPTP and malonate in animal models (Beal *et al*., 1994; Schulz *et al*., 1996b). An alternative strategy is to increase brain energy stores of the high-energy compound phosphocreatine by creatine administration. We recently showed that oral creatine administration in rats attenuates neurotoxicity induced by the succinate dehydrogenase inhibitor 3-NP (Matthews *et al*., 1998). In addition, increases in cerebral lactate levels and decreases in levels of high-energy phosphate compounds seen in the striata of 3-NP treated rats were attenuated by pretreatment with creatine.

B. Oxidative Damage

Oxidative damage can affect cell viability directly, via oxidation of DNA and other neuronal macromolecules, or indirectly, for example by impairing mitochondrial energy metabolism (Schulz *et al*., 1996b; Browne *et al*., 1999a). Evidence for oxidative damage in Huntington's disease is steadily accumulating. Findings include increased incidence of DNA strand breaks, exacerbated lipofuscin accumulation (a marker of lipid peroxidation), elevated DNA oxidative damage products such as 8-hydroxydeoxyguanosine (OH8dG), and increased immunohistochemical staining of oxidative damage products in Huntington's disease striatum and cortex, including staining for 3-nitrotyrosine (a marker for peroxynitrite-

mediated protein nitration), malondialdehyde (marker for oxidative damage to lipids), heme oxygenase (formed during oxidative stress), and OH8dG (Goebel *et al*., 1978; Tellez-Nagel *et al*., 1995; Ferrante *et al*., 1996; Browne *et al*., 1997, 1999a).

A potential mechanism of mitochondrial dysfunction is via increased generation of free radicals and oxidants. Free radicals including superoxide ($O_2^{\cdot -}$) and hydroxyl radicals ($HO^{\cdot}$) are constantly produced as by-products of aerobic metabolism, but production increases under circumstances of electron transport chain inhibition or molecular defects (Schapira *et al*., 1992). These agents can induce oxidative damage to cell macromolecules including DNA, proteins, and lipids by a number of different mechanisms, including DNA strand breaks or formation of DNA adducts (e.g., OH8dG), protein carbonylation, or lipid peroxidation. Potential functional consequences include perturbations in DNA transcription and translation, protein synthesis, enzyme activities, and membrane fluidity. Mitochondria are thought to be particularly vulnerable to oxidative injury since most intracellular free radicals are generated by the mitochondrial electron transport chain. Mitochondrial DNA is extremely susceptible due to its localization in the mitochondrial matrix, lack of protective histones, and limited repair mechanisms (Linnane *et al*., 1989). Thus any increase in free radical production, for example due to impaired activity of a regulatory enzyme such as Cu/Zn SOD or glutathione peroxidase, could reduce the functional capacity of the respiratory transport chain. In addition, the tricarboxylic acid cycle enzyme aconitase, which is severely affected in Huntington's disease, is a prime target for free radical-mediated oxidative damage. The slow, progressive nature of neuronal injury in neurodegenerative disorders may be explained by cycling of free radicals and mitochondrial dysfunction. We have previously found increased levels of oxidative markers in both Huntington's disease and aminotrophic lateral sclerosis. Nuclear DNA OH8dG levels are significantly elevated in Huntington's disease caudate relative to controls (Browne *et al*., 1997, 1999a). Further evidence supporting a role for oxidative damage in Huntington's disease is that the energetic defects seen in Huntington's disease brain are similar to those induced in cell culture by peroxynitrite, which preferentially inhibits complex II-III and (to a lesser extent) complex IV activity in the electron transport chain (Bolanos *et al*., 1995).

VI. State of the Art Approaches: Animal Models Provide Insights into Disease Etiology

A. Mitochondrial Toxin Models

A role for mitochondrial energy metabolism dysfunction in the pathogenesis of neuronal degeneration in Huntington's disease is further supported by observations, in both humans and in experimental animals, that the basal ganglia neurons are particularly vulnerable to mitochondrial toxins. These include the complex II inhibitors 3-NP and malonate, AOAA (complex I), potassium cyanide, and sodium azide (complex IV) (Browne and Beal, 1994). Ingestion of 3-NP, an irreversible inhibitor of succinate dehydrogenase (complex II), produces selective basal ganglia lesions and delayed dystonia in humans (Ludolph *et al*., 1990). Systemic administration of 3-NP to both rats and primates produces age-dependent striatal lesions which are strikingly similar to those seen in Huntington's disease (Brouillet *et al*., 1993, 1995). In primates, chronic 3-NP administration produces selective striatal lesions which spare NADPH-d neurons, and induce proliferative changes in the dendrites of spiny neurons. Animals also show both spontaneous and apomorphine-inducible movement disorders resembling Huntington's disease (Brouillet *et al*., 1995). 3-NP basal ganglia lesions in rats are associated with elevated lactate levels, similar to the increased lactate production seen in Huntington's disease patients (Jenkins *et al*., 1993). 3-NP lesions can be prevented by prior removal of glutamatergic excitatory corticostriatal inputs by decortication, by glutamate release inhibitors, and by glutmate receptor antagonists, suggesting that 3-NP toxicity is mediated by secondary excitotoxic mechanisms (Beal, 1994a; Schulz *et al*., 1996b).

Intrastriatal injection of either malonate or 3-NP in rats is also associated with increased oxidative damage. We found that the rate of hydroxyl free radical production is elevated in the striatum, as detected by microdialysis (Schulz *et al*., 1996a). Increased OH^8dG levels in striatum are also detected following systemic 3-NP administration, and elevated 3-nitrotyrosine concentrations are reported after either systemic 3-NP or intrastriatal malonate injection. Further, the finding that 3-NP-induced lesions and concomitant increases in oxidative damage markers were markedly attenuated in mice overexpressing the superoxide free radical scavenger Cu/Zn superoxide dismutase (SOD1) implies that oxidative free radicals contribute to lesion formation (Beal *et al*., 1995). Furthermore, malonate and 3-NP striatal lesions were attenuated by free radical spin traps and NOS inhibitors. Inhibition of nitric oxide (NO) generation in mice lacking the gene for the neuronal isoform of NOS (nNOS) also resulted in reduced volume of malonate lesions (Schulz *et al*., 1996b). Hence there is substantial evidence that nitric oxide-mediated oxidative damage is involved in cell death processes following energetic disruption in these models.

B. Transgenic Mouse Models of Huntington's Disease

One of the major drawbacks of relying on human tissue for asessment of neurological disease progression is the inability to adequately map early events in the disease etiology. Substantial evidence of a causative role in the disorder would be provided by evidence of occurrence prior to symptoms and pathology in models of Huntington's disease. Over the past few years, the development of methodology to generate transgenic mouse lines expressing the physiological phenotypes associated with human gene mutations has provided much needed *in vivo* models to circumvent many of these issues. A number of different groups have developed several different transgenic and ''knock-in'' mouse models of Huntington's disease, which vary in terms of the transgene incorporation technique employed. As a result, mouse phenotypes vary between lines, the features manifested by the animals depending on the nature of the transgene incorporated (i.e., full-length human mutant huntingtin, or a huntingtin *HD* gene fragment incorporating the mutant region in exon 1, or merely an expansion

inserted into the murine *HD* homolog *Hdh*); CAG repeat length; copy number of the mutant gene incorporated; promoter used, and hence cellular specificity of expression; background strains; and expression levels of the mutant gene. The different mouse lines reported to date are discussed below and listed in Table 49.1, which compares the salient features of each of the models.

1. Transgenic Mice Expressing Full-Length Human Mutant Huntingtin

The *HD89* and YAC72 mice discussed below represent two of the most useful transgenic mouse lines developed to date. Their utility is encumbent on the fact that disease-length huntingtin mutations are expressed in the context of the human

TABLE 49.1 Characteristics of Transgenic and Knock-in Mouse Models Expressing the Huntington Disease Mutation

Mutant mouse lines	Background strain	Promoter	Insert	CAG repeat	Symptom onset (weeks)	NII onset (weeks)	Neuronal loss (at end stage)	Life span (weeks)
HD[a]								
HD16 (Wt)	FVB/N	CMV	Full-length	16+/− (A–E)	None	None	None	Normal
HD48			*HD* cDNA,	48 +/− (B,D)	8	12	Stri, CTX >	29–31

Note. The models listed reflect those reported by February 2000. CBL, cerebellum; CTX, neocortex; Hip, hippocampus; N/D, not determined to date; NII, neuronal intranuclear inclusions; Stri, striatum; Tet, tetracyclin; Thal, thalamus; wks, weeks of age; Wt, wild type.
[j]Evident in striatal medium spiny neurons by 52 weeks of age.

full-length gene inserted into the mouse genome, rather than just a gene fragment. In contrast to some other putative Huntington's disease models (such as the *Hdh* knock-in mice and R6/2 mice), animals develop region-specific neuronal degeneration over their life span, which provides a suitable context for measuring the efficacy of potential neuroprotective agents.

a. HD48 *and* HD89 *Mice.* Tagle and colleagues generated mice expressing 16 (wild type), 48, and 89 glutamines from full-length human huntingtin cDNA constructs. Using the human promoter, huntingtin expression is widespread throughout the brain and periphery. In these mice, copy number of the gene incorporated varied from two to six in mutant CAG lines. Both 48 and 89 CAG repeat mice showed motor deficits from an early age, developing foot clasping and stereotypic hyperkinetic activity, followed by hypokinesis and locomotor deterioration. Mice die prematurely (24–32 weeks). By about 24 weeks of age marked neuronal cell loss and astrogliosis is evident in the striata of both *HD48* and *HD89* mice, but few neuronal intranuclear inclusions occur. The lack of a distinct correlation between CAG repeat number and disease progression is thought to be associated with the levels of expression in each of the mouse lines, which vary from approximately endogenous levels in 89/89 mice to fivefold higher in 48/48 mice (Reddy *et al*., 1998).

b. YAC HD Tg *Mice.* Hodgson *et al*. (1999) used yeast artificial chromosome (YAC) technology to generate transgenic mice expressing normal (YAC18: 18 glutamines) and mutant huntingtin (YAC46 and 72: 46 and 72 glutamines, respectively). Mutations are expressed in the context of full-length huntingtin protein. By 12 months of age YAC72 mice have a selective degeneration of medium spiny neurons in the lateral striatum (similar to the selective cell death seen in Huntington's disease patients). Neurodegeneration seems to require nuclear translocation of N-terminal huntingtin fragments, but not neuronal intranuclear inclusion formation. Both YAC46 and YAC72 develop progressive electrophysiological abnormalities at approximately 7 months of age that precede nuclear translocation of huntingtin and cell death. Behavioral changes are manifest in YAC72 mice at 7 months of age.

2. "Knock-in" Mice Expressing Full-Length Huntingtin

"Knock-in" mice arguably represent an excellent model system for investigating the effects of the huntingtin mutation, since the mutation is expressed in the context of the full-length murine huntingtin analog, *Hdh*. Hence, the system uses the endogenous promoter to produce protein at normal murine expression levels, so any differences between animals may be attributed to different polyglutamine repeat lengths. In reality their utility is confounded to some extent by the fact that they do not develop overt, quantifiable, neurodegenerative, or behavioral changes over the animals' life spans. However, as discussed below, there is some evidence of cellular dysfunction associated with the CAG expansion in these models which may be useful as testable parameters for investigating disease mechanisms.

The reason for the lack of neuropathological features of Huntington's disease in these models is thought to result from the combination of low expression levels of the gene and the short life span of mice. In support of this hypothesis, HD48 mice, which do show selective cell death, neuronal intranuclear inclusion, cytoplasmic inclusion formation, and motor disturbances, express up to 5 × wild-type endogenous levels of full-length huntingtin protein (Reddy *et al*., 1998). However, in the knock-in lines only endogenous murine levels of huntingtin are expressed. Also, the CAG repeat number required to confer toxicity in mice seems to be longer than in humans, perhaps reflecting the short life span of the animals.

a. H*dh knock-in* Mice. White *et al*. (1997) developed a mouse model of Huntington's disease by extending the polyglutamine tract of the murine homolog (*Hdh*) of the human huntingtin gene (*HD*). CAG repeats from an *HD* chromosome were inserted into the appropriate position in *Hdh* exon 1, altering the mouse *HD* homolog to encode huntingtin protein with 50, 92, or 111 glutamine residues, instead of the 7 normally found in the mouse protein. The transgene has the endogenous promoter, and mice express wild-type levels of huntingtin protein. Mice homozygous for mutant huntingtin do not exhibit any behavioral symptomatology up to 18 months of age. However, recent observations have shown CAG length-dependent translocation of huntingtin protein from cytosol to the nucleus, and eventual neuronal intranuclear inclusion formation in Hdh^{Q92} and Hdh^{Q111} mice (Wheeler *et al*., 2000). Although there is no evidence of selective cellular pathology in any of these mouse lines yet, we have found that cerebral glucose metabolism and mitochondrial enzyme activities are impaired in Hdh^{Q92} mice at 4 months of age (Browne *et al*., 1999b, and unpublished observations). This corresponds with a time point preceding neuronal intranuclear inclusion formation in these mice, and may be indicative of early bioenergetic changes associated with the huntingtin mutation (Fig. 49.2, see color insert).

b. CAG71 *and* CAG94 *Mice.* Similar to the technique in *Hdh* mice, the endogenous murine *Hdh* gene was modified by replacing a portion of mouse exon 1 and the adjacent intron with a human sequence containing an expanded CAG repeat region (71 or 94) from a juvenile Huntington's disease lymphoblastoid cell line (Levine *et al*., 1999). Although no overt cell loss has been reported to date in this model, there is evidence of neuronal dysfunction in CAG94 knock-ins, which showed an increased sensitivity of cortical and striatal cells to *N*-methyl-D-aspartate (NMDA) receptor activation. In contrast, mice expressing fewer glutamines (94) CAG71 knock-ins were less affected than CAG94 knock-ins, showing NMDA responses similar to littermate controls. No cerebral neuronal intranuclear inclusions have been detected in either mouse line.

c. H*dh*4/Q80 *and* H*dh*6/Q72 *Mice.* Another knock-in Huntington's disease model was generated by Shelbourne and colleagues (1999). They inserted an expanded CAG repeat (72–80) into the murine *Hdh* by homologous recombination and generated two heterozygous knock-in lines, *Hdh4/Q80* and *Hdh6/Q72*. These mice do not develop any neuropathological abnormalities at the cellular level by 17 months of age, but do exhibit a 10–15% reduction in brain size, which is evident by 4 months of age. Neuronal intranuclear inclusions have not been

seen in either line to date, but mice do display an abnormal behavioral phenotype, in the form of chronically increased aggressive behavior toward other mice from about 3 months of age, which is more prevalent in males than in females. There is also evidence of reduced long-term potentiation in hippocampal neurons (Usdin *et al*., 1999), which the authors suggest reflects the cognitive impairments seen at an early stage in Huntington's disease.

3. Transgenic Mice Expressing Human Mutant Huntingtin Fragments

a. N171 HD M*ice*. N171 transgenic mice express a truncated portion of Huntington's disease cDNA, consisting of 171 amino acids from the N-terminal, with an expanded glutamine repeat of 44 or 82 (N171-44Q and N171-82Q). Wild-type N171-18Q express 18 glutamines (Schilling *et al*., 1999). N171-82Q mice display a phenotype of uncoordination, ataxia, and weight loss with onset at approximately 3–4 months, and die prematurely at about 6 months of age. On pathologic examination brains show neuronal intranuclear inclusions when labeled with antibodies to ubiquitin or the N-terminal of huntingtin protein and evidence of neuronal degeneration in the striatum.

b. L63 HD M*ice*. The L63 mouse line express a FLAG–huntingtin cDNA fusion protein consisting of the first 3221 huntingtin bases from the N-terminal, with 46 or 100 glutamines (Laforet *et al*., 1998). Motor defects and approximately 20% loss of striatal neuron occur in most mice with 100 CAGs by 6 months of age. Low levels of neuronal intranuclear inclusions are also seen in striatum by 6 months (Laforet *et al*., 1998; Aronin *et al*., 1999).

c. R6 HD M*ice*. The R6 mouse lines were the first Huntington's disease transgenic mice developed and are therefore the best characterized to date. Importantly, it was the development of this model which led to the identification of neuronal intranuclear inclusion formation in the disease paradigm. The R6 mouse lines are transgenic for a fragment of the human *HD* gene, containing 1 kb of the *HD* promoter region and exon 1 containing the abnormal CAG repeat expansion and 262 bp of intron 1 (Mangiarini *et al*., 1996). The R6/2 line expressing 144 CAGs is the most studied to date, since these animals develop a rapidly progressing neurological phenotype reminiscent of Huntington's disease, before dying prematurely at 17–22 weeks of age. The first motor symptoms occur at about 8 weeks of age, but are preceded by neuronal intranuclear inclusion deposition throughout the brain by 3.5 weeks of age (although it may occur even earlier) (Davies *et al*., 1997). The motor disorder includes abnormal gait, a resting tremor, abrupt shuddering movements, and stereotypic grooming. However, some features of the disease phenotype do not bear much resemblance to the human disease, including the propensity for seizures in these animals, the lack of overt striatal-specific cell death, and the development of diabetes (Mangiarini *et al*., 1996; Davies *et al*., 1997; Hughes *et al*., 1999; Hurlbert *et al*., 1999; Sathasivam *et al*., 1999). Neurotransmitter and receptor abnormalities also occur in R6/2 mice, including dopamine D1 and D2 receptor loss by 8 weeks of age, and alterations in levels of the glutamatergic mGluR1, mGluR2, mGluR3, and mGluR5 metabotropic receptors by 12 weeks of age (Cha *et al*., 1998). Further, *in situ* studies revealed that D1 and mGluR receptor mRNA is abnormal by as early as 4 weeks of age, preceding the onset of symptoms in these animals. However, contrary to the picture in Huntington's disease brain, GABAergic and NMDA receptor binding levels are not altered in these animals, although AMPA and kainate receptors show some downregulation (Cha *et al*., 1998). Similarly, neurotransmitter changes do not bear close resemblance to the pattern seen in Huntington's disease. For instance, Reynolds *et al*. (1999) report that striatal GABA levels are unaltered in symptomatic 12-week-old mice, although a slight decrease was observed in the cerebellum. Further, levels of serotonin and 5-hydroxyindoleacetic acid (5-HIAA) are reduced in all brain regions of R6/2 mice, while noradrenaline is decreased in the hippocampus. In contrast, dopamine levels in the striatum are reduced in aged animals, consistent with changes seen in Huntington's disease brain.

As discussed earlier, metabolic defects prior to disease onset are also typical of Huntington's disease. In the R6/2 mouse line, Tabrizi *et al*. (2000) reported that complex II-III and aconitase activities are impaired in the brains of 12-week-old R6/2 Huntington's disease transgenic mouse brains, but these alterations do not precede the onset of the behavioral phenotype and neuronal intranuclear inclusion deposition (S. E. Browne and M. F. Beal, unpublished observations). However, at 12 weeks of age R6/2 mice show an increased vulnerability to metabolic stress, as demonstrated by increased free radical generation and lesion size in response to a 3-NP toxic insult (Bogdanov *et al*., 1998). Further, we have recently found that treatment of R6/2 mice with creatine, administered in feed from the time of weaning, significantly increases survival and delays brain atrophy, striatal neuron atrophy, and the formation of nuclear inclusions (Ferrante *et al*., 2000). In addition, prevention of huntingtin cleavage by caspase inhibitors has recently been shown to delay phenotype onset and animal death in this mouse model (Ona *et al*., 1999).

4. "Inducible" Transgenic Mice Transiently Expressing Mutant Huntingtin

Perhaps the most exciting development in the past few years is the generation of a reversible Huntington's disease mouse model, which incorporates a "tet off" system to modulate expression of the huntingtin gene mutation (Yamamoto *et al*., 2000). The expression promoter is α-CamKII, which facilitates high levels of expression in the forebrain. Mutant gene expression is under the regulation of a tetracyclin binding sequence, bi-TetO, linked to galactosidase, and then to exon 1 of mutant huntingtin containing an expanded CAG repeat. Tetracyclin binding switches huntingtin transcription off. Yamamoto and colleagues raised mice up to 18 weeks of age in the absence of tetracyclin. Animals developed a severe, progressive motor phenotype, characterized by tremor and foot clasping. Galactosidase staining showed that mutant huntingtin was widely expressed throughout the forebrain in homozygous gene-positive mice, as well as the striatum, hippocampus, hypothalamus, septum, and neocortex. No immunoreactivity was detectable in heterozygote mice. The animals also developed neuronal intra-

nuclear inclusions in all gal-positive regions, but neuronal intranuclear inclusion deposition was limited to brain regions where mutant huntingtin was expressed. Mice went on to develop striatal atrophy, gliosis, and reduced D1 and D2 receptor binding densities in the striatum, indicative of GABAergic cell loss or dysfunction. Most interestingly, all of these parameters of neuronal dysfunction could be reversed, to some extent, by effectively switching expression of the transgene off by treating the animals with the tetracycline analog doxycycline. Animals treated for 4 months showed a marked reduction in the number of neuronal intranuclear inclusions in the striatum and neocortex and partial recovery of striatal atrophy and D1 and D2 binding levels, suggesting that there may be a therapeutic window for disease treatment in postsymptomatic patients. This breakthrough development opens up a plethora of opportunities to observe the consequences of manipulating huntingtin gene expression and to test potential therapeutic strategies.

VII. Conclusions

Although the pathogenic mechanism in Huntington's disease does not seem to be directly linked to the formation of intranuclear huntingtin inclusions, there is an association between the cell death process and CAG repeat length in mutant huntingtin. This is well demonstrated by the observation that incorporation of an expanded CAG repeat stretch (146 CAGs) into a murine gene normally lacking CAG repeats, the hypoxanthine phosphoribosyltransferase gene (*hprt*), resulted in a mouse phenotype reminiscent of other human CAG repeat disorders (JO1 mice, Ordway *et al*., 1997). Mice develop a progressive neurological phenotype consisting of a late-onset resting tremor, ataxia, decreased open field motor activity, propensity to fall from the rotarod, foot clasping, some incidence of seizures, and premature death at approximately 42–53 weeks of age. CAG length-dependence of these traits was verified by the observations that mice expressing 70 CAG repeats in the *hprt* gene did not develop a behavioral phenotype by 35 weeks of age, whereas the first behavioral symptoms are evident by 12 weeks in JO1 mice (Ordway *et al*., 1997). A great deal of conjecture now surrounds the question of whether translocation of huntingtin protein into the nucleus, with or without aggregate formation, is an essential step in the pathogenic process in Huntington's disease. Several groups have suggested that huntingtin translocation into the nucleus precedes cell pathology (Saudou *et al*., 1998; Hackam *et al*., 1999; Hodgson *et al*., 1999; Wheeler *et al*., 1999). Interestingly, in another polyglutamine disease ataxin-1 movement into the nucleus has been shown to be a prerequisite for pathogenesis, and has been associated with gene downregulation in SCA-1 transgenic mice (Lin *et al*., 2000).

Whereas the definitive pathway underlying cell death in Huntington's disease is yet to be determined, the development and characterization of transgenic and knock-in mouse models of the disorder can only help achieve this goal. In the meantime, it is heartening that initial studies of metabolic enhancers and caspase inhibitors are showing some degree of efficacy in delaying disease onset and extending survival in animal models of the disease.

Biochemical and Anatomical Changes in Basal Ganglia of Aging Animals

Deterioration of motor function is a hallmark of senescence in humans and other mammalian species. The similarity of age-related motor deterioration to the symptoms of Parkinson's disease has focused research efforts upon the basal ganglia and particularly the nigrotriatal dopaminergic system. In this chapter, age-related structural and functional characteristics of basal ganglia of several laboratory animal species were reviewed. Although some studies have demonstrated loss of substantia nigra pars compacta dopaminergic neurons with age, the degree of loss does not appear sufficient to account for the marked motor decrements that occur in senescence. Consequently, studies of age-related changes in nigrostriatal function have increased. Reported changes in the basal ganglia of aged animals include decreased numbers of dopamine receptors and transporters as well as decreased dopamine synthesis, release, and uptake. There is also evidence for changes in the interactions between dopamine and other neurotransmitters in the basal ganglia. These age-related changes in nigrostriatal dopaminergic function may account for the majority of the motor deficits that accompany normal aging.

I. Introduction

Along with memory loss, a cardinal feature of senescence is deteriorating motor function. Indeed, slow movements, tremor, stooped posture, and a shuffling gait—also symptoms of Parkinson's disease—are hallmarks of old age as well as parkinsonism in the elderly (Mortimer and Webster, 1982; Teräväinen and Calne, 1983; Bennett *et al.*, 1996). Similar motoric disturbances have also been reported in a variety of mammalian species (e.g., Irwin *et al.*, 1994; Emborg *et al.*, 1998; Hebert and Gerhardt, 1998). When it was discovered that the brains of individuals who suffered from Parkinson's disease were deficient of the neurotransmitter dopamine (Ehringer and Hornykiewicz, 1960) and that these symptoms were successfully reversed by the dopamine precursor L-dopa (Cotzias *et al.*, 1967, 1969), researchers were provided with a neurochemical mechanism underlying these deficits. Consequently, the basal ganglia became the primary neuroanatomical loci for studies of not only Parkinson's disease but also of nonpathological age-related declines in motor function. Although the majority of previous studies have focused upon age-related structural alterations in the basal ganglia, more recent studies have attempted to characterize changes in neuronal function. These functional decrements arguably account for much of the deterioration of motor capabilities that are observed in senescence.

A. The Basal Ganglia

The basal ganglia are group of interconnected subcortical nuclei that interact with neocortical and limbic regions to produce meaningful, goal-directed behavior (Gray, 1995). They are composed of the striatal and pallidal portions of the basal telencephalon, the substantia nigra, ventral tegmental area, and the subthalamic nucleus (Marin *et al.*, 1998; Wilson, 1998). The striatal and pallidal components of the basal ganglia are functionally segregated into dorsal and ventral portions. The dorsal component is composed of the dorsal striatum, i.e., caudate nucleus and putamen (in primates and carnivores) or caudate-putamen (in other mammals), the internal and external segments of the globus pallidus (in primates), or globus pallidus and entopeduncular nucleus, respectively (in nonprimates). The ventral component is composed of the ventral striatum, i.e., the nucleus accumbens and portions of the olfactory tubercle and the ventral pallidum (Marin *et al.*, 1998).

B. Animal Models of Aging

Understanding the basic mechanisms leading to age-related functional impairment in humans necessitates the use of animal models. As mentioned previously, a variety of mammalian species exhibit age-related motor deficits that parallel those observed in humans. While many laboratory animals species

are used in aging studies, the majority of studies of age-related changes in the nigrostriatal dopaminergic system have been conducted with rodents, specifically Fischer 344 (F344), Wistar, and Sprague–Dawley rats or C57BL mice (Austad, 1997). Recent studies involving nonhuman primates have also uncovered age-related changes in nigrostriatal and mesolimbic dopaminergic systems. These studies have provided new insights into the mechanisms underlying age-related alterations in movement.

One outstanding issue in aging research has been the lack of a standardized scheme of classifying an animal of a particular species as ''aged.'' Ideally such a scheme would be based upon comparative data regarding the species' life span and the extent to which the species' age-related alterations parallel those of aging humans. Considering the absence of such standards, a review of the literature suggests considerable uniformity in what is defined as ''aged'' in aging studies. Although there is some variation between rat strains regarding longevity (Masoro, 1990; Sprott and Austad, 1996), researchers have generally defined rats as aged at $\geq$22 months and C57BL mice are generally classified as aged at $\geq$21 months. Cats are typically labeled aged at $\geq$11 years, rabbits at 5 years, and the aged group in studies using monkeys is typically $\geq$22 years of age. Subjects in human studies in which age-related effects have been reported are generally $\geq$70. In each of these species, marked age-related deficits in movements have been reported. Because, with few exceptions, these are the ages typically employed to classify subjects as ''aged,'' studies that report a lack of age effect in animals younger than the aforementioned values are not included in this review. Age-related changes in humans will be cited throughout the chapter for comparative purposes.

C. Changes to Be Covered

Because of its role in motor behavior, the nigrostriatal dopaminergic system has been the focus of the majority of studies examining age-related decrements in basal ganglia function. For this reason, this chapter will focus predominately upon the ascending nigrostriatal dopaminergic tract. The discussion will include alterations in the structural integrity of dopaminergic neurons and their connections in senescence, as well as the functional capacity of pre- and postsynaptic neuronal mechanisms. The chapter will conclude with a brief review of age-related alterations in other neurotransmitter systems that interact with dopaminergic neurons in the aged basal ganglia. In all cases we have tried to be comprehensive. However, undoubtedly we have failed to include some pertinent data and citations.

II. Morphological Changes

A. Cell Number

It has been a biological doctrine that normal (i.e., nonpathological) aging is accompanied by widespread neuronal loss. This commonly accepted belief was based largely upon early studies in which extensive cell death was inferred from measurements of decreased neuronal densities in brain regions known to be affected in Alzheimer's disease—specifically, regions of the neocortex and hippocampus (Brody, 1955; Dayan, 1970; Colon, 1972). Likewise, the prevalence of parkinsonian-like symptoms that often accompany aging has led to the suggestion that normal aging occupies a ''preparkinsonian'' position on a continuum which includes Parkinson's disease as a manifestation of accelerated aging (Barbeau, 1973; McGeer *et al.*, 1977; Beck, 1978; Mann and Yates, 1982; Mortimer and Webster, 1982). This hypothesis seems to be supported by reports of age-associated decreases in the number of human substantia nigra pars compacta neurons on the order of 30 to 50% between 20 and 90 years of age (McGeer *et al.*, 1977; Mann and Yates, 1983; Fearnley and Lees, 1991; however, see references cited in McNeill and Koek, 1990, for evidence to the contrary). Likewise, a 50% decrease in the number of substantia nigra neurons of aged (25- to 27-year-old) Rhesus monkeys has also been reported (Emborg *et al.*, 1998). However, dopaminergic cell loss in the aged squirrel monkey and rodent substantia nigra pars compacta has not been observed (Flood and Coleman, 1988; McNeill and Koek, 1990; Emerich *et al.*, 1993; Irwin *et al.*, 1994).

Several caveats regarding the interpretation of age-related dopaminergic cell death as it relates to functional deficits should be considered. While there have been reports of decreased numbers of dopaminergic neurons in aged primates, there are quantitative as well as qualitative differences between the physiological substrates of normal age-related motor deficits and the pathophysiological substrates of Parkinson's disease (e.g., Fearnley and Lees, 1991; Kish *et al.*, 1992; Hubble, 1998). These differences have become recognized as a result of critical analyses of previous data, improvements in histopathological methodology, and analysis of the distinct etiologies of the motor deficits that accompany each of these conditions. Other considerations relate to the methods used to determine age-related loss of dopaminergic neurons. Recent studies using unbiased stereological cell-counting methods in regions other than the basal ganglia have cast doubt on the long-held belief that neuronal death is an inevitable consequence of aging (West and Gundersen, 1990; West, 1993; West *et al.*, 1994; see also Morrison and Hof, 1997). Stereological methods have also challenged previous findings regarding the inevitability of nigral cell loss with age (Strothjohann *et al.*, 1993; Irwin *et al.*, 1994; Pakkenberg *et al.*, 1995). Nevertheless, a recent study using stereological methods to determine age-related nigral cell loss reported a 50% reduction of tyrosine hydroxylase (TH)-immunoreactive neurons in the substantia nigra of aged monkeys (Emborg *et al.*, 1998). Interestingly, these investigators also determined that their quantification of dopaminergic cell number did not correlate with age-related functional changes in the aged monkeys. Caution should be exercised when interpreting studies in which the number of dopamine-containing neurons was determined based on the immunoreactivity of cells to TH, however, as decreases in TH immunoreactivity may overestimate dopaminergic neuronal loss as a result of functional deficiencies in residual cells and staining methods (McGeer *et al.*, 1977; Emborg *et al.*, 1998).

Notwithstanding these methodological concerns, the extent of age-related dopaminergic cell loss reported in these studies was generally less than 50%. Although age-related motor deficits may coincide with modest dopaminergic neuronal loss,

reported decreases in the number of dopaminergic neurons barely approach the magnitude of loss that would be necessary to decrease striatal dopaminergic levels by ≥80%, the amount required for gross functional impairment in humans with Parkinson's disease or in animal models of Parkinson's disease (Hornykiewicz, 1963; Stricker and Zigmond, 1976; Lloyd, 1977). Indeed, if Parkinson's disease cell-loss criteria were employed, extrapolation of the regression lines reported in studies of age-related dopaminergic cell loss would not place individuals at risk of gross motor decline until they were 100 years old (McGeer *et al.*, 1977; Mortimer and Webster, 1982; Kish *et al.*, 1992). Clearly, dopaminergic cell loss is an insufficient explanation for gross, age-related declines in motor function.

B. Pathological Accumulations

The escalating presence of lipofuscin in nerve cells is considered to be a sign of neuronal aging, as the amount of the pigment has been shown to gradually increase with age in a variety of tissues in several species (Sohal and Wolfe, 1986; Peters *et al.*, 1991). Age-related accumulation of lipofuscin in dopaminergic neurons of the substantia nigra pars compacta have been reported in C57BL/6J and C57BL/6NNia mice (McNeill *et al.*, 1984; Ingram *et al.*, 1993). While the observations of McNeill and colleagues (1984) were not quantitative, they reported increases in lipofuscin beginning at 10 months of age, with a preponderance of accumulation at 30 months. Ingram and colleagues (1993) quantified the increase, reporting that lipofuscin accumulation was approximately 20% higher in 18-month-old as compared to 3-month-old mice. Although the presence of lipofuscin at low levels does not necessarily support pathology, with increasing accumulation it may be associated with progressively lower levels of ribonucleic acid in the cytoplasm (Peters *et al.* 1991). This may indicate an increasing decrement of the cell's exocytotic capacity (Sohal and Wolfe, 1986) or an alteration in the cell's metabolic or neuronal activity (McNeill *et al.*, 1984).

While the pathological significance of lipofuscin is debatable, Lewy bodies, which are a histological signature of Parkinson's disease (Kopin, 1993), are readily associated with basal ganglia pathology. Lewy bodies have been observed in the substantia nigra of a small percentage of nonparkinsonian human controls over the age of 50 (e.g., 6% reported by Fearnley and Lees, 1991). Although Fearnley and Lees (1991) reported increases in the prevalence of incidental Lewy bodies with age, they argued that the presence of Lewy bodies are not an aspect of normal aging, but are indicative of presymptomatic Parkinson's disease. This suggestion is supported by a lack of reports of Lewy bodies in aged animals.

C. Connections

In studies that have reported age-related changes in morphological features of neurons in the basal ganglia, most have focused on the dendrites of striatal neurons. Levine (1988) reported decreases of 40–49% in spinal densities of medium spiny GABAergic neurons in the caudate nucleus of old (15–18 years) cats compared to mature (1–3 years) cats. Furthermore, total dendritic length, average dendrite length, average branch length, and the radius of the dendritic field of these principal neurons were also decreased by between 30 and 40% in the caudate nucleus of the aged cats. These decreases began in 13-year-old cats and may have been the basis for altered striatal electrophysiological responses to cortical and nigral stimulation.

In a study utilizing C57BL/6N mice, McNeill and colleagues (1990) found that medium spiny neurons in the caudal striata of aged mice exhibited significant dendritic elongation (138%) between 25 and 30 months. This elongation was partially attributed to compensatory responses to degeneration of neighboring neurons. The caudal striatal medium spiny neurons of young (3 month), motor-unimpaired aged (30 months), and motor-impaired aged (30 month) mice were compared. Although each group had total dendritic lengths that were comparable, when frequency distributions based upon ranges of dendritic lengths (0–600, 601–1200, 1201–1800, >1800 μm) were compared, the neurons of the motor-impaired aged mice differed from those of the other two groups. Specifically, the number of neurons containing "compact dendritic arbors" (i.e., neurons with total dendritic lengths of <600 μm) in the motor-impaired aged mice was 244% higher than the young mice and 684% higher than the motor-unimpaired aged mice (recall that the dendrites were elongated in the nonimpaired aged group, accounting for a lower frequency of neurons with compact dendritic arbors). The authors also reported such qualitative observations as an increased prevalence of cells exhibiting small shrunken dendrites, and atypical dendrites with terminal swelling (instead of the growth cones observed in the nonimpaired aged mice) indicative of cellular degeneration in the motor-impaired aged mice.

Although the majority of studies examining age-related morphological changes in the basal ganglia have been limited to the striatum, a few have examined dopaminergic neurons in the substantia nigra. Emborg and colleagues (1998) recently reported qualitative observations of degeneration (i.e., decreased neuropil, abnormally shaped perikarya, stunted neurites) of nigrostriatal dopaminergic neurons in aged (25–27 years) Rhesus monkeys. The altered morphological structure of nigral dopaminergic neurons is consistent with similar findings in the substantia nigra pars compacta of aged humans (Cruz-Sánchez *et al.*, 1995).

D. Receptors and Transporters

Numerous studies have reported decreases in dopamine receptor densities—especially the D_2-type—with age in mammals. In humans (>70 years) and Rhesus monkeys (22 years), age-related decreases of 30–42% of D_2 binding sites in caudate nucleus have been reported (Severson *et al.*, 1982; Wong *et al.*, 1984; Lai *et al.*, 1987; Morgan *et al.*, 1987). Age-related decreases in D_1 and D_2 receptor concentrations have been reported to range from 30–60% in rats and mice (>22 months) (Severson and Randall, 1985; Giorgi *et al.*, 1987; Lai *et al.*, 1987; Morgan and Finch, 1988; Han *et al.*, 1989). Decreases in dopamine receptor densities have been attributed to decreased production of the receptor protein, as both steady-state levels and synthesis of the D_2 receptor mRNA have been reported to be diminished by 50% in the striata of aged (>22 month) Wistar rats (Mesco *et al.*, 1991, 1993).

Several groups have reported reductions in dopamine-stimulated striatal adenylate cyclase in aging. Govoni and colleagues (1977) reported that the activity of adenylate cyclase in 20- to 24-month-old Sprague–Dawley rats was 64% lower than that of 2- to 3-month-old rats following dopamine stimulation. Likewise, Makman and colleagues (1979, 1980) reported that dopamine-stimulated adenylate cyclase activity was 50% lower in rabbits $\geq$5 years old than it was in rabbits $<$1 year old. These reported alterations may be the result of age-related decreases in D_1 dopamine receptor densities (Giorgi *et al.*, 1987) since this receptor has been demonstrated to be positively coupled with adenylate cyclase (Kebabian and Calne, 1979). Age-related changes in cAMP and adenylate cyclase activity appear to be regionally specific, as changes have been reported in the striatum but not within the nucleus accumbens (Sugawa and May, 1993).

Age-related decreases in transmembrane proteins are not limited to dopamine receptors. Positron emission tomography studies in humans have revealed that age-related losses in D_2 dopamine receptors were correlated with losses in dopamine transporters (Volkow *et al.*, 1998). Dopamine transporters provide the primary mechanism for terminating synaptic dopaminergic signals (Giros *et al.*, 1996) and are therfore essential in regulating dopaminergic neurotransmission. Age-related decreases of approximately 70% in the number of dopamine transporters between 19 and 90 years have been reported in humans (Allard and Marcusson, 1989; De Keyser *et al.*, 1990). Significant age-related decreases in dopamine transporters have also been reported in rats and monkeys, although the relative decrease is less than the decrease observed in humans. Emborg and colleagues (1998) reported decreases in dopamine transporter number of 33% and dopamine transporter density of 24% in the substantia nigra of 25- to 27-year-old Rhesus monkeys. Hebert and colleagues (1999) reported decreases in dopamine transporters of $>$50% in striatum and $>$74% in substantia nigra of aged 24-month-old F344 rats. Age-related decreases in dopamine transporter mRNA in 24-month-old rats ($\sim$22%; Himi *et al.*, 1995) and 65- to 72-year-old humans (up to 75%; Bannon and Whitty, 1997) have also been reported. Since age-related decreases in dopamine transporter mRNA exceed the magnitude of dopaminergic neuron loss, the observed reductions in dopamine transporters have been attributed primarily to decreased dopamine transporter mRNA rather than decreased numbers of dopaminergic terminals (De Keyser *et al.*, 1990).

III. Functional Changes

Many factors intrinsic to principal dopaminergic neuronal elements are essential for optimal functioning. In the previous section, evidence regarding age-associated structural changes in the basal ganglia was reviewed. While the notion of widespread neuronal death in the aging basal ganglia is not supported by the literature, there is evidence for such morphological alterations in dopaminergic neurons as decreased dendritic complexity and density of receptor and uptake sites in the striatum. Reports of these alterations are corroborated by the functional changes that are addressed below. These changes include such presynaptic processes as neurotransmitter synthesis, storage, metabolism, release, and reuptake/uptake, as well as such postsynaptic processes as receptor functioning, metabolism, and interactions with other neuromodulators. Compromises in these processes potentially account for the majority of age-related changes in the basal ganglia.

A. Presynaptic Changes

1. Dopamine Synthesis

The synthesis of dopamine has been reported to be decreased by 26–28% in the striatum of aged ($\geq$25 months) rats (Ponzio *et al.*, 1978; Watanabe, 1987; Marshall and Rosenstein, 1990). This decrease in dopamine synthesis may be related to reported age-related decreases of approximately 40% in the level of TH mRNA in substantia nigra of aged (24 months) rats (Himi *et al.*, 1995), and consequential decreased TH activity in striatum (93% decrease reported by Algeri *et al.*, 1977; 32% decrease reported by Ponzio *et al.*, 1982) and substantia nigra (31% decrease reported by Ponzio *et al.*, 1982) of aged (18–30 months) rats. Likewise, decreases of 24–28% in levels of dihydroxy-L-phenylalanine (DOPA) accumulation following the administration of the aromatic acid decarboxylase inhibitor NSD-1015 have been reported in aged (24–27 months) rats (Watanabe, 1987; Marshall and Rosenstein, 1990; Venero *et al.*, 1991). Some researchers, however, have reported no changes in striatal dopamine synthesis in aged rats as assessed by levels of dopamine and its metabolites in postmortem tissues (Demarest *et al.*, 1980; Friedemann and Gerhardt, 1992; Hebert and Gerhardt, 1998). However, these tissue measures may reflect synthesis capacity and not necessarily synthesis rates of dopamine in aged rats.

2. Dopamine Storage

Studies examining age-related differences in dopamine storage (or content) have also produced conflicting results. For example, decreases of 20–60% in dopamine whole tissue content have been reported in the striata of rodents (24- to 29-month-old rats; 24- to 28-month-old mice) and in the caudate nucleus and putamen of humans ($>$72.5 years) (Finch, 1973; Carlsson and Winblad, 1976; Joseph *et al.*, 1978; Demarest *et al.*, 1980; Osterburg *et al.*, 1981; Kish *et al.*, 1992; Yurek *et al.*, 1998). Likewise, a 34% decrease in striatal dopamine levels was also reported in aged (18 years) Rhesus monkeys (Goldman-Rakic and Brown, 1981). Furthermore, Irwin and colleagues (1994) reported a 30% decrease in dopamine levels in putamen, but not caudate nucleus in aged (20 years) squirrel monkeys. However, no significant differences in dopamine levels between young and aged animals and humans were found in other studies (Adolfsson *et al.*, 1979; Rose *et al.*, 1986; Friedemann and Gerhardt, 1992; Hebert and Gerhardt, 1998). Although there is a lack of consensus regarding age-related alterations in dopamine content, the point may be functionally moot. These reported decreases in dopamine levels are not considered large enough to produce Parkinson's disease-like effects in animals and humans (Hornykiewicz, 1963; Stricker and Zigmond, 1976; Lloyd, 1977). Furthermore, it has been demonstrated that the amount of

dopamine stored within neurons does not necessarily relate to the release capacity of dopaminergic neurons (Rose *et al.*, 1986; Friedemann and Gerhardt, 1992; Dobrev *et al.*, 1995; Hebert and Gerhardt, 1998).

3. Dopamine Release

Numerous studies have reported decreases in stimulus-evoked dopamine release in the aged striatum (e.g., Rose *et al.*, 1986; Gordon *et al.*, 1995; Kametani *et al.*, 1995; Friedemann and Gerhardt, 1996; Hebert and Gerhardt, 1998; Yurek *et al.*, 1998). Diminished potassium-evoked dopamine release of 22–50% has been demonstrated in the striatum of aged (12–24 months) rats (Gregerson and Selmanoff, 1990; Dobrev *et al.*, 1995; however, see Kametani *et al.*, 1995, and Gerhardt and Maloney, 1999, for exceptions) and monkeys (Gerhardt *et al.*, 1995). Likewise, age-related decreases of 30–60% in amphetamine-evoked dopamine overflow has been reported in the rat (Dluzen *et al.*, 1991; Kametani *et al.*, 1995; Yurek *et al.*, 1998; Gerhardt and Maloney, 1999). Since the neuronal release of dopamine has been demonstrated to be mediated through either calcium-dependent or calcium-independent mechanisms, both of these mechanisms may be susceptible to age-related alterations. While decreased calcium regulation in aged animals has been reported (Reimann *et al.*, 1993), other mechanisms thought to be responsible for diminished dopamine release include alterations in the efficacy of neuromodulators and other neurotransmitters that modulate dopamine release (Buck *et al.*, 1981; Chesselet, 1984; Joseph and Roth, 1988a,b; Friedemann and Gerhardt, 1996) and decreases in dopamine synthesis (Nakano and Mizuno, 1996).

Decreased dopamine release may be responsible for decreased locomotor activity observed in aging. For example, although some studies have failed to reveal age-related decreases in spontaneous locomotor activity in rats, when rats are habituated to the activity monitor, age-related decreases are robust and stable over time (Hebert and Gerhardt, 1998). The finding that potassium-stimulated dopamine release was lower in aged rats than in young rats, along with the demonstration that nomifensine, a dopamine-uptake inhibitor, increased locomotor activity in aged rats (Hebert and Gerhardt, 1998), suggests that prolonging the postsynaptic dopaminergic signal may reverse the age-related decline in spontaneous locomotor activity.

4. Autoreceptor Feedback

As previously mentioned, age-related decreases in the number of D_2 dopamine receptors have been reported for a number of species. The fact that presynaptic dopaminergic autoreceptors are classified as the D_2 type (Morelli *et al.*, 1988) leads to the question of whether dopaminergic autoreceptors are likewise affected by age. In a behavioral assay that is thought to reflect dopaminergic autoreceptor function in rats, Stoessl and colleagues (1989) reported that old (23–26 months) Sprague–Dawley rats exhibit diminished yawning following low-dose apomorphine administration when compared to mature (6–8 months) rats. Since dopaminergic autoreceptors provide the neuron with feedback regarding the synaptic dopaminergic signal, this decreased feedback may provide a compensatory mechanism with which to counter age-related decreases in dopaminergic release. Furthermore, the decrease in dopaminergic autoreceptor density may also have functional consequences for dopamine uptake, as the latter process has been reported to be linked in part to D_2 dopaminergic autoreceptors (Cass and Gerhardt, 1994).

5. Reuptake/Uptake

As stated earlier, the number of dopamine transporters decrease with age in rats and humans. Declines in the number of dopamine transporters of up to 70% in aged humans' caudate nucleus (De Keyser *et al.*, 1990) and 50% in aged rats' striatum (Hebert *et al.*, 1999) have been reported. In addition, the amount of dopamine transporter mRNA has been shown to decline with age in rats ($\sim$22% decrease) and humans ($\sim$75% decrease) (Himi *et al.*, 1995; Bannon and Whitty, 1997). These decreases have generally not been accompanied by alterations in binding affinities (Allard and Marcusson, 1989; Shimizu and Prasad, 1991; Hebert *et al.*, 1999). Functional consequences of these changes have been measured through *in vivo* stimulus-evoked dopamine release and dopamine clearance (Friedemann, 1992; Friedemann and Gerhardt, 1992; Hebert and Gerhardt, 1999). For example, dopamine uptake capacity can be measured by examining the amplitude and decay of exogenously applied dopamine. Hebert and Gerhardt (1999) demonstrated that when 20 pmol of dopamine was locally applied in the dorsal striatum of 24-month-old F344 rats, the amplitude of the dopaminergic signal was almost 3 times greater than the signal recorded in a 6-month-old rat given the same dose. Furthermore, the uptake rate was slower in the aged rats than in the young rats. When uptake rate/μM dopaminergic signal amplitude was measured, this value was 39% slower in aged rats than in young rats. Likewise, the maximal uptake rates for aged rats were 72% slower than those for young rats. In studies which have utilized the dopamine uptake inhibitor nomifensine to measure dopamine transporter function, the effectiveness of the drug in blocking the clearance of dopamine in aged (24–30 months) rats was diminished by almost 50% when compared to young (6 months) rats (Friedemann, 1992; Friedemann and Gerhardt, 1992; Hebert and Gerhardt, 1999). These age-related changes in dopamine clearance may be regionally specific, as Hebert and Gerhardt (1999) reported a slowing of dopamine clearance in the dorsal striatum but not in the nucleus accumbens.

Whereas there is a decrease in striatal dopamine release with age, the decline in number of uptake sites may be a compensatory mechanism through which the dopaminergic neuron adapts to decreased dopaminergic signal. This compensation would be consistent with the remarkable adaptive capacity of the nigrostriatal dopamine system (Hornykiewicz and Kish, 1987; Zigmond *et al.*, 1990; Cass *et al.*, 1995). For example, the density of dopamine transporters has been reported to decrease in individuals with PD (Uhl *et al.*, 1994), suggesting that a downregulation of dopamine transporters may be an adaptive mechanism through which to increase the amount of extracellular dopamine. Likewise, there may be a downregulation of dopamine transporters to adapt to the decreased dopaminergic signal that has been demonstrated to occur in normal aging.

6. Monoamine Oxidase

The relationship between the catabolic enzyme monoamine oxidase (MAO) and age is controversial (Irwin *et al.*, 1997; Shih, 1975). Studies that have examined MAO levels in rodents during aging have generally reported a positive relationship between age and the level of the ''B''-type of MAO isoform (MAO-B) in the basal ganglia. By contrast, either no change or a decrease in the ''A''-type of MAO isoform (MAO-A) has been reported. Increases in MAO-B have been demonstrated to be from 124 to 170% higher in basal ganglia of aged rats (24–25 months) and mice (10–25 months) when compared to young controls (Benedetti and Keane, 1980; Arai and Kinemuchi, 1988; Venero *et al.*, 1991; Saura *et al.*, 1994; Irwin *et al.*, 1997). Conversely, no effect of age was seen in the levels of MAO types A and B as a function of age in squirrel monkeys (Irwin *et al.*, 1997). Irwin and colleagues (1997) argued that their failure to find age-related increases was a true species difference and not related to methodology, since they did find an age-related increase in mice. They further suggest that their results may be a more accurate reflection of age-related changes in MAO, since the results of human studies are potentially confounded by uncontrolled disease states as well as by postmortem interval.

B. Postsynaptic and Extracellular Changes

1. Cellular Electrophysiology

There is considerable evidence for altered electrophysiological properties of aged nigrostriatal neurons. Most studies have reported an increased threshold for elicited responses with age (Levine, 1988; Cepeda *et al.*, 1996; Gould *et al.*, 1996). The increased thresholds have been demonstrated under several conditions. Cepeda and colleagues (1996) reported that the average iontophoretic current intensities necessary to elicit a response to excitatory amino acid (glutamate, NMDA) ejections in *in vitro* striatal cells of aged (24–26 months) rats were 147–161% higher than in young rats. Likewise, Levine (1988) stimulated corticostriatal and nigrostriatal cells electrically while recording responses of cells in the caudate nucleus of aged (11- to 14-year-old) cats *in vivo*. In this preparation, the electrical current necessary to elicit responses from caudate nucleus cells in aged cats increased 44% for cortical stimulation and 41% for nigral stimulation (however, the current necessary to produce corticostriatal responses in the 6- to 7-year-old cats was 79% higher than young cats). Finally, using pressure ejections of selective D_1 and D_2 dopamine receptor agonists (SKF 38393 and quinpirole, respectively), Gould and colleagues (1996) measured the doses required to produce *in vivo* changes of 50% in striatal neuronal firing rate. They reported that the ED_{50} (measured in psi $\times$ sec) required were 315 and 289% higher for SKF 38393 and quinpirole, respectively, in 26- to 27-month-old versus 3-month-old rats. Somewhat unexpectedly, Levine (1988) found that the average latencies of orthodromically evoked action potentials decreased with age in the caudate nucleus of cats. Upon further examination, however, this decrease was not attributed to increased speed of conduction, but to a loss of long-latency responses in the aged cats. Also reported in some studies were age-related diminishments in paired-pulse facilitation (Levine, 1988; Walsh and Ou, 1994), a deficit that may underlie the relatively diminished capacity for aged rats to habituate to a familiar environment or repeated stimulus (Hebert and Gerhardt, 1998).

In addition to increased response thresholds following either pharmacological or orthodromic stimulation, there are a variety of other altered response characteristics of aged striatal neurons. These include the following: a general lack of response, decreased proportion of neurons responding in a distinctive manner, ''unusual'' responses, reduction in the components of a response, significant changes in the proportion of occurrence of different types of responses, increased durations of response inhibitions, and decreased average spontaneous firing rates of caudate nucleus neurons (Levine, 1988; Cepeda *et al.*, 1996).

2. Neurotransmitter Interactions

Despite this chapter's deliberately exclusive concentration on age-related dopaminergic function, dopamine does not exist and function in isolation in the basal ganglia. Potential changes in other neuronal systems that impact on dopaminergic neurons may indirectly alter the function of dopaminergic neuronal systems in aging. The principal output neuron of the striatum is the medium spiny GABAergic neuron which is modulated not only by nigrostriatal dopaminergic neurons, but also by corticostriatal glutamatergic neurons and striatal acetylcholinergic interneurons (Di Chiara *et al.*, 1994; Parent and Hazrati, 1995; Wilson, 1998). There have been very few studies to date reporting age-related changes in the interactions between different neurotransmitter systems in the basal ganglia. When examined in isolation, reports of age-related changes in corticostriatal glutamatergic function are equivocal. Some studies have found stability of corticostriatal glutamatergic function (e.g., Donzanti *et al.*, 1993; Porras *et al.*, 1993; Sanchez-Prieto *et al.*, 1994), while others have found age-related diminutions or alterations (Cepeda and Levine, 1991; Castorina *et al.*, 1994; Cepeda *et al.*, 1996). Striatal γ-aminobutyric acid (GABA) function has been reported to remain steady with age (McGeer and McGeer, 1975; Govoni *et al.*, 1980; Strong *et al.*, 1982). Studies of age-related acetylcholinergic function have reported declines in synthesis (Gibson *et al.*, 1981), loss of striatal muscarinic cholinergic receptors (Norman *et al.*, 1986; Briggs *et al.*, 1989), and diminished cholinergic receptor binding (Freund, 1980).

Although age-related changes in these non-dopaminergic striatal neurotransmitter systems appear to vary considerably, when age-related deficits occur in the nigrostriatal depaminergic system, the balance between these modulators of basal ganglia motor output may be compromised (Randall, 1980; Porras and Mora, 1995; Cepeda *et al.*, 1996). For example, in striatal brain slices from aged rats and cats the ability of dopamine to modulate excitatory amino acid receptor-mediated responses was reduced when compared to slices from young rats and cats (Cepeda *et al.*, 1996). Specifically, depending upon the type of receptor, the response to dopamine was either lost or the threshold for the response was increased by 232%. Likewise, in the young rat striatum it has been demonstrated that the mixed D_1–D_2 dopamine receptor agonist apomorphine produces concentration-dependent increases in

glutamate and GABA release. This modulation was altered in older rats. As the glutamatergic response to apomorphine was decreased the threshold for apomorphine-induced GABA release was increased (Porras and Mora, 1995). Finally, the importance of dopamine input to acetylcholinergic function is evidenced by previous studies which have demonstrated that acetylcholinergic neurons become hyperactive following loss of dopamine input (Stoof *et al.*, 1992). Likewise, it has been demonstrated that the colocalization of dopamine autoreceptors and muscarinic and/or nicotinic cholinergic receptors provides a means for cholinergic agonists to enhance striatal dopamine release by inhibiting dopamine autoreceptors (Chesselet, 1984). Previous studies have demonstrated that the capacity for cholinergic agonists to enhance potassium-evoked dopamine release is decreased in aged rats (Joseph *et al.*, 1988; Kametani *et al.*, 1995).

IV. Conclusions

In conclusion, the evidence for age-related decrements in basal ganglia function is considerable and the nigrostriatal dopaminergic system seems to incur the majority of age-related deterioration. However, additional studies are needed to investigate potential changes in dopaminergic systems in mesolimbic dopaminergic pathways and in other areas of the basal ganglia that contain dopaminergic fibers. Although there is evidence for loss of dopaminergic neurons with age, the degree of loss is not of sufficient magnitude to account for the decrements in movement that accompany senescence that are often termed parkinsonism (Bennett *et al.*, 1996). Of the age-related alterations in the nigrostriatal pathways that correlate with these decrements, most involve functional decrements of neuronal machinery. These include decreases in dopamine receptors, transporters, as well as dopamine release and reuptake. Further work, however, needs to be carried out in the areas of dopamine synthesis, storage, and release, as previous studies examining these processes have produced equivocal results.

With the increasing use of techniques that can study the dynamics of neuronal function, we have only begun to quantify the capacities of neural systems and how these capacities are affected by age. The fact that the weight of evidence indicates a primary role for alterations in the function of existing neurons—and not neuronal loss—in age-related movement disturbances is encouraging. Research into these processes may facilitate the development of treatments that can increase the functional capacity of dopaminergic neurons, resulting in the attenuation of age-related movement deficits.

Male Sexual Behavior during Aging

As men age, there are clear changes in sexual behavior. For example, young married men report a strong desire for sexual activity and typically engage in sexual intercourse more than once per week. In contrast, older age men report desire for sexual activity (albeit to a lesser degree), but do not engage in frequent sexual intercourse because of erectile dysfunction or health problems. The factors responsible for these changes include an age-associated decrement in the serum testosterone concentration (andropause) which likely results in diminished libido and various health disorders which cause erectile dysfunction. For example, older age is associated with atherosclerotic vascular disease, which is the most frequent cause of inadequate erections. There are very little data on the effect of aging on orgasmic function. In essence, older age (in the absence of disease) is associated with modest decrements in sexual interest, ability, and activity. However, the majority of Americans develop various diseases as they age (i.e., diabetes mellitus) which impair erectile function. Ideally, these diseases can and should be prevented, thereby allowing older married couples to enjoy at least a modicum of the sexual pleasures they enjoyed during their youth.

I. Introduction

As men proceed through the various stages of life, there is a decrease in the frequency of sexual intercourse with older age (Leigh *et al*., 1993). Twenty-nine percent of 18- to 29-year-old men report having intercourse three to four times per week, whereas only 7% of men ages 60–69 years and 2% of men ages $\geq$70 years report the same frequency (i.e., three to four times per week). Kinsey *et al*. (1948) reported that by age 80 years, the average frequency of intercourse decreases to once every 10 weeks. Pfeiffer *et al*. (1968) found that 95% of men ages 46–50 years had intercourse once a week, while in the 66- to 71-year-old group, only 28% were having intercourse once a week. In the Bretschneider and McCoy (1988) study of Caucasian, healthy, upper-middle-class men ages 80–102 years, 26% reported their frequency of sexual intercourse to be several times per month to several times per week. They found that prior importance of sex correlated positively with current frequency and enjoyment of intercourse in older men.

The prevalence of engaging in any sexual activity also declines with aging. Bretschneider and McCoy found that 63% of healthy men over the age of 80 still engaged in sexual intercourse (at least once per year). Pfeiffer *et al*. (1968) found that 50% of 60- to 71-year-old men still engaged in sexual intercourse, whereas only 15% of men older than 78 years reported any sexual activity. In a subgroup of this population, followed longitudinally for 10 years, 70% were sexually active at the starting age of 67, but only 25% were still active by age 77 (Pfeiffer *et al*., 1969). Likewise, Diokno *et al*. (1990) found sexual intercourse was present in 80% of married men ages 65–69 years but only 28% in those over age 80 years. In nursing home residents, 80% no longer engaged in coitus despite availability of a sexual partner, moderately strong libido, and preference for vaginal intercourse. However, 17% reported sexual intercourse while on home visits once a month (Mulligan and Palguta, 1991). Thus, although there is a decline in sexual activity with aging, there is no specific age of sudden cessation. Furthermore, sexual interest and desire often persist despite decreased activity.

In men ages 30–99 years old, Mulligan and Moss (1991) found that sexual interest decreases with age, but total absence of interest was never reported. Similarly, Pfeiffer *et al*. (1969) reported continued sexual interest in 80% of men 67 years old; 75% of the same subjects still reported sexual interest at age 76 years. In the Bretschneider and McCoy healthy males ages 80–102, 88% still fantasized about sexual activity, and 66% indicated sexual activity to be of importance in their current lives. Schiavi *et al*. (1990) surveyed healthy couples ages 45–74 years and reported frequency of desire for sexual contact to decrease from a mean score of 6 (based on a scale where 1 = never and 8 = daily) in 45- to 54-year-old men to a mean score of 3 for men age 65–74 years. In another study, of healthy, well-educated men attending a sexuality and aging lecture series (ages 56–85 years), 92% reported that they would like to have sexual activity at least once per week (Wiley and Bortz, 1996). However, only 33% currently engaged in sexual activity at least once per week. This desired frequency was similar to their recall of their frequency of sexual activity 10 years previously. In nursing home residents,

Mulligan and Palguta (1991) reported continued sexual interest, especially among those with partners; those without partners stated they would have greater interest if a partner was available. Overall, 66% of all their subjects reported sexual interest, albeit less than in younger years.

Even with old age, the preferred sexual activity remains vaginal intercourse. Mulligan and Moss (1991) reported that 82% of men preferred intercourse regardless of age. With the decline in intercourse, however, they did not find a compensatory increase in other forms of sexual contact, such as kissing, caressing, petting, oral sex, or masturbation. In contrast, Bretschneider and McCoy (1988) reported that 83% of their subjects engaged in touching or caressing without sexual intercourse at least several times per year. Furthermore, 74% expressed moderate to great enjoyment from this activity. In fact, touching or caressing without intercourse was the most common activity (83%). Similarly, Wiley and Bortz (1996) found in their self-selected group of attendees at sex lectures that sexual intercourse and orgasm were the highest rated forms of sexual activity 10 years previously. Currently, however, these forms of sexual expression declined but with an increase in expressions of intimacy without intercourse. The majority of nursing home residents in the Mulligan and Palguta study also preferred vaginal intercourse, but 21% preferred hugging or caressing, 5% preferred kissing, and 2% preferred masturbation.

Despite the lower level of sexual activity, many older males still express sexual satisfaction. Mulligan and Palguta (1991) found that nursing home residents were reasonably satisfied sexually with a mean score of 6 (scale 1 = not at all satisfied and 10 = extremely satisfied). However, the nursing home residents who had nonresident partners reported higher levels of sexual distress (mean score of 3 on scale from 1–10 with 1 = not at all distressed and 10 = extremely distressed); those without partners had a mean sexual distress score of 2. Age, functional status, and intercourse frequency were independently and positively correlated with sexual satisfaction in these nursing home residents. Schiavi *et al*. (1990) found in their study of couples that mean male marital sexual satisfaction scores were 6 (1 = not enjoyable and 7 = very enjoyable) for men ages 45–54 years and 6 for men ages 65–74 years.

An important social factor in sexual behavior during aging is the role of the sexual partner. Bretschneider and McCoy (1988) found that marital status significantly correlated with frequency and enjoyment of sexual activities. Diokno *et al*. (1990) also demonstrated that availability of a marital partner is an important factor with sexual activity occurring in 74% of married men and 31% of unmarried men. Among those with sexual partners, Pfeiffer *et al*. (1968) found that men tended to attribute cessation of sexual intercourse to themselves, while 74% of the women attributed it to their spouses. The main reasons cited were loss of potency, decreased libido, and medical illness. In those men who blamed their spouses for stopping, 62% attributed the cause to illness, 37% to loss of interest, and 5% to loss of potency. In addition, relationship incongruity and libido ''mismatches'' may inhibit sexual overtures toward a partner and further reduce sexual function and activity (Kaiser, 1996).

The causes of the age-associated changes in sexual behavior are multifactorial, including organic and social factors. To understand these causes, we will review the anatomy and physiology of male sexual function and then the pathophysiology of dysfunction.

II. Normal Physiology of Sexual Function

A. Anatomy

The penis consists of three components, two dorso-lateral corpora cavernosa and a ventral corpus spongiosum which surrounds the penile urethra and distally forms the glans penis. A thick fibrous sheath, the tunica albuginea, surrounds each of the corpora cavernosa, and all three corpora are bound together by Buck's fascia. The ischiocavernosus and bulbospongiosus muscles surround the proximal portions of the corpora cavernosa (Williams and Warwick, 1980). Each corpus consists of smooth muscle bundles, elastic fibers, collagen, and loose fibrous tissue which form the trabeculae. Between the trabeculae are blood-filled lacunar spaces which are lined by flat endothelial cells (Bossart *et al*., 1980).

The arterial supply to the penis is the internal pudendal arteries, which become the penile arteries. Each penile artery terminates in bulbar, urethral, dorsal, and cavernosal arteries. The paired cavernosal arteries penetrate the tunica albuginea and enter the crura of the corpora cavernosa. Each ends in multiple twisted branches called helicine arteries that supply the lacunae. There may be two circulatory routes in the human corpora. One route goes from the cavernosal artery to capillary networks underlying the tunica albuginea with the capillaries serving as nutritional vessels. This pathway is the main circulatory route during the flaccid state. The second route is via anastomoses from the cavernosal artery through the helicine arteries to the cavernosa, which then empties into the postcavernous venules and serves as the main vascular pathway in the mechanism of erection (Banya *et al*., 1989).

Venous return from the pendulous penis occurs through the deep and superficial dorsal veins of the penis. Subtunical venules located between the periphery of the erectile tissue and the tunica albuginea drain the lacunar spaces. They coalesce to form emissary veins which penetrate the tunica albuginea and drain into the deep dorsal vein or the circumflex system. Drainage from the proximal crura is mainly through the cavernosal and crural veins. Superficial dorsal veins communicate with the external pudendal vein and/or the saphenous vein to drain the skin and prepuce of the penis (Aboseif and Lue, 1988; Tudoriu and Bourmer, 1983).

B. Mechanism of Erection

1. Neural Component

Penile erection is a complex event, occurring as a result of the integration of central (cerebral and spinal) and local (smooth muscle and endothelium) factors (Anderson and Wagner, 1995). It arises in response to sensory stimuli, fantasy, or genital stimulation. Specialized areas in the hypothalamus and thalamus organize the autonomic response to these stimuli (Sachs, 1995).

Sympathetic preganglionic nerve fibers to the penis arise from neurons in the intermediolateral cell columns of T12–

L2 spinal cord segments, while parasympathetic input to the penis arises in the S2–S4 sacral spinal cord segments. Sympathetic impulses travel via the hypogastric nerve, and parasympathetic impulses travel via the pelvic nerve. The pelvic plexus serves as the peripheral integration center for autonomic input to the penis. The pelvic plexus then branches into the cavernous nerves that traverse the posterolateral aspect of the prostate and continue on both sides of the urethra as the cavernosal nerves (Steers, 1990).

In the flaccid state, there is tonic contraction of the arterial and corporal smooth muscles mediated by α 2 adrenergic receptors which maintains high penile arterial resistance (Wagner *et al*., 1989). With erotic stimulation, there is a decrease in sympathetic tone and an increase in parasympathetic activity. Central to erection is a hemodynamic change which decreases penile arterial resistance with resultant increased penile blood flow (Lue and Tanagho, 1987).

Parasympathetic stimulation activates cholinergic receptors via acetylcholine, stimulating endothelial cells to produce a nonadrenergic, noncholinergic transmitter, nitric oxide (NO). NO relaxes trabecular smooth muscle (Saenz de Tejada *et al*., 1988), and is considered the major neurotransmitter controlling relaxation of penile smooth muscle (Kim *et al*., 1991; Rajfer *et al*., 1992). NO is formed by conversion of L-arginine into L-citrulline by the enzyme, nitric oxide synthase (NOS) (Burnett, 1995a). NOS is activated by the influx of calcium ions that occurs with parasympathetic stimulation. The increased oxygen levels derived from the arterialization of cavernosal blood flow further activates NOS and thereby maintains erection.

NO moves from cell to cell through gap junctions and by diffusion into smooth muscle cells providing the rapidity of the response within the penis (Korenman, 1998). NO activates guanylate cyclase thereby increasing production of cyclic guanidine monophosphate (cGMP). cGMP depletes intracellular calcium and further induces smooth muscle relaxation with resultant penile vasodilation (Burnett, 1995b; Ignarro *et al*., 1990; Lugg *et al*., 1995a; Moncada, 1992).

Other chemical entities have been implicated in the control of erection, including prostaglandins E1 (PGE1) and E2 (PGE2) and vasoactive peptide. PGE1, PGE2, and vasoactive peptide stimulate the production of cyclic adenosine monophosphate (cAMP) which decreases intracellular calcium and induces smooth muscle relaxation. Vasoactive peptide may also interact with either endothelial or corporal smooth muscle cells to stimulate local formation of NO, and thereby sustaining penile erection (Makhlouf and Grider, 1993; Said, 1992).

Genital stimulation elicits neural impulses which traverse the dorsal nerve of the penis to the pudendal nerve. From the pudendal nerve, the impulses travel to the sacral spinal cord (S2–S4). Efferent impulses travel along the parasympathetic pelvic nerves and produce an erection as described above.

2. Vascular Component

Tonic sympathetic stimulation constricts the trabecular smooth muscle and helicine arteries keeping the penis in its flaccid state. During flaccidity, blood pressure in the cavernosal lacunae is similar to venous pressure. With sexual stimulation, sympathetic tone decreases and there is parasympathetic-mediated relaxation of arteriolar and trabecular smooth muscle. Penile arterial resistance decreases, resulting in increased blood flow into the corpora cavernosa. The increase in blood volume expands the lacunar spaces and compresses the subtunical venules between the expanding corpora cavernosa and the unyielding tunica albuginea. This results in reduction of venous outflow and trapping of blood within the penis. Penile rigidity develops as intracavernosal pressure rises to mean arterial pressure. Detumescence typically occurs after orgasm. During detumescence, there is a decrease in the arterial flow into the penis, decrease in intracavernosal pressure, increased venous drainage, and restoration of sympathetic nerve impulses returning the penis to the flaccid state (Newman and Northup, 1981; Wespes and Schulman, 1993).

C. Libido

Libido results from an interplay of psychological, social, physical, and endocrine factors. Animal research suggests that libido is centered in the medial preoptic area of the hypothalamus (Cunningham and Hirshkowitz, 1995). This area of the brain has androgen receptors and it appears that testosterone (and/or its metabolite dihydrotestosterone) is necessary for normal sexual desire. Udry *et al*. (1985) studied hormonal and social effects on adolescent male sexual behavior. Through self-administered questionnaires and serum hormone assays in 102 adolescent boys, they found that serum free-testosterone concentration was a strong predictor of sexual motivation and behavior. When the free-testosterone index was divided into quartiles, 16% of those with the lowest free-testosterone index reported having had intercourse, whereas 69% of boys in the highest free-testosterone index quartile reported intercourse. Similar findings occurred for noncoital sexual activity and libido. This suggests that the serum free-testosterone concentration appears to affect sexual activity and desire directly.

Bagatell *et al*. (1994) examined the role of physiological serum concentrations of testosterone in maintaining sexual behavior in eugonadal men. In a randomized, double-blind study of healthy, eugonadal men, they utilized a GnRH antagonist, Nal–Glu, without testosterone replacement to produce acute and profound reversible androgen deficiency. They found that subjects experienced decreased frequency of sexual desire, fantasies, and intercourse. There was also a decrease in noncoital sexual activity such as kissing, fondling, and masturbation. However, even low dose testosterone replacement was adequate to maintain normal sexual function and behavior. In a study of eugonadal men complaining of loss of sexual desire, O'Carroll and Bancroft (1984) found that with testosterone injection therapy, there was a modest increase in sexual desire, but no effect on erectile function. Anderson *et al*. (1992) examined the effects of supraphysiological levels of testosterone on sexual behavior and found that sexual awareness and arousability increased with the higher testosterone levels but these changes did not produce modifications of overt sexual behavior. This was in contrast to hypogonadal men in whom testosterone replacement stimulated both sexual interest and activity (Burris *et al*., 1992). From these and other studies, it appears that the major contribution of testosterone on sexuality is related to libido (Kwan *et al*., 1983).

D. Orgasm

Sexual intercourse usually terminates with the motor acts of emission and ejaculation, along with the sensory perception of orgasm. However, there is limited investigation and knowledge regarding orgasm. Orgasm occurs in conjunction with the physical events of contraction of smooth muscle of vas deferens, prostate, seminal vesicles, and the buildup of pressure within the penis. The pleasure of orgasm may derive from the development of this pressure, its release by relaxation of the distal sphincter, and the clonic striated muscle contractions of ejaculation (Newman *et al*., 1982). Electromyography reveals that the onset of the perception of orgasm precedes ejaculation by a few seconds (Kollberg *et al*., 1962). Orgasm may also be elicited cerebrally without afferent input from the penis. For example, orgasm has been reported during psychomotor seizures in patients with temporal lobe lesions (Blumer, 1970). Clearly, this area of human sexuality is in need of further research.

E. Emission and Ejaculation

Emission is the propulsion of semen into the posterior urethra. It is accomplished by peristaltic contractions of the vas deferens, ampulla, seminal vesicles, and prostatic smooth muscles. Emission is a spinal cord reflex in response to genital stimulation, but it may be voluntarily stopped, indicating partial cerebral control. It can also be elicited by cerebral erotic stimulation in the absence of afferent genital stimulation. Sympathetic fibers traversing the hypogastric nerves and plexi are the motor efferents producing emission. Parasympathetic fibers in the pelvic nerves mediate prostatic secretion.

Expulsion of semen from the urethra marks ejaculation. Intermittent relaxation of the distal sphincter allows semen to enter the bulbous urethra. Contractions of the bulbocavernosae muscles propel the semen through the pendulous urethra. Ejaculation is a reflex reaction in response to semen entrance into the bulbous urethra. Its neural center resides in the spinal cord between T12 and L2 and communicates with the ventral horn cells in the sacral cord controlling the perineal and pelvic striated muscles. The integrity of the vesicle sphincters determines the direction of seminal expulsion. Antegrade ejaculation is achieved by firm closure of the proximal sphincter and a functional distal sphincter. Dripping emission occurs if the distal sphincter is paralyzed, and retrograde ejaculation into the bladder occurs if the proximal sphincter is malfunctioning.

III. Erectile Dysfunction and Aging

The term *impotence* has been used to identify the inability of the male to achieve and maintain penile erection sufficient for sexual intercourse. However, this term has also been used to refer to anorgasmia, lack of libido, and inability to satisfy the partner. Therefore, the NIH consensus panel on impotence suggested that the term *erectile dysfunction* be used to describe the inability to achieve an erection (NIH Consensus Conference, 1993). It is estimated that 10–30 million American men have erectile dysfunction (Nelson and McLemore, 1988; National Center for Health Statistics, 1989). According to the Massachusetts Male Aging Study conducted on a community-based, random sample of men ages 40–70 years in the Boston area, the overall prevalence of erectile dysfunction was 52% (Feldman *et al*., 1994). Kaiser *et al*. (1988) found complete erectile failure in 41% of the men ages 60–79 years in their cross-sectional study. None of the men above the age of 70 years was able to achieve a full erection. Mulligan *et al*. (1988) also found high prevalence of sexual dysfunction in a veteran population, with 27% of men ages 65–75 years and 50% in those over 75 years reporting erectile dysfunction. This high prevalence of sexual dysfunction is important because men with erectile dysfunction report impaired quality of life when compared with unaffected men (Jonler *et al*., 1995).

A. Vascular Disease

The most common etiology of erectile dysfunction in aged men is vascular disease. In men over 60 years old who were being evaluated for inadequate penile rigidity, 21% of the cases were due to vascular disease (Mulligan and Katz, 1989). In a study by Virag *et al*. (1985) of 178 men with organic erectile dysfunction, arteriograms revealed arterial lesions in 68%. They also found that the risk of organic erectile dysfunction increased with the number of vascular risk factors (diabetes mellitus, smoking, hyperlipidemia, and hypertension); 100% of the patients with three or more risk factors had erectile dysfunction. Finally, Morley *et al*. (1988) showed that erectile dysfunction is a predictor of major atherosclerotic vascular disease (i.e., myocardial infarction and stroke).

Vascular disease results in erectile dysfunction by two mechanisms, arterial insufficiency and venous leakage. Obstruction from atherosclerotic arterial occlusive disease of the hypogastric-cavernous arterial bed decreases the perfusion pressure and arterial flow to the lacunar spaces which is necessary to achieve a rigid erection (Krane *et al*., 1989). In an animal model using New Zealand White male rabbits, Azadzoi and Goldstein (1992) demonstrated that hemodynamic alterations created by hypercholesterolemia and atherosclerotic occlusive disease of the iliac arteries caused erectile dysfunction. Additionally, atherosclerotic vascular disease may cause ischemia of trabecular smooth muscle and result in replacement of smooth muscle by connective tissue. Jevtich *et al*. (1990) examined corpora cavernosal tissue by electron microscopy. The tissue from impotent men showed marked thickening of the basal lamina, a paucity of contractile filaments, minimal or no glycogen, and fewer vesicles on the cell surface. The degree of smooth muscle cell alteration correlated with the severity of symptoms. Using New Zealand white rabbits, Nehra *et al*. (1998) found that the severity of arterial occlusion correlated with the decrease in trabecular smooth muscle content in the corpus cavernosum. This decrease in smooth muscle content impaired cavernosal expandability.

Venoocclusive dysfunction or venous leakage is characterized by excessive outflow through the subtunical venules, preventing the development of high pressure within the corpora cavernosa and, thereby, interfering with maintenance of a rigid erection. Venous leakage can result from La Peyronie's disease, arteriovenous fistula, or trauma-induced communication between the glans and the corpora (Azadzoi *et al*., 1996). In a study of men with erectile dysfunction who failed to achieve

an erection with intracorporeal papaverine, 86% had evidence of venous leakage (Rajfer *et al*., 1988). Tudoriu and Bourmer (1983) found an increase in both the size and the number of venous outflow channels with advancing age in human cadavers. The structural alteration in the fibroelastic components of the trabeculae causes a loss of compliance and inability to expand the trabeculae against the tunica albuginea, which is necessary to compress the subtunical venules. This decrease in fibroelasticity may be from increased cross-linking of collagen fibers induced by nonenzymatic glycosylation (Cerami *et al*., 1987). It may also result from vascular factors, such as hypercholesterolemia associated with altered collagen synthesis (Fischer *et al*., 1980). Finally, venoocclusive dysfunction can occur from insufficient relaxation of trabecular smooth muscle in an anxious patient who has excessive adrenergic-constrictor tone and in patients with injured parasympathetic dilator nerves (Krane *et al*., 1989).

B. Neurological Disease

Neurological disease accounts for the second most common cause of erectile dysfunction in elderly men. Partial or complete erectile dysfunction can result from disorders which affect the parasympathetic sacral spinal cord or the peripheral efferent autonomic fibers to the penis. Such disorders impair penile smooth muscle relaxation and prevent the vasodilation needed for erection. Suprasacral lesions may also cause erectile dysfunction through the lack of input from higher neural centers. In spinal cord injury patients the degree of erectile dysfunction is largely dependent on the completeness and the level of the spinal injury. Those patients with complete lesions or injury to the lower part of the spinal cord are more likely to have loss of erectile function. However, 25% of spinal cord injury patients with erectile capabilities have erections adequate for penetration. Multiple sclerosis is also associated with erectile dysfunction. Mattson *et al*. (1995) found that 78% of men with multiple sclerosis experienced sexual dysfunction including erectile problems, decreased sensation, and inability to reach orgasm. In the older man, diabetes mellitus, stroke, and Parkinson's disease can cause autonomic dysfunction resulting in erectile failure. Additionally, surgical procedures such as radical prostatectomy, cystoprostatectomy, and proctocolectomy frequently disrupt the autonomic nerve supply to the corporal bodies and result in postoperative erectile dysfunction (Quinlan *et al*., 1991).

C. Diabetes Mellitus

The prevalence of erectile dysfunction in diabetes mellitus has been reported to be as high as 75%. Erectile dysfunction occurs more frequently and at a younger age in the diabetic population when compared with the population as a whole. Greater than 50% of diabetic patients report erectile dysfunction within 10 years of the diagnosis of diabetes; for some it is the presenting symptom (Kaiser and Korenman, 1988). In addition to erectile dysfunction, diabetic patients report decreased sexual desire, activity, and satisfaction when compared to age-matched healthy controls (Schiavi *et al*., 1993).

Although the etiology of diabetic erectile dysfunction is multifactorial, the major cause in older diabetic patients is vascular disease; autonomic neuropathy plays a more important role in younger patients (Morley and Kaiser, 1989). In a survey of 200 diabetic men, 59% had erectile dysfunction and 88% of the impotent subjects had neuropathy. Only 12% of the potent diabetics had clinical signs of neuropathy (Ellenberg, 1971). Palmer *et al*. (1986) reported that the correlation with impotence was highest when neuropathic symptoms coexisted with slowing of motor nerve conduction velocity. In a later study, Buvat *et al*. (1985) found that motor and sensory median nerve conduction velocity was not useful in discriminating between potent and impotent diabetic patients. They concluded that most diabetic impotence arises from an abnormality of the autonomic nervous system and arterial factors.

This controversy in the importance of the neurological factors in diabetic erectile dysfunction may be confounded by the fact that many studies failed to categorize the diabetic patients into type I versus type II. Bemelmans *et al*. (1994) studied type I diabetic patients and found neuropathy in 85% of the impotent diabetic patients. Neuropathy was more severe in comparison to potent diabetic and impotent nondiabetic patients. They also found that 58% of impotent diabetic patients had vascular disease, as suggested by the inability to achieve an erection with intracavernosal injection of papaverine. They concluded that in type I diabetic patients, neurologic factors have a crucial role in the etiology of diabetic erectile dysfunction. Nevertheless, vascular disease may be the most common etiology of erectile dysfunction in diabetic men.

Impotent diabetic men may also have impaired penile cholinergic nerve synthesis and release of acetylcholine, resulting in decreased ability to relax trabecular smooth muscle (Blanco *et al*., 1990). *In vitro* study of human corpus cavernosum tissue from diabetic and nondiabetic impotent patients revealed that impotent diabetic men have impairment in both the autonomic and the endothelium-dependent mechanisms which facilitate relaxation of smooth muscle (Saenz de Tejada *et al*., 1989). Autonomically mediated contractions were maintained despite impairment in autonomically mediated relaxation of corporal tissue from diabetic subjects. Thus, there was an imbalance favoring detumescence rather than erection. The decreased response to acetylcholine in tissue from impotent diabetic men is likely due to decreased synthesis or release of NO, the endothelium-derived relaxing factor.

Another factor contributing to decreased vasodilation in diabetic impotent men may be the inactivation of endothelium-derived NO by basement membrane advanced glycosylation end products (Hogan *et al*., 1992). Advanced glycosylation end products which accumulate on tissue proteins such as basement membrane collagen, have been implicated in other long-term complications of diabetes mellitus such as vascular disease. Finally, Vernet *et al*. (1995) demonstrated a decrease in penile NOS in types I and II diabetic rats with erectile dysfunction and have suggested that this is due in part to androgen deficiency.

D. Testosterone and Erectile Dysfunction

The role of androgens in erection is controversial (Mulligan and Schmitt, 1993). Androgen receptors have been demonstrated in sacral parasympathetic nuclei and hypothalamic and limbic system neurons, suggesting potential hormonal reg-

ulation of centers involved in erectile function (Krane *et al*., 1989). However, patients with castrate levels of testosterone can attain erections in response to visual sexual stimuli (Bancroft and Wu, 1983). Hypogonadal patients show smaller and slower ability to develop erections in response to fantasy, and androgen replacement improved erectile response. These findings suggest that erections to certain types of sexual stimuli (i.e., direct penile stimulation) may be androgen independent while response to fantasy may be androgen dependent. In contrast, Kwan *et al*. (1983) found no difference in erectile response to erotic film and fantasy in hypogonadal versus eugonadal subjects. Davidson *et al*. (1979) showed that in hypogonadal men there were dose-related responses to androgen treatment in frequencies of nocturnal erection and coitus.

Androgen may indirectly affect penile smooth muscle relaxation and resultant rigidity through NOS. Chamness *et al*. (1995) demonstrated decrease in NOS activity and amount of NOS protein in the penis of adult rats after castration. These changes were reversed by testosterone replacement. The effect of testosterone was blocked by finasteride, a 5α-reductase inhibitor, suggesting that the active androgen may be dihydrotestosterone (Lugg *et al*., 1995b). These investigators also demonstrated a decrease in erectile response with castration and a concomitant decrease in total penile NOS activity. However, in men, despite a decline in serum testosterone concentration with aging, no age-related decline in dihydrotestosterone has been found (Gray *et al*., 1991). Overall, therefore, testosterone appears to play a minor role in erectile function in humans.

E. Drug-Induced Erectile Dysfunction

Many commonly used medications have been associated with erectile dysfunction (Anonymous, 1992). Slag *et al*. (1983) reported 25% incidence of drug-induced impotence in a medical outpatient clinic population. Almost all the data available on drug-induced erectile dysfunction are subjective, however, based on observations, case reports, patient and physician surveys, and pre- and postmarketing drug studies (Benet and Melman, 1995).

The mechanism of drug-mediated erectile dysfunction, for the most part, is unknown. Medications such as antidepressants, antipsychotics, and antihistamines have anticholinergic effects which may contribute to erectile dysfunction by blocking parasympathetic-mediated penile artery vasodilatation and trabecular smooth muscle relaxation (Godschalk *et al*., 1997). Virtually all antihypertensive agents have been associated with erectile dysfunction, but with a higher incidence for beta-blockers, thiazide diuretics, reserpine, clonidine, and alpha-methyldopa. The mechanism for erectile dysfunction with these medications may be the lowering of blood pressure below the critical threshold necessary to maintain sufficient blood flow for penile erection, particularly in patients who already have penile arterial disease. Antipsychotic medications such as phenothiazines, thioxanthines, and butyrophenones can cause erectile dysfunction through sedation, anticholinergic effects, central anti-dopaminergic effect, and elevation of prolactin serum concentrations (Wein and Van Arsdalen, 1988). Other medications which can cause erectile dysfunction through effects on the central nervous system include tricyclic antidepressants, lithium, and monoamine oxidase inhibitors.

F. Psychogenic Erectile Dysfunction

Reports on the prevalence of psychogenic erectile dysfunction vary from 10 to 90%, and the likelihood of psychogenic impotence inversely correlates with age; the younger patient has a greater likelihood that his erectile dysfunction is psychogenic (Carrier *et al*., 1993). Slag *et al*. (1983) reported 14% of their outpatient impotent males had a psychogenic etiology. Mulligan and Katz (1989) attributed psychopathology as the cause of erectile dysfunction in 9% of their aged impotent male veteran population. Psychogenic impotence may occur via increased sympathetic stimuli to the sacral cord inhibiting the parasympathetic dilator nerves to the penis, and thereby inhibiting erection. Common causes of psychogenic erectile dysfunction include performance anxiety, conflicts in relationships, sexual inhibition, childhood sexual abuse, and fear of sexually transmitted diseases (Smith, 1988). A classic psychogenic cause of erectile dysfunction in the older male is the ''widower's syndrome,'' where the older man involved in a new relationship feels guilt and develops impotence as a defense against his unfaithfulness to his dead spouse (Morley and Kaiser, 1989).

G. Other Factors in Erectile Dysfunction

In addition to hypogonadism, other endocrine abnormalities have been implicated in the etiology of erectile dysfunction, albeit in less than 5% (Johnson and Jarow, 1992). Hyperthyroidism, hypothyroidism, and hyperprolactinemia have been associated with impotence. In hyperprolactinemia, there is an associated decrease in serum testosterone concentration due to inhibition of gonadotropin-releasing-hormone secretion by the elevated prolactin concentration (Morley, 1986). However, normalizing the serum testosterone level does not restore potency in many patients with hyperprolactinemia. This suggests antagonism by prolactin to the peripheral action of testosterone. Low testosterone secretion and elevated prolactin may also contribute to the erectile dysfunction seen with hypothyroidism. Hyperthyroidism is more often associated with decline in libido rather than erectile dysfunction.

Chronic alcoholism with associated hypogonadism can impair erectile function. Hypogonadism in alcoholism occurs through alcohol toxicity at the gonadal and hypothalamic–pituitary levels (Van Thiel *et al*., 1982). Spontaneous reversal of erectile dysfunction has been shown to occur with sobriety for at least 1 year, but only if there is no gonadal atrophy. Alcoholic neuropathy may also contribute to erectile dysfunction. Chronic obstructive lung disease is thought to contribute to erectile dysfunction through hypoxia suppressing the hypothalamic–pituitary–gonadal axis (Semple *et al*., 1984).

IV. Libido and Aging

Despite the increased prevalence of erectile dysfunction, libido does not vary as much with advancing age. Mulligan *et al*. (1988) found that in an ambulatory geriatric population,

53% of those over the age of 75 years still reported intact libido. When a decline in libido occurs, it is often associated with androgen deficiency (Vermeulen, 1991). Burris *et al*. (1992) found low sexual interest in their hypogonadal subjects, and testosterone replacement increased libido in a dose-dependent manner. Davidson *et al*. (1983) found decreasing serum total and free-testosterone concentrations with aging and a parallel decline in sexual activity, libido, and potency. Schiavi *et al*. (1991) found that bioavailable testosterone showed positive correlation with sexual desire and arousal, but not with frequency of coitus in a healthy older population.

V. Alterations in Emission, Ejaculation, and Orgasm with Aging

In addition to alterations in erectile function, the four stages of sexual response, excitement, plateau, orgasm, and resolution, all change with aging (Masters and Johnson, 1970). During the excitement phase, there is a delay in erection, tensing of the scrotal sac decreases, and testicular elevation may not occur (Kaiser, 1991; Rowland *et al*, 1993). There is a prolonged duration of the plateau stage and decreased preejaculatory secretion from Cowper's gland. Orgasm is diminished in duration, and there are decreased or spastic prostatic contractions, decreased urethral contractions, and decreased force of emission. Orgasm is less intense with a smaller quantity of ejaculate being expelled. In the resolution stage, there is rapid detumescence and testicular descent. The refractory period between erections is prolonged with aging (Ludeman, 1981). Most young healthy males are capable of achieving an erection, engaging in intercourse, attaining a climax, and repeating this process within minutes. With aging, this rest or refractory period needed before erection and sexual intercourse can be repeated gradually lengthens. Masters and Johnson (1970) reported that at least several hours were usually needed before full erection could be attained again. This prolonged refractory period may contribute to the decline in the frequency of sexual intercourse in older men. Older males may experience retrograde ejaculation due to a damaged proximal sphincter following transurethral prostatic resection. Diabetic autonomic dysfunction can also cause retrograde ejaculation and a decline in orgasmic sensation. Last, there is a decrease in penile sensitivity to vibration and light touch with aging. Sexual function and penile sensitivity may be closely related since penile vibrotactile thresholds are higher in subjects with erectile dysfunction than in age-matched control subjects (Rowland *et al*., 1991). Rowland *et al*. (1989) found a higher penile threshold for vibratory stimulation in aged men.

VI. Summary

Sexuality remains an important issue in the older population (Ludeman, 1981). In spite of a decreased ability to achieve an erection, there clearly is continued sexual desire. Many studies suggest that erectile dysfunction in the aged is primarily due to age-associated chronic disease rather than normal, healthy aging. Therefore, preventive measures aimed at the underlying diseases should be sought. Nevertheless, effective treatment options are now available to successfully regain sexual function and thereby improve quality of life.

Sexual Behavior in Aging Women

I. Introduction

The perimenopause is a time of significant hormonal changes. The hallmark of these hormonal changes is vasomotor symptoms such as night sweats and hot flashes. Other purported effects of changing hormones include sexual dysfunction, sleep disruption, mood disturbances, and a host of other ''symptoms.'' However, the evidence for these purported effects of menopause has not been clearly established. Complicating research in this area is the difficulty in separating direct and indirect effects of changing hormone levels. Vasomotor symptoms may impact sleep, which may in turn affect mood. All of these effects may impact sexual functioning. In addition, some of the effects of these hormonal changes may increase with age (e.g., vaginal dryness), whereas others appear to be transitory (e.g., mood effects). The issues addressed in this chapter concern the functional impact of these neuroendocrine changes and their interrelatedness.

The primary purpose of this chapter is to review the epidemiologic literature on changes in sexual functioning with age, with a particular focus on menopause. Because sexual functioning is interrelated with hormonal changes, hot flashes, and mood, these areas will be reviewed as well. Prior to reviewing this literature, it is important to first look at methodological issues in this area of research.

II. Methodological Issues

Several methodological issues are important to consider in reviewing this area of research. These include the distinction between clinic and population-based samples, defining menopause status, measuring mood and sexual functioning, and limitations of cross-sectional research.

A. Clinic versus Population-Based Samples

Much of the research on menopause and sexual functioning or mood is based on patient samples of women who report problems or women who have sought treatment for menopause-related problems. These patient samples present a biased view of sexual functioning and mood changes in the general population. Patient- or clinic-based samples are generally not representative of the general population, and it is well-established that people who seek treatment or generally use the health care system differ in a number of important ways from nonpatient samples; they are often less healthy, report greater psychological symptoms, and experience greater stress. Community or population-based studies are important because they provide information on the prevalence, incidence, and distribution of function and dysfunction in the general population. The population perspective also informs the clinician as to whether a condition is underdetected (i.e., more prevalent in the general population) or restricted to patient samples.

Data from such patient-based studies represent only women who seek medical care. This is particularly problematic for samples of women seeking treatment for acute menopausal symptoms. Studies have shown that fewer than half of menopausal women seek menopause-related treatment (Brown and Brown, 1976; Rose, 1977; Weideger, 1977; Ballinger, 1985; Morse *et al*., 1994; Avis *et al*., 1997) and those who do seek treatment tend to report more life stress and suffer more from clinical depression, anxiety, and psychological symptoms than women in nonpatient samples (Ballinger, 1985; Morse *et al*., 1994).

As data from population and community-based samples have become available, it is apparent that this research presents a very different picture of menopause than does patient-based research and challenges many of our long-held beliefs about menopause.

B. Defining Menopausal Status

The inconsistency with which researchers have defined menopause status presents a major challenge in comparing studies in this area (Holte, 1998). In relating any outcome to menopause status, it is important to use consistent definitions of pre-, peri-, and postmenopause. Some earlier studies (Bungay *et al*., 1980) used age (45–55) as a surrogate for menopause status. However, this is an imprecise measure of status as women between 45 and 55 can be pre-, peri-, or postmeno-

pausal. Pansini *et al*. (1994) have shown the considerable age overlap among menopause status groups.

The standard epidemiological definition of natural menopause is 12 consecutive months of amenorrhea in the absence of surgery or other pathological or physiological cause (e.g., pregnancy, lactation) that would terminate menstruation (World Health Organization, 1996). While perimenopause has been less consistently defined, the currently accepted epidemiological definition is having menses in the past 12 months with changes in regularity or no menstrual cycle in the past 3–11 months (Brambilla *et al*., 1994; Cooper and Baird, 1995). However, some studies have classified women as postmenopausal following only 6 months of amenorrhea. These women would be classified as perimenopausal by other investigators. Some studies combine pre- and perimenopausal or peri- and postmenopausal women for analysis.

An additional consideration is the distinction between surgical and natural menopause. Surgical menopause is defined as occurring when a surgical procedure stops menstruation. Women who have had a bilateral oophorectomy or a hysterectomy with or without removal of the ovaries are generally included in this category. Women who have a surgical menopause tend to be younger, of poorer health, and use health care more frequently (Roos, 1984; Kjerluff *et al*., 1993; Brett *et al*., 1997). Their menopause experience is also quite different, in that they experience more sudden hormonal changes, as well as a surgical procedure. A number of studies have found that women who have had a surgical menopause report more distress than women who experience a natural menopause (McKinlay *et al*., 1987; Kanfert *et al*., 1992; O'Connor *et al*., 1995; Kuh *et al*., 1997). Sexual functioning may also be more affected in this group (Dennerstein *et al*., 1977), but well-controlled prospective studies are rare. Therefore, women experiencing a surgical menopause must be considered separately from those experiencing a natural menopause.

C. Measurement of Sexual Functioning and Mood

Another challenge in this area is the wide variation in the measurement of these variables. This is most pronounced in the area of sexual functioning, but is also seen in the area of mood. With respect to sexual functioning, there are no standard scales used across studies. Researchers often use study-specific questions that range from a single item or two (Bungay *et al*., 1980; Køster and Garde, 1993; Dennerstein *et al*., 1994a), a group of items or symptoms (Hunter *et al*., 1986; Hunter, 1990), or several domains of sexual functioning (Hällström, 1977; Osborn *et al*., 1988; Dennerstein *et al*., 1997; Avis *et al*., in press). These same problems occur in the area of mood. Some studies use single symptoms from a symptom list such as feeling blue or depressed (Avis *et al*., 1993) or irritable (Jaszman *et al*., 1969; Boulet *et al*., 1994), while others studies use a set of symptoms derived from factor analyses of symptom lists that are labeled depressed mood or dysphoria (Dennerstein *et al*., 1993; Collins and Landgren, 1995) or psychological symptoms (Porter *et al*., 1996; Kuh *et al*., 1997). While still other studies have used a standard questionnaire such as the Center for Epidemiologic Studies Depression Scale, known as the CES-D (McKinlay *et al*., 1987; Avis *et al*., 1994; Woods and Mitchell, 1997). Clearly, one needs to be careful in comparing studies when such different outcomes are used.

Further, for those studies that use an index or scale consisting of several different aspects of sexual functioning or mood states, it is not possible to examine the impact of age or menopause on specific aspects of sex or mood. Use of factor scales with different symptoms or moods does not allow one to make distinctions among moods or aspects of sexual functioning, making it difficult to tease out specific changes associated with menopause.

D. Limitations of Cross-Sectional Research

The vast majority of research in this area is cross-sectional and therefore can look only at associations (real or spurious). Longitudinal cohort designs facilitate those associations that are most likely to reflect a cause–effect relationship, through observations of temporal sequences in events or rate changes. While cross-sectional research can point to associations, it is not possible to determine the causal ordering (McKinlay and McKinlay, 1973). Cross-sectional studies can neither control for premenopausal characteristics of women nor separate effects of aging from those of menopause. This is particularly problematic in establishing the relationship among variables.

Related to the difficulties of cross-sectional research is the problem of univariate analyses or incomplete models that do not control for important variables in analyses that are also related to the outcome of interest. For example, research on menopause and sexual functioning often does not control for other variables that also change with age, such as health and partner limitations. Models that do not include vasomotor symptoms and sleep cannot tease out direct versus indirect effects of menopause.

III. Sexual Functioning

It is generally recognized that sexual behavior changes with age. In particular, frequency of sexual activity declines with age (Kinsey *et al*., 1948, 1953; Pfeiffer *et al*., 1972; Laumann *et al*., 1994). Reasons for this decline among women include loss of or lack of a partner, partner's sexual problems, health changes, and physiological changes due to changing hormonal levels. The impact of menopause on declines in sexual functioning is of particular interest because of decreases in ovarian hormones at this time (which may be directly or indirectly related to aspects of sexual functioning) and because menopause can be viewed as a marker in the aging process. There is much debate, however, over the relative impact of menopause on sexual functioning. Much of the research in this area is based on patient samples, or women who are having sexual problems. Furthermore, changes in ovarian hormones often lead to vasomotor symptoms, sleep disruption, and possibly mood changes. All of these factors may also impact sexual functioning. Thus, any attempt to understand the role of menopause per se on sexual functioning needs to take into account these factors.

A. Aspects of Sexual Functioning

In general, sexual functioning is studied in terms of satisfaction, frequency of activity (intercourse, masturbation, orgasm),

desire (including interest and sexual thoughts or fantasies), arousal, attitudes toward sexuality, and difficulties such as pain during intercourse and problems reaching orgasm. These reflect the characterization of sexual functioning in terms of libido and potency (Davidson, 1985; Iddenden, 1987). Libido includes sexual interest, desire, drive, motivation, and pleasure. Potency is the physiologically measurable event during sexual arousal/activity—the sexual response (Masters and Johnson, 1966). Although postmenopausal declines in ovarian hormone production and reproductive atrophy may increase the incidence of dyspareunia and vaginal dryness (potency), it is less clear how menopause affects sexual interest or libido (Davidson, 1985).

B. Sexual Functioning and Age

The earliest studies of normative sexual behavior were conducted about 50 years ago by Kinsey and his colleagues (1948, 1953). While the Kinsey samples were volunteers and not randomly selected or population-based, much of their pioneering work still holds up today. Kinsey and his colleagues interviewed large numbers of men and women over a period of 15 years. The majority of their samples were between the ages of 16–25, while approximately 2600 women were between 26 and 60. Kinsey and colleagues found a decline with age in incidence and frequency of marital coitus and of coitus to the point of orgasm. However, they did not find a decline in women's solitary activity until well after 60 years of age. For men, they found impotence to be an age-dependent disorder with a prevalence of 1.9% at age 40 years and 25% at age 65 years.

Subsequent work by Pfeiffer and colleagues (1972; Pfeiffer and Davis, 1972) also showed a decline in sexual interest with age in their sample of men and women ages 46–71, but the reasons for this decline differed by gender. When those who had stopped having sexual relations were asked why, Pfeiffer *et al*. (1972) found that men were most likely to report that they were unable to perform sexually. On the other hand, women reported that cessation of sexual relations was due to the death of a spouse, illness of spouse, or spouse unable to perform sexually. Only 10% of women reported that cessation of activity was due to their own illness, loss of interest, or inability to perform sexually. Pfeiffer and Davis (1972) conducted multiple regression analyses of factors related to sexual interest, enjoyment, and frequency of intercourse for men and women. For men, the primary factor related to these aspects of sexual functioning was age, with older men reporting lower levels of all outcomes. Age was followed in importance by present health. For women, the primary factor related to sexual functioning was marital status, with married women reporting higher levels of these outcomes. Also related were age and education. For women, health was not related to sexual functioning. Being postmenopausal did contribute somewhat to lower sexual interest and frequency, but not to enjoyment.

These early results suggest that while age impacts sexual functioning for both men and women, the reasons for this may differ.

Perhaps the largest population-based survey of sexual behavior is the National Health and Social Life Survey (NLSLS) conducted in 1992 by researchers at the University of Chicago (Laumann *et al*., 1994). This in-person interview of a national probability sample of 1410 men and 1749 women ages 18–59 included an extensive set of questions on sexual function and dysfunction. The NLSLS confirms earlier findings of frequency of sex declining with age. This decline appears to begin in the late 30s and is greater for women than men. For both men and women, only a small percentage reported that sex was not pleasurable and this did not vary much by age (although after age 35, fewer women said that sex was not pleasurable). In additional analyses of the NHSLS, Laumann *et al*. (1999) found that lack of interest in sex significantly increased with age for men, but not for women.

Laumann *et al*. (1999) further examined aspects of sexual dysfunction and factors related to dysfunction. Interestingly, pain during sex, which is often associated with menopause, was lowest in the women ages 50–59. However, trouble lubricating increased with age and was highest among the 50–59 age group. For women, the significant factors related to lack of interest in sex were emotional problems or stress, a decrease in household income, and ever having a sexually transmitted disease. This study is noteworthy for its large and representative sample. Unfortunately the study sample stops at age 59. Further, the focus is mostly on dysfunction, rather than function.

C. Sexual Functioning and Menopause

1. Research on Menopause Status

Research among general populations of women does not show clear associations between menopause and declines in sexual functioning. While some studies have found lower sexual interest among peri- or postmenopausal women as compared to premenopausal women (Hällström, 1977; Hunter *et al*., 1986; Dennerstein *et al*., 1994a; Cawood and Bancroft, 1996), other studies have not found an association between menopause status and sexual functioning (Osborn *et al*., 1988; Køster and Garde, 1993; Hawton *et al*., 1994; Dennerstein *et al*., 1997). In a study of 567 Swedish women ages 38, 46, 50, and 54 randomly selected from the general population, Hällström (1977) found progressive decline in sexual interest across menopausal stages over and above the effects of age. Compared to pre- and perimenopausal women, postmenopausal women reported lower sexual interest in the previous 5 years. In a cross-sectional survey of 682 women ages 45–56 recruited from a general ovarian screening clinic, Hunter *et al*. (1986) also found that peri- and postmenopausal women reported lower sexual interest than premenopausal women, but sexual satisfaction did not differ by menopause status. Dennerstein *et al*. (1994a) report cross-sectional results of a large ($n = 1879$) population-based sample of women ages 45–55 in Melbourne, Australia. They asked women to report whether in the past 12 months there had been any change in sexual interest. While the majority of women reported no change in sexual interest, menopause status was related to declining interest, with postmenopausal women most likely to report less interest. Postmenopausal women were more likely to report unusual pain on intercourse. Cawood and Bancroft (1996) report results of 141 women ages 40–60 from Edinburgh where they found that postmenopausal women reported

a significantly greater loss of interest in sex. However, there was no correlation between menopause status and orgasm.

On the other hand, Osborn *et al*. (1988) did not find an association between menopause status and sexual dysfunction among 436 women ages 35–59 recruited from two general practices in Oxford England. Sexual interest was considered part of a general measure of sexual dysfunction including impaired interest in sexual activity, frequency of orgasm, dyspareunia, and vaginal dryness. In their sample of 472 Danish women ages 51, Køster and Garde (1993) did not find an association between menopause status and sexual desire in multivariate regressions.

Hawton *et al*. (1994) found no association between menopause status and frequency of sexual activity, frequency of orgasm, or satisfaction in an age-matched comparison of pre- and postmenopausal British women who had partners. In their smaller cohort study ($n = 200$), Dennerstein *et al*. (1997) looked at six aspects of sexual functioning: feelings for partner, sexual responsivity, frequency of sexual intercourse, libido, partner problems, and vaginal dryness. They found no significant differences on any of these variables by menopause status.

The Massachusetts Women's Health Study, one of the most comprehensive community-based studies of women transitioning through the menopause, found that menopause status was significantly related to lower sexual desire, a belief that interest in sexual activity declines with age, and women's reports of decreased arousal compared to when in their 40s (Avis *et al*., in press). Menopause status was unrelated to frequency of sexual intercourse, satisfaction with one's sexual relationship, difficulty reaching orgasm, and pain during or after intercourse in either unadjusted or multiple regression analyses.

In general, satisfaction with one's sexual relationship has not been found to be related to menopause or age (Hunter *et al*., 1986; Hawton *et al*., 1994; Avis *et al*., in press). There are at least three possible explanations for this: (1) frequency of activity is not related to satisfaction, (2) people accommodate to the age-related declines that occur, and (3) people's expectation with respect to sexual activity or desire declines with age.

The vast majority of research in this area is cross-sectional. McCoy and Davidson (1985) conducted the first longitudinal study of sexual activity among perimenopausal women in which perimenopausal women were followed at 4-month intervals until they were postmenopausal (one year without cycling). During this time, hormone levels and weekly rates of intercourse were measured. Results showed that following menopause, the women reported fewer sexual thoughts or fantasies, more lacked vaginal lubrication, and they were less satisfied with their partners than prior to menopause. Unfortunately, while 39 women began the study, their final sample size was only 16. As McCoy and Davidson point out, not only was the remaining sample extremely small, it was also potentially quite biased. Hunter (1990) followed 36 postmenopausal women who had been recruited from an ovarian screening clinic for 3 years. All women became peri- or postmenopausal during this time. She found some change in sexual behavior over the 3 years, but these differences were not statistically significant. Unfortunately, her small sample may not have provided enough power to detect statistically different changes. Thus, both of these prospective studies suffer from small and potentially biased samples. Further, they do not account for potential age-related changes.

Taken as a whole, these studies suggest that menopause may have an impact on some aspects of sexual functioning, but not others. Some inconsistencies in findings can be explained by the wide variation in the specific sexual functioning questions that are asked, the time frame used (e.g., past month, past year, etc.), whether women without partners are included in analyses, and nature of the study sample. Further, many of these studies only look at univariate associations and do not adjust for other variables in the analyses that may be related to sexual functioning (e.g., age, partner problems, health).

2. Factors Other Than Menopause Status

Psychosocial and aging factors are often reported as more important determinants than ovarian function of sexual functioning among middle-aged women (Leiblum *et al*., 1983; Hagstad, 1988; Køster and Garde, 1993; Hawton *et al*., 1994). Some of these factors include the availability of a partner (Pfeiffer *et al*., 1972; Leiblum *et al*., 1983; Køster and Garde, 1993), previous sexual behavior and enjoyment (Christensen and Gagnon, 1965; Pfeiffer *et al*., 1972), the marital relationship (Clark and Wallin, 1965; Bachmann *et al*., 1985; Hawton *et al*., 1994; Cawood and Bancroft, 1996), mental health (Dennerstein *et al*., 1994a; Hawton *et al*., 1994; Avis *et al*., in press), general physical health (Hunter, 1990; Køster and Garde, 1993), stress (Hunter, 1990), expectations (Køster and Garde, 1993), and male partner problems (Pfeiffer *et al*., 1972).

Hawton *et al*. (1994) found that psychiatric status and marital adjustment were variables most related to sexual functioning. Cawood and Bancroft (1996) found that quality of the marital relationship was quite strongly related to frequency of sexual intercourse and quality of sexual activity and that menopause status was not related in multivariate analysis. In multivariate models, Dennerstein *et al*. (1994a) found that declining sexual interest was significantly associated with lower emotional well-being; not working full-time; greater vasomotor, cardiopulmonary, and skeletal symptoms; and use of hormone replacement therapy, as well as menopause status. Van Keep and Kelherhals (1974) reported a significant association between social factors and sexual behavior. Koster and Garde (1993) found that significant predictors of low sexual desire were low frequency of sexual intercourse, being single, poor physical fitness, lower social status, and anticipation of decreased sexuality measured at age 40.

In the Massachusetts Women's Health Study (MWHS), Avis *et al*. (in press) found that health was a significant variable related to all aspects of sexual functioning. Depression and greater psychological symptoms were related to lower satisfaction, frequency, and desire. Interestingly, smoking was related to less desire and lower frequency of sexual intercourse. This finding is consistent with results reported by Greendale *et al*. (1996) and are consistent with other research on the negative effects of smoking on sex steroid levels (Johnnton *et al*., 1983; Merchnovitz and Bradlow, 1990).

3. Sexual Functioning and Hormones

If changes in sexual functioning and activity are directly related to menopause, one would expect to find an association

between sexual functioning and hormones, particularly estradiol, which significantly decreases during the menopause transition. While only a few studies have examined sexual functioning and hormones, they consistently do not find a relation between estrogen and sexual functioning (Leiblum *et al*., 1983; Bachmann *et al*., 1984, 1985; McCoy *et al*., 1985; Cawood and Bancroft, 1996; Dennerstein *et al*., 1997; Avis *et al*., in press). Some of these studies, however, look at frequency of sexual intercourse (Leiblum *et al*., 1983; McCoy *et al*., 1985), which may be a poor indicator of sexual functioning for women, since frequency of activity is often determined more by the male partner. The one exception to these negative findings was a study by Cutler *et al*. (1987) who found that a subset of perimenopausal women with especially low estradiol levels (< 35 mg/pl) had reduced coital frequency. However, their outcome was frequency of intercourse.

On the other hand, studies that have looked at other aspects of sexual functioning such as desire or interest also do not find an association with hormone levels (Bachmann *et al*., 1984, 1985; Cawood and 1996; Dennerstein *et al*., 1997; Avis *et al*., in press). In the MWHS, pain was the only aspect of sexual functioning that was related to E_2. Others have also found that lowered estrogen levels have been associated with vaginal dryness (Hutton *et al*., 1979; Morrel *et al*., 1984; Sarrel, 1987; Dennerstein *et al*., 1997).

Two small studies have looked at physiologic signs of arousal by using vaginal pulse amplitude in response to erotic films to compare physiologic response among pre- and postmenopausal women (Myers and Morokoff, 1986; Myers *et al*., 1990). Myers and Morokoff (1986) found no diminished vasocongestive response in postmenopausal women with low estradiol levels compared to other postmenopausal women on hormone replacement therapy and to premenopausal women. They also found no correlation between estradiol level and vaginal pulse amplitude, although estradiol level was significantly correlated with subjective reports of greater vaginal lubrication. Myers *et al*. (1990) found that hormone treatment did not significantly alter psychophysiologically measured sexual arousal or sexual behaviors.

In general, these studies suggest that elevated estrogen levels are not an important factor in libido or potency, but are related to levels of vaginal lubrication. Thus, while hormone levels affect vaginal dryness and dyspareunia, they do not appear directly related to sexual drive or interest.

Unfortunately, most of the studies measuring estrogen levels do not take into account the availability of E_2 to target tissues. For example, it has been well-established that body weight is correlated with circulating levels of estrone and estradiol (Judd *et al*., 1976; Vermeulen and Verdonck, 1978) and also influences the availability of E_2 to target tissues by an inverse relationship to the circulating concentration of sex-hormone blinding globulin (Nisker *et al*., 1980). Thus, univariate analyses of estrogen and sexual functioning may not be expected to yield significant results.

A number of researchers have argued that androgens, and not estrogens, are the relevant hormone in relation to sexual functioning. Investigators have found that androgens maintain sexual interest after surgical menopause, while estrogens do not (Sherwin and Gelfand, 1987; Sherwin, 1991). Most of this work has been conducted among women who have an oophorectomy and are given supraphysiologic levels of the hormone. Two recent, well-designed studies of sexual functioning and testosterone within normal physiologic ranges show inconsistent results. In their study of 40 postmenopausal women followed for 10 weeks, Myers *et al*. (1990) found a significant increase in pleasure from masturbation among women who received estrogen plus testosterone, compared to those who received estrogen alone or estrogen plus medroxyprogesterone acetate. However, there were no group or treatment effects in either pleasure from sexual activity or sexual desire. Davis *et al*. (1995) found that among 34 postmenopausal women randomly assigned to either estradiol or estradiol plus testosterone implant (with considerably higher levels of testosterone than Myers *et al*., 1990), the estradiol plus testosterone group showed significantly greater improvement for sexual activity, satisfaction, pleasure, and orgasm, but not for libido or fantasies. These effects tended to decrease at 24 months.

Only a few studies have examined the relation between natural androgens and sexual functioning (McCoy *et al*., 1985; Cawood and Bancroft, 1996; Dennerstein *et al*., 1997) and none of these studies found an association. In fact, Dennerstein *et al*. (1997) found only weak evidence for androgen involvement (FAI with libido), but in a negative direction. In their small longitudinal study, McCoy and Davidson (1985) did find a relation between coital frequency and testosterone, but as previously mentioned, their sample was small and potentially biased since it was based on only 16 of an initial 39 women. In their cross-sectional analyses of the full sample of 43 women, they did not find an association between testosterone and frequency of intercourse (McCoy *et al*., 1985). These differences could be due to sample differences or problems with using frequency of sexual activity as a measure. A review by Campbell and Udry (1994) concluded that while some amount of testosterone is important to maintain sexual motivation, there is no evidence that within the normal range of testosterone, there is an association between testosterone and libido.

4. Summary

In conclusion, menopause appears to have some impact on sexual functioning, which is as much psycho-social-cultural, as biological. Estradiol is primarily related to vaginal dryness and pain, but not libido. Studies of natural androgens have not yet demonstrated a significant effect. Other factors (e.g., health, partner availability, partner limitations, etc.) appear to have greater impact on sexual functioning than menopause.

It is important to point out that most studies of the impact of menopause on sexual functioning are conducted among women who are newly postmenopausal. It is possible that the effects of declines in ovarian functioning do not impact sexual functioning until later. We have very little data on sexual functioning among the general population of women in their 60s and 70s.

IV. Hot Flashes

Vasomotor symptoms such as hot flashes (or flushes) and night sweats are potential mediators of the association between

menopause and sexual activity. Women describe a hot flash as a sensation of heat, primarily on the upper body, the chest, neck, face, and scalp. A hot flash is generally accompanied by a flushing of the skin, primarily on the upper body, and by sweating. Often there is an increase in heart rate, sometimes experienced as palpitations (Kronenberg, 1990). Longitudinal data from the MWHS show that hot flashes are often most prevalent in the perimenopausal period and peak prior to the last menstrual cycle (McKinlay *et al*., 1992). Hot flushes typically last from 0.5 to 5.0 years after natural menopause, but may persist longer (Bachmann, 1990). Estimates of the incidence of hot flashes from population studies in United States and worldwide show huge variability with ranges from 24 to 93% of women (Kronenberg, 1990).

It is well-established that hot flashes are generally associated with declining estrogen levels (Kronenberg, 1990). Data show that women who report hot flashes, on average, have lower circulating estrogen levels than women who are asymptomatic (Erlik *et al*., 1982). However, there is not a one-to-one association between serum estrogen levels and the onset of hot flashes and the actual cause(s) of hot flashes remains speculative (Bachmann, 1990). For example, vasomotor flashes do not occur in prepubertal girls whose estrogen levels are low, there is no particular threshold level of serum estradiol below which hot flashes always occur. Many women experience a decrease in estrogen yet do not experience hot flashes. Hot flashes do tend to occur when there is an abrupt and significant drop in estrogen level. For example, hot flashes often occur in pre- or perimenopausal women soon after chemotherapy or an ovariectomy, and similarly they often occur in men soon after orchiectomy for the treatment of prostate cancer (Kronenberg, 1990). While hot flashes have been associated with a pulse of luteinizing hormone (Casper and Wilkes, 1979; Tataryn *et al*., 1980), there is not a causal association as hot flashes can occur in women who have no episodic LH release, such as after hypophysectomy (Mulley *et al*., 1977). Further, Casper and Wilkes (1979) found that the increase in LH occurred after the onset of symptoms, thus suggesting it is not responsible for the hot flashes. Other hormones found to increase in association with hot flashes include β-endorphin, β-lipotropin, adrenocorticotropic hormone, cortisol (Genazzani, *et al*., 1984; Meldrum *et al*., 1984), and epinephrine (Kronenberg *et al*., 1984).

For many women, hot flashes may be occasional, mild, transient sensations of warmth. Others may experience frequent night sweats that disrupt sleep and increase fatigue and irritability. Erlik *et al*. (1981) demonstrated a significant correlation between the occurrence of hot flashes and waking episodes among menopausal women as compared to premenopausal women. Hot flashes and night sweats may be related to sexual functioning in several ways: the discomfort of hot flashes might inhibit sexual behavior, sleep disturbances resulting from night sweats could lead to fatigue and irritability which may in turn affect sexual behavior, regular sexual activity might protect against lowered steroid levels, and/or hot flashes and sexual desire may both be hormonally related. Unfortunately, this area has not been well studied.

Correlational data have shown that regular weekly sexual behavior is highly associated with the absence of hot flashes (Cutter *et al*., 1983; McCoy *et al*., 1985). As previously mentioned, however, frequency of sexual intercourse is not a good indicator of desire or interest for women. In the Massachusetts Women's Health Study, we explored the association between hot flashes and three measures of sexual activity: satisfaction, frequency of intercourse, and arousal among 206 women who had a sexual partner (Johannes *et al*., 1995). While in univariate analysis, hot flashes were related to sporadic frequency of sexual intercourse, in multivariate analysis, the only significant predictors of frequency were partner limitations, recent pap test, and estrogen use. On the other hand, hot flashes were found to be significantly related to lowered sexual satisfaction and arousal, adjusting for estrogen use, partner limitations, and other health-related covariates. In longitudinal analyses, hot flashes at one interview were related to decreased satisfaction and arousal 1 year later, but were unrelated to frequency. Estradiol levels were unrelated to hot flashes or sexual activity. These results suggest that hot flashes may be related to lowered sexual satisfaction and arousal and may be independent of lowered estrogen levels.

Unfortunately, the majority of research in the area of sexual functioning has not included vasomotor symptoms in multivariate models. Clearly, future research needs to take these symptoms into consideration when studying the impact of menopause and or hormonal changes and sexual functioning. Research on vasomotor symptoms and mood is reviewed in the next section.

V. Mood

A. Cross-Sectional Research

Numerous cross-sectional studies have examined the association between menopause status and mood. Most of these studies do not find a relation between menopause status and depression or dysphoric or negative mood, using such measures as the CES-D (McKinlay *et al*., 1987; Kaufert *et al*., 1992; Porter *et al*., 1996; Woods and Mitchell, 1997), a psychiatric interview (Hällström and Samuelsson, 1985; Gath *et al*., 1987), dysphoric mood (Dennerstein *et al*., 1993), negative affect (Dennerstein *et al*., 1994b), nervousness and mood lability (Holte and Mikkelsen, 1991), anxiety/fears (Hunter *et al*., 1986), psychological symptoms (Porter *et al*., 1996; Kuh *et al*., 1997), and individual symptoms of irritability, anxiety, and/or depression (Ballinger, 1976; Cawood and Bancroft, 1996).

On the other hand, several studies have found a relation between menopause status and mood, mostly in the perimenopause (Ballinger, 1975; Hunter *et al*., 1986; Avis *et al*., 1993; Collins and Landgren, 1995). Hunter *et al*. (1986) found higher rates of depressed mood (including loss of interest in things, lack of enjoyment, feeling miserable and sad, no feelings of well-being, life not worth living, irritability, and loss of appetite) among peri- and postmenopausal women in a sample of 682 women ages 45–65 recruited from an ovarian screening clinic. They did not find a relation between menopause status and symptoms labeled anxiety/fears or sleep problems. While their sample was not recruited from a menopause clinic, it is a clinic sample, and not a population-based sample.

Avis *et al*. (1993), conducted an analysis of responses to feeling blue or depressed by menopause status among community-based samples of women in the United States, Japan, and Canada. They found that for women in the United States sample, peri- and surgical menopausal women reported higher rates of ''feeling blue or depressed'' in the past 2 weeks than pre- or postmenopausal women. There was no relation between status and symptom reporting for the Canadian or Japanese samples.

In a large Swedish sample of 1324 women, all age 48, Collins and Landgren (1995) found higher rates of negative mood (including tension, depression, spells of crying, early wakening, insomnia, and difficulty concentrating) among postmenopausal women. Collins and Landgren defined postmenopausal as 6 months amenorrhea and therefore this category of women probably included some women who would be classified as peri-menopausal, using the WHO criteria. In multivariate analysis, only vasomotor symptoms were significantly related to status. They did not analyze the group of perimenopausal women, which was quite small.

Thus, while the majority of cross-sectional studies do not find a significant association between menopause status and various measures of mood disturbances, several studies have reported slight increases among perimenopausal women. These studies, however, generally have not controlled for vasomotor symptoms. The one study that did control for symptoms found that the association disappeared when vasomotor symptoms was included in the model (Collins and Landgren, 1995).

B. Prospective and Longitudinal Studies

While, the majority of studies in this area have been cross-sectional, several prospective or longitudinal studies have been conducted (Hällström and Samuelsson, 1985; Hunter, 1990; Matthews *et al*., 1990; Holte, 1992; Kaufert *et al*., 1992; Avis *et al*., 1994; Woods and Mitchell, 1996; Kuh *et al*., 1997). Each of these studies analyzes their longitudinal data somewhat differently. Neither Kaufert *et al*. (1992) nor Woods and Mitchell (1996) found that the onset of menopause was related to increased depression using the CES-D scale. The Pittsburgh Healthy Women study compared psychological characteristics and symptoms between pre- and postmenopausal women, after 3 years of follow-up of a sample of 541 initially premenopausal women. Controlling for age and baseline levels of characteristics, they found that natural menopause did not adversely affect anxiety or depression (Matthews *et al*., 1990). Hällström and Samuelsson (1985) conducted a psychiatric interview on 899 women from the general population in Sweden, on two occasions, 6 years apart. They found no increase in onset of mental disorder at menopause. Holte (1992) reports a longitudinal follow-up of 59 women from his cross-sectional study who were premenopausal at the beginning of the study and postmenopausal at its end, 4 years later, and not taking hormone replacement therapy. Holte did not find an increase in anxiety or depression as measured by Goldberg's General Health Questionnaire.

Kuh *et al*. (1997) surveyed a nationally representative sample of over 1200 British women born in 1946 when they were 36 years of age and again at age 47. Psychological symptoms at age 47 were unrelated to natural menopause status, except for a slight rise in irritability among perimenopausal women. However, women who had had a hysterectomy or were on hormone replacement therapy reported significantly more psychological symptoms. They further found that psychological symptoms at age 47 were strongly related to current family life and work stress, anxiety, depression, and health problems at age 36.

Two exceptions to these findings are reported by Hunter (1990) and Avis *et al*. (1994). Using data from the Massachusetts Women's Health Study, Avis *et al*. (1994) addressed the effect of change in menopause status on depression as measured by the CES-D scale, while controlling for prior depression. To study change in menopause status, a menopause transition variable was created that took into account a woman's menopausal status at the two time points (27 months apart) at which depression was measured (referred to as T_1 and T_2). Across all menopause statuses, those women who were classified as depressed at T_1 had higher rates of depression at T_2. For women who were not depressed at T_1, the rate of depression at T_2 increased slightly as women moved from pre-premenopausal to pre-perimenopausal, and was highest for women who remained perimenopausal for at least 27 months. The rate of depression began to decrease as women moved from peri- to postmenopause, and was lowest for those women who were postmenopausal for at least 27 months. Controlling for premenopausal depression, there was still a slight increase in depression among the peri-perimenopausal women.

In further analyses of the MWHS data, Avis *et al*. examined whether this increased rate of depression among the perimenopausal-perimenopausal women could be attributed to symptoms associated with menopause (i.e., hot flashes, night sweats, and menstrual problems). When menopausal symptoms was added to the regression model, it became a significant predictor of T_2 depression, and menopausal transition was no longer statistically significant. Over all menopause transition categories, those women who reported experiencing hot flashes, night sweats, and/or menstrual problems consistently showed higher rates of depression.

Hunter (1990) reports follow-up data on 36 women who were initially premenopausal and became peri- or postmenopausal 3 years later. While she found that the women reported significantly more depressed mood at follow-up, she did not have a comparison group to control for age and she did not control for vasomotor symptoms in analysis. There was no change in anxiety. She found no evidence of an increase in psychiatric caseness as defined by the General Health Questionnaire.

In summary, it thus appears that from longitudinal studies there is no evidence that onset of perimenopause leads to increased depression. One study that examined length of the perimenopause (Avis *et al*., 1994) did find a small increase in depression associated with a long perimenopause, which was not significant when vasomotor symptoms were included in the model.

C. Psychosocial and Health Factors and Prior History

Cross-sectional studies of depression and menopause have shown that psychosocial factors account for more of the varia-

tion in depressed mood among women at the time of menopause than does menopause itself (Ballinger, 1975; Greene and Cooke, 1980; Dennerstein, 1987; McKinlay *et al*., 1987; Holte and Mikkelson, 1991; Kaufert *et al*., 1992; Kuh *et al*., 1997; Woods and Mitchell, 1997). For example, Greene and Cooke (1980) conducted a detailed cross-sectional study of postmenopausal women in Glasgow and found that stressful life events involving exits from a woman's social network were associated with reports of psychological symptoms. These events accounted for a greater proportion of the variation in reports of psychological symptoms than did menopause status. In a survey of women ages 40–55 from general practitioner lists, Ballinger (1975) found that the death of a parent and changing patterns of relations with children were related to psychiatric morbidity. In a cross-sectional analysis of 2500 women from the MWHS, McKinlay *et al*. (1987) looked at the relative contributions of health and social circumstances, and menopause to depression. They found that the variables most associated with depression were lower education, marital status (widowed, divorced, and separated women have higher rates), physical health, and stress from worry about others. Other studies have also shown that socioeconomic status (Hunter *et al*., 1986; Holte and Mikkelsen, 1991), stress (Hunter, 1990), negative attitudes toward menopause and aging (Dennerstein *et al*., 1993; Kuh *et al*., 1997), and negative expectations of menopause (Holte and Mikkelsen, 1991) are related to more negative mood during menopause. Other studies have found that health is significantly related to depression (McKinlay *et al*., 1987; Kaufert *et al*., 1992; Dennerstein *et al*., 1994b; Woods and Mitchell, 1996).

In longitudinal research, Hunter (1990) found that negative stereotyped beliefs about the menopause and being under stress before the menopause, together with not working outside the home and being working class, were related to depression. Together, these factors accounted for 51% of the variation in depressed mood when these women became peri- or postmenopausal. Hällström and Samuelsson (1985) found that the weighted sum of life events, but not menopause, was associated with onset risk of mental disorder. Kaufert *et al*. (1992) found that the likelihood of becoming depressed was increased for women with areas of current stress in their lives—particularly if it was related to husbands or children.

Longitudinal data suggest that prior depression is the primary factor related to depression during menopause. In addition to the previously reported findings of Avis *et al*. (1994), Hunter (1990) also found that depressed mood during the menopause was most strongly predicted by premenopausal depression. In their prospective study, Kuh *et al*. (1997) found depression at age 36 was highly related to depression at age 47. In their cross-sectional study, Porter *et al*. (1996) found that depression was higher among those women who reported a past history of depression or anxiety.

Studies have also found that women who report greater mood disturbances at menopause also report menstrual cycle or reproductive related problems. These include previous or current premenstrual symptoms or complaints (Dennerstein *et al*., 1993; Stewart and Boydell, 1993; Collins and Landgren, 1995; Woods and Mitchell, 1996), dysmenorrhea (Collins and Landgren, 1995), and postpartum depression (Stewart and Boydell, 1993). Stewart and Boydell (1993) divided women attending a menopausal clinic into those experiencing high or low psychological distress. Those reporting high psychological distress were significantly more likely to report past psychiatric history, dysphoric premenstrual syndrome, and postpartum depression. Woods and Mitchell (1996) found that both a history of premenstrual syndrome and postpartum depression differentiated women with consistently depressed mood (measured at two points in time, 1 year apart) from those recovering from depressed mood or not depressed. Holte and Mikkelson (1991) found that women who reported experiencing greater depression during their menstrual periods earlier in life were more likely to report nervous complaints and mood lability at ages 45–55. Menopause status was unrelated to either nervous complaints or mood lability. It is not clear from these findings, however, whether this pattern of symptom reporting related to reproductive events is hormonally based or a result of greater symptom sensitivity or greater symptom reporting in general.

D. Endogenous Hormones and Mood

The most direct evidence of a relation between hormones and mood would come from studies concurrently measuring both hormones (specifically estrogen) and mood among menopausal women. Unfortunately, very few such studies exist.

Chakravarti *et al*. (1979) studied 82 premenopausal women seen at a menopause clinic. They found that while mean plasma estradiol concentrations were associated with vasomotor symptoms, there was no clear association between hormone levels and symptoms (including depression and irritability).

In 1987, Ballinger *et al*. studied hormone profiles and psychological symptoms in 85 perimenopausal women ages 40–55. Over half of their sample consisted of women attending a gynecology outpatient clinic. In general, they found no differences in hormone profiles of women with high or low psychological symptoms. However, they did find that among 18 women in the early postmenopause group (last menstrual period 1 to 4 years ago) those with higher symptom scores had significantly higher levels of estradiol than women with lower scores. The 48 women who were recruited from the gynecology clinic were interviewed for depression using a clinical interview. There were no significant differences in hormone profiles between the depressed and nondepressed groups.

Cawood and Bancroft (1996) concurrently measured mood (according to the multiple affect adjective checklist) and hormones among 145 women ages 40–60 recruited from the community. Women completed an initial interview and four subsequent interviews 1 week apart. They found no relation between estrone or estradiol and depression or positive affect plus sensation seeking (the only moods analyzed). However, they did find that feelings of tiredness were significantly related to depression and positive affect. Tiredness was also positively correlated with hot flushes.

In the MWSH, we are examining the relation between hormones (specifically E_2), symptoms, and depression among women traversing the menopause. Preliminary evidence does not suggest a relation between hormones and depression. However, experiencing hot flashes or night sweats or having trouble sleeping do appear related to depression.

While biochemical research on the neurobiology of estrogen and mood is an active area of investigation, there is insufficient evidence at this time to support a biochemical hypothesis for menopause and mood disturbances. While researchers have shown that estrogen can impact brain neurotransmitter activity in several ways, the majority of this research has been conducted in animals and the extent to which neurotransmitter activity interacts with menopause related mood changes has yet to be determined (Schmidt and Rubinow, 1991). There is no clear understanding of the mechanisms whereby hormonal changes mediate change in mood (Brace and McCauley, 1997). A review by Blehar and Oren (1995) on the psychobiology of depression concluded that biological factors (compared to genetic, environmental, and psychological factors) are the weakest in terms of what research can tell us about depression.

E. Summary

Epidemiologic studies of menopause and mood do not show consistent evidence of a relation between menopause and depression or other negative moods in the general population. This conclusion was also reached by other recent reviews of the literature on menopause and depression (Nicol-Smith, 1996; Pearlstein *et al*., 1997). Factor analyses of symptom lists have quite consistently shown that vasomotor symptoms load on a factor separate from psychological symptoms (Avis *et al*., 1999). Community- or population-based studies consistently show that in the general population of women, only a minority of peri- or postmenopausal women evidence signs of depression or other mood disturbance. While some studies have found more negative mood among perimenopausal women, it appears that the majority of mood disturbance seen at the time of menopause can be attributed to prior depression, vasomotor symptoms, or non-menopause-related factors such as health problems or social circumstances.

While there is no evidence that menopause is associated with increased mood disturbance on a population level, an unanswered question is whether some women may be more vulnerable to mood effects of hormonal changes. Several researchers have proposed that while menopause does not cause mood disturbances in all women, there may be a subgroup of women at higher risk for depression or other mood changes (Steiner, 1992; Charney, 1996; Brace and McCauley, 1997). It has been suggested that women with a history of premenstrual syndrome have an increased sensitivity to hormone changes (Bancroft and Bäckström, 1985) and that women with previous affective disorders that are cyclic or associated with reproductive events are at higher risk (Pearlstein *et al*., 1997). While the postpartum period is not always associated with depression, women with previous depression, a history of premenstrual dysphoric disorder, or a history of bipolar disorder are at increased risk for postpartum depression (Blehar and Oren, 1995). However, it is premature to conclude that this pattern is related to a hormonal imbalance. Other factors that may be related are coping style or a greater sensitivity to symptoms. Further, since most studies involve retrospective reporting of reproductive and psychiatric history, there is the inherent problem of selective recall among women experiencing problems at the time of the study.

VI. Conclusions

Menopause is thought to alter central nervous system function as manifested by hot flashes, impaired sexual functioning, mood changes, and sleep disturbances. However, only vasomotor symptoms such as hot flashes and night sweats have been clearly and consistently associated with menopause. Epidemiologic studies of menopause and sexual functioning show some impact of menopause on sexual functioning, but this does not appear directly related to changing hormones. Estradiol has been related to vaginal dryness and painful intercourse, but not other aspects of sexual function. Androgens are thought to be important for libido, but have not been shown to be related to sexual functioning and natural menopause.

Epidemiologic studies of menopause and mood do not show consistent evidence of a relation between menopause and depression or other negative moods in the general population. While menopausal symptoms are related to depression, correlational studies of mood and hormone levels have failed to show a relation between depressed mood and estrogen levels. Evidence suggests that the rate of hormonal changes may be the important regulatory variable, rather than absolute hormonal level (Schmidt and Rubinow, 1991), which may explain why associations between hormones and mood disorders and sexual functioning are stronger for women undergoing a bilateral oophorectomy than for naturally menopausal women. Further, while all women experience a decline in estrogen following menopause, not all women report sexual problems, vasomotor symptoms, or mood disturbances. These results suggest that other factors mediate the relation between hormonal level and these variables.

The domino theory of menopausal symptoms proposes that vasomotor symptoms lead to other effects such as sexual dysfunction and mood disturbances. In the area of sexual functioning this has not been well studied. However, with respect to mood, the domino theory has some support. A number of studies have found a strong association between vasomotor complaints and depressed mood both cross-sectionally (Holte and Mikkelsen, 1991; Hunter, 1992; Palinkas and Barrett-Connor, 1992; Oldenhave *et al*., 1993; Collins and Lundgren, 1995) and longitudinally (Holte, 1992; Hunter, 1992; Avis *et al*., 1994). These findings suggest that studies need to control for vasomotor symptoms in analyses of any direct effect of menopause on mood. However, many studies do not find a relation between menopause and mood, even when vasomotor symptoms have not been controlled for. Further, other studies suggest that not all women who have vasomotor symptoms experience mood disturbances. Future research should examine more closely whether asymptomatic women show fluctuations in mood.

Other theorist argue that other factors concurrent with menopause have a greater impact on sexual functioning and mood than menopause per se. In the area of sexual functioning, this theory has considerable support. Research has shown that general mental health and male partner's health and limitations affect a woman's sexual functioning. Research also provides consistent evidence that social circumstances have a strong effect on mood during the menopause transition. Studies that have included measures of stress or life changes have typically found that social factors are highly related to mood, and often more so than menopause status. Thus, there is strong support

for the social circumstances perspective that menopause per se is less responsible for mood effects than life events of middle-aged women.

There is much needed research in this area. Future research should examine the longer term impact of the decline in ovarian function among women, as well as the role of androgens. Most research has been conducted among newly menopausal women. The effects of decreased estrogen on sexual functioning may be pronounced as women age. The role of androgens in women who experience a natural menopause has barely been looked at. While androgens may not be linearly associated with sexual functioning, it is quite possible that women with particularly low levels of testosterone may have lower levels of libido. We need research to determine if women vary in their rate of testosterone decline and if this rate changes as a result of menopause. Longitudinal research of large samples that can control for multiple covariates is greatly needed.

Future research needs to focus on developing a better understanding of women who may be at risk for mood effects of the menopause transition and whether there is a pattern in response to periods of hormonal fluctuations. Are such effects due to abnormal biochemical changes resulting from hormonal fluctuations, a woman's general sensitivity to symptoms, or a coping style? Prospective research needs to follow women during their reproductive years to examine continuity with respect to responses to times of hormonal change.

Finally, we need to understand how these various changes relate to each other. Are changing hormones, vasomotor symptoms, and sleep disturbances independently related to sexual functioning and mood or is there a causal chain? Researchers need to begin to develop and test models of these associations.

Factors Influencing the Onset of Female Reproductive Senescence

Striking similarities exist between the mechanisms governing neuroendocrine and ovarian functions in the rat and in the human. Furthermore, age-related declines in reproductive cyclicity and fertility are also similar between the two species. Thus, the middle-aged female rat provides a relevant and practical model for studying the mechanisms controlling reproductive functions. Researchers have utilized aging rodent models to examine how advanced age affects the interactions between ovarian function and the neuroendocrine control of gonadotropin secretion. In young female rats, increased estradiol secretion by maturing follicles elicits a surge of luteinizing hormone on proestrus, which stimulates progesterone secretion by preovulatory follicles and induces ovulation the next morning. As the female rat ages, the magnitudes of the preovulatory surge of luteinizing hormone and associated progesterone secretion gradually decrease, serving as an early marker of the imminent loss of regular ovulatory cycles. The decline in the neuroendocrine regulation of luteinizing hormone secretion is associated with alterations in hypothalamic functions, involving both stimulatory and inhibitory pathways regulating gonadotropin-releasing hormone release. In addition, clear changes in the number and function of ovarian follicles occurs during aging, associated with declines in oocyte quality. Interestingly, the temporal onset of reproductive declines during aging can be modulated by factors such as exposure to ovarian steroid hormones, caloric intake, parity, and genetic influences. This chapter reviews previous and recent studies demonstrating that such extrinsic factors can significantly delay or advance the effects of aging on neuroendocrine and reproductive functions.

I. Introduction

The maintenance of normal reproductive function in mammals is dependent upon tightly balanced feedback interactions between the hypothalamus, pituitary, and gonads. It is clear from many studies in female rodents that age-related declines in reproductive competence are associated with not only alterations in the neural mechanisms regulating gonadotropin secretion, but also changes in pituitary and ovarian functions. Due to the highly interactive nature of the hypothalamic-pituitary-ovarian axis, it has been difficult to ascertain the initial locus at which such age-related changes occur. For example, just as aging-associated declines in the neural regulation of gonadotropin secretion surely influence ovarian function, it is also clear that altered gonadal steroid and peptide secretion can influence neuroendocrine aging. Indeed, studies by several investigators indicate that both intrinsic and extrinsic factors modulate the onset of reproductive senescence. This chapter will review our current understanding of age-related changes in hypothalamic, pituitary, and ovarian functions in the female rodent model, focusing on the influences of factors such as ovarian steroid exposure, parity, diet, and genetics on the progression of reproductive aging.

II. Female Rodents as a Model of Reproductive Aging

A. Neuroendocrine Regulation of Reproductive Functions

Although the ovulatory cycle of the female rat is relatively short (4 to 5 days long) compared to that of women, the basic interactions and mechanisms governing neuroendocrine and ovarian functions in the rat are in general similar to that in the human. Furthermore, age-related changes in reproductive cyclicity and fertility during the transition to reproductive senescence appear to be similar between the two species. Thus, the middle-aged female rat has provided investigators with a relevant, practical model in which to study the effects of aging on neuroendocrine and ovarian functions, and to examine the dynamic interactions between hypothalamic, pituitary, and ovarian functions.

In female rats of the Long-Evans strain, regular estrous cycles have a duration of 4 days (termed diestrus day 1, diestrus day 2, proestrus, and estrus) and repeat every 4 days in the absence of mating with a male. During each cycle, gonadotropins released from the pituitary stimulate the development,

growth, maturation, and steroidogenesis of ovarian follicles, and follicular growth is accompanied by a gradual, marked increase in estradiol (E2) secretion. On proestrus afternoon, high levels of plasma E2 act upon the neuroendocrine axis, triggering the hypothalamic release of gonadotropin-releasing hormone (GnRH), which stimulates the surge release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from the anterior pituitary. Soon after initiation of the LH surge, rising plasma levels of LH stimulate ovarian expression of cytochrome P450 side chain cleavage (P450scc), the rate-limiting enzyme in progesterone (P4) biosynthesis (Strauss and Miller, 1991), in preovulatory follicles. This results in high circulating P4 levels on proestrus afternoon and evening, which facilitate and potentiate the preovulatory LH surge (Mahesh and Brann, 1992). In addition, the LH surge is essential in inducing ovulation of preovulatory follicles in the early morning of estrus. Under the luteinizing action of LH, the ruptured follicles form corpora lutea, which secrete substantial amounts of P4 during diestrus days 1 and 2 of the subsequent cycle. In addition to the preovulatory LH surge, the FSH surge on proestrus afternoon may also contribute to the processes of ovulation and luteinization of preovulatory follicles (Galway *et al*., 1990). The primary FSH surge on proestrus is followed immediately by a second increase in FSH release in the early morning of estrus. This secondary FSH surge is believed to be GnRH-independent and to play an important role in the selection and growth of preovulatory follicles for the next cycle (Hirshfield and De Paolo, 1981).

B. Characteristics of Reproductive Aging in Female Rodents

In the female rat, reproductive senescence is characterized by a gradual loss of regular ovulatory cycles and declines in fertility and fecundity (Ingram, 1959; Meites and Huang, 1976; Lu *et al*., 1979; Matt *et al*., 1987a). By 9–11 months of age, increasing numbers of multiparous rats (retired breeders) exhibit attenuated preovulatory LH surges on proestrus during regular estrous cycles (Cooper *et al*., 1980; Wise, 1982a; Nass *et al*., 1984), associated with a reduced rise in plasma P4, decreased ovulation rate, decreased fertility, and a declining reserve of ovarian follicles (Mandl and Shelton, 1959; Gray *et al*., 1980; Wise, 1982b; Matt *et al*., 1987a; LaPolt *et al*., 1998). Four to 6 weeks after exhibiting attenuated proestrous LH surges, middle-aged females begin to display lengthened, irregular estrous cycles characterized by a significant delay or absence of preovulatory LH surge and ovulation. Once aging female rats have entered an irregularly cyclic state, most are no longer able to maintain fertile gestations (Matt *et al*., 1987a). In middle-aged women, a similar transition from regular menstrual cycles to irregular ovulatory cycles, with an accompanying decline in fertility, occurs during the perimenopausal phase of reproductive life (Treloar *et al*., 1967; Sherman and Korenman, 1975), suggesting that common mechanisms may contribute to reproductive senescence in both humans and rodents.

After a brief period of displaying lengthened, irregular estrous cycles, aging female rats enter an acyclic, spontaneously persistent-estrous state, often lasting for 6 months or longer. During the prolonged period of acyclicity, the ovaries of middle-aged persistent-estrous rats continue to exhibit some degree of follicle growth and E2 secretion, but do not exhibit spontaneous LH surges or follicular ovulation (Lu *et al*., 1979). Thus, in aging persistent-estrous rats, the prolonged acyclic state is associated with a moderately elevated plasma E2 but persistently diminished circulating P4 levels, due to the absence of spontaneous LH surges. Interestingly, persistent-estrous rats will display LH surges and ovulate in response to mating with males, although their ovulation rates and subsequent fertility are very low (Matt *et al*., 1987b; Day *et al*., 1988). It should be noted that the acyclic persistent-estrous state in aging rats is not analogous to the menopause in middle-aged women, as there is some degree of follicular development and steroidogenesis taking place in the ovaries of persistent-estrous rats, as opposed to the relative depletion of ovarian follicles and loss of E2 production in postmenopausal women.

C. Changes in Ovarian Function in Middle-Aged Rats

As in the human, there is a marked decline in the numbers of ovarian follicles during aging in the rat (Mandl and Shelton, 1959; Block, 1968; Richardson and Nelson, 1990). Presumably, a minimal threshold of follicles is required to maintain normal patterns of feedback interactions with the neuroendocrine axis. During the reproductive life span, there is a constant, gonadotropin-independent recruitment of resting primordial follicles that begin growth, resulting in a gradual, continuous depletion of the ovarian follicular pool. The majority of these recruited follicles become atretic, with only a few being selected and stimulated by FSH for continued development to the preovulatory stage. The ovarian and/or endocrine substances which trigger a resting primordial follicle to begin growth are unknown, but hold the key to determining the rate of follicular depletion and, hence, reproductive senescence. Interestingly, there is an accelerated loss of ovarian follicles during the decade preceding menopause in women (Richardson and Nelson, 1990; Faddy *et al*., 1992), although the cause of such increased follicular depletion remains speculative. The importance of the ovary in reproductive aging of rodents is suggested by studies utilizing experimental manipulations that decrease the rate of follicular depletion. Treatments such as food restriction or progesterone treatments early in life (see below) are associated with a delayed onset of reproductive senescence and decelerated loss of ovarian follicles (Lintern-Moore and Everett, 1978; Merry and Holehan, 1979; Nelson *et al*., 1985; LaPolt *et al*., 1998). In contrast, experimental approaches that reduce the follicle pool, such as hemiovariectomy, shorten reproductive life span in rodents (Sopelak and Butcher, 1982; Meredith and Butcher, 1985). Thus, age-related declines in follicle number appear to contribute to the onset of reproductive senescence in rodent species, similar to that in humans.

In middle-aged cyclic female rats, the decline in the ovarian follicular pool results in fewer developing follicles early in each cycle (Peluso *et al*., 1979). However, there is accelerated follicle growth and E2 production by individual follicles (Lerner *et al*., 1990), apparently resulting in similar numbers of large, preovulatory follicles on proestrus between middle-aged and young cyclic females. Although the numbers of preovulatory follicles appear similar in young and middle-aged rats, it is not known whether age-related differences in follicu-

lar and oocyte function may occur. For example, the reduced increase in P4 secretion on proestrus afternoon in middle-aged rats (Gray *et al*., 1980; Wise, 1982b) may be related to a decreased follicular responsiveness to gonadotropin stimulation. In addition, although young and middle-aged rats have similar numbers of preovulatory follicles, there are age-related declines in ovulation rate (Matt *et al*., 1987a; Day *et al*., 1989) and oocyte quality (Peluso and Hutz, 1980; Peluso *et al*., 1980) which suggest differences in follicular function. In this regard, our recent studies examined the ovarian ovulatory responsiveness to gonadotropin stimulation in middle-aged cyclic as compared to young rats (Anzalone *et al*., 1998). Young and middle-aged proestrous rats were treated with sodium pentobarbital to block endogenous LH surges. That afternoon, rats were treated with various doses of human chorionic gonadotropin (hCG) and resulting ovulation rates were determined. Both young and middle-aged cyclic rats exhibited dose-dependent increases in ovulation rate with increasing doses of hCG. In addition, there was no significant difference in the ovulatory response to hCG between young and middle-aged proestrous rats (Anzalone *et al*., 1998). Thus, decreased ovulation rates in middle-aged cyclic females likely result from insufficient gonadotropin stimulation due to attenuated preovulatory LH surges, rather than a decreased ovarian sensitivity to LH. However, middle-aged acyclic persistent-estrous females did exhibit impaired ovulatory responses to exogenous gonadotropin stimulation, indicating decreased sensitivity to the stimulatory effects of LH in these acyclic females (Anzalone *et al*., 1998). Thus, the ovarian ovulatory responsiveness to gonadotropin stimulation in aging rats is dependent upon the reproductive status of the animal studied.

Declines in fertility are associated with decreased oocyte quality in both human and rodent species. However, it has not been clear whether declines in oocyte quality during aging reflect inherent defects in the last oocytes to be recruited during the reproductive life span, or changes in the pattern of follicular development and oocyte maturation that contribute to such defects. Recent studies by Eppig and O'Brien (1995) reveal that oocytes from aged mice matured *in vitro* have normal rates of *in vitro* fertilization and embryonic development. In contrast, induction of oocyte maturation *in vivo* resulted in decreased rates of embryonic development. This finding suggests that impaired oocyte quality during aging does not result from inherent defects in the oocyte, but rather from an altered course of oocyte development and maturation in the aging ovary. In this regard, alterations in follicular development rates have been documented in aging rodents (Lerner *et al*., 1990), and it is feasible that concomitant changes in oocyte maturation occur as well. Whether such age-related changes in follicle development result from altered levels of gonadotropin secretion during follicular development are unknown. Clearly, further studies are required to elucidate specific age-related changes in ovarian follicular growth, maturation, and steroidogenesis that contribute to the onset and progression of reproductive senescence and neuroendocrine aging.

D. Effect of Aging on Neuroendocrine Regulation of Gonadotropin Secretion

Alterations in ovarian function in middle-aged rats may reflect well-described effects of aging on the neuroendocrine regulation of gonadotropin secretion, particularly the preovulatory LH surge on proestrus. The preovulatory rise in circulating E2 is essential in eliciting the positive feedback stimulation of gonadotropin surges on proestrus. In this regard, previous studies demonstrated that the proestrous LH surge is abolished in young cyclic females after ovariectomy or administration of E2 antibodies or antagonists (Brom and Schwartz, 1968; Ferin *et al*., 1969; Labhsetwar, 1970). In addition to the stimulatory effect of E2 on gonadotropin surges, it is also clear that a major rise in circulating P4 on proestrus afternoon also acts upon the neuroendocrine axis to facilitate and potentiate the LH surge (Peduto and Mahesh, 1985; Lee *et al*., 1990; Mahesh and Brann, 1992). Thus, in young rats both E2 and P4 contribute to the initiation and full potentiation of proestrous gonadotropin surges.

Beginning around 9–11 months of age, increasing numbers of regularly cyclic, multiparous female rats exhibit attenuated preovulatory LH surges on proestrus (Cooper *et al*., 1980; Wise, 1982a; Nass *et al*., 1984), associated with smaller rises in plasma P4, reduced ovulation rates, and decreased fertility. There is considerable heterogeneity among aging females regarding the temporal onset of neuroendocrine aging. While some middle-aged rats show significantly attenuated proestrous LH surges and subsequently lose regular cyclicity within 2 months, other females of the same age exhibit a normal profile of the LH surge and continue to display regular cycles for at least 2 more months (Nass *et al*., 1984). These findings indicate that attenuation of the preovulatory LH surge serves as an early marker of neuroendocrine aging and is a reliable predictor of the imminent loss of regular ovulatory cycles.

Age-related declines in proestrous LH surge magnitude are believed to reflect altered hypothalamic function, as evidenced by decreased neuroendocrine response to the positive feedback effects of E2 (Lu *et al*., 1981; Wise, 1984), altered hypothalamic neurotransmitter turnover (Wise, 1984), changes in diurnal rhythmicity (Cohen and Wise, 1988; Weiland and Wise, 1990; Krajnak *et al*., 1998), and altered expression of immediate–early genes, such as Fos, in GnRH neurons, indicating deficits in neuronal activation and subsequent release of GnRH (Rubin *et al*., 1994, 1995; Lloyd *et al*., 1994). A previous study has demonstrated that middle-aged cyclic rats that are bilaterally ovx and primed with E2 exhibit attenuated LH surges, but normal surges of prolactin (Wise, 1984). These findings indicate that the effects of aging on the neuroendocrine control of pituitary hormone secretion are specific and differential. Inasmuch as an increased plasma P4 can facilitate and potentiate the E2 induced LH surge (Peduto and Mahesh, 1985; Lee *et al*., 1990), further studies are required to assess the causal relationship between an attenuated proestrous LH surge and a reduced rise in plasma P4 in middle-aged cyclic rats.

The neuroendocrine induction of the proestrous LH surge is associated with increased activity of several hypothalamic neurotransmitters, such as norepinephrine, serotonin, and neuropeptide Y (NPY). In young female rats, the steroid-induced LH surges are associated with a concomitant diurnal rise in the turnover rates and/or levels of these neurotransmitters (Barraclough, 1983; Vitale and Chiocchio, 1993; Sahu *et al*., 1995; Sahu and Kalra, 1998). Furthermore, administration of these factors stimulates GnRH release (Hery *et al*., 1976; Nowak and Swerdloff, 1985; Besecke *et al*., 1994). During aging, the patterns of stimulatory neurotransmitter activity and recep-

tor expression are altered (Wise, 1984; Cohen and Wise, 1988; Weiland and Wise, 1990; Sahu and Kalra, 1998). Together, such studies indicate that impaired positive feedback stimulation of LH release in aging rats is related to altered activity of several hypothalamic neurotransmitters which stimulate GnRH release.

In addition to stimulatory pathways, GnRH release is also regulated by inhibitory neurotransmitters as well. Thus, it is likely that alterations in inhibitory pathways also contribute to age-related declines in LH release, although relatively little research has been performed in this regard. It has been shown that endogenous opioid tone inhibits LH release in the rat, and there is evidence that a decline in opioid tone is partially responsible for the onset of the proestrous LH surge in young cyclic rats (Allen and Kalra, 1986). Treatment of middle-aged, acyclic female rats with the opioid antagonist naltrexone is sufficient to successfully reinstate estrous cycles and LH surges (Field and Kuhn, 1989), suggesting a potential limiting role of the opioid system in neuroendocrine aging. While some reports indicate a decline in expression of proopiomelanocortin, the precursor to β-endorphin, during aging (Lloyd *et al*., 1991), there is little direct information about the levels of various opioid receptor ligands (such as endormorphins, enkephalines, and endorphins) in aging rats. The effects of E2 and P4 on opioid inhibition-associated LH surges appear to also reflect a decline in opioid receptor binding (Jacobson and Kalra, 1989; Maggi *et al*., 1993). To date, no studies have been performed to address the effects of aging on hypothalamic regulation of opioid receptors. Thus, the role of the opioid system in altered neuroendocrine function during aging requires further investigations. Similarly, the neurotransmitter γ-aminobutyric acid (GABA) also exerts inhibitory effects on GnRH release (Adler and Crowley, 1986; Leonhardt *et al*., 1995) and there is a decline in hypothalamic GABA release during steroid-induced LH surges (Jarry *et al*., 1988, 1995). However, there is little information regarding potential changes in GABA expression or receptor levels in aging female rats. Thus, the role of potential age-related changes in inhibitory neurotransmitter pathways requires further consideration.

In addition to well-characterized influences of age on the hypothalamus, there is evidence that attenuated preovulatory LH surges on proestrus in middle-aged cyclic rats reflect in part a decline in pituitary LH response to GnRH stimulation. Previous reports by Smith *et al*. (1982) described decreased GnRH-stimulated LH release from hemipituitaries taken from middle-aged proestrous rats as compared to that from young rats. More recently, a study by Brito *et al*. (1994) examined the relation of pituitary responsiveness to LH surge magnitude in middle-aged cyclic rats, demonstrating that middle-aged rats with normal patterns of proestrous LH surge (comparable to those in young females) subsequently exhibit normal pituitary responsiveness to exogenous GnRH stimulation. In contrast, middle-aged cyclic females exhibiting attenuated LH surges subsequently showed decreased LH response to GnRH. Thus, declines in pituitary responsiveness to GnRH do occur in aging female rats displaying regular estrous cycles, but only in those aging females exhibiting attenuated proestrous LH surges. Whether such a decline in pituitary responsiveness to GnRH is secondary to a tonic decrease in hypothalamic GnRH release and/or reflects alterations in GnRH receptor expression or signal transduction remains to be determined.

III. Factors Influencing the Onset of Reproductive Senescence in Rodents

As with other outcomes of aging, there is considerable heterogeneity regarding the temporal onset of reproductive senescence among populations. Based on a number of studies, reviewed below, it is clear that a combination of environmental factors and genetic influences affect the timing of reproductive decline for a given individual.

A. Influences of Ovarian Steroid Exposure and Parity on the Onset of Reproductive Aging

The temporal onset of reproductive senescence in female rodents is strongly influenced by the duration and pattern of exposure to circulating levels of E2 and P4 during their lifetime. This conclusion has evolved from a number of studies. Early findings demonstrated that injection of supraphysiological levels (2 to 5 mg) of estrogen (estradiol valerate) to young female rats markedly impaired the neuroendocrine regulation of LH secretion, associated with chronic anovulation and the induction of a polycystic ovarian state (Brown-Grant and ter Haar, 1977; Brawer *et al*., 1978; Mobbs *et al*., 1984a). Whether the effects of these high doses of E2 on reproductive function represent an acceleration of normal aging processes is not clear. However, subsequent studies utilized subcutaneous implants and oral administration of E2, revealing that more physiological levels of E2 also caused the loss of regular ovulatory cycles and impaired neuroendocrine function (Lu *et al*., 1981; Kohama *et al*., 1989). The relationship between exposure to E2 and neuroendocrine aging is more clearly demonstrated in the studies of Lu and colleagues (1981). They observed that old (over 18 months) persistent-estrous rats maintain moderately elevated plasma E2 (around 30 pg/ml), slightly lower than the peak levels observed on proestrus afternoon. Treatment of acutely ovariectomized, old persistent-estrous rats with E2 followed by P4 failed to elicit an LH surge, in contrast to that observed in young females. However, five weeks after ovariectomy, an LH surge could be induced in formerly persistent-estrous rats by E2 and P4 treatment. Thus, positive feedback responses were reinstated in aged persistent-estrous rats following removal of the source of endogenous E2 production. To confirm that a chronic rise in circulating E2 is the factor inhibiting neuroendocrine responsiveness, ovariectomized young rats were treated with E2 implants subcutaneously for 7 weeks, resulting in circulating E2 levels similar to that in intact persistent-estrous females. This treatment of young rats with E2 implants effectively abolished the stimulatory actions of E2 and progesterone on LH release. Subsequent studies advanced further the hypothesis that estrogen exposure contributes to neuroendocrine dysfunction during aging. In both young rats and mice, long-term ovariectomy delays age-related declines in the neuroendocrine regulation of LH secretion, indicating that repetitive, cyclic increases in circulating E2 exert a cumulative, inhibitory effect on neuroendocrine function (Blake *et al*., 1983; Mobbs *et al*., 1984b). In accord

with these findings, it has been shown that, in mice, oral administration of E2 hastens the loss of ovulatory cycles, an effect partially counteracted by ovariectomy (Kohama *et al*., 1989). Together, these findings indicate that prolonged exposure to circulating E2 inhibits the neuroendocrine mechanisms regulating positive feedback of E2 on LH secretion, contributing to age-related infertility.

Other related studies from our laboratory have shown that parity of the female can influence the onset of reproductive aging, and that age-related declines in regular ovulatory cycles and normal fertility occur considerably earlier in virgin than in multiparous rats (LaPolt *et al*., 1986; Matt *et al*., 1987a). Similarly, continued caging of retired breeder females with fertile males significantly delays the onset of reproductive senescence, compared with females that do not have continued contact with males (Nass *et al*., 1982). During pregnancy, plasma levels of P4 are persistently elevated, whereas E2 levels remain low throughout the first two-thirds of gestation (LaPolt *et al*., 1986; Matt *et al*., 1986). Thus, the effects of repeated pregnancy in delaying reproductive aging may be due to the elevation of P4 levels and/or inhibition of E2 production during pregnancy. To test this hypothesis, young virgin rats and middle-aged retired breeder females received repeated treatments with subcutaneous P4 implants, which suppress ovarian E2 production and mimic the endocrine environment of pregnancy in the rat. During P4 implant treatments, the ovarian production of E2 is suppressed for a long period, compared with the repetitive cyclic increases in plasma E2 seen every few days in control females (LaPolt *et al*., 1986, 1988). The findings from these studies reveal that successive treatments of young and middle-aged rats with P4 implants effectively prevent attenuation of the proestrous LH surge, and delay the age-related loss of regular ovulatory cycles and fertility (Lu *et al*., 1985; LaPolt *et al*., 1986). To clarify whether the effects of P4 implants in delaying reproductive aging are due to elevated P4 levels or to an inhibition of E2 production, subsequent studies were performed. Concomitant treatments of young rats with P4 and E2 implants abolished the beneficial effects of P4 treatment on reproductive life span (LaPolt *et al*., 1988), indicating that the effects of P4 implants are dependent upon inhibition of E2 production. Based on these observations and the studies discussed above, it has been proposed that cyclic increases in plasma E2 (once every 4 days) during successive ovulatory cycles cumulatively inhibit the neuroendocrine mechanisms regulating gonadotropin release, resulting in the attenuation and eventual loss of preovulatory LH surges. While our recent study reveals that P4 implant treatments delay the ovarian depletion of the follicular pool (LaPolt *et al*., 1998), further studies are required to elucidate the specific mechanisms by which exposure to ovarian steroids influences the onset of reproductive senescence.

B. Caloric Restriction and the Prolongation of Reproductive Life Span

One of the most widely studied environmental influences on reproductive aging and life span is caloric intake, as examined with a number of studies utilizing various food restriction models. Several reports have shown that food restriction in mice and rats not only results in an increased longevity, but also delays reproductive senescence (Holehan and Merry, 1985; Nelson *et al*., 1995; McShane and Wise, 1996). The effects of caloric restriction on reproductive aging are associated with slower declines in the ovarian follicular reserve (Lintern-Moore and Everett, 1978; Nelson *et al*., 1985) and subsequent maintenance of the neural mechanisms regulating LH secretion after normal diet is resumed (McShane and Wise, 1996; McShane *et al*., 1999). During many regimens of food restriction, there is a temporary cessation of ovulatory cycles. During such treatments, the expression of gonadotropin subunit mRNAs in the anterior pituitary gland is reportedly decreased (Han *et al*., 1998), although positive feedback of LH and FSH responses to ovarian steroids are maintained (Sprangers and Piacsek, 1997). The efficacy of food restriction in delaying reproductive senescence does not, however, appear to be dependent upon the cessation of estrous cycles during reduced caloric intake. McShane and Wise (1996) have shown that female rats subjected to a moderately restricted diet (60% of fed rats ad libitum) continued displaying estrous cycles during experimental caloric reduction, and yet subsequently showed a delayed loss of regular estrous cycles and enhanced pulsatile secretion of LH. Thus, the beneficial effects of caloric restriction on reproductive life span are not dependent upon the cessation of cyclicity during the period of reduced caloric intake. The detailed mechanisms by which reduced caloric intake maintain normal reproductive functions during aging remain to be determined.

C. The Influence of Genetics on Reproductive Aging

Previous studies comparing different strains of inbred and wild-caught mice have revealed distinctive differences in the rate of ovarian follicular depletion and loss of estrous cycles and fertility with age, indicating genetic influences on the progression of reproductive aging. The temporal onset of aging differs in inbred mice of different strains, and is apparently influenced by genes associated with the H-2 major histocompatibility complex (Lerner *et al*., 1988) and other loci (Nebert *et al*., 1984). Several studies have demonstrated that it is possible to selectively breed mice to develop strains with increased or decreased reproductive longevity, demonstrating a genetic influence on reproductive life span (Miyamoto *et al*., 1995; Nagai *et al*., 1995). In addition, selection of mice to develop strains with high plasma magnesium levels and low magnesium levels resulted in strains with differing reproductive longevity as well; the low magnesium level strain exhibits a higher reproductive capacity than the high magnesium level strain (Motta *et al*., 1998). Other strain differences in reproductive longevity have also been described. One recently reported strain of mice exhibits a delayed onset of both fertility and reproductive senescence, continuing to breed into the second and third years of life (Biddle *et al*., 1997). In all of these cases, the specific interactions between genetics and the neural and ovarian mechanisms regulating reproductive longevity remain enigmatic. Furthermore, it is evident that even within a cohort of animals of a given genetic background, there is marked heterogeneity in the reproductive life span. Thus, while there are clear genetic influences on the progression of reproductive aging, much further research remains to be done to elucidate the specific genes modulating reproduc-

tive senescence and to understand the interactions between genetic and environmental factors.

IV. Conclusions

It is evident from this review that female reproductive senescence involves alterations occurring at the hypothalamic, pituitary, and ovarian levels, as would be predicted from the close feedback interactions that link these endocrine organs. Furthermore, the progression of reproductive aging is highly variable among individuals in a population and is influenced by genetic and endocrine factors. Whereas the finite numbers of ovarian follicles represent one definite constraint on reproductive life span, the identities of other factors which alter variables such as maintenance of diurnal rhythmicity, appropriate neurotransmitter release, the rate of follicular depletion, and the magnitude of steroid hormone action remain to be elucidated. Further studies on animal models with increased reproductive life span, whether due to food restriction, progesterone treatments, parity, or genetic influences, may provide new insights into the identity of primary factors responsible for reproductive senescence.

Female Sexuality during Aging

Studies of sexuality and aging are few in number but generally are consistent in finding a decline in sexual interest and activity for both sexes with sexual activity declining faster than interest. Undeniably, one major purpose of sexual behavior is reproduction and survival of the species; thus, at the end of women's fertility and reproductive lives, when menstrual cycling ceases and sex hormone production decreases, it should not be surprising that female sexuality begins to decline.

Our attempts to understand what happens to female sexuality and its behavioral expression during aging are facilitated by utilizing the three basic concepts of sexual behavior in female mammals that were proposed by Beach in 1976. These characteristics of the sexuality of female mammals as applied to the human female are *attractivity*, or a woman's value as a sexual stimulus—her sexiness, *proceptivity*, or a woman's sexual motivation or desire and the behavior reflecting it, and *receptivity*, or a woman's willingness and ability to respond sexually (lubrication, orgasm, etc.). While surveys find that both reported sexual desire and sexual response inferred from reported frequency of sexual activity decline during aging, sexual attractiveness as a major component of female sexuality worthy of research has been largely ignored by all but popular women's magazines.

Understanding how sexual interactions involving these three components change with age requires an understanding of sexual interaction during the reproductive period. Perper (1985) has provided a detailed analysis of dyadic sexual behavior using data derived from observation of young adults in natural settings. What is important to our understanding of female sexuality during aging is that these data indicate that the human female initiates sexual encounters. Acting proceptively, in a progressive step-by-step escalation toward sexual intimacy in this dyadic courtship sequence, she signals her interest and arouses the male by her behavior. If the female is sexually attractive and succeeds in arousing the male, then the couple reaches what Perper terms a ''power transition'' in which the responsibility for the action changes to the male who must initiate the sexual foreplay/behavior and arouse the female (Perper, 1985, p. 181). If one accepts the existence of this pattern, then it suggests that declines in female sexuality during aging may involve decreased readiness to engage in proceptive behavior by the female and, more importantly, a decline in female attractivity or sexual attractiveness which results in decreased male interest and an end to the interaction prior to the initiation of sexual behavior/foreplay by the male. While we do not have similar data concerning such sexual interactions in the aging female, Perper's description of the courtship sequence is a rich source of hypotheses concerning changes in the sexual interaction of the aging couple. Knowledge of the courtship sequence also offers an explanation for the findings from survey research in which both women and men say that it is the man who is responsible for cessation of sexual activity (Pfeiffer *et al*., 1968, 1972; George and Weiler, 1981). If it is the responsibility of the man to initiate the sexual foreplay/behavior, then regardless of the reason, when such behavior does not occur, it follows that he is the one held accountable.

Related to this issue, Sarrel (1982) has published data strongly suggesting that sexual problems related to estrogen deficiency in the female (dryness, dyspareunia) often give rise to sexual problems such as erectile difficulties and premature ejaculation in the male and these may ultimately bring about a cessation of sexual activity.

I. Sexuality Research with Age as the Major Variable

A. Sex, Age, Marital Status, and Religiosity

Kinsey and his colleagues (1953) carried out some of the earliest scientific work on women's sexuality gathering data from almost 6000 subjects ages 16 to over 71. Although they considered their sample inadequate beyond age 50, their data clearly showed a lower frequency of sexual activity to orgasm in women compared to men at all ages and a decline with age in the number of both single and married women who were sexually active. They also observed that married women engaged in more sexual activity than single, widowed, divorced, or separated women and that religious devoutness was negatively associated with sexual activity. Table 54.1 lists subsequent studies of aging and sexuality and the variables each identified as associated with women's sexual activity. Clearly,

TABLE 54.1. Variables Associated with Sexuality in Women from Studies of Aging and Sexuality

Study	No. of subjects	Age of subjects (years)	Variables
Duke Study I			
Newman and Nichols (1960)	250; ? Women, 47 married women	60–93	Sex, age, marital status, past sexual urge, physical health
Pfeiffer *et al*., (1968)	254; 131 Women	60–94	Sex, age
Verwoerdt *et al*., (1969a)	Same	Same	Sex, age, marital status
Verwoerdt *et al*., (1969b)	Same	Same	Sex, age, marital status
Christenson and Gagnon (1965)	241 Women	50–70; 73% between 50–60	Age, marital status, early sexual activity, relative age of husband, religious devoutness
Duke Study II			
Pfeiffer *et al*., (1972)	502; 241 Women	45–69	Sex, age
Pfeiffer and Davis (1972)	Same	46–71	Sex. For women: Marital status, age, past sexual enjoyment
George and Weiler (1981)	278 Married; 108 married women	46–71 6-year longitudinal	Sex, no significant change in sex in 6 years for 46- to 55-, 56- to 65-, and 66- to 71-year-old women, decline across age group cohorts
Christenson and Johnson (1973)	71 Never-married women	50–69; 80% between 50–60	Age, early sexual activity, religiosity
De Nicola and Peruzza (1974)	85; 32 Women	62–81	Sex, age
Persson (1980)	432; 266 Women 219 married; 91 married women	70-Year-olds	Sex, marital status, Married women: physical/mental health, premarital sexuality, younger healthy husband, coital pleasure, attitude to sexual activity in aged, quality of marriage
Todarello and Boscia (1985)	300; 141 Women	55–90	Sex, age, marital status, noninstitutional living
Bretschneider and McCoy (1988)	202; 102 Women	80–102 Mean=86.1	Sex, marital status, past importance of sex, past extramarital sex, regular church attendence
Lindgren *et al*., (1993)	1867 Women	55, 57, 59, 65	Age, years since menopause, partner status, lack of desire, natural vs surgical menopause

all studies obtaining data from both sexes found a sex difference in favor of men. Some have pointed out that the sex difference in activity favoring men and seen at all ages may be confounded with the age of the partner given that women's partners tend to be several years older and men's partners several years younger than they are.

All studies found a decline in women's sexuality with age and that married women engaged in more sexual activity than other women. Some researchers have noted an exception to the decline with age with their oldest group of women reporting less or no decline in interest and/or activity compared with the preceding younger age group (Verwoerdt *et al*., 1969b; Pfeiffer *et al*., 1972; Bretschneider and McCoy, 1988). Pfeiffer and his colleagues (1972) explained this by suggesting that women of advanced age are "elite survivors from whose midst less highly advantaged individuals had already been removed." In addition to age, a comparatively recent study (Lindgren *et al*., 1993) has also identified years since the menopause, lack of desire, and surgical menopause as factors contributing to declining sexual activity.

Several of these studies as well as Kinsey *et al*. (1953) found religiosity to be negatively associated with sexual activity. Physical and mental health as positive factors were reported by two of these studies, but clearly, such variables have not turned up often, because individuals in poor physical and mental health have tended not to participate in such research and samples have tended to be rather homogeneous for these variables.

B. Past Sexuality

Several studies have found measures of past sexual interest or sexuality in the younger years to be positively associated with current levels of sexual activity. Table 54.1 reveals a number of aspects of past sexual behavior significantly associated with current sexuality. Such variables are past sexual urge, early sexual activity, past sexual enjoyment, premarital sexuality, past extramarital sex, and past importance of sex. Because sexual data concerning the past and the present are usually obtained from subjects at the same time, it is possible that relationships found between them are spurious. I would argue against this view given that such relationships are found routinely and make a great deal of sense based upon what we know about the general consistency of individual behavior across the life span.

C. Sexual Activity

Another factor in women's sexuality suggested by Masters and Johnson (1966) and clearly related to marital status is continued activity with age—a "use it or lose it" hypothesis. Employing direct observation of the sexual response cycle, Masters and Johnson studied only 34 women over the age of 50, but observed three remarkable women subjects, two in their 60s and one in her 70s, who responded to sexual stimulation with vaginal lubrication "in a manner expected of a 20–30-year-old woman" (p. 234). The explanation they offered for this was that these three women had "maintained active sexual connections once or twice a week throughout their mature lives" (p. 234).

Several studies using a vaginal atrophy index derived from direct examination by a trained physician have found that sexually active older women had significantly less vaginal atrophy or greater vaginal health than sexually inactive women of the same age (Leiblum *et al*., 1983; Bachmann *et al*., 1984; Bachmann and Leiblum, 1991). Leiblum and her colleagues (1983) found that active women had significantly higher levels of androstenedione, testosterone, and luteinizing hormone (LH). In the 1984 study by Bachmann and her colleagues, the active women had significantly higher levels of LH, but there were no significant differences in hormone levels between active and inactive women in the 1991 study by Bachmann and Leiblum. While sexual activity could have played a causal role in reducing vaginal atrophy, it is also possible that a third variable such as the level of sex hormones may have acted to increase both sexual activity and vaginal health.

II. Sexuality Research with Menopause as the Major Variable

During the 1980s, menopause appeared as a significant variable in research concerning female sexuality during aging. Much earlier, Kinsey and his colleagues (1953) had examined the effects of menopause but discounted its importance. They examined the data from a group of 127 postmenopausal women who had experienced orgasm within the past year; 48% stated they believed that their sexual response and activity had been decreased by menopause, and 53% stated they believed that menopause had brought about a decrease in the frequency of their sexual behavior (total outlet). Nonetheless Kinsey *et al*. (1953) continued to view declines in women's sexuality as related to the male. They stated:

> . . .the declining frequencies of sociosexual activities among females are not primarily dependent on an aging process in the female, but upon an aging process in the male which reduces his interest in having frequent coitus (p. 735).

Commenting further they stated:

> Some of the decreased frequencies also depended upon the fact that some of these women had seized upon menopause or their ovarian operations as an excuse for discontinuing sexual relationships in which they were never particularly interested (p. 736).

In another older study, Pfeiffer and Davis (1972) (see Table 54.1) conducted a regression analysis with postmenopausal status as a predictor variable. The inclusion of this variable accounted for less than 2% of the explained variance for both sexual interest and frequency of sexual intercourse in women; the major part of the variance was explained by marital status and age. In their study of never-married women, Christenson and Johnson (1973) also examined menopause as a variable but reported that 50% of the 17 postmenopausal women reported no change in erotic feelings after menopause; 25% each reported an increase and a decrease, respectively.

Before menopause could be acknowledged as a significant variable in understanding sexuality during aging, it was necessary to show that menopause and not age was the significant variable. Conducting research in Sweden, Hallström (1979) demonstrated this with a large sample of 800 women ages either 38, 46, 50, or 54. By grouping the 50-year-old women on the basis of pre-, peri-, early post-, and late postmenopausal phase, he was able to show significant decreases in sexual interest (see Fig. 54.1), capacity for orgasm, and coital frequency with advancing menopausal status while holding age constant. These data clearly implicate menopause rather than age as the dominant causal variable.

A. Menopause and Sex Hormones

Women have as many as 400,000 ovarian follicles at birth of which 400 will actually produce eggs (Richardson and Nelson, 1990). "Menopause" refers to the last menstrual cycle and is preceded by a period of 2 to 8 years with an average of 4 years commonly referred to as the menopausal transition period (McKinlay *et al*., 1992). This period typically begins in the early to mid 40s when the number of the remaining follicles drops below a certain threshold level (Soules *et al*., 1998). This situation results in an increase in gonadotropin levels

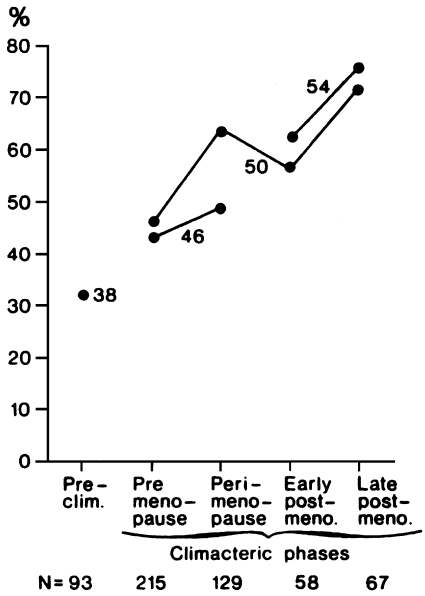

FIG. 54.1. Incidence of declining sexual interest by age and menopausal phase. (From Hallström, 1979 with permission of Combridge University Press.)

and an increase in the number of follicles recruited which then gives rise to higher estrogen levels (Santoro *et al*., 1996). Change in menstrual cycling during the transition proceeds from shorter regular cycles to irregular cycles or cycles of different lengths to skipping cycles to cessation of cycling (Treloar, 1981). Menopause occurs at the average age of 51 or 52 when the supply of ovarian follicles is depleted and follicles that remain are insensitive to stimulation (Costoff and Mahesh, 1975). Once menstrual cycling has stopped, production of sex hormones drops approximately 85% for estradiol (E2), 58% for estrone (E1), 67% for androstenedione, and only 29% for T (Longcope *et al*., 1981). There is little to no circulating progesterone. Significant production of E2 by the postmenopausal overies has ceased by one year past the last cycle (Vermeulen, 1980; Metcalf *et al*., 1982), although theca-like cells in the stromal tissues of the postmenopausal ovary produce significant amounts of testosterone in response to LH in at least 50% of women (Judd *et al*., 1974; Andreyko *et al*., 1992; Stevens and Lowe, 1992). Consistent with these findings, Sluijmer *et al*. (1998) have reported that the amount of stromal hyperplasia in the ovary was positively correlated with ovarian vein levels of androstenedione and testosterone in postmenopausal women.

The adrenal cortex is a second source of sex hormones in women. Androgens produced by the adrenal cortex peak in women between the ages of 16 and 19 and decline steadily thereafter, reaching a low point around the time of menopause or a few years following it (Orentreich *et al*., 1984). After the last cycle, adrenal dihydroepiandrosterone (DHA) continues to be a source of androstenedione and E1 as well as small amounts of testosterone and E2 through aromatization.

Women who have had their ovaries removed will obviously have no postmenopausal hormone production by their ovaries and, in addition, the loss of the ovaries apparently results in a decrease in the production of adrenal androgens (Cumming *et al*., 1982). These sequelae will also tend to occur in women whose ovaries have been damaged by chemotherapeutic agents (Kaplan, 1992). Women who had their ovaries removed had significantly lower levels of androstenedione, testosterone, dihydrotestosterone, and DHA (Vermeulen, 1976). If one assumes a relationship between sex hormones and sexuality, ovariectomized women should experience larger deficits in their postmenopausal sexuality than intact women of the same age. This prediction is consistent with the findings of Sherwin and her colleagues (Sherwin *et al*., 1985; Sherwin and Gelfand, 1987) and others (Lindgren *et al*., 1993).

B. Sexuality and Sex Hormones

Clearly, if the menopause plays a significant role in a decline in female sexuality during aging, then such a decline must be related directly or indirectly to the decrease in hormone production associated with menopause. An understanding of the relationship between menopause and female sexuality requires an understanding of the role that sex hormones play in female sexuality. Unfortunately our understanding in this area is incomplete.

1. Estrogens

The reproductive organs, the breast, and the vagina, vulva, urethra, and neck of the bladder have many estrogen receptors and are supported by estrogens (Smith and Judd, 1994). Over time following menopause and the drop in sex hormone production, low estrogen levels cause atrophic changes to take place in these structures. Masters and Johnson (1966) have provided a detailed account of the physical changes in sexual response. Through direct observation they were able to compare the sexual response of their sample of 348 women ages 18 to 50 with their sample of 34 women ranging in age from 51 to 78. After age 51 they found a marked reduction of the vasocongestion reactive potential of the breasts. Engorgement of the areolae occurred but typically with diminished intensity. Myotonia or general muscle-tension elevation in response to sexual stimulation was lessened and sex flush was rare. Clitoral response continued unchanged, but in women over 60, obvious tumescence of the clitoral glans was also rare. The flattening, separation, and elevation of the labia majora and the vasocongestive thickening of the labia minora that normally develop with increased sexual tension during the sexual response cycle in younger women were not observed. The walls of the vagina were described as tissue paper thin, light pinkish in color, and had lost their usual rough, corrugated appearance. The vagina was shorter in length, width, and some of its expansive ability was lost. Women over 60 took 1 to 3 minutes to develop significant vaginal lubrication compared to 10 to 30 sec in young women. Masters and Johnson (1966) concluded:

> Generally, the intensity of physiologic reaction and duration of anatomic response to effective sexual stimulation are reduced through all 4 phases of the sexual cycle with the advancing years. . .steroid starvation has the primary influence of reducing rapidity and intensity of physiologic response. (p. 238)

Thus, following menopause the decline in sex hormone production particularly that of estrogens appears to attenuate sexual ''receptivity'' or women's ability if not willingness to respond to sexual stimulation.

Estrogens are probably also involved in female attractivity or sexual attractiveness. In studies with nonhuman primates, females with the highest E2 peaks during the cycle were the most attractive to males during the entire cycle (McCoy, 1991). Female pheromones may be associated with ovulatory menstrual cycles and play a significant role in women's sexual attractiveness, but we still know comparatively little about this (Cutler, 1999).

2. Androgens

It is generally accepted that androgens are the hormone of sexual desire in both men and women (Sherwin, 1988). Nonetheless it has been difficult to demonstrate this relationship in naturally cycling women (Campbell and Udry, 1994). The best evidence we have for this relationship has been a prospective crossover study of women who underwent total hysterectomy with bilateral salpingo-oophorectomy (Sherwin *et al*., 1985). Women's sexual desire, frequency of sexual fantasies, and arousal increased significantly over preoperative baselines when women received androgens alone or androgen with estrogen following their surgery. This was not the case for women receiving estrogen alone or placebo who had significantly lower scores on all three measures than they had prior to surgery.

In a study of intact cycling women, Persky *et al*. (1978) studied 11 couples intensively over three menstrual cycles. Women gave blood for sex hormone assays twice a week, and each day completed a six-item self-gratification scale with questions concerning the extent of daily sexual arousal and activity. These researchers found significant correlations between average testosterone and average daily self-gratification scores for each of the three cycles (r_s=0.54, 0.63, 0.66). Thus, average testosterone does appear to be related to reported levels of sexual arousal and activity.

We might assume that average testosterone would be related to frequency of sexual intercourse, but that does not seem to be the case. Interestingly, Persky and his colleagues (1976, 1978) have reported that sexual frequency per cycle was related to women's peak testosterone level around midcycle, a finding that was replicated by Morris and her colleagues in 1987. Such puzzling findings suggest that peak testosterone level may be serving as a marker for the quality of that menstrual cycle as a whole.

3. Progestagens

Progesterone is the major progestagen and is produced in significant amounts during the luteal phase of the menstrual cycle and during pregnancy. Progesterone is an anti-androgen because it competes with androgens for androgen receptors and an anti-estrogen because it downregulates estrogen receptors (Johnson and Everitt, 1995). In a study of oral contraceptive users, the findings of Udry and his colleagues (1973) suggested the possibility that progesterone made women less sexually attractive to men. Progesterone does not play a significant role in the sexuality of naturally postmenopausal women, but its effects become relevant when it is used continuously as part of hormone replacement therapy.

C. Menopause and Sexuality

Studies concerned with the menopause are many, but studies concerning the effects of menopause on sexuality are comparatively few. In order for a study to implicate the menopause as playing a role in changes in sexual behavior, it is necessary to have data at a minimum of two different points during the menopausal transition. Many studies have done this through the less than satisfactory practice of using retrospective data. In studies of menopause and sexuality, sexual information has usually been obtained using questionnaires or interviews; daily recording of sexual activity on calenders was used by only one group of investigators (McCoy and Davidson, 1985; McCoy *et al*., 1985). Sexual variables that have been studied the most are sexual interest, vaginal dryness, and frequency of sexual intercourse. Fewer studies have examined vaginal discomfort (dyspareunia), capacity for orgasm, and satisfaction with the sex partner or relationship.

A description of 16 studies that have examined sexual variables at a minimum of two points during the menopausal transition is presented in Table 54.2. Although these studies have certainly suffered from methodological problems (McCoy, 1998), their findings are consistent. Ten of 11 studies found a decline in sexual interest from an earlier to a later point in the menopausal transition. Eight of eight found a decline in frequency of sexual intercourse, and six of six an increase in vaginal dryness. Three of five studies found some decline in orgasmic capacity, two of three an increase in pain or discomfort with sexual intercourse, and one of two found less satisfaction with the sexual partner.

In the only longitudinal study from pre- to postmenopause with daily recording of cycling and sexual behavior (McCoy and Davidson, 1985), frequency of sexual behavior dropped significantly in relationship to the last menstrual period (see Fig. 54.2). However, there was already a considerable decline 1 year prior to the last cycle. Using one cycle per month as a standard, reasearchers found that during the 12 to 24 month period prior to the last cycle, women were cycling an average of 80% of the time. During the year prior to the last cycle they were cycling an average of only half the time which may be related to this decline in frequency of sexual intercourse.

III. Research on Hormone Replacement Therapy and Sexuality

The fact that cessation of cycling results in decreases in sex hormone production and is associated with a decline in sexual interest, vaginal lubrication, and frequency of sexual intercourse suggests the possibility that hormone replacement therapy will effectively treat sexual complaints related to menopause. What evidence do we have on this issue? As was true for studies concerning menopause, there are many studies concerning hormone replacement therapy but only relatively few that have examined the effects of hormone replacement therapy on sexuality and fewer still that were placebo-controlled. Table 54.3 contains the results of 12 placebo-controlled studies of hormone replacement therapy that examined its effect on various aspects of sexuality.

In considering the effects of hormone replacement therapy on sexuality, it is important to understand that sex hormones in hormone replacement therapy products can be structurally the same or differ from those found naturally in the human female and that the way in which the hormones are delivered can vary from oral to transdermal to percutaneous to implant. Both the structure of the hormone and the mode of delivery can make a difference in the hormone's effects on the individual. Both oral delivery and nonhuman structure can contribute to an overproduction of a variety of proteins produced by the liver (L'Hermite, 1990; Lorrain *et al*., 1999). This effect on liver proteins is referred to as a first-pass effect and does not occur when nonoral modes of delivery are used. One of these liver proteins that is overproduced is sex hormone-binding globulin, which preferentially binds testosterone (Johnson and Everitt, 1995). Thus, Mathur and his colleagues (1985) have reported that oral use of conjugated equine estrogens results in a significant decline in bioavailable testosterone.

A. Vaginal Dryness, Atrophy, and Pain with Coitus

Five placebo-controlled studies examined vaginal dryness and found a significant decrease using a variety of estrogen products (see Table 54.3). Three other studies examined vaginal smears, measured change in atrophic vaginitis, or asked about inadequate lubrication. While atrophic vaginitis and

vaginal smears improved with hormone replacement therapy. Myers *et al.*, (1990) found no change in reported inadequate lubrication with naturally menopausal women. One study (Coope *et al.*, 1975) used a combination of an oral, structurally nonhuman estrogen and progestagen and obtained no change in dryness. The failure of this study to find a significant change in vaginal dryness may be due to the anti-estrogenic properties of progestagens.

Of six studies examining pain with sexual intercourse, only Coope *et al.* (1975) reported any positive change and in only 6 of 30 women subjects. The failure to find significant change probably has to do with the relatively short length of these studies. Semmens and his colleagues (1985) did a 2-year study of 23 postmenopausal women (ages 51–70), giving women conjugated equine estrogen and using direct observation of vaginal fluid, vaginal pH, vaginal blood flow, and transvaginal potential difference. There was significant improvement in these variables at 1 month, with the exception of transvaginal potential difference, which showed significant improvement by 6 months. Both vaginal blood flow and transvaginal potential difference showed further significant increases at 12 months and vaginal blood flow continued to increase. Thus, this work suggests that estrogens appear to correct vaginal atrophy serious enough to cause pain, but more than 3 to 6 months time may be required before women report significant improvement.

B. Sexual Interest

Table 54.3 describes 12 placebo-controlled studies that have examined hormone replacement therapy in relationship to sexuality. Eight of these placebo-controlled studies have involved surgically menopausal women, but only three studies have investigated the effects of androgens on sexual interest. Using methyl testosterone, an oral, structurally nonhuman androgen, Greenblatt and his colleagues (1950) found a 42% increase in sexual interest for a mixed group of ovariectomized and naturally menopausal women. Using an injection of testosterone enanthate alone or combined with estradiol, Sherwin *et al.* (1985) reported a significant increase over placebo in sexual interest, sexual arousal, and sexual fantasy in ovariectomized, hysterectomized women. Using the same dose of methyl testosterone as Greenblatt *et al.* (1950) combined with conjugated equine estrogen, Myers *et al.* (1990) found no effect of the combination on sexual interest in a group of nine naturally and one surgically menopausal women compared with 10 naturally menopausal women using a placebo. The only significant finding for sexuality in this study was that the group getting methyl testosterone and conjugated equine estrogen reported significantly more pleasure in masturbation than women given a placebo. Because the assay used in this study was not sensitive to methyl testosterone the assay for testosterone revealed that giving methyl testosterone to these women had significantly lowered the endogenous production of testosterone compared with baseline levels.

Bakke (1965) gave 27 hysterectomized women a birth control pill containing the usual oral, structurally nonhuman

CA, cancer; hyx, hysterectomy; M, mean age; ovx, ovariectomy.

estrogen and a progestin and found that 22% of women reported increased sexual interest. Paterson (1982) used a sequential oral contraceptive type product with hysterectomized and ovariectomized, hysterectomized women and found no change in sexual interest. Dennerstein *et al*. (1980) used an oral contraceptive and found a significant increase over placebo in sexual interest in surgically menopausal women receiving a high dose of unopposed ethinyl estradiol. This very strong, structurally nonhuman estradiol commonly found in oral contraceptives is no longer used in hormone replacement therapy with postmenopausal women.

Interestingly, in a small group of naturally menopausal women, Fedor-Freybergh (1977) found a change from absence of sexual interest to slight presence using an oral but structurally human estradiol. In the largest of the placebo-controlled studies of hormone replacement therapy, Nathorst-Böös *et al.* (1993) also examined the effects of estradiol on sexual interest in naturally menopausal women. Not surprisingly, he found a significant increase in sexual interest over placebo with a transdermal estradiol patch.

None of five studies examining the effects of conjugated equine estrogens on sexual interest in either naturally or surgically menopausal women has found any change. This is not surprising given the fact that conjugated equine estrogen derived from pregnant mares' urine causes overproduction of sex hormone-binding globulin which selectively binds androgens and, to some extent, estrogens as well (Geola *et al*., 1980; Myers *et al*., 1990).

While the 12 studies in Table 54.3 are difficult to compare given their many differences, nonetheless these data suggest some tentative conclusions: (1) To improve sexual interest, fantasy, and arousal in surgically menopausal women, it is necessary to include testosterone in hormone replacement therapy. (2) If testosterone is administered to naturally menopausal women you may depress their own production of testosterone. (3) Naturally menopausal women may show an increase in sexual interest in response to estrogens if they are structurally human and administered transdermally; oral conjugated equine estrogen lowers bioavailable testosterone, is not effective in increasing sexual interest, and may decrease it.

C. Frequency of Sexual Intercourse

All eight studies in Table 54.2 that examined frequency of sexual intercourse found a decrease from early to later in the menopausal transition, but none of the four studies in Table 54.3 found that hormone replacement therapy increased the frequency of sexual intercourse or activity. Either frequency of sexual intercourse is very difficult to change with replacement hormones or future studies must follow subjects for considerably longer than 3 to 6 months in order to see a positive effect.

IV. Summary and Conclusions

Female sexuality is best conceptualized as having the three components of sexual attractiveness, interest, and responsiveness. Previous research makes it clear that female sexual interest and activity decline both with age and in relationship to the menopause. In one sense menopause and age are confounded because the number of years since menopause reflects both increasing age and increasing years with decreased hormone levels both centrally and peripherally. One effect occurring over time is atrophy of reproductive structures. Such atrophy due to hormone deficiency has the effect of increasing the time it takes to respond and reducing the intensity of the response to adequate sexual stimulation.

Research focusing on change with age has identified marital status, regular sexual activity, past sexuality, physical and mental health, and religious devoutness as important variables in relationship to sexual interest and activity. Thus, a married, mentally and physically healthy woman who has been sexually interested and active in the past, who has regular sexual activity with her functioning partner, and is not very religious, is more likely to maintain sexual activity with advancing age.

Studies concerned with the effects of menopause on sexuality have found rather consistent declines in sexual interest, vaginal lubrication, and frequency of sexual intercourse with mixed findings and fewer studies for orgasmic capacity and satisfaction with the partner. No good evidence exists on the effect of menopause on sexual attractiveness, but the obvious hypothesis is that the effect is a negative one.

Placebo-controlled studies of hormone replacement therapy and sexuality show a consistent positive effect of estrogen products on vaginal dryness and vaginal atrophy. Such studies also support the need for androgen replacement in surgically menopausal women in order to restore sexual interest and arousal. Our understanding of feminine sexual interest in naturally postmenopausal women is still incomplete. It is a reasonable conclusion that estrogen as well as androgens play major roles. A better understanding of sexual attractiveness or ''sexiness'' in cycling women, including the role of pheromones, would undoubtedly shed further light on this issue.

Hypothalamic Neuropeptide Gene Expression in Postmenopausal Women

I. Introduction

Menopause marks the cessation of function in a dynamic physiological system regulating the cyclic release of pituitary and gonadal hormones. Menopause, with a mean onset age of 51, occurs relatively early in a woman's life span. Thus, the average woman will spend approximately one-third of her life in the postmenopausal phase. At the time of the last menstrual cycle, the profound loss of ovarian cyclicity stands in sharp contrast to the continued functioning of all the other organ systems. In addition, there are millions of young women who experience premature ovarian failure or surgical removal of the ovaries. Many of these women are offered hormone replacement therapy, yet there is little information on the effects of hormone withdrawal and replacement on the human brain.

The loss of ovarian estrogen secretion has been linked to many of the symptoms of menopause including vasomotor flushes (hot flashes), mood changes and an increased risk for osteoporosis and cardiovascular disease (Gambrell, 1986; Speroff, 1993). Interestingly, outcomes such as osteoporosis and cardiovascular disease seem to represent accelerated aging changes, suggesting an interaction between gonadal steroids and somatic aging. In contrast, hot flashes and mood changes likely represent direct effects of hormone withdrawal on central nervous system mechanisms regulating body temperature and mood (Casper and Yen, 1985; Fink *et al*., 1998). Treatment with exogenous ovarian hormones is now standard practice in the management of the symptoms and risk factors associated with estrogen deficiency. Hormone replacement therapy eliminates hot flashes in postmenopausal women while reducing the risk of age- and hormone-related degenerative conditions. Furthermore, hormone replacement therapy enhances mood and improves some aspects of cognitive function in estrogen-deficient women (Sherwin, 1991, 1996). Finally, some evidence suggests that hormone replacement therapy might delay the onset of and/or ameliorate symptoms in Alzheimer's disease (Paganini-Hill, 1996; Henderson, 1997). These findings have stimulated interest in identifying the sites and mechanisms of steroid hormone action in the primate central nervous system.

The hypothalamus is a regulator as well as a major target of gonadal steroid hormones. Clearly, many of the targets of estrogen in the hypothalamus are involved in the regulation of reproduction. However, it is likely that hypothalamic neurons also mediate the effects of gonadal hormones on other parts of the nervous system. Estrogen withdrawal-induced vasomotor flushes, for example, reflect activation of the autonomic nervous system secondary to disrupted hypothalamic thermoregulatory mechanisms. In addition, ovarian steroid receptors in the hypothalamus could mediate hormonal effects on mood through connections with the limbic system (Sherwin, 1996), or via descending input to the midbrain and interactions with the mesolimbic dopamine system (Nauta and Haymaker, 1969; Spanagel *et al*., 1992). Two subtypes of estrogen receptors (ERs) have now been identified, ERα (Greene *et al*., 1986) and ERβ (Kuiper *et al*., 1996). In addition to actions via the classical intranuclear receptors, steroid hormones may have direct membrane effects (Nabekura *et al*., 1986).

II. Control of the Reproductive Cycle through Reciprocal Interactions between Ovarian Secretions, Pituitary Gonadotrophs, and the GnRH Pulse Generator in the Medial Basal Hypothalamus

The reproductive axis is a dynamic, highly regulated control system with the timing of the menstrual cycle relying upon reciprocal interactions among the ovary, pituitary, and brain. Gonadotropin-releasing hormone (GnRH) is synthesized by neurons in the hypothalamus and released into the hypophyseal portal circulation. GnRH is transported to the anterior pituitary gland where it stimulates the production and release of the gonadotropins, luteinizing hormone (LH), and follicle-stimulating hormone (FSH). LH and FSH reach the ovary via the systemic circulation and regulate folliculogenesis, ovulation, and the secretion of steroid and protein hormones. Two types

of ovarian secretions control gonadotropin secretion: ovarian steroids such as estrogen and progesterone, and the glycoprotein hormones including inhibin and activin. Inhibin is a secretory product of both the male and the female gonads that is capable of suppressing FSH secretion directly at the level of the pituitary gland (Burger, 1989).

Normal reproductive function relies on the pulsatile release of GnRH into the hypophyseal portal circulation. The frequency and amplitude of GnRH pulses vary over the menstrual cycle and these patterns have physiological significance. Constant exposure to GnRH or its analogs, for example, desensitizes the pituitary, resulting in little or no LH secretion and a hypogonadal state (Belchetz *et al*., 1978; Nakai *et al*., 1978). Furthermore, alterations in the pulsatile pattern of LH secretion may have deleterious effects upon ovarian follicle development (Pohl *et al*., 1983). The neural circuits subserving pulsatile GnRH secretion in the primate are located within the medial basal hypothalamus (Knobil, 1990). Destruction of the MBH, for example, results in the cessation of LH and FSH secretion (Plant *et al*., 1978). Gonadotropin secretion is stimulated in these animals, however, by the administration of exogenous GnRH, indicating intact pituitary function (Nakai *et al*., 1978). Interestingly, complete removal of all afferent input to the medial basal hypothalamus does not interfere with the negative feedback effects of estrogen on LH secretion (Krey *et al*., 1975). In fact, many animals subjected to this treatment display relatively normal reproductive function, including normal pulsatile LH secretion and spontaneous ovulation (Krey *et al*., 1975). These findings suggest that the neural substrate responsible for the rhythmic release of GnRH (the hypothetical ''GnRH pulse generator'') resides within the medial basal hypothalamus.

Electrophysiological correlates of the GnRH pulse generator have been demonstrated in the medial basal hypothalamus (Knobil, 1990). There is synchronized, multiunit activity in the medial basal hypothalamus that is coincident with pulses of LH in the peripheral circulation (Silverman *et al*., 1986). These multiunit volleys are affected by many of the variables that alter pulsatile LH secretion. The frequency of synchronized multiunit activity varies, for example, over the menstrual cycle (O'Byrne and Knobil, 1993). In addition, removal of the ovaries leads to a greatly prolonged duration and an increase in the maximal frequency of synchronized neuronal activity in the medial basal hypothalamus, an effect rapidly reversed by estrogen replacement (O'Byrne *et al*., 1993). The neurochemical identity of hypothalamic neurons that contribute to the multiunit activity of the GnRH-pulse generator has not been established. Part of the activity may originate within the intrinsic rhythmic activity of the GnRH neurons (Wetsel *et al*., 1992), but contributions by other neuronal populations seems highly likely.

The timing of the menstrual cycle is critically dependent upon the pattern of estrogen secretion from the dominant ovarian follicle. Throughout most of the menstrual cycle, estrogen restrains the level of LH secretion from the anterior pituitary gland (negative feedback). At mid-cycle, however, rapidly increasing estrogen levels result in a surge of LH (positive feedback), culminating in ovulation of the dominant follicle. The feedback effects of estrogen on LH secretion are complex and occur at the level of both the pituitary and the hypothalamus (Ferin *et al*., 1984). GnRH neurons do not express estrogen receptors (Shivers *et al*., 1983). Steroid receptors, however, are present in many other hypothalamic neurons that express a variety of neurotransmitters or neuropeptides. Thus, estrogen may modify GnRH secretion through genomic effects via one or more interneurons that synapse on GnRH neurons (Herbison, 1998). The intricate interplay of transmitter systems allows for modification of the function of the reproductive axis in response to various physiological and pathological states.

III. The Perimenopausal Period Is Characterized by an Accelerated Loss of Ovarian Follicles and a Selective Rise in FSH Secretion

Ultimately, menopause is a consequence of ovarian failure. The human ovary contains a finite number of germ cells *in utero*. In the first four decades after birth, there is a exponential decline of primordial follicles (Block, 1952). At approximately 38 years of age, follicular loss accelerates (Richardson *et al*., 1987). Menopause finally occurs when insufficient follicles are available to maintain ovarian hormone secretion. The cause of follicular decline, especially the accelerated phase, remains to be elucidated.

Alterations in gonadotropin secretion occur prior to menopause. One of the earliest and most consistent changes in hormone secretion in the perimenopausal period is a selective increase in plasma FSH (the monotropic FSH rise) (Reyes *et al*., 1977; Ebbiary *et al*., 1994). This rise in FSH secretion has been postulated to be responsible for the accelerated follicular decline by promoting increased numbers of follicles into the growing pool (Nelson *et al*., 1995). Once in the growing pool, follicles must either ovulate or become atretic. Whether the early, monotropic FSH rise is due to ovarian or hypothalamic factors is a current subject of investigation and controversy (Nelson *et al*., 1995; Wise *et al*., 1997; Soules *et al*., 1998). In favor of the ovarian hypothesis is the recent demonstration that elevated FSH secretion in older premenopausal women is correlated with a significant decrease in inhibin B in peripheral blood (Klein *et al*., 1996). These data suggest that the lifelong decline in follicles ultimately reaches a threshold, resulting in decreased ovarian inhibin secretion and, as a result, increased FSH secretion (Soules *et al*., 1998).

Alternatively, studies in experimental animals have demonstrated that hypothalamic mechanisms may produce a selective rise in FSH secretion. In particular, slowing of the GnRH pulse frequency results in an elevation in FSH secretion without increasing LH secretion (Wise *et al*., 1979; Wildt *et al*., 1981). In support of this theory is a recent study showing a reduction in LH pulse frequency (a reflection of GnRH pulse frequency) in older vs younger premenopausal women (Matt *et al*., 1998). Ovarian function is also directly sensitive to alterations in the patterns of pulsatile gonadotropin secretion (Pohl *et al*., 1983), thereby providing a second explanation for how hypothalamic factors could promote ovarian failure (Finch *et al*., 1984). Unlike the ovary, however, the human

hypothalamus and pituitary are still capable of functioning in postmenopausal women, as evidenced by the ability of exogenous ovarian hormones to stimulate an LH surge (Odell and Swerdloff, 1968).

IV. The Postmenopausal State Is Characterized by Profound Estrogen Deficiency and Gonadotropin Hypersecretion

Regardless of the cause, the hormonal milieu of postmenopausal women is characterized by a profound estrogen deficiency. The loss of ovarian follicles results in levels of estrogen and progesterone that are comparable to the levels in women who have undergone therapeutic oophorectomy (Wallach *et al*., 1970; Monroe *et al*., 1972; Chakravarti *et al*., 1977). Hypersecretion of pituitary gonadotropins occurs secondary to the loss of ovarian hormones, and continues for decades. Indeed, the mean gonadotropin concentration, LH pulse frequency, and pulse amplitude are not significantly different between young oophorectomized and older postmenopausal women (Alexander *et al*., 1990). In advanced age, the levels of LH and FSH may become attenuated (Rossmanith *et al*., 1991). Alternatively, the hypersecretion of gonadotropins may continue undiminished in some women at 90–100 years of age (Scaglia *et al*., 1976).

Determining the precise mechanism for gonadotropin hypersecretion in the postmenopausal period has been hampered by the difficulty of measuring alterations in hypothalamic GnRH secretion (Crowley *et al*., 1985). Clearly, the invasive techniques employed to investigate hypothalamic reproductive control mechanisms in laboratory animals cannot be used in human subjects. GnRH is not detectable in the peripheral circulation due to a short half-life and the relative confinement of the peptide to the hypophyseal portal circulation. Studies in humans, therefore, have relied heavily on pharmacological manipulations, using agonists and antagonists of neurotransmitters and neuropeptides that are putatively involved in the regulation of GnRH secretion. Following the administration of these agents, pulsatile LH release is measured in the peripheral circulation. Because pulses of LH in peripheral plasma are linked to pulsatile secretion of GnRH into the portal system (Clarke and Cummins, 1982), alterations in hypothalamic GnRH secretion are inferred from changes in peripheral LH pulses. However, a change in the amplitude of LH secretion may reflect alterations at either the hypothalamic or pituitary level. Furthermore, if pituitary sensitivity is altered, a pulse of GnRH may not always translate into a pulse of LH. Thus, although much has been learned using this indirect approach, uncertainty as to the sites and mechanisms of actions of various pharmacological agents limits the conclusions that can be made about the role of central neuropeptides and neurotransmitters in human reproduction.

A recent approach to studying hypothalamic regulatory mechanisms in the human is to quantify relative levels of messenger RNAs (mRNAs). The technique of *in situ* hybridization histochemistry is particularly well suited for the investigation of human autopsy material due to the relative stability of mRNA species with prolonged postmortem intervals (Johnson *et al*., 1986). In addition, alterations in gene expression have been correlated with changes in neuronal activity (Comb *et al*., 1987; Young and Zoeller, 1987; Blum *et al*., 1987; Uhl and Nishimori, 1990; Petersen *et al*., 1991). Therefore, a change in neuropeptide gene expression may provide an indirect assessment of neuronal activity in the postmortem human brain. A further level of anatomical resolution is provided by the localization of mRNA species within tissue sections.

V. Anatomy of GnRH Neurons in the Primate Hypothalamus and Basal Forebrain

During prenatal development, GnRH neurons originate outside the brain in the olfactory placode and then migrate along the terminal nerve to enter the forebrain (Schwanzel-Fukuda and Pfaff, 1989; Wray *et al*., 1989; Schwanzel-Fukuda *et al*., 1996). Two waves of GnRH neurons migrate from the olfactory placode at different times in embryogenesis in monkeys (Quanbeck *et al*., 1997). In adult monkeys, GnRH neurons are diffusely distributed (Barry *et al*., 1985). One subpopulation of GnRH neurons resides within the medial basal hypothalamus (Silverman *et al*., 1982; Goldsmith and Song, 1987), in the region of the GnRH pulse generator (Silverman *et al*., 1986). These neurons project to the median eminence where the peptide is released in the primary capillary plexus of the portal system (Silverman *et al*., 1977,1982; Goldsmith and Song, 1987). Extrahypothalamic GnRH projections have also been identified. For example, GnRH neurons send projections to the midbrain, amygdala, hippocampus, and olfactory structures (Barry *et al*., 1985). These pathways suggest that GnRH may function in the brain as a neuromodulator as well as a hypophysiotropic hormone. Indeed, GnRH has been shown to promote sexual behavior, including lordosis, in female rodents (Moss and McCann, 1973; Pfaff, 1973).

In the human brain, *in situ* hybridization studies have identified a diffuse distribution of GnRH neurons with three morphological subtypes (Rance *et al*., 1994). A group of small oval neurons with high levels of gene expression (type I) were present within the medial basal hypothalamus, the putative control center for reproduction in the primate (Fig. 55.1A). A second population of small, round to oval, lightly labeled GnRH neurons (type II) were identified within the septal-preoptic region, the bed nucleus of the stria terminalis–amygdala continuum, and the ventral globus pallidus (Fig. 55.1B). Finally, a third population of large, round GnRH neurons, intermediate in labeling intensity (type III), were located in the magnocellular basal forebrain complex, ventral globus pallidus, and putamen (Fig. 55.1C). The presence of these subpopulations of GnRH neurons in the primate central nervous system has recently been confirmed using immunocytochemical methods (Quanbeck *et al*., 1997). Interestingly, the type II and type III neurons migrate from the olfactory placode earlier in embryogenesis than the type I GnRH neurons. The limited immunoreactivity of the type II and type III neurons to most GnRH antisera (Quanbeck *et al*., 1997) explains the failure of the previous

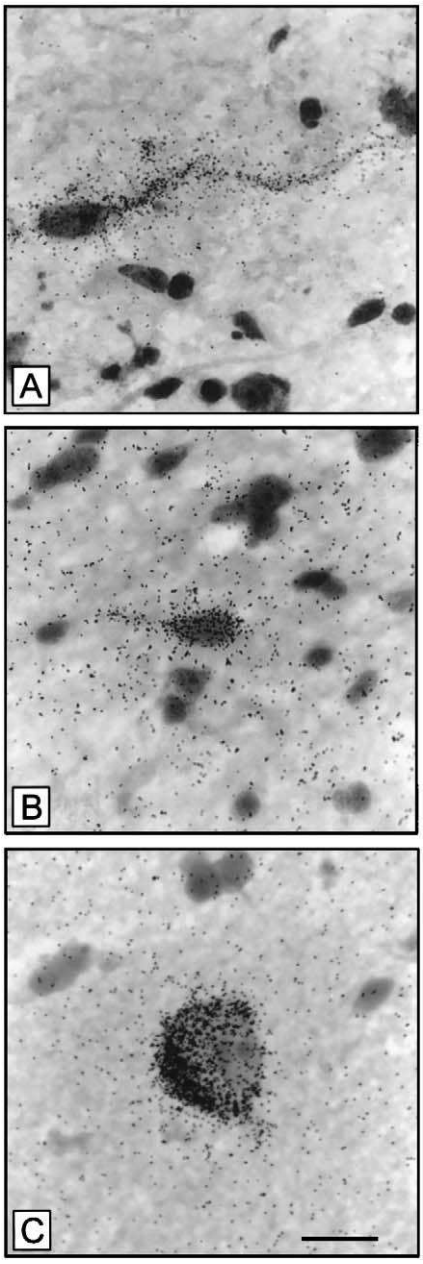

FIG. 55.1. Photomicrographs of three subtypes of neurons expressing GnRH mRNA in the human hypothalamus and basal forebrain. The silver grains mark the location of mRNA and the sections are counterstained with toluidine blue. (A) Small, elongated type I neuron in the medial basal hypothalamus. (B) Small, oval type II neuron in the septal-preoptic region. (C) Large, type III GnRH neuron in the putamen. The section in (A) was developed after 1 week exposure, compared to 3 months exposure for (B) and (C). The cell bodies of the type I neurons after 3 months of exposure are completely obscured because of the intense labeling. (Modified with permission from Rance *et al*., 1994), © Wiley-Liss, Inc., a subsidiary of John Wiley and Sons, Inc.)

immunohistochemical studies to identify these neurons in the human brain (Stopa *et al*., 1991). The location of these neurons in many extrahypothalamic regions implies that the function of GnRH neurons is not limited to reproductive processes.

VI. Gene Expression Is Increased in a Subpopulation of GnRH Neurons in the Medial Basal Hypothalamus of Postmenopausal Women

The presence of morphological subgroups of GnRH neurons suggests that different functional subpopulations of GnRH neurons exist within the human brain. Additional support for this hypothesis was obtained in a study comparing GnRH gene expression in pre- and postmenopausal women (Rance and Uswandi, 1996). In particular, the gene expression of the heavily labeled type I neurons increased in the medial basal hypothalamus of postmenopausal women (Fig. 55.2). In contrast, there was no change in gene expression in small, lightly-labeled subpopulation of type II GnRH neurons in the septal-preoptic area (Fig. 55.2). Thus, gene expression is regulated differentially among the two morphological subtypes of GnRH neurons in the human hypothalamus. More importantly, this study provided the first demonstration of an increase in GnRH gene expression in the postmenopausal human hypothalamus. Based on animal studies (Sagrillo *et al*., 1996; Herbison, 1998) we proposed that the increase in GnRH gene expression in postmenopausal women is secondary to estrogen withdrawal. This hypothesis is supported by a recent demonstration that estrogen replacement decreases GnRH gene

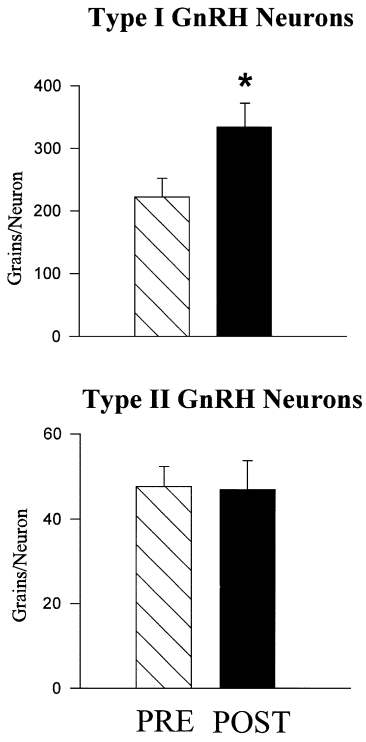

FIG. 55.2. Number of grains per neuron associated with type I (top) and type II (bottom) GnRH neurons in the hypothalamus of premenopausal and postmenopausal women. * $P<0.05$. GnRH gene expression is increased in the heavily labeled neurons (type I) in the medial basal hypothalamus but not the lightly labeled (type II) neurons in the septal-preoptic area. (Modified with permission from Rance and Uswandi, 1996, © The Endocrine Society.)

expression in the medial basal hypothalamus of ovariectomized monkeys (El Majdoubi *et al*., 1998).

The increase in GnRH gene expression in the medial basal hypothalamus of postmenopausal women provides evidence that increased GnRH secretion contributes to the elevated levels of circulating gonadotropins in these women. The hypothalamic content of the GnRH peptide, however, decreases in postmenopausal and oophorectomized young women (Parker and Porter, 1984). Although these data may appear contradictory, it is possible that the decline in peptide content reflects decreased storage of hormone due to increased release of GnRH peptide into the portal system. An analogous situation is the decrease in GnRH concentration in several discrete areas of rat hypothalamus during the proestrus surge of LH (Wise *et al*., 1981). Estrogen and inhibin withdrawal may also have direct effects on the anterior pituitary gland, contributing to the hypersecretion of gonadotropins in postmenopausal women. The loss of ovarian inhibin would directly increase FSH secretion from the anterior pituitary gland. In addition, the anterior pituitary gland in postmenopausal women is highly responsive to GnRH stimulation (Hanker *et al*., 1981). Finally, there are biochemical changes in the pituitary gland that may prolong the half-life of LH in peripheral blood (Sharpless *et al*., 1999).

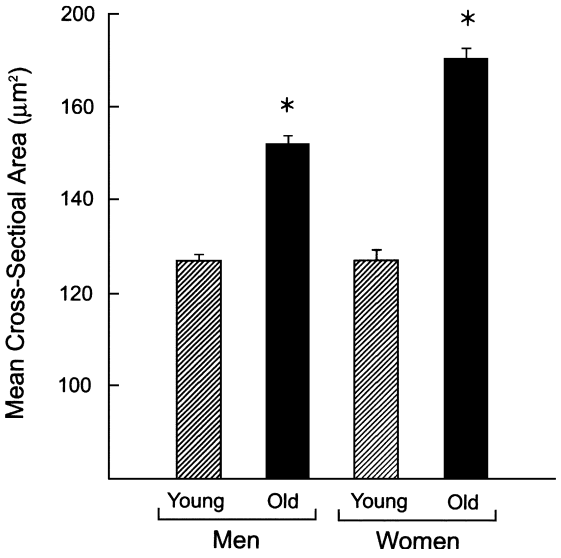

FIG. 55.3. Mean profile areas of neurons in the infundibular nucleus of men and women. * Significantly different from all other groups with $P<0.05$. (From Rance *et al*., 1993, with permission from Elsevier Science.)

VII. Postmenopausal Hypertrophy of Neurons Expressing Estrogen Receptor mRNA in the Human Infundibular Nucleus

More than 30 years ago, Sheehan and Kovacs (1966) described neuronal hypertrophy in the hypothalamus of postmenopausal women. Using semiquantitative methods, these investigators observed a pronounced enlargement of neurons in a subregion of the infundibular nucleus that they named the subventricular nucleus. The enlargement of these neurons was associated with morphologic features of hypertrophy including increased Nissl substance and enlarged nuclei and nucleoli. Based on similar findings in other hypogonadal conditions, the authors proposed that postmenopausal neuronal hypertrophy resulted from the complete loss of ovarian estrogen (Sheehan, 1967). The significance of these findings was not clear at the time, however, because relatively little was known about the role of the infundibular nucleus in reproductive regulation.

The observation of neuronal hypertrophy in the infundibular nucleus of postmenopausal women was subsequently confirmed using quantitative computer microscopy (Rance *et al*., 1990). These studies showed that the mean profile area of Nissl-stained neurons was increased by 30% in postmenopausal women. Neuronal hypertrophy also occurs in the infundibular nucleus of older men, but to a modest extent compared to that seen in postmenopausal women (Fig. 55.3) (Rance *et al*., 1993). These findings correlate well with the differences in gonadal function between the two groups. Gonadal steroids decline to castrate levels in older women (Baird and Guevara, 1969), compared to only a mild decrease in the circulating levels of testosterone in older men (Pirke and Doerr, 1970; Royer *et al*., 1984; Tenover *et al*., 1987).

The association of neuronal hypertrophy with estrogen withdrawal and gonadotropin hypersecretion in postmenopausal women suggests that the hypertrophied neurons participate in the hypothalamic circuitry regulating estrogen negative feedback. The identification of ERα mRNA within the hypertrophied neurons provided strong support for this hypothesis (Rance *et al*., 1990). Indeed, the presence of ER mRNA provides a selective marker for the subpopulation of hypertrophied infundibular neurons. The hypertrophied neurons, however, did not express GnRH mRNA (Rance *et al*., 1990). This finding was not surprising in light of previous studies showing that estrogen receptors are not present within GnRH neurons in the hypothalamus of laboratory rats (Shivers *et al*., 1983).

VIII. Hypertrophy and Increased Gene Expression of Neurons Expressing Substance P, Neurokinin B, and Estrogen Receptor mRNA in the Infundibular Nucleus of Postmenopausal Women

To determine the neuropeptide/neurotransmitter identity of the hypertrophied neurons, hypothalamic sections from postmenopausal women were screened with a panel of more than 10 oligonucleotide probes (Rance and Young, 1991). The oligonucleotide probes were targeted to peptides that have been shown to be present in the arcuate nucleus (the homolog of the primate infundibular nucleus) of laboratory rats or implicated in the hypothalamic control of reproduction. These studies revealed that the hypertrophied neurons expressed Substance P (SP) and neurokinin B (NKB) gene transcripts (Fig. 55.4). SP and NKB are both members of the tachykinin peptide family and share the same C-terminal sequence (Maggio, 1988). The SP, NKB, and ERα probes labeled a majority

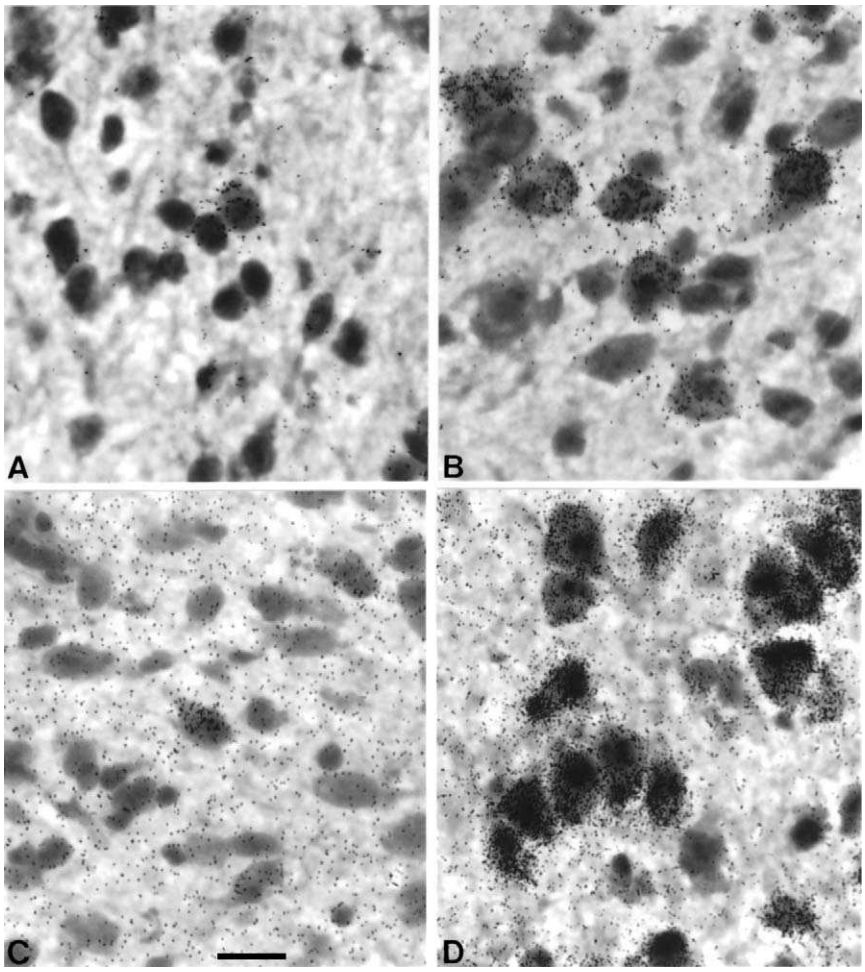

FIG. 55.4. Photomicrographs of neurons in the infundibular nucleus of a premenopausal (A,C) and a postmenopausal (B,D) woman labeled by *in situ* hybridization using probes complementary to substance P (A,B) or neurokinin B (C,D) mRNAs. The silver grains mark the location of the mRNAs and the sections are counterstained with toluidine blue. In postmenopausal women, Substance P and neurokinin B neurons are larger, more numerous, and display increased numbers of autoradiographic grains. (From Rance and Young, 1991, with permission. © The Endocrine Society.)

of hypertrophied neurons in adjacent sections, providing indirect evidence for the colocalization of these mRNAs (Rance and Young, 1991). Neurons expressing SP and NKB gene transcripts nearly doubled in mean profile area in the postmenopausal group and was accompanied by an increase in the number of autoradiographic grains per cell. The most prominent finding, however, was a marked increase in the number of neurons expressing both SP and NKB gene transcripts (Fig. 55.4). The dramatic increase in tachykinin gene expression in the hypertrophied neurons provided further evidence that the activity of these neurons increases in postmenopausal women.

The hypertrophy of ERα, SP, and NKB mRNA-containing neurons in postmenopausal women occurred in association with ovarian failure, estrogen withdrawal, increased hypothalamic GnRH gene expression, and gonadotropin hypersecretion. These findings suggest that the hypertrophied neurons participate in a hypothalamic circuit mediating estrogen negative feedback on LH release (Rance and Young, 1991). This hypothesis is further supported by animal studies suggesting a role for SP in the regulation of LH secretion. Tachykinin neurons in the rat arcuate nucleus contain receptors for gonadal steroids (Akesson and Micevych, 1988; Ciofi *et al*., 1994) and are modulated by ovarian steroids (Antonowicz *et al*., 1982; Tsuruo *et al*., 1984; Jarry *et al*., 1988; Brown *et al*., 1990; Akesson *et al*., 1991). In addition, tachykinin levels in the median eminence, as well as the number and size of arcuate tachykinin-immunoreactive neurons vary over the rat estrous cycle (Antonowicz *et al*., 1982; Tsuruo *et al*., 1984; Micevych *et al*., 1988). Furthermore, tachykinin immunoreactive neurons in the arcuate nucleus project to and synapse on LHRH neurons in the rat hypothalamus (Tsuruo *et al*., 1991).

Both inhibitory (Kerdelhué *et al*., 1997) and stimulatory (Arisawa *et al*., 1990) effects of SP on LH secretion have been described. The positive effects have been demonstrated by the stimulation of LH secretion into peripheral blood by intracerebroventricular injection of SP (Vijayan and McCann, 1979; Arisawa *et al*., 1990) and the inhibitory effect by injection of SP antiserum (Dees *et al*., 1985; Arisawa *et al*., 1990).

Moreover, intracerebroventricular injection of an SP antagonist inhibits LH secretion in castrated male rats (Dees *et al*., 1985). In an *in vitro* perfusion system, SP stimulates LH release from the rat hypothalamus and pituitary in a dose-dependent manner (Ohtsuka *et al*., 1987). More importantly, SP induces LHRH release from the isolated medial basal hypothalamus (Ohtsuka *et al*., 1987). These data suggest that the increased activity of the hypertrophied tachykinin neurons in postmenopausal women may contribute to the gonadotropin hypersecretion observed after the menopause. In contrast to the data on SP, virtually no information is available to ascertain if NKB plays a role in reproductive regulation.

IX. Long-Term Gonadectomy Results in Increased Neurokinin B Gene Expression in the Arcuate Nucleus of Both Male and Female Rats

The finding of ERα mRNA within the hypertrophied neurons in postmenopausal women provides strong support for the hypothesis that the changes in morphology and tachykinin gene expression are secondary to ovarian failure. The observations comparing pre- and postmenopausal women are confounded, however, by the presence of two variables, age and gonadal status. Although it would be of great interest to determine if ovariectomy of young women produces similar changes in the human hypothalamus, these tissues are not readily available. Therefore, the rat was used as a model to determine if withdrawal of gonadal steroids could produce alterations in neuronal morphology or tachykinin gene expression in the arcuate nucleus, the homolog of the human infundibular nucleus.

Studies of the rat arcuate nucleus provide convincing evidence that gonadal steroids modulate NKB gene expression. Long-term gonadectomy resulted in increased numbers of arcuate neurons expressing NKB gene transcripts in both males and females (Rance and Bruce, 1994; Danzer *et al*., 1999). No change in cell size was observed in female rats (Rance and Bruce, 1994). In male rats, however, the profile area of NKB neurons was increased by gonadectomy (Danzer *et al*., 1999). Furthermore, testosterone or estrogen replacement in orchidectomized male rats reduced NKB gene expression to levels observed in intact animals (Danzer *et al*., 1999). Finally, it has recently been shown that hormone replacement therapy dramatically decreases NKB gene expression in the ovariectomized long-tailed macaque monkey (described in section XII).

Interestingly, the changes in cell size after long-term gonadectomy of male rats are not confined to arcuate NKB neurons. Long-term orchidectomy also results in an increase in the mean somatic profile area of arcuate neuroendocrine neurons. These neurons are characterized by projections to the primary capillary plexus of the medium eminence. The increase in cell size after orchidectomy was accompanied by a significant growth in the dendritic tree and an increase in dendritic spines (Danzer *et al*., 1998). These data suggest that the withdrawal of gonadal steroids ultimately results in a substantial remodeling of hypothalamic neuronal circuits in the arcuate nucleus.

X. Opioid Peptides Provide an Inhibitory Influence on the Regulation of Gonadotropin Secretion in the Macaque Monkey

Endogenous opioids have an important role in the regulation of gonadotropin secretion in humans (Yen *et al*., 1985; Gindoff and Ferin, 1987; Howlett and Rees, 1987; Genazzani and Petraglia, 1989). Morphine, an opioid agonist, has a powerful inhibitory influence on LH secretion (Gindoff and Ferin, 1987). Conversely, naloxone, an opioid antagonist, increases both the frequency and amplitude of LH pulses in peripheral plasma (Ropert *et al*., 1981). Naloxone also stimulates GnRH release from an *in vitro* preparation of the human fetal hypothalamus (Rasmussen *et al*., 1983). Studies in nonhuman primates provide compelling evidence that the inhibitory effects of endogenous opioids occur at the level of the hypothalamus. Opioid antagonists increase the levels of GnRH secretion into the hypophyseal portal blood of monkeys (Pau *et al*., 1996). Furthermore, the GnRH pulse generator in the primate medial basal hypothalamus is inhibited by morphine, an effect that is blocked by naloxone (Kesner *et al*., 1986).

The efficacy of the opioid antagonists to induce LH secretion depends on the ovarian steroid milieu. In young women, naloxone stimulation of LH secretion is absent in the low-estrogen environment of the early follicular phase (Quigley and Yen, 1980) and following oophorectomy (Shoupe *et al*., 1985). Similarly, naloxone fails to increase LH secretion in estrogen-deficient postmenopausal women (Reid *et al*., 1983; Melis *et al*., 1984; Casper and Alapin-Rubillovitz, 1985; Dawood *et al*., 1986; Cagnacci *et al*., 1991). Hormone replacement therapy in oophorectomized or postmenopausal women reestablishes the LH response to naloxone (Melis *et al*., 1984; Casper and Alapin-Rubillovitz, 1985; Shoupe *et al*., 1985; Dawood *et al*., 1986; Cagnacci *et al*., 1991). These data suggest that the endogenous opioid inhibition of LH secretion (''opioid tone'') is reduced when estrogen levels are low.

There is considerable evidence that β-endorphin, one of the endogenous opioid peptides, participates in the control of reproduction in the primate. β-Endorphin neurons are located within the primate medial basal hypothalamus in the region of the GnRH pulse generator. β-Endorphin neurons synapse on GnRH neurons in the monkey hypothalamus (Thind and Goldsmith, 1988) and secretion of β-endorphin into the hypophyseal portal blood of macaque monkeys varies over the menstrual cycle (Wehrenberg *et al*., 1982). Furthermore, ovariectomy reduces the secretion of β-endorphin in portal blood, and this effect is reversed by estrogen replacement (Wardlaw *et al*., 1982b).

β-Endorphin neurons are also sensitive to the effects of aging, as demonstrated by the consistent age-associated decrease in the levels of β-endorphin peptide or precursor mRNA in the hypothalamus of both male and female rodents (Gambert *et al*., 1980; Barden *et al*., 1981; Forman *et al*., 1981; Missale *et al*., 1983; Rogers *et al*., 1985; Nelson *et al*., 1988; Lloyd *et al*., 1991; Gruenewald and Matsumoto, 1991). Therefore, both aging and changes in the levels of ovarian steroids have been linked to alterations in hypothalamic β-endorphin neurons in experimental animals.

XI. Menopause Is Associated with a Decline in the Number of Neurons Expressing Proopiomelanocortin mRNA in the Human Infundibular Nucleus

We recently showed that menopause is associated with a change in the hypothalamic expression of proopiomelanocortin mRNA, the precursor mRNA for β-endorphin. *In situ* hybridization and computer-assisted microscopy were used to investigate two anatomical sites, the infundibular nucleus and the retrochiasmatic area. In contrast to the elevation in tachykinin and GnRH gene expression in postmenopausal women, the number of infundibular neurons expressing proopiomelanocortin mRNA was reduced. This finding was region-specific, as no change was detected in the number of proopiomelanocortin neurons in the retrochiasmatic area (Fig. 55.5).

The decrease in proopiomelanocortin gene expression in postmenopausal women is consistent with the decreased ability of naloxone to elicit LH secretion in this group of women (Reid *et al*., 1983). Thus, a decline in the inhibitory input by proopiomelanocortin neurons could contribute to the elevation in GnRH gene expression and gonadotropin hypersecretion of menopause (Rance and Uswandi, 1996). In addition, β-endorphin and other products of the posttranslational processing of proopiomelanocortin have been implicated in the modulation of virtually every hypothalamic function, including reproduction, temperature regulation, nociception, reinforcement, feeding and energy balance, stress responses, and immune function (Grossman, 1983; Koob and Bloom, 1983; Reid, 1983; Ferin *et al*., 1984; Khachaturian *et al*., 1985; Mountjoy and Wong, 1997; Lipton *et al*., 1998). Endogenous opioids have also been implicated in the ovarian steroid modulation of mood (Reid, 1983) and in the mechanism of postmenopausal flushes (Casper and Yen, 1985). Therefore, an alteration of proopiomelanocortin neuronal function could have a considerable impact on the physiology of postmenopausal women.

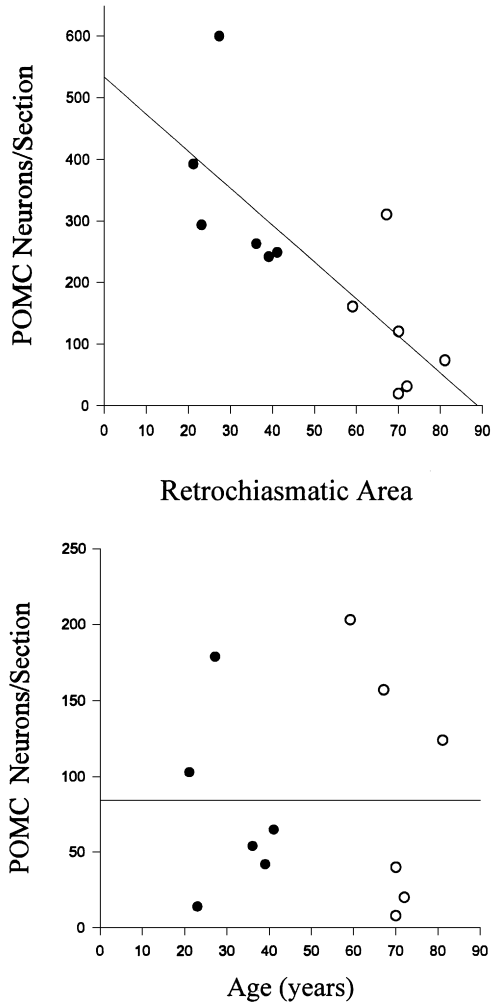

FIG. 55.5. Scatterplots and regression lines showing the relationship between age and number of neurons containing proopiomelanocortin mRNA in the infundibular nucleus (top) and retrochiasmatic area (bottom) of premenopausal (closed circles) and postmenopausal (open circles) subjects. Each data point represents the mean of one subject. There is a significant inverse relationship between subject age and number of proopiomelanocortin neurons in the infundibular nucleus ($r=-0.78$, $P=0.003$). In contrast, there is no correlation between age and the number of labeled neurons in the retrochiasmatic area. (From Abel and Rance, 1999, with permission from Elsevier Science.)

XII. Effects of Hormone Replacement Therapy on Hypothalamic Neuropeptide Gene Expression in a Primate Model of Menopause

In a study of proopiomelanocortin neurons in the infundibular nucleus of pre- and postmenopausal women (section XI), a strong inverse correlation was found between the number of neurons expressing proopiomelanocortin gene transcripts and subject age (Fig. 55.5) (Abel and Rance, 1999). These findings suggest that the decline in proopiomelanocortin gene expression is secondary to aging rather than loss of ovarian hormones. This interpretation is complicated, however, by studies in experimental animals showing modulation of β-endorphin neurons by gonadal steroids (Wardlaw *et al*., 1982a; Chowen-Breed *et al*., 1989; Adams *et al*., 1991). Therefore, a contribution from ovarian failure to changes in proopiomelanocortin gene expression in postmenopausal women could not be excluded. These questions were further explored using young, ovariectomized long-tailed macaque monkeys as a primate model of menopause (Abel *et al*., 1999). This animal model was used to test the effects of hormone replacement on hypothalamic neuropeptide gene expression.

Young, ovariectomized monkeys represent an excellent model of postmenopausal women for several reasons. The patterns of gonadotropin and ovarian steroid secretion over the monkey menstrual cycle are nearly identical to those of humans (MacDonald, 1971; Jewett and Dukelow, 1972; Williams and Hodgen, 1982; Robinson and Goy, 1986). Monkeys also exhibit ovarian failure with increasing age which culminates in menopause (Hodgen *et al*., 1977). In addition, ovariectomy in young monkeys results in an endocrine profile characterized by markedly reduced ovarian steroid levels with concomitant gonadotropin hypersecretion (Monroe *et al*., 1972) similar to the endocrine profile of menopause. Furthermore, evidence suggests that castration in young monkeys is

followed by thermoregulatory instability that shares many features of the postmenopausal flush (Jelinek *et al*., 1984; Dierschke, 1985). These data suggest that the ovariectomized young monkey is an excellent model for determining the relative contributions of gonadal steroid withdrawal and aging to postmenopausal alterations in hypothalamic gene expression.

Young monkeys were ovariectomized and divided into three groups: ovariectomized without hormone replacement therapy, ovariectomized plus estrogen, and ovariectomized plus estrogen and progesterone. Hormone replacement therapy was administered for a period of 30 months in doses designed to mimic current therapeutic regimens. *In situ* hybridization was used to label neurons expressing either NKB or proopiomelanocortin mRNAs. In the infundibular nucleus of ovariectomized monkeys without hormone replacement therapy, there were large neurons expressing NKB gene transcripts. Hormone replacement therapy, however, markedly suppressed NKB gene expression (Fig. 55.6). Indeed, no NKB neurons were visualized in the infundibular nucleus of any of the monkeys receiving hormone replacement therapy. In contrast, administration of hormone replacement therapy had no effect on several parameters of the proopiomelanocortin neurons, including the number of neurons expressing proopiomelanocortin gene transcripts, the size or shape of these neurons, or the number of autoradiographic grains per cell (Abel *et al*., 1999).

The contrasting effects of hormone replacement therapy on neuropeptide mRNAs in the macaque monkey model suggest that the changes in proopiomelanocortin and NKB gene expression in postmenopausal women may be mediated by different variables. Clearly, NKB gene expression in the primate hypothalamus is exquisitely sensitive to alterations in the steroid milieu. These data provide strong support for the hypothesis that increased NKB gene expression occurs in the hypothalamus of postmenopausal women secondary to the estrogen withdrawal of menopause. In contrast to the effects of estrogen on NKB gene expression, there was no effect of hormone replacement therapy on the proopiomelanocortin system of neurons. Thus, factors other than ovarian estrogen withdrawal may be more important in influencing this peptide system in postmenopausal women. The close correlation between the decline in proopiomelanocortin gene expression and subject age suggests that aging may be a more important factor (Fig. 55.5).

The ovariectomized, long-tailed macaque monkey was also used to determine whether long-term hormone replacement therapy produces signs of estrogen toxicity in the primate hypothalamus (Abel *et al*., 1999). The toxic effects of long-term, continuous estrogen in the arcuate nucleus of female rodents have been well-described (Finch *et al*., 1984; Desjardins *et al*., 1995), but it was not known if a similar syndrome occurs in primates. Two parameters that have been shown to be sensitive and specific markers of estrogen toxicity in the rat were examined: proopiomelanocortin neurons and microglial cells (Brawer *et al*., 1983; Desjardins *et al*., 1995). In the infundibular nucleus of ovariectomized monkeys receiving hormone replacement therapy no alterations were identified in the system of neurons expressing proopiomelanocortin mRNA or in microglial cells. Thus, we found no evidence for a neuropathological effect of sustained, unopposed estrogen in the primate hypothalamus (Abel *et al*., 1999). These findings are of considerable importance given the millions of women who are currently receiving continuous hormone replacement therapy.

XIII. Summary

Menopause is characterized by ovarian failure, gonadotropin hypersecretion, and dramatic changes in morphology and neuropeptide gene expression in medial basal hypothalamus. The

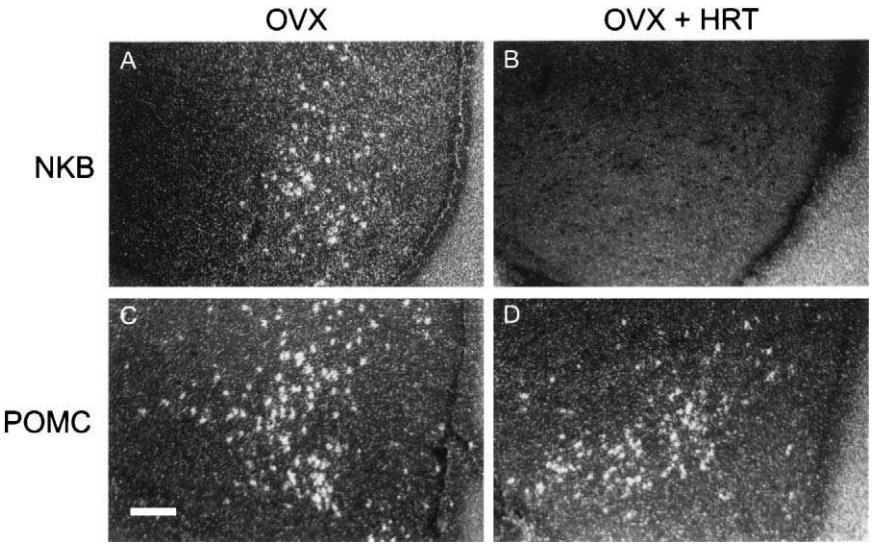

FIG. 55.6. Darkfield photomicrographs of the infundibular nucleus of ovariectomized monkeys either untreated (A and C) or receiving hormone replacement therapy (B and D). The sections have been hybridized to radiolabeled oligonucleotide probes complementary to NKB (A and B) or proopiomelanocortin (POMC; C and D) mRNAs. The clusters of silver grains show the location of labeled neurons. Administration of hormone replacement therapy (HRT) resulted in complete suppression of NKB gene expression. In contrast, proopiomelanocortin gene expression was unaffected. (From Abel *et al*., 1999, with permission. © The Endocrine Society.)

most pronounced change is the increased NKB and SP gene expression in hypertrophied infundibular neurons that coexpress ERα mRNA. GnRH gene expression also increases, but in a separate subpopulation of neurons within the medial basal hypothalamus. In contrast, the number of neurons expressing proopiomelanocortin gene transcripts is decreased within the infundibular nucleus.

Changes in gene expression have been interpreted as reflecting alterations in neuronal activity and subsequent neurosecretion. In each of the hypothalamic systems that are altered in postmenopausal women, there is evidence to support this interpretation. For example, the increase in hypothalamic tachykinin gene expression is accompanied by neuronal hypertrophy, a classic morphological sign of increased activity. In addition, the rise in GnRH gene expression is accompanied by a hypersecretion of LH and FSH from the anterior pituitary gland. Finally, pharmacological studies have demonstrated a decrease in the inhibitory influence of endogenous opioid peptides on LH release in the postmenopausal human.

The rise in tachykinin gene expression in postmenopausal women is most likely due to the estrogen-deficient state. This conclusion is based on the increase in NKB gene expression after gonadectomy of male and female rats and the suppression of NKB gene expression after hormone replacement therapy in the ovariectomized monkey. There are also considerable data in experimental animals to support the concept that removal of estrogen negative feedback results in increased hypothalamic GnRH gene expression and secretion of GnRH into hypophyseal portal blood (Sagrillo *et al*., 1996; Herbison, 1998). The mechanism for the decline in proopiomelanocortin gene expression appears more elusive, as both aging and steroid hormones have been shown to regulate this peptide in experimental animals. Hormone replacement therapy did not alter proopiomelanocortin gene expression in the ovariectomized long-tailed macaque monkey, however, suggesting that age may be a more important factor. Thus, the changes in gene expression in postmenopausal women may be both a reflection of the GnRH axis operating in a steroid-free environment and the superimposed effects of hypothalamic aging.

What is the physiological relevance of the changes in hypothalamic gene expression? The simplest explanation is that the increase in GnRH gene expression and the gonadotropin hypersecretion of menopause are secondary to an increased stimulation by tachykinin peptides, combined with a decline in the inhibitory influence of opioid peptides. This conjecture fits well into our current understanding of hypothalamic physiology in which the various patterns of GnRH secretion depend upon the coordinated participation of multiple afferent systems (Kalra *et al*., 1997). From this perspective, it also appears likely that other neuropeptide systems will be altered in postmenopausal women, although perhaps none more robustly than the tachykinin system. In addition to reproductive physiology, however, hypothalamic alterations in postmenopausal women could be related to the various symptoms associated with menopause such as hot flushes, mood changes, and subtle alterations in cognitive function. Hot flushes in particular are related to the hypothalamic control of thermoregulation, and timed with the pulsatile release of LH. Thus, understanding the hypothalamic changes in menopause will shed light not only on regulation of gonadotropin secretion and hypothalamic aging in the human, but may also have practical implications for the health of postmenopausal women.

Neuroendocrine Aspects of Female Reproductive Aging

I. Introduction

The female reproductive system has been a well studied model in research on aging of neuroendocrine systems for several reasons. First, it illustrates how changes in complex positive and negative interactions between the hypothalamus, pituitary, and peripheral endocrine targets each contribute and ultimately lead to permanent age-related changes. Second, age-related infertility occurs relatively early during the life span of many mammalian species. Therefore, we anticipate that this system will provide insights into the aging process in the absence of confounding pathological changes that complicate many studies in aging. Third, since the average life span of women has increased dramatically during the past century, an increasing fraction of women will live a larger proportion of their lives in the postmenopausal state. Hence, understanding the regulation of the menopausal transition and the repercussions of the menopause will aid in the treatment of health care needs of a significant portion of the elderly population. Fourth, it has become increasingly clear that estrogen affects far more than just reproductive functions and ''classic'' reproductive target organs. Indeed, estrogen influences bone and mineral metabolism, blood pressure and cardiovascular function, memory and cognition, circadian rhythmicity and the incidence and progression of age-related neurodegenerative diseases, such as Alzheimer's disease. Thus, the cessation of menses and resulting hypoestrogenicity impacts multiple and diverse physiological systems and a better understanding of the factors that lead to age-related infertility becomes more and more important.

For many years, it has been accepted that the menopause resulted simply from an exhaustion of the pool of follicles in the ovary (vom Saal *et al*., 1994) and that hypothalamic/pituitary alterations occurred in response to deteriorating ovarian function. However, recent findings suggest that both the brain and the ovaries are involved in female reproductive senescence. Although ovarian follicles are virtually depleted in postmenopausal women (Block, 1952; Costoff and Mahesh, 1975), several lines of evidence have led investigators to believe that the brain contributes to the sequence of events that lead to reproductive decline. Thus, subtle changes in the temporal pattern and synchrony of neural and endocrine signals, which are detectable in both women (Matt *et al*., 1998) and animal models (Wise *et al*., 1997) prior to the cessation of reproductive cycles, may contribute to the accelerated loss of follicles that occurs during the middle-age transition to acyclicity and infertility.

Most of the studies on the role of the neuroendocrine axis in the transition to infertility have been performed in laboratory animal models since many of the approaches are invasive and/or require euthanizing the animal. By definition, rodents do not undergo the ''meno''-pause, since they never experience menses during their reproductive life span. Nevertheless, rodents have been excellent experimental models and have provided important insights into factors that regulate other stages of reproductive life such as pre- and perinatal development, puberty, and maintenance of regular cycles in the adult. In some cases, studies using indirect methods suggest that parallel changes occur in humans and laboratory rodents during normal or pathological aging. Therefore, it is likely that changes in the hypothalamic–anterior pituitary axis occur during middle age in women and contribute to the cascade of events that lead to the menopause. Furthermore, we believe that information gained from studies performed in laboratory animal models regarding mechanisms that regulate the transition to acyclicity and infertility can be extrapolated to humans and will allow us to formulate concepts that may be generalized to human reproductive aging.

Some of the earliest evidence suggesting that the hypothalamus plays a role in reproductive aging came from two experimental approaches. First, transplantation of ovaries of old animals to the kidney capsule of young ovariectomized females hosts, revealed that follicular development and ovulation occurred under the influence of neuroendocrine signals of the young host (Peng and Huang, 1972; Aschheim, 1983). This shows that depletion of ovarian oocytes is not the cause of the acyclic state Second, administration of drugs that restored the level of activity of monoaminergic neurotransmitters,

progesterone treatment or electrochemical stimulation of the preoptic area of old rats (Everett, 1940, 1943, 1980; Clemens *et al*., 1969; Quadri *et al*., 1973; Huang *et al*., 1976; Clemens and Bennett, 1977; Cooper, 1977; Cooper and Walker, 1979; Everett and Tyrey, 1982) resulted in restoration of estrous cyclicity. These results implicate changing hypothalamic function as a crucial element in reproductive decline. More recent studies that have focused their attention on the middle-age transition period, suggest that hypothalamic changes, although subtle, may contribute to the onset of irregular cycles that ultimately lead to acyclicity (for review, see Wise *et al*., 1997).

II. Changes in the Pattern of Gonadotropin Secretion Occur during Middle Age

The patterns of secretion of both luteinizing hormone (LH) and follicle stimulating hormone (FSH) are altered during middle age and may reflect changes in hypothalamo-pituitary function. Both the preovulatory surge of LH, as well as the pulsatile secretion of LH, are altered during middle age. The preovulatory LH surge is delayed and attenuated in middle-aged rats prior to overt changes in the length or regularity of the LH surge (Cooper *et al*., 1980; Wise, 1982b; Nass *et al*., 1984). In fact, Nass *et al*. (1984) found that alterations in the preovulatory LH surge occurred in only some of the middle-aged rat and that this was an excellent predictor of which animals were likely to begin the transition to irregular cycles within the next few cycles (Fig. 56.1). Changes in pulsatile LH secretion are apparent in middle-aged laboratory animals and in women (Fig. 56.2). We (Scarbrough and Wise, 1990) found that the interpulse interval and average duration of individual pulses increased with age and with reproductive decline and the amplitude of LH pulses decreased. Similar changes have been reported recently in middle-aged women prior to any change in menstrual cycle length. Matt *et al*. (1998) demonstrated a significant increase in the interpulse interval and the duration of individual LH pulses in regularly cycling middle-aged women during the mid to late follicular phase of the menstrual cycle. Interestingly, other investigators have found either an increase in LH pulse frequency or no change during the perimenopausal period (Reame *et al*., 1996). Thus, it appears that changes in the characteristics of pulsatile gonadotropin secretion may depend upon the time of the menstrual cycle studied, whether subjects have already exhibited changes in menstrual cycle length or the method used to analyze LH pulses. Together, these data strongly suggest that subtle changes in the integrity of the GnRH pulse generator occur early, prior to the transition from regular to irregular cycles, and may be a component of the cascade of events that contributes to reproductive aging.

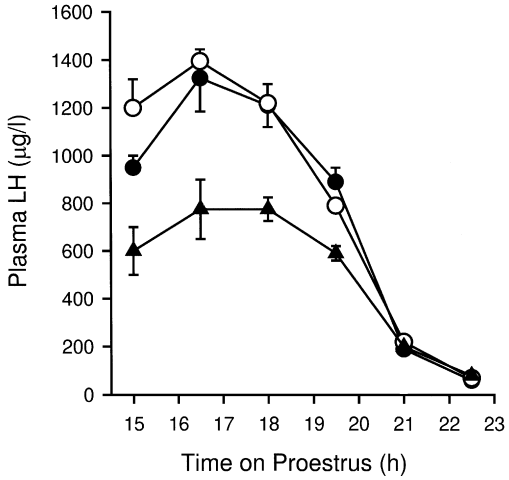

FIG. 56.1. Plasma LH concentrations in young and middle-aged rats on proestrus. Middle-aged rats that became irregularly cycling within 1–2 months after the blood samples were collected (triangles) showed significantly attenuated LH surges compared to young (solid circles) or middle-aged rats that continued to cycle (open circles). Each data point represents the mean ± SE. From Nass *et al*. (1984).

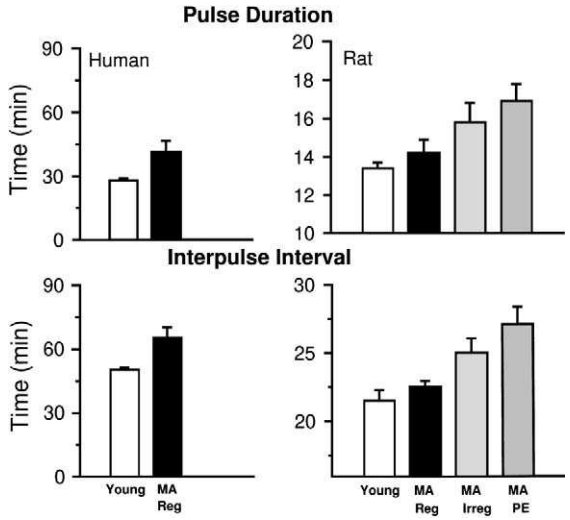

FIG. 56.2. (Left) LH pulse duration and interpulse interval obtained from 8 hr of sampling during the mid to late follicular phase of menstrual cycle in young and middle-aged women. Each data point represents the mean ± SE. Modified from Matt *et al*. (1998). (Right) LH pulse duration and interpulse interval of ovariectomized young and middle-aged rats at various stages of reproductive senescence obtained from 3 hr of sampling.). Each data point represents the mean ± SE. Modified from Scarbrough and Wise (1990).

Increases in plasma FSH have been reported in both middle-aged rats and women; however, whether these alterations can be explained by changes in hypothalamic influences or by changes in ovarian inhibin secretion are not clear. Using a newly developed assay that differentiates between inhibin A and B and the nonbiologically active forms, Klein *et al*. (1996) reported a significant selective decline in plasma inhibin B in middle-aged women who exhibited a selective increase in plasma FSH (Fig. 56.3). These data are strikingly similar to the selective increase in FSH reported in middle-aged cycling rats that were detectable when inhibin-like activity in the ovarian vein decreased (DePaolo, 1987) (Fig. 56.3). Both of these groups of investigators argued that the rise in FSH resulted only from changes in ovarian function. However, it is important to bear in mind that the ratio of FSH:LH secreted is influenced by the pattern of pulsatile GnRH secretion. FSH

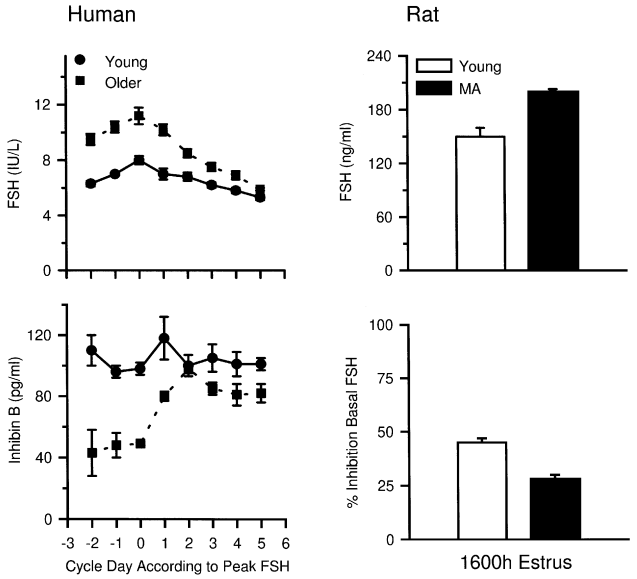

FIG. 56.3. (Left) Daily FSH (top) and inhibin B (bottom) in older and younger women. Each data point represents the mean ± SE. Modified from Klein *et al*. (1996). (Right) Plasma FSH and FSH suppressing activity in ovarian vein serum in 3- and 7-month-old rats during the periovulatory period. Each data point represents the mean ± SE. Modified from DePaolo (1987).

secretion is favored by a slowing in the frequency of GnRH pulses (Knobil, 1980), which is thought to occur with age. Thus, the selective and monotropic rise in FSH during the early stages of the menopausal transition may result from changes at both the level of the ovary and hypothalamus.

III. Age-Related Changes in GnRH Neurons

It has been difficult to evaluate intrinsic age-related changes in GnRH neurons because there are surprisingly few GnRH neurons and they are diffusely distributed. In rats, GnRH cell bodies are scattered throughout the medial preoptic area, organum vasculosum of the lamina terminalis and diagonal band of Broca and axons from the majority of these neurons terminate in the lateral regions of the external lamina of the median eminence, where GnRH is released into the hypophysial portal plexus (Silverman, 1994). Furthermore, some GnRH neurons, which may not be anatomically or morphologically discrete subpopulations, appear to have functions that are not directly involved in gonadotropin secretion (Jennes *et al*., 1997). In humans, there appear to be at least two anatomically distinct populations of GnRH neurons, one in the preoptic region and a second in the tuberoinfundibular region of the hypothalamus (Rance and Uswandi, 1996). Whether these populations reflect distinct functional populations is not clear. For all of these reasons, it has been difficult to quantify GnRH release patterns over extended periods of time in individual animals under controlled experimental condition; although a few investigators have successfully achieved this technically difficult feat in several animal models (Levine and Ramirez, 1982; Levine and Duffy, 1988; Rubin and Bridges, 1989). As an alternate strategy, investigators have utilized semiquantitative *in situ* hybridization to assess gene expression in individual cells (Rubin *et al*., 1997) and dual label immunocytochemistry (Lloyd *et al*., 1994; Rubin *et al*., 1995) to identify activated GnRH neurons. Using *in situ* hybridization, Rubin and colleagues (1997) recently showed that the diurnal pattern of GnRH gene expression is altered in middle-aged steroid-treated rats (Fig. 56.4). In young rats, GnRH mRNA levels in the preoptic region decreased from morning to afternoon and then were restored during the evening. In contrast, in middle-aged rats, there was no change through the day. Assessment of the activation of GnRH neurons using the expression of Fos within the nuclei of GnRH neurons as an index of neuronal activation demonstrates that although GnRH peptide may not change, the extent of their activation is attenuated during middle age (Lloyd *et al*., 1994; Rubin *et al*., 1995) (Fig. 56.5). In young animals, Fos is expressed in GnRH neurons coincident with both proestrous and steroid-induced LH surges (Lee *et al*., 1990, 1992). In contrast, in middle-aged proestrous rats that continue to display regular cycles, the

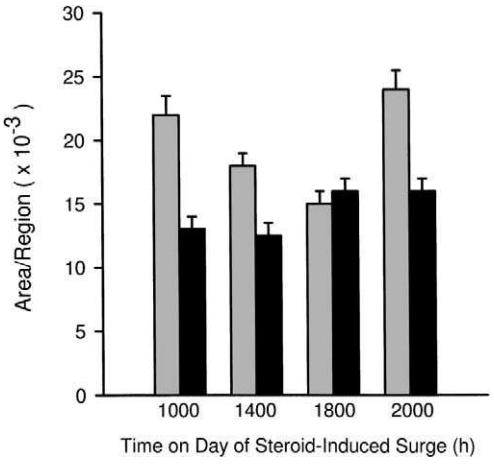

FIG. 56.4. GnRH mRNA in anatomically matched sections through the rostral preoptic area on the day of a steroid-induced LH surge in young (stippled bars) and middle-aged (black bars) rats. Mean hybridization area/region provides an estimate of the summed number of GnRH mRNA-positive neurons. From Rubin *et al*. (1997).

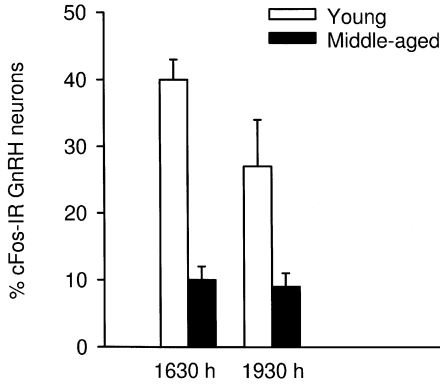

FIG. 56.5. Percentage of GnRH neurons expressing Fos during the proestrous LH surge in young and middle-aged rats. From Lloyd *et al*. (1994).

intensity of Fos staining in GnRH neurons is lower, the percentage of Fos-expressing GnRH neurons is dramatically lower around the time of peak LH release, the neuroanatomical distribution of activated GnRH neurons is different and the extent of activation no longer correlates with serum LH levels. This suggests an age-related desynchronization of the mechanisms involved in generating the proestrous LH surge.

Rubin and Bridges (1989) reported alterations in GnRH release from the mediobasal hypothalamus of steroid-primed middle-aged rats, as detected by perfusion of the preoptic area using push–pull cannula methods. These functional changes become apparent prior to any detectable change in the morphology or distribution of GnRH neurons of aging male rats (Witkin, 1987), any age-related differences in the number of GnRH mRNA containing cells (Rubin *et al*., 1997), or the distribution of GnRH-immunoreactive forms expressed in GnRH neurons (Hoffman and Finch, 1986). Thus, functional changes in GnRH neurons appear to occur prior to changes in the ability to maintain regular estrous cyclicity and are a more sensitive measure of the status of GnRH neuronal activity than morphological criteria.

Very few studies have been performed in postmenopausal women, and none have examined directly GnRH neuronal changes during the perimenopausal transition. Parker and Porter (1984) demonstrated that GnRH levels in the medial basal hypothalamus were lower in postmenopausal women than in young women. In contrast, Rance and Uswandi (1996) found that GnRH mRNA levels in the tuberoinfundibular region were elevated in postmenopausal women; however, levels in the preoptic region were not influenced by aging. As mentioned previously, the functional significance of these anatomically discrete populations of GnRH neurons is not clear; however, it appears that the GnRH containing neurons whose cell bodies are located in the medial basal hypothalamus respond to the hypoestrogenic state. Obviously, many more studies must be done before we know whether changes in mRNA are translated into alterations in GnRH peptide.

IV. Age-Related Changes in Afferent Inputs to GnRH Neurons

A plethora of neurotransmitters and neuropeptides are thought to regulate or modulate GnRH synthesis and/or release. Excellent reviews provide a rich historical appreciation of the experimental approaches that have been used to delineate the roles of each of these (Barraclough *et al*., 1984; Kalra, 1986; Kalra and Crowley, 1992; Kordon *et al*., 1994; Brann and Mahesh, 1994, 1997). We have limited our discussion to only those that thus far have been studied rather extensively with regard to reproductive aging. Specifically we will focus on norepinephrine, excitatory amino acids, neuropeptide Y (NPY), and endogenous opioid peptides.

Generally, studies that examined the neuronal circuitry that regulates GnRH neurons have focused on two principal pathways: (1) brain stem circuitry, primarily monoaminergic neurons in the medulla and pons, and (2) local circuit integration by way of cells in the hypothalamus and in immediate proximity to the GnRH neurons. The importance of neuronal input into GnRH neurons cannot be underestimated. They not only provide information from the environment and integrate reproductive function with other neuroendocrine systems, but they are the pathway that communicates information on steroidal milieu since GnRH neurons did not appear to express estrogen receptors (Shivers *et al*., 1983; Herbison and Theodosis, 1992). More recent studies, however, suggest that GnRH neurons may express low levels of estrogen receptor (Butler *et al*., 1999; Skynner *et al*., 1999).

A. The Role of Excitatory and Inhibitory Inputs into GnRH Neurons in Young Animals

A great deal of evidence indicates that noradrenergic neurons, originating predominantly from the A1 and A2 regions of the brain stem (Gitler and Barraclough, 1988), exert powerful and essential stimulatory effects on GnRH neurons that lead to LH release. Therefore, numerous studies have focused on these neurons to assess whether changes in this population of cells can explain changes in the pattern of gonadotropin secretion with age. Destruction of norepinephrine neurons or local blockade of α-adrenergic receptors decreases pulsatile release of LH (Weick, 1978; Hancke and Wuttke, 1979). Furthermore, endogenous GnRH secretion correlates with changes in pulsatile norepinephrine release, suggesting that norepinephrine plays a role in driving GnRH rhythms (Terasawa *et al*., 1988). Expression of GnRH mRNA is positively regulated by central noradrenergic neurotransmission, suggesting that norepinephrine also regulates GnRH synthesis (He *et al*., 1993; Kim *et al*., 1994). The generation of the LH surge also depends on the functional integrity of brain stem noradrenergic neurons since inhibition of norepinephrine synthesis or blockade of α-adrenergic receptors prevents the LH surge and subsequent ovulation (Kalra *et al*., 1972; Kalra and McCann, 1974; Clifton and Sawyer, 1979; Adler *et al*., 1983; Coen and Coombs, 1983). Further support for a role of norepinephrine in triggering the LH surge is the evidence that norepinephrine turnover rates (Rance *et al*., 1981; Wise *et al*., 1981) and release, as measured by push–pull perfusion (Mohankumar *et al*., 1994), increase in discrete regions of the hypothalamus that regulate GnRH synthesis and/or release at the time of the preovulatory and steroid-induced LH surge. Together, these diverse lines of evidence suggest that norepinephrine plays an important stimulatory role in GnRH neuronal activity, GnRH secretion, and ultimately LH secretion.

Norepinephrine/GnRH interactions may be mediated by both direct and indirect pathways. Noradrenergic nerve terminals have been found to end in close proximity to GnRH-containing neurons in the medial septum-diagonal band of Broca complex and medial preoptic area (Jennes *et al*., 1982; Leranth *et al*., 1988). It appears that α_{1B}-adrenergic receptors exist on GnRH neurons (Hosny and Jennes, 1998); therefore, it is likely that norepinephrine stimulates GnRH synthesis and/or release directly. On the other hand, noradrenergic synapses are also observed on GABAergic neurons in the medial preoptic area (Leranth *et al*., 1988), thus raising the possibility that norepinephrine works by multiple mechanisms to regulate GnRH release.

A lion's share of GnRH regulation appears to be accomplished by local circuitry. Anatomical studies have demonstrated that GnRH neurons are extensively innervated by

neurons whose cell bodies reside within the preoptic area, septum, and arcuate nucleus. The major neurotransmitters and neuropeptides in this category that have been examined in young animals and are thought to be relevant to aging are excitatory amino acid-containing neurons that are presumably scattered in the vicinity of GnRH cell bodies and NPY- and β-endorphin-containing neurons whose cell bodies reside in the arcuate nucleus.

Excitatory amino acid neurotransmission in the brain is carried out primarily by the two acidic amino acid neurotransmitters, glutamate and aspartate. Two main types of receptors mediate the effects of the excitatory amino acids: the metabotropic receptor family and the ionotropic receptor family (for review, see Brann, 1995). The ionotropic family of receptors includes the AMPA-, kainate-, and NMDA-preferring receptors. All three ionotropic receptor subtypes appear to be involved in the regulation of LH secretion. Excitatory amino acids induce a rapid increase in GnRH and/or LH release (Ondo *et al*., 1988; Bourguignon *et al*., 1989; Donoso *et al*., 1990; Lopez *et al*., 1992; Arias *et al*., 1993) and enhance GnRH mRNA and protein expression (Lee *et al*., 1993; Gore and Roberts, 1994). Conversely, studies utilizing the pharmacological blockade of NMDA, AMPA, and kainate receptors have shown that the excitatory amino acids play a role in both pulsatile LH release as well as the generation of the LH surge (Brann and Mahesh, 1991a,b; Brann *et al*., 1993; Luderer *et al*., 1993; Ping *et al*., 1994b). Further evidence that their release is an important physiological trigger of GnRH secretion is suggested by the findings that increased glutamate and aspartate release in the preoptic region, as measured with push–pull perfusion or *in vivo* microdialysis, slightly precedes and/or parallels the LH surge (Demling *et al*., 1985; Jarry *et al*., 1992, 1995; Ping *et al*., 1994a).

The excitatory amino acids may act on GnRH neurons, in part, via interactions with noradrenergic or nitric oxide neurotransmission (Rettori *et al*., 1993; Suh *et al*., 1994; Bhat *et al*., 1995). In support of direct action of excitatory amino acids on GnRH neurons, Eyigor and Jennes (1996) reported that kainic acid-2 (KA2)-receptor immunoreactivity is present in the cell bodies of many GnRH neurons and in their axon terminals in the median eminence.

NPY, a 36 amino acid peptide, acts at the level of hypothalamus as well as the anterior pituitary and has a clear role in facilitating GnRH release (Crowley and Kalra, 1987; Sabatino *et al*., 1989; Besecke *et al*., 1994) and potentiating the responsiveness of the gonadotroph to GnRH (Crowley *et al*., 1987; Bauer-Dantoin *et al*., 1991; 1992a). NPY innervation of the hypothalamus and preoptic area originates from two cell populations, one in the arcuate nucleus and the other in the brain stem where it is colocalized with norepinephrine (Sawchenko *et al*., 1985). Although NPY has been shown to influence pulsatile LH release (Kalra and Crowley, 1984), most of the attention has focused on its involvement in the generation of the LH surge. Evidence supporting a stimulatory action for NPY at the level of the hypothalamus in the culmination of the LH surge includes the findings that immunoneutralization of NPY (Wehrenberg *et al*., 1989), as well as blockade of NPY synthesis with antisense oligonucleotides (Kalra *et al*., 1995), prevent the LH surge in steroid-treated rats. Moreover, NPY gene expression and release are elevated prior to the proestrous and steroid-induced LH surge (Crowley *et al*., 1985; Bauer-Dantoin *et al*., 1992b; Watanobe and Takebe, 1992; Sahu *et al*., 1994). It is not clear if NPY exerts its effects through a direct effect on GnRH neurons or indirectly by altering the activity of other neuronal systems that in turn regulate GnRH release. However, NPY-containing terminals are found in close apposition to GnRH neurons in the medial preoptic area (Tsuruo *et al*., 1990).

A considerable body of evidence demonstrates that endogenous opioid peptides constitute an important inhibitory component of the neural circuitry that regulates LH secretion. Activation of opioid receptors with β-endorphin, dynorphin, and met-enkephalin analogs inhibits LH secretion (Bruni *et al*., 1977; Cicero *et al*., 1979; Kinoshita *et al*., 1980, 1982; Leadem and Kalra, 1985). More importantly, the demonstration that the general opioid antagonist, naloxone, enhances LH secretion on all days of the cycle (Gabriel *et al*., 1983; Piva *et al*., 1985) and advances the timing of the preovulatory LH surge (Allen and Kalra, 1986) has led to the hypothesis that endogenous opioid peptides normally exert an inhibitory tone on LH secretion and that a significant decrease in this inhibitory tone occurs to allow the expression of the neural trigger of the LH surge. Furthermore, steroids may exert their negative and positive feedback on GnRH through opiate peptides (Gabriel *et al*., 1983; Wise *et al*., 1990; Petersen *et al*., 1993).

The finding that the opioid receptor mRNAs (i.e., μ, δ, and κ) are all detectable within preoptic area cells but not on GnRH neurons, as assessed by dual label *in situ* hybridization, raises the question whether opioid peptides directly affect GnRH synthesis and/or release (Sanella and Petersen, 1997) However, it should be noted that Eckersell and Micevych (1998) recently demonstrated that both μ- and δ-opioid receptor immunoreactivity colocalized with GnRH fibers throughout the hypothalamus. Certainly, substantial evidence exists for both norepinephrine and excitatory amino acids as mediators of opioid peptide influences on GnRH secretion (Kalra, 1981; Kalra and Simpkins, 1981; Van Vugt *et al*., 1981; Adler and Crowley, 1984; Akabori and Barraclough, 1986; Miller and Gibson, 1994; Zhen and Gallo, 1995). Thus, endogenous opioid peptides most likely exert both indirect and direct actions on GnRH neurons.

B. Age-Related Changes in the Neurotransmitter Activity May Influence Patterns of GnRH and LH Secretion

In general, much less work has been done in aging animals. Thus, our knowledge relative to what changes take place and when they occur relative to reproductive senescence is still only rudimentary. In particular, few studies have focused on the middle-age transitional period and how these alterations may relate to changes in the pattern of GnRH synthesis and secretion, the ability to induce LH surges, and the maintenance of regular reproductive cycles. Nevertheless, several lines of evidence suggest that changes in pattern of stimulatory and/or inhibitory modulators of GnRH neuronal activity may play an important role during middle age. Over 20 years ago, Simpkins and colleagues (1977) proposed that alterations in catecholamine activity in the hypothalamus of old male rats may account for changes in gonadotropin secretion. We later

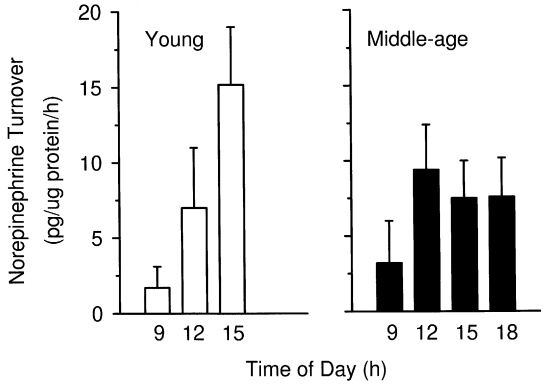

FIG. 56.6. norepinephrine turnover rates in the suprachiasmatic nucleus of young and middle-aged rats on proestrus. Turnover rates increased at the time of the LH surge in young rats, but failed to exhibit any change during the afternoon in middle-aged rats. Modified from Wise (1982a).

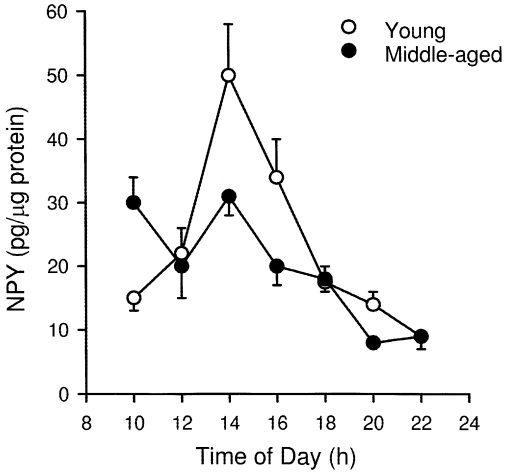

FIG. 56.7. NPY levels in the median eminence of young and middle-aged rats on proestrus. Each data point represents the mean ± SE. From Sahu and Kalra (1998).

reported changes in the rhythm of norepinephrine turnover rates in specific hypothalamic nuclei on proestrus (Wise, 1982a) and in estradiol-treated ovariectomized (Wise, 1984) middle-aged rats (Fig. 56.6). Interestingly, we found that the initial changes in rhythmicity were confined to the anterior hypothalamic regions that included the preoptic area. This region of the hypothalamus is thought to be directly innervated by neurons emanating from the suprachiasmatic nuclei that drive daily rhythms in multiple neurotransmitters (van der Beek *et al*., 1993, 1997). Similar age-related changes in norepinephrine release in the preoptic region have been confirmed using push–pull cannulae (Mohankumar *et al*., 1994). It is important to emphasize that at these early stages of aging alterations in the rhythmicity of neurotransmitter activity occur in the absence of overall changes in the average level of activity or concentrations of the neurotransmitter. At more advanced ages, changes in the average concentrations of norepinephrine (Walker *et al*., 1980; Simpkins, 1984) and dopamine (Simpkins *et al*., 1977; Estes and Simpkins, 1980; Gudelsky *et al*., 1981; Sarkar *et al*., 1982; Reymond *et al*., 1984; Simpkins, 1984) have been reported in males and females.

Several studies have shown that both glutamate content in many brain regions (Banay-Schwartz *et al*., 1989) and the responsiveness of GnRH neurons to glutamate are altered with age (Arias *et al*., 1996; Zuo *et al*., 1996). This decline in responsiveness becomes more pronounced with increased age such that hypothalami of 18-month-old rats release only 25% of the amount of GnRH seen in young adult animals in response to NMDA. These results are supported by *in vivo* studies which show dramatic increases in NMDA-mediated LH release after intrahypothalamic injections of NMDA in young rats but not in 18-month-old animals (Arias *et al*., 1996). Interestingly, male rats did not exhibit the same age-related changes (Bonavera *et al*., 1998).

NPY peptide and mRNA levels have been measured in young and middle-aged proestrous rats. Sahu and Kalra (1998) found that in young rats, NPY levels increased just prior to the LH surge and then decreased progressively during the surge. In contrast, in middle-aged rats, NPY levels did not change concomitant with an attentuate LH surge. The lack of changes in peptide were accompanied by similar age-related absence in a diurnal rhythm of hypothalamic NPY mRNA (Fig. 56.7).

Investigators have tested whether changes in opioid peptides occur with age since these peptides exert strong inhibitory actions on GnRH and are modulated by estradiol. Most studies have been performed in males. However, a few have focused on changes in the levels of proopiomelanocortin mRNA levels (Wise *et al*., 1990; Miller *et al*., 1995) and levels of β-endorphin, a major peptide that for which this mRNA codes, in females. We (Weiland *et al*., 1992) reported that proopiomelanocortin mRNA levels exhibited a daily rhythm in estradiol-treated ovariectomized young rats and that, by middle age, this rhythm was undetectable and the overall average mRNA level was suppressed (Fig. 56.8). No further decrease in mRNA

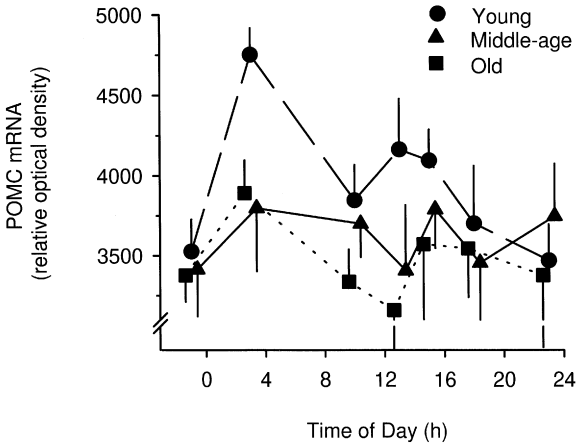

FIG. 56.8. Diurnal rhythm in proopiomelanocortin mRNA levels in the arcuate nuclei of young, middle-aged, and old ovariectomized, estradiol-treated rats. Proopiomelanocortin gene expression exhibits a diurnal rhythm in young rats; however, no rhythm is detectable in middle-aged or old rats. From Weiland *et al*. (1992).

levels occurred in older rats. Nelson and colleagues (1988; Karelus and Nelson, 1992) reported similar decreases in average level of proopiomelanocortin mRNA and an inability of estradiol to influence gene expression in aging mice.

C. Changes in Rhythmicity of Neurotransmitter Input into GnRH Neurons: A Potential Role for the Suprachiasmatic Nucleus

During the past 10 years, we have examined several aspects of some of the neurotransmitters that are thought to modulate GnRH release: turnover rates, neurotransmitter receptor densities, and gene expression. We have found a common theme that appears frequently, which is that the daily rhythmicity in the activity of many neurotransmitters (Wise, 1982a, 1984; Cohen and Wise, 1988), density of their receptors (Weiland and Wise, 1990), or the level of gene expression (Weiland *et al*., 1992) dampens or becomes completely undetectable with age in hypothalamic regions involved in regulating GnRH synthesis or secretion. Interestingly, we observed alterations when animals were middle-aged, as they were entering the transition to irregular cycles. These changes are subtle and may not be detectable if end points are measured at only one or two times of day.

Disruption of the coordination of multiple neural signals that is required for the proper precise timing of GnRH release, may ultimately lead to deterioration in the ability of rats to maintain regular estrous cycles. Everett and colleagues (1949) clearly established over 50 years ago that small changes in the temporal integrity of neurochemical events become greatly magnified in terms of the ability to maintain regular estrous cycles. This effect is different from the effects of timing on any other neuroendocrine system, which can be shifted by several hours without any major compounding impact on the peripheral endocrine rhythms that they drive. For example, desynchronization of neurochemical messages does not cause the CRH/ACTH/glucocorticoid rhythm to skip an entire day.

It is possible that fundamental changes at the level of the "biological clock" or the coupling to its outputs may cause increasing temporal desynchronization of neurotransmitter rhythms that are critical for stable, precise, and regular reproductive cycles. The suprachiasmatic nucleus of the hypothalamus is the master circadian pacemaker, or biological clock, in mammals (Moore-Ede *et al*., 1982; Turek, 1985; Turek and Van Cauter, 1994). These bilateral nuclei exhibit endogenous circadian rhythmicity: they continue to exhibit circadian electrophysiological activity and neuropeptide secretion patterns when maintained *in vitro* unlike any other region of the brain. Efferent connections to various regions of the brain communicate temporal information and drive outputs resulting in a pervasive circadian rhythmicity in most physiological functions. When lesioned, virtually all circadian rhythms (e.g., drinking, rest/activity, endocrine, temperature, metabolic) are abolished. We speculated that delay in the neural circadian pacemaker may lead to desynchronization in the timing of neurotransmitter signals that must be coordinated to trigger and LH surge or to maintain LH pulses of normal duration, amplitude, and frequency. Increased variability of diurnal hormone release, may, in turn, lead to estrous cycles of irregular and unpredictable length, and ultimately to acyclicity. Support for this hypothesis comes from studies that demonstrate that transplantation of fetal suprachiasmatic nucleus into the third ventricle of middle-aged animals restored the light-induced pattern of Fos immunoreactivity to that which was temporally and anatomically similar to that of young animals (Cai *et al*., 1997). Second, suppression of a key neuropeptide in the suprachiasmatic nucleus which communicates with GnRH neurons can mimic the effects of age on the estradiol-induced surges of LH (Harney *et al*., 1996). Recent evidence from our laboratory (Krajnak *et al*., 1998) suggests that the integrity of the cellular pacemakers that make up the biological clock may not age simultaneously since the diurnal rhythm of some neuropeptides of the clock remain intact even into old age; while others suffer from the effects of age relatively early during the life span (Fig. 56.9). These data would suggest that the cellular communication between cells of the suprachiasmatic nucleus and their ability to coordinate outputs of the clock may be the underlying cause of desynchronization of neurotransmitter signals to GnRH neurons.

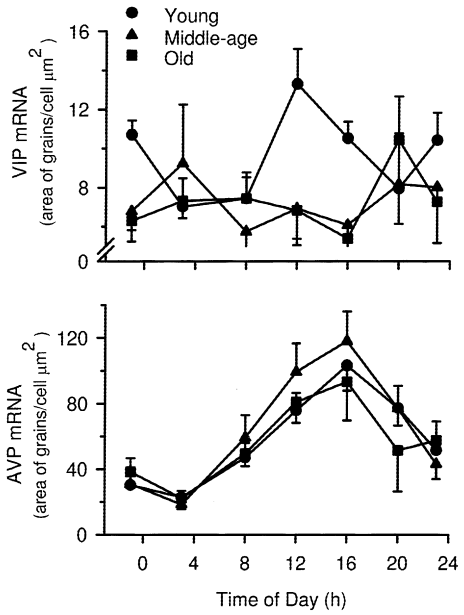

FIG. 56.9. Diurnal rhythm in vasoactive intestinal peptide (VIP) (top) and arginine-vasopressin (AVP) (bottom) mRNA levels in young and middle-aged female rats. The rhythm in VIP mRNA is present in young, but absent in middle-aged rats. In contrast, the rhythm in AVP mRNA levels remains unchanged with age. From Krajnak *et al*. (1998).

V. Summary

Accumulating evidence strongly supports the concept that the brain contributes to the transition from regular reproductive cycles to irregular cycles during aging in the female. Certainly, many more studies must be performed to thoroughly understand the role of each in the process that lead to reproductive senescence. However, compelling evidence from both human studies and those performed in animal models provide support for the idea that the brain, pituitary, and ovary work as a

precisely integrated system in adulthood and that desynchronization of signals among these elements of the reproductive axis lead to deterioration in the carefully timed cycle. Our goal must be to better understand the constellation of factors that interact to maintain regular reproductive cyclicity and how this dynamic balance changes with age. Only then will we understand the complex fabric of the functioning system and the multiple triggers that lead to reproductive decline. Ultimately we will be able to treat postmenopausal women more effectively during this period in their lives.

Hypothalamic Changes Relevant to Reproduction in Aging Male Rodents

As a recipient of sex steroid feedback and neuromodulatory input from other central nervous system areas, the gonadotropin-releasing hormone (GnRH) neuronal system forms a final common pathway for brain regulation of reproduction. Therefore, aging-related changes in GnRH secretion could be due either to intrinsic alterations in GnRH neuronal function or alterations in hormonal feedback and other neuromodulatory influences that affect GnRH secretion. Currently available evidence indicates that GnRH gene expression and peptide content are decreased in the medial preoptic area of aging male rodents, consistent with a decrease in GnRH synthetic capacity with aging. Furthermore, this decrease is independent of testicular feedback factors such as sex steroids.

In addition to these age-related changes in GnRH neurons themselves, changes in other neurons that project to GnRH neurons may contribute to declining GnRH secretion with aging. For example, hypothalamic neuropeptide Y (NPY) gene expression declines with aging, suggesting that decreased NPY neuronal input contributes to a decrease in GnRH and luteinizing hormone (LH) secretion with aging. However, no one component of the complex, interactive network of neurons and hormones regulating GnRH secretion has been identified that fully accounts for declining GnRH secretion with aging. Indeed, it is likely that altered GnRH neuronal function with aging reflects the integration of all changes in neuromodulatory influences affecting GnRH-containing neurons, together with intrinsic changes in GnRH-containing neurons themselves. Further studies are needed to determine the relative importance of each of these factors, and these studies should optimally be performed in models that are validated for reproductive aging studies and exhibit reproductive aging changes that are similar to those occurring in humans, e.g., the male Brown Norway rat.

I. Introduction

The hypothalamus plays a vital role in the regulation of reproductive function. Gonadotropin-releasing hormone (GnRH), a decapeptide synthesized in the brain, stimulates pituitary secretion of the gonadotropins, luteinizing hormone (LH) and follicle-stimulating hormone (FSH), which in turn stimulate testicular testosterone production and spermatogenesis. GnRH secretion is regulated by testosterone feedback from the testes and by excitatory and inhibitory neurotransmitters and neuromodulatory substances within the central nervous system. As a recipient of sex steroid feedback and neuromodulatory input from other central nervous system sources, the GnRH neuronal system forms a final common pathway for brain regulation of reproduction.

In recent years, our understanding of the regulation of GnRH function in adult animal models has become increasingly sophisticated. Neuroanatomical studies have not only identified and mapped neuronal pathways impinging on GnRH-containing neurons and demonstrated their interrelationships, but have also shown that in some cases more than one neurotransmitter or neuropeptide may be colocalized within the same neurons. For example, neuropeptide Y (NPY) and γ-aminobutyric acid (GABA) are colocalized within a subset of neurons in the arcuate nucleus of the hypothalamus (Horvath *et al*., 1997), suggesting the potential for coordinated regulation of GnRH release by these neurons (Kalra *et al*., 1997). At the same time, an increasing number of substances modulating GnRH secretion have been identified, including the neuropeptide galanin (Cheung *et al*., 1996), the excitatory amino acid glutamate (Brann, 1995) and nitric oxide, a diffusable gas that may mediate neuroendocrine signals from other neuromodulators (Bonavera *et al*., 1993; Kalra *et al*, 1997).

Research into the effects of aging on neuroendocrine regulation of reproduction has benefited from these advances in our knowledge of reproductive regulation in adult animals, but our understanding of aging processes is considerably less complete. Beginning with studies of aging effects on indirect indices of GnRH pulse generator function such as pulsatile LH release and *in vitro* studies of basal and stimulated GnRH release, investigators later turned to tools such as mRNA hybridization techniques to describe changes in gene expression under baseline conditions as an index of GnRH synthetic capacity and release. Further studies of aging have focused on

GnRH gene expression in response to experimental manipulation of variables affecting GnRH neuronal function, such as steroid hormonal milieu and other neurotransmitters and neuropeptides. Based on these studies, it is now possible to begin to determine the relative contributions of intrinsic changes in GnRH secretory capacity, changes in hormonal milieu, and altered neuropeptide and neurotransmitter input affecting GnRH neurons to the overall alterations in hypothalamic reproductive regulation with aging.

An important consideration for aging studies involving animal models is to ensure that the model selected is appropriate for the physiological system under study. Historically, however, little attention has been paid to controlling for potentially confounding disease-related variables in most animal studies, which as discussed below turns out to be crucial in separating the effects of aging per se from the effects of age-associated pathologies. In addition, it is desirable to select a model with attributes that resemble the human condition as closely as possible, in order to provide insights relevant to human aging. For these reasons, this chapter will emphasize studies involving the male Brown Norway rat, which appears to be the best available rodent model for studies of male reproductive system aging as evidenced in the following discussion.

A. Rodent Models of Male Reproductive Aging

1. Primary and Secondary Testicular Failure

In man, aging of the reproductive system is associated with both primary and secondary testicular dysfunction. Primary testicular failure is evidenced by low bioavailable testosterone levels in many healthy elderly men (Swerdloff and Wang, 1993), together with a decreased testosterone response to exogenous LH administration (Harman and Tsitouras, 1980) and diminished Leydig cell mass (Vermeulen, 1991). As a result of reduced testosterone negative feedback, serum gonadotropin levels show a compensatory elevation, but the degree of this increase is inappropriately low compared to that seen in younger men with low serum testosterone levels (Vermeulen, 1991), and the frequency of pulsatile LH release relative to the level of circulating testosterone is abnormally slow (Deslypere *et al*., 1987). These findings indicate that hypothalamic/pituitary control of testicular function is also altered in aging men.

In contrast, most of the studies in male rat models of aging such as the Sprague–Dawley and Fischer 344 (F344) rat have demonstrated only secondary testicular failure (i.e., hypothalamic/pituitary dysfunction). For example, in Sprague–Dawley rats, testicular Leydig cell mass tends to rise with increasing age (Kaler and Neaves, 1981), and testosterone production in response to human chorionic gonadotropin stimulation *in vitro* is unchanged with aging, whereas serum LH levels at baseline and in response to exogenous GnRH are decreased in old compared to younger rats (Pirke *et al*., 1978a). Similarly, both gonadotropin and testosterone levels decrease substantially with aging in male F344 rats (Gruenewald *et al*., 1992), indicating marked hypogonadotropic (i.e., secondary) hypogonadism.

2. Other Problems with Aging Rat Models

An additional problem with aging rat models for the study of reproductive system aging is the common occurrence of pituitary adenomas and other tumors of the endocrine system (Hollander, 1976). For example, aging outbred Sprague–Dawley rats commonly develop both pituitary adenomas and pancreatic islet cell tumors (Hollander, 1976; Cohen *et al*., 1978; Sandusky *et al*., 1988). Indeed, all rats have a degree of susceptibility to pituitary adenomas (Hazzard *et al*., 1992), indicating that evaluation for these tumors at postmortem examination is essential to exclude affected individuals. Regardless of the presence of macroscopic pituitary adenomas, hyperprolactinemia is a potentially confounding variable in studies of reproductive aging, because of the inhibitory effect of elevated prolactin levels upon GnRH and gonadotropin secretion (McNeilly, 1987). Hyperprolactinemia has been reported in several studies involving aging male rats of strains including F344 (Bethea and Walker, 1979), Long–Evans (Demarest *et al*., 1980), and Wistar rats (Simpkins *et al*., 1977). Despite this, prolactin levels have usually not been reported in studies of reproductive system aging that used these models.

Of even greater concern is the marked tendency of male F344 rats to develop testicular Leydig cell tumors with advancing age (Turek and Desjardins, 1979). These tumors are often functional, and may secrete large quantities of progesterone and other steroids (Amador *et al*., 1985; Gruenewald *et al*., 1992). We found that in old F344 rats, orchidectomy caused circulating gonadotropins and prepro-GnRH mRNA content in the medial preoptic area of the brain to be similar to that in young orchidectomized rats, and that circulating levels of progesterone were inversely correlated with serum gonadotropin levels (Gruenewald *et al*., 1992). These findings suggested that excessive progesterone secretion from testicular tumors in aging male F344 rats exerts a significant negative feedback effect on the reproductive hypothalamic–pituitary axis. Based on these findings, the intact F344 rat is inappropriate for studies of normal male reproductive aging.

The aging male F344/Brown Norway F1 hybrid model is another potential model for male reproductive aging studies, and has the advantage of a low incidence of age-related pathology (Sprott, 1991). However, like the male F344, these rats develop Leydig cell tumors with aging, although these tumors are less frequent and occur at older ages than in the F344 (Bronson, 1989; Masoro, 1991; Thurman *et al*., 1995). Age-related changes in steroid hormone secretion have not yet been fully characterized in the male F344/Brown Norway F1 rat, therefore elevated circulating levels of progesterone and other steroids secreted by Leydig cell tumors may be a confounding factor in aging studies using this model. Further studies are needed to rule out excessive steroid secretion from Leydig cell tumors before the aging male F344/Brown Norway F1 rat model can be considered appropriate for studies of reproductive axis aging.

3. Male Brown Norway Rat—Best Available Rat Model of Male Reproductive System Aging

Based on the foregoing, studies of normal male reproductive system aging in rodents require the use of a model that is relatively free of these confounding variables, and approximates as closely as possible the hormonal milieu of aging men. To this end, we (Gruenewald *et al*., 1994a) and others (C. Wang *et al*.,

1993; Zirkin *et al*., 1993; Chen *et al*., 1994) have evaluated the effects of aging on reproductive function in the male Brown Norway rat. In this inbred strain, testis function is relatively preserved until old age, when old (approximately 24-month-old) and senescent (approximately 30-month-old) rats exhibit decreased serum testosterone levels and Leydig cell testosterone production and histological evidence of testicular atrophy in the face of stable LH and progressively rising FSH levels with aging, consistent with primary testicular failure. Moreover, hypothalamic/pituitary dysfunction is also evident in the failure of LH levels to increase in intact aging rats despite low testosterone levels, and the progressive decrease in LH and FSH in orchidectomized aging BN rats (Gruenewald *et al*., 1994a). This combination of primary and secondary testicular dysfunction is more analogous to the situation in aging men than the other available rodent models of aging.

In addition, the Brown Norway rat has other advantages for aging studies, including a long, relatively disease-free survival rate; the relative absence of specific endocrine disorders such as hyperprolactinemia and high circulating progesterone levels, pituitary adenomas and Leydig cell hyperplasia and tumors; the genetic homogeneity of this inbred strain; and the ready availability of rats at different ages that are barrier-reared under specific pathogen-free conditions. Localized bladder cancer is the most common major disease of the aging Brown Norway rat, occurring in 35% of male rats at an average age of 27 months (Burek and Hollander, 1977). Most other significant diseases such as cardiomyopathies and other neoplasms do not occur in this rat strain until 26 to 30 months of age (Bronson, 1989). Considering all of these advantages together with the relatively few disadvantages, the Brown Norway rat appears to be the best available rat model for studies of male reproductive aging.

4. Mouse Models

The (C57BL/6N $\times$ C3H/HeN)F_1 hybrid (B6C3F_1) mouse is commonly used for aging studies. Its advantages include long survival (approximately 80% at 26 months), comparable to F344 rats (Cameron *et al*., 1985). In males, the most common age-related pathologies are hepatic adenomas and hepatocellular carcinomas (which are metastatic in 12%), malignant lymphomas and leukemias, lung adenomas, and adenocarcinomas (Tamano *et al*., 1988).

In aging male CBF_1 mice, progressive reductions in mating success and sperm production have been described with aging, which correlate with decreased serum LH and testosterone, consistent with secondary (hypothalamic/pituitary) testicular failure (Bronson and Desjardins, 1977). Moreover, the frequency of pulsatile LH release is decreased with aging in these mice (Coquelin and Desjardins, 1982), consistent with impaired hypothalamic GnRH pulse generator activity with aging. Thus, these mice demonstrate a hormonal profile consistent with predominantly secondary testicular failure, similar to most rat strains other than the Brown Norway rat. To our knowledge, no studies have been published that describe alterations in GnRH or its regulation in aging male mice.

Based on the foregoing discussion of the importance of the model in studies of male reproductive aging, these considerations will be included in the following sections covering age-related changes in hypothalamic regulation of reproductive function in male rodents.

II. The GnRH Neuronal System

A. Indirect Indicators of Aging Effects on GnRH Neurons

1. Aging and the Frequency of Pulsatile Gonadotropin Secretion

Aging effects on hypothalamic GnRH pulse generator function may be inferred from indirect measures such as changes in the frequency of pulsatile gonadotropin release. In the 1980s, studies were performed in male Sprague–Dawley rats to investigate the role of hypothalamic/pituitary alterations in mediating the decline in testosterone levels in old rats. In one study, sampling of blood was performed every 10 min through indwelling venous catheters for 8 hr in unanesthetized, intact 3- and 22-month-old male rats for measurement of LH levels by radioimmunoassay (RIA) (Steiner *et al*., 1984). The frequency of pulsatile LH release was found to be decreased in old rats, and compared to young rats the frequency was inappropriately low for the level of circulating testosterone. This decrease in pulsatile LH release suggested that hypothalamic GnRH pulse generator activity was impaired with aging in these rats. In a second study, 3-, 18-, and 26-month-old male Sprague–Dawley rats were orchidectomized, and frequent blood sampling for LH levels was performed 3 weeks later (Karpas *et al*., 1983). In the absence of testosterone negative feedback, LH pulse frequency was significantly decreased in old compared to middle-aged and young rats, indicating that this effect of aging on the hypothalamic pulse generator was not merely a result of alterations in testosterone feedback sensitivity with aging. In addition, the amplitude of LH pulses was also decreased with aging in both of the above studies, but this could have been the result of either decreased GnRH secretion, decreased pituitary responsiveness to GnRH, or both. Prolactin levels were not reported in either study, although in the study of orchidectomized rats, animals were free of gross evidence of pituitary tumors.

Similar to these studies in rats, Coquelin and Desjardins (1982) found a decrease in the frequency and amplitude of pulsatile LH secretion in 27- to 28-month-old compared to 6- to 8-month-old male CBF_1 mice, again suggesting an impairment in hypothalamic GnRH pulse generator activity with aging.

In contrast to this apparent reduction in GnRH pulse generator activity in aging mice and Sprague–Dawley rats, in intact young (3- to 4-month), middle-aged (12- to 13-month), and old (21- to 22-month) male Brown Norway rats, FSH pulse frequency increased with aging and LH pulse frequency tended to increase with aging, although the latter was not significant (Bonavera *et al*., 1997). Alterations in pulsatile gonadotropin secretion was not investigated in orchidectomized animals, so age-related changes in GnRH pulse generator activity in the absence of testosterone negative feedback are not known in this strain. However, despite the tendency for LH pulse frequency to increase in old rats, the amplitude and the total area under the LH pulses were reduced, indicating a decrease in the amount of LH secreted per pulse (Fig. 57.1). These findings

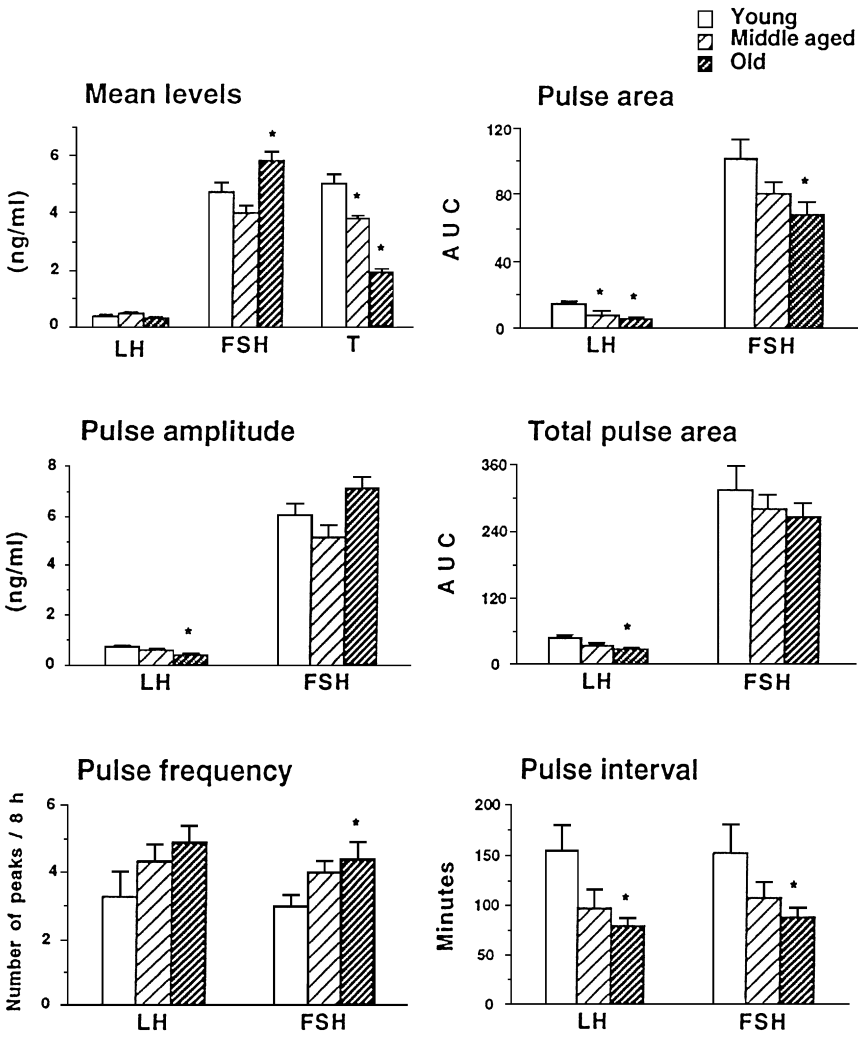

FIG. 57.1. Effects of age on mean hormone levels and on luteinizing hormone (LH) and follicle-stimulating hormone (FSH) pulsatile parameters over an 8-hr sampling period in young (3- to 4-month), middle-aged (12- to 13-month), and old (21- to 22-month) male Brown Norway rats. Data are expressed as the mean ± SEM (*$P < 0.05$ vs 3- to 4-month-old rats). Used with permission (Bonavera *et al.*, 1997).

indicate that although the effects of aging on pulsatile gonadotropin secretion differ between male Brown Norway rats and the other models, hypothalamic–pituitary regulation of the gonadal axis is altered with aging in all of these models.

2. Aging and Circadian Variations in Testosterone and LH Levels

Circadian variations in hormone secretion are thought to be regulated by the central nervous system, specifically, the suprachiasmatic nucleus of the hypothalamus. In men, aging is associated with a dampening of a number of circadian biorhythms, including those of pulsatile LH and testosterone secretion, which is thought to reflect, in part, an alteration in circadian rhythmicity of the GnRH pulse generator with aging (Tenover *et al.*, 1988).

In male Brown Norway rats, Bonavera *et al.* (1997) found that testosterone levels were higher in the morning and early afternoon than in the late afternoon in young but not in older animals (Fig. 57.2), suggesting a loss of circadian variation in testosterone levels analogous to that occurring in aging men. We also assessed age-related changes in the circadian rhythm of circulating testosterone levels in male Brown Norway rats, by measuring testosterone levels every 6 hr over a 24 hr period in rats of different ages. Three- to 4-, 12- to 13-, and 23- to 24-month-old rats were randomly assigned to one of five groups ($n = 8–9$ per group for each age), to be sacrificed every 6 hr over a 24-hr period. The differences between baseline and peak testosterone levels were used as an index of testosterone circadian variation and were compared between age groups. Testosterone levels over 24 hr declined progressively with aging, and showed a bimodal diurnal variation in young rats that was not evident in older animals. The magnitude of the diurnal variation as determined by the differences between peak and baseline testosterone levels over 24 hr decreased progressively from young (3.9 ± 0.7 ng/ml) to middle-aged

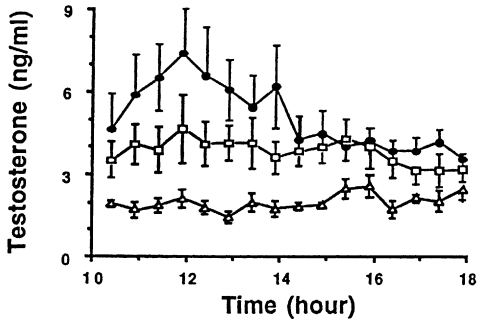

FIG. 57.2. Mean plasma testosterone levels between 10:00 and 18:00 hr in 3- to 4-month (filled circles), 12- to 13-month (open squares), and 21- to 22-month (open triangles) old male Brown Norway rats. Data are expressed as the mean ± SEM. Used with permission (Bonavera *et al*., 1997).

(1.7 ± 0.4 ng/ml) to old rats (0.8 ± 0.2 ng/ml, $P<0.01$ for young vs middle-aged and old rats) (Fig. 57.3). As in the report by Bonavera *et al*., (1997), testosterone levels were higher in the late morning than in the late afternoon in young but not in older male Brown Norway rats. However, unlike Bonavera *et al*., we sampled blood over a 24 hr period, revealing an apparent late evening surge in testosterone levels in young Brown Norway rats that was not present in older animals.

We also observed an apparent LH circadian rhythmicity in young rats that diminished with aging, although we were unable to show a statistically significant difference between age groups in the amplitude of LH circadian rhythmicity over a 24 hr period (Fig. 57.3). This loss of the circadian variation in testosterone and apparently LH levels with aging may reflect altered central nervous system control of the LH circadian rhythm (Tenover *et al*., 1988). It is possible that the variations in testosterone levels we observed in young rats were due to pulsatile secretion of testosterone, and loss of the apparent diurnal variation in testosterone levels with aging could reflect a decrease in the amplitude of pulsatile testosterone secretion. Nevertheless, the fact that we and others have found higher testosterone levels in the late morning than in the late afternoon in young but not in old rats suggests that the age-related reductions in testosterone were due, at least in part, to alterations in the circadian rhythm of testosterone levels.

Indirect studies of pulsatile gonadotropin release and circadian rhythmicity such as these suggest altered hypothalamic regulation of reproductive axis function with aging. However, these studies do not indicate whether such age-related changes are due to intrinsic alterations in GnRH-containing neurons with reduced GnRH synthetic capacity, or to changes in other neurotransmitters and neuropeptides affecting reproductive axis function (e.g., neuropeptide Y, catecholamines, and endogenous opioid peptides). Other approaches are needed to address these questions.

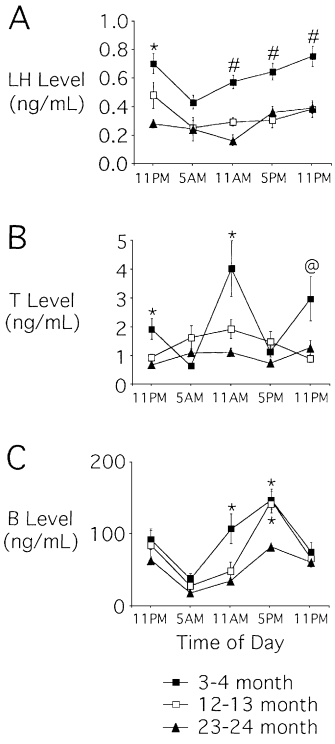

FIG. 57.3. Circadian variation in serum luteinizing hormone (LH; A), testosterone (T; B), and corticosterone (B; C) levels measured by radioimmunoassay in young (3- to 4-month-old, filled squares), middle-aged (12- to 13-month-old, open squares), and old (23 hr to 24-month-old, filled triangles) male Brown Norway rats sacrificed at 6 hr intervals over a 24 hr period ($n = 8$–9/time point for each age group). Values shown are means ± SEM ($^{*}P<0.05$ vs old; $^{\#}P<0.01$ vs middle-aged and old; $^{@}P=0.05$ vs old). Note that testosterone levels exhibited a bimodal diurnal variation in young but not older rats, and B levels exhibited a circadian rhythm with a decreasing amplitude in old compared to younger rats. Used with permission (Gruenewald *et al*., 1999).

3. Aging and Androgen Feedback Sensitivity and Action in the Brain

An age-related increase in the sensitivity of gonadotropin secretion to androgenic feedback has been reported in a number of studies in male rats (Shaar *et al*., 1975; Pirke *et al*., 1978b; Gray *et al*., 1980) and men (Winters *et al*., 1984; Deslypere *et al*., 1987). The primary observation in support of increased feedback sensitivity with aging in most of these studies was that circulating gonadotropin levels were suppressed to a greater degree by androgen replacement in old than in younger males. Furthermore, studies in men reported a greater inhibitory effect of androgens on gonadotropin pulse frequency in old than in younger men (Winters *et al*., 1984), indicating involvement of the hypothalamic GnRH pulse generator. Potential contributors to increased androgenic feedback sensitivity with aging have been suggested, including increased endogenous opiate activity, age-related hyperprolactinemia, impairment of pituitary gonadotropin secretory function, and impaired central nervous system stimulation of the pituitary–gonadal axis (Gray *et al*., 1980). However, the actual mechanism(s) responsible for this increased hypothalamic androgen feedback sensitivity with aging have remained unclear. Data from our laboratory suggest the possibility that this may be due to changes at the level of the hypothalamus, and specifically GnRH gene expression (see section II.C.2, below).

Alterations in androgen feedback sensitivity and action in the brain with aging could be due to changes in sex steroid hor-

mone receptor binding or active androgen metabolism (e.g., aromatization to estradiol (E_2) or 5α-reduction to dihydrotestosterone (DHT)) within the central nervous system. In male F344 rats, Chambers *et al*. (1991) reported that nuclear androgen receptor binding was decreased in the hypothalamus and preoptic area of old rats and activity of aromatase (the enzyme that converts androgens to estrogens) in the preoptic area declined with aging. To determine whether these deficits in androgen receptor binding and active metabolism of testosterone were due to low testosterone levels in the old rats, young and old rats were orchidectomized and given testosterone replacement, resulting in testosterone levels that were similar in the two age groups but higher than in intact young rats. Nuclear androgen receptor binding was similar in old orchidectomized/testosterone-replaced compared to young intact rats, although binding levels were not as high as in young orchidectomized/testosterone-replaced animals. Thus, age-associated alterations in androgen receptor binding appear to be due in part to testosterone deficiency. There were no age-related differences in the induction of aromatase activity by testosterone, implying that testosterone deficiency does not account for the decreased aromatase activity in intact old rats. Functionally, none of the old intact rats ejaculated during tests of sexual behavior, whereas all of the young rats ejaculated. When animals were orchidectomized and testosterone replaced, young rats continued to exhibit ejaculation in all cases, whereas 25% of the old rats ejaculated. Thus, there was some improvement in sexual functioning with restoration of testosterone levels, but not to levels observed in young rats.

In further studies by this group, old (24.5 months) male F344 rats exhibited lower nuclear estrogen receptor levels in the amygdala than young (5 months) animals, but this was not a consequence of decreased circulating estradiol levels which were similar in the two age groups (Roselli *et al*., 1993). Administration of testosterone to orchidectomized old males restored testosterone to normal young adult levels but failed to increase nuclear estrogen receptor levels in the amygdala to levels observed in young rats. Taken together, these findings suggested that the inability of testosterone treatment to increase aromatase activity in the hypothalamus and nuclear estrogen receptor levels in the amygdala may contribute to the impairment in sexual performance observed in old males. Furthermore, the decrease in central nervous system synthesis and binding of estrogen derived from circulating testosterone may lead to decreased androgen responsiveness with aging.

It has been suggested that some androgen actions in brain and feedback effects of testosterone on gonadotropin secretion are mediated, in part, by conversion of testosterone to DHT and 5α-androstane-3α,17β-diol (3α-diol), which are produced through the actions of 5α-reductase and 3α-hydroxysteroid dehydrogenase, respectively (Piva *et al*., 1993). Using tissues from young (3-month-old) and old (20+-month-old) male rats, Piva *et al*. found no age-related impairment in the ability of hypothalamic tissue *in vitro* to metabolize testosterone into either DHT or 3α-diol (Piva *et al*., 1993). Furthermore, testosterone replacement of old rats did not exert any effect on levels of these metabolites of testosterone. These data suggest that alterations in testosterone feedback sensitivity with aging are not due to alterations in the hypothalamic metabolism of testosterone to either DHT or 3α-diol.

B. Morphological Considerations

The perikarya of GnRH-containing neurons in the medial preoptic area (MPOA) of the male F344 rat do not appear to deteriorate with age, but morphologic evidence of nerve terminal deterioration in the median eminence has been reported (Sladek *et al*., 1980), suggesting the existence of a primary age-related defect in the secretory capacity of GnRH-containing neurons. However, a 10-fold increase in synaptic input onto GnRH perikarya was observed in the brains of aging male F344 rats, with an increase in the proportion of synaptic boutons associated with an inhibitory morphology (Witkin, 1987). To determine whether this apparent increase in inhibitory input was due to increased input from GABAergic neurons, a follow-up study was performed in aging virgin male Sprague–Dawley rats (Witkin, 1992a) employing dual label immunocytochemistry to identify neurons positive for GnRH and glutamic acid decarboxylase, the enzyme required for GABA synthesis. A threefold increase in synaptic density was observed in old rats, similar to the previous findings in aging F344 rats. However, the density of GABAergic synaptic input was similar in young and old male Sprague–Dawley rats, and GABAergic input decreased with aging as a percentage of the total synaptic input onto GnRH neurons. Further complicating the interpretation of these studies was the finding that synaptic input onto GnRH-containing neurons did not increase in retired breeder males of the Sprague–Dawley strain (Witkin, 1992b), indicating an important effect of reproductive experience on the density of synaptic input onto GnRH-containing neurons in these animals. Nevertheless, it is intriguing that synaptic input to GnRH-containing neurons increases with aging in some male rat models, suggesting that some of the changes in hypothalamic regulation of reproduction with aging may be due to altered neurotransmitter or neuropeptide input affecting GnRH-containing neurons.

To our knowledge, no similar studies have been performed in Brown Norway rats, nor are quantitative data available regarding aging effects on synaptic input by other excitatory or inhibitory neuron types onto GnRH neurons (e.g., opioid peptide-containing and catecholaminergic neurons).

C. Aging and GnRH Synthetic and Secretory Capacity

Many of the early studies intended to directly determine the effects of aging on GnRH-containing neurons involved the measurement of hypothalamic GnRH content in aging animals. GnRH content was reported to be stable (Dorsa *et al*., 1984) or decreased (Riegle *et al*., 1977; Bedrak *et al*., 1983) in the hypothalamus of aging male rats and decreased in senescent white-footed mice (Steger *et al*., 1980a). In addition, GnRH content in the median eminence, the location of the terminal neuroendocrine boutons of GnRH neurons, was reported to be decreased in old male rats (Simpkins *et al*., 1977). However, the interpretation of studies of GnRH peptide content is difficult, because a decrease in GnRH content, for example, could represent either a decrease in GnRH synthesis or an increase in GnRH release or metabolism. Nevertheless, these alterations in hypothalamic GnRH content suggested that age-related changes in GnRH synthetic or secretory capacity might contribute to altered pituitary–gonadal function with aging.

1. Basal and Stimulated GnRH Release *in Vitro*

Further investigations were performed *in vitro*, to determine the effects of aging on GnRH release from superfused hypothalami. These studies, performed under both baseline and stimulated conditions, have yielded contradictory results. In one study, the mediobasal hypothalamus was removed from 6- and 18-month-old male Sprague–Dawley rats, and were perfused *in vitro* (Zanisi *et al*., 1987). The levels of GnRH were measured in the effluent, under basal conditions and after exposure to a depolarizing concentration of K^+ (110 mM). The mean basal concentration of GnRH was similar in young and old rats. Exposure to K^+ enriched medium for 5 min every 30 min resulted in an increase in GnRH levels in the effluent in each of the six exposure periods (Fig. 57.4). The magnitude of the GnRH response was less in old than in young animals, but this was not statistically significant.

In a second study, GnRH release was measured *in vitro* from the median eminence of 4-, 11-, 18-, and 27-month-old male F344 rats under basal conditions and after 30 min of exposure to a stimulating concentration (60 μM) of norepinephrine (Steger *et al*., 1985). In this study, basal concentrations of GnRH in the effluent increased progressively with aging, although only the 4- and 27-month-old groups were significantly different. Norepinephrine tended to stimulate GnRH release in all age groups except the 11-month-old rats, but the increase in GnRH release over the baseline values in the same age group was significant only for the 27-month-old rats.

Finally, a third group compared GnRH release *in vitro* from the medial basal hypothalamus of 2- and 23-month old male F344 rats, under basal conditions and in response to stimulating concentrations (20 μM) of norepinephrine followed by 40 μM of naloxone (Jarjour *et al*., 1986). The pituitary fossa was inspected at the time animals were sacrificed, and no macroscopic evidence of tumor was found. Basal GnRH levels in the effluent were significantly lower in old than in young rats (Table 57.1). Both young and old rats responded to stimulation with norepinephrine and naloxone, with a similar relative and absolute magnitude of response to stimulation to these agents in young and old rats. However, like the basal GnRH levels, the stimulated GnRH output from the medial basal hypothalamus of old rats was less than from the young rats.

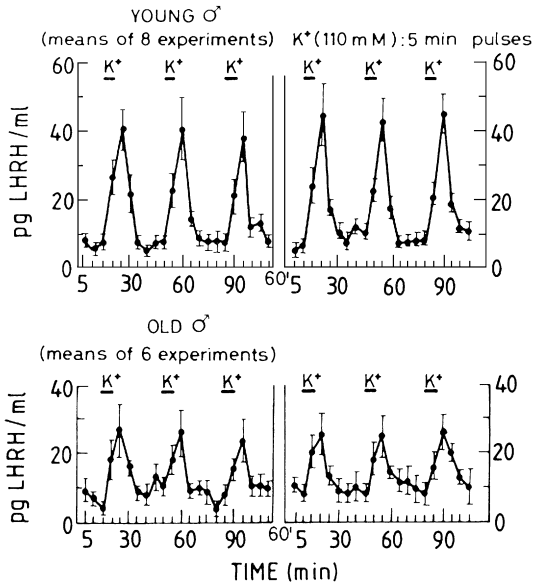

FIG. 57.4. GnRH release *in vitro* from mediobasal hypothalami from 6-month (top)- and 18-month (bottom)-old male Sprague–Dawley rats under basal conditions and after perfusion with potassium-enriched medium (110 mM). Values shown are means of eight and six experiments, respectively. Used with permission (Zanisi *et al*., 1987).

TABLE 57.1 Basal and Stimulated GnRH Output from Medial Basal Hypothalamus (MBH) of 2- and 23-Month-Old Male Fischer 344 Rats *in Vitro*

	2-Month	23-Month
Basal	33.5*	13.1
	(25.8–43.5)	(11.8–14.5)
Norepinephrine (20 μM)	98.1*,#	38.5#
	(57.9–166.3)	(21.9–67.8)
Naloxone (40 μM)	57.9*,#	36.6#
	(37.5–89.4)	(27.1–49.5)

Note. Data adapted from Jarjour *et al*. (1986); used with permission. Values shown are geometric means (95% confidence limits) of GnRH output from chambers (four young and four old) in pg/6 MBH/min.
*$P < 0.05$ vs 2-month-old.
#$P < 0.01$ vs basal.

In summary, basal and stimulated GnRH release from hypothalamic fragments *in vitro* have been reported to be unchanged, increased, and decreased with aging, depending on the rat strain and secretagogue used. Two of these studies used the aging male F344 rat model; therefore, as noted above, data from these studies may be confounded by the effects of excessive sex steroid feedback from testicular tumors on GnRH secretion. The remaining study performed in Sprague–Dawley rats suggests no major change in GnRH release with aging. However, a trend was observed toward a decrease in GnRH release and postperfusion GnRH content with aging, consistent with a modest decrease in GnRH secretory capacity. To our knowledge, no studies of this type have been performed in the aging male Brown Norway rat.

2. Prepro-GnRH mRNA and GnRH Peptide Content

To further investigate the possibility of altered GnRH synthetic capacity in aging animals, we tested the hypothesis that the age-related decrease in GnRH secretion is due to decreased GnRH gene expression. In intact 3- and 24-month-old male F344 rats, we used *in situ* hybridization histochemistry (ISHH) to compare prepro-GnRH (ppGnRH) mRNA in the MPOA and the diagonal band of Broca and measured GnRH peptide content in microdissected regions of the arcuate nucleus and median eminence by radioimmunoassay (Gruenewald and Matsumoto, 1991). ppGnRH mRNA levels were quantified in anatomically matched sections of the MPOA and the diagonal band of Broca by using the number of silver grains per cell as an index of cellular ppGnRH mRNA content and the number of labeled cells counted per brain section as an index of the number of neurons expressing the GnRH gene.

In rats, most of the cell bodies of GnRH-producing neurons are localized in the MPOA, and to a lesser extent in the diag-

onal band of Broca and medial septal nucleus, rather than in the hypothalamus. In addition, many but not all of the GnRH neurons located in septal, preoptic, and hypothalamic structures have been found to project to the median eminence (Silverman *et al*., 1987; Merchenthaler *et al*., 1989) and are therefore thought to be directly involved in the regulation of gonadotropin secretion. However, deafferentation and lesioning studies suggest that preoptic, but not septal nuclei are essential for normal gonadotropin secretion (Koves and Molnar, 1986; Silverman *et al*., 1987). Thus, by combining measurements of ppGnRH mRNA levels in the MPOA and the diagonal bond of Broca with GnRH peptide content measured in the arcuate nucleus and median eminence, which contain the infundibular tract and terminal neuroendocrine boutons of GnRH neurons, we were able to obtain a more complete picture of changes in synthetic capacity of GnRH neurons directly regulating gonadotropin secretion than with either technique alone.

We found an age related decrease in the number of neurons expressing the GnRH gene in the MPOA of intact (sham-operated) male F344 rats, although cellular ppGnRH mRNA content was unchanged with age. Furthermore, GnRH peptide content was decreased with aging in the arcuate nucleus and tended to decrease with aging in the median eminence. Finally, serum gonadotropin levels were lower in old than in young rats. Taken together, these findings suggested that GnRH synthetic capacity is decreased with aging.

In addition, since sex steroids modulate GnRH secretion, we determined hypothalamic–pituitary responsiveness to removal of testicular feedback by comparing ppGnRH mRNA and gonadotropin levels in intact (sham-operated) and orchidectomized 3- and 24-month-old F344 rats. In contrast to intact rats, neither the number of cells expressing GnRH nor cellular ppGnRH mRNA content were altered with aging in the MPOA of orchidectomized rats, suggesting that the age-related decrease in GnRH synthetic capacity was dependent upon testicular feedback. The age-related decrease in ppGnRH mRNA and gonadotropins observed in intact but not in orchidectomized rats could have been due to increased hypothalamic sensitivity to testosterone negative feedback with age. The concept of increased testosterone feedback sensitivity with aging has experimental support from other studies in aging male rats and humans (Pirke *et al*., 1978b; Steiner *et al*., 1984; Winters *et al*., 1984), as noted above (see section II.A.2). Alternatively, we postulated that increased production of factors other than testosterone by the aging testis may have inhibited hypothalamic GnRH synthesis in intact but not orchidectomized old rats. Our subsequent work examining the effects of excessive progesterone secretion from testicular tumors on gonadotropin levels in the aging male F344 rat (see section I.A.2, above) (Gruenewald *et al*., 1992) seemed to support the latter explanation and suggested that the apparent decline in GnRH synthetic capacity and reproductive function with aging may have been due to a suppressive effect of excessive progesterone secretion on the reproductive hypothalamic/pituitary axis rather than aging per se.

Based on this major concern regarding potential confounding factors in the F344 model, we performed further studies of aging and hypothalamic GnRH gene expression in the male Brown Norway rat. We compared ppGnRH mRNA in the MPOA and the diagonal band of Broca by ISHH, and GnRH peptide content in microdissected brain areas by radioimmunoassay in intact (sham-operated) 3- to 4-, 12- to 13-, and 22- to 24-month-old male Brown Norway rats (Gruenewald *et al*., 1999). We found that in intact male Brown Norway rats, the number of neurons expressing GnRH decreased progressively from young (11.8 ± 0.4 cells/section) to middle-aged (11.1 ± 0.6 cells/section) to old (9.9 ± 0.4 cells/section) rats ($P < 0.05$ for young vs middle-aged and old rats) (Fig. 57.5A and 57.5B). The cellular ppGnRH mRNA content was also decreased with aging and was significantly lower in 22- to 24-month-old (102.6 ± 2.8 grains/cell) than in 3- to 4-month-old (110.3 ± 1.9 grains/cell) or 12- to 13-month-old (109.1 ± 4.0 grains/cell) animals ($P < 0.05$).

We also determined hypothalamic–pituitary responsiveness to removal of testicular feedback by comparing ppGnRH mRNA and gonadotropin levels in intact (sham-operated) and orchidectomized young, middle-aged, and old Brown Norway rats. In contrast to aging male F344 rats, cellular ppGnRH mRNA content decreased progressively with aging in young (118.8 ± 2.8 grains/cell), middle-aged (115.9 ± 1.8 grains/cell), and old (109.6 ± 4.4 grains/cell, $P < 0.05$) orchidectomized as in intact rats (Figs. 5C and 5D), although the number of neurons expressing ppGnRH mRNA was unchanged with aging in these rats (young, 11.2 ± 0.7 cells/section; middle-aged, 11.1 ± 0.3 cells/section; old, 10.8 ± 0.5 cells/section).

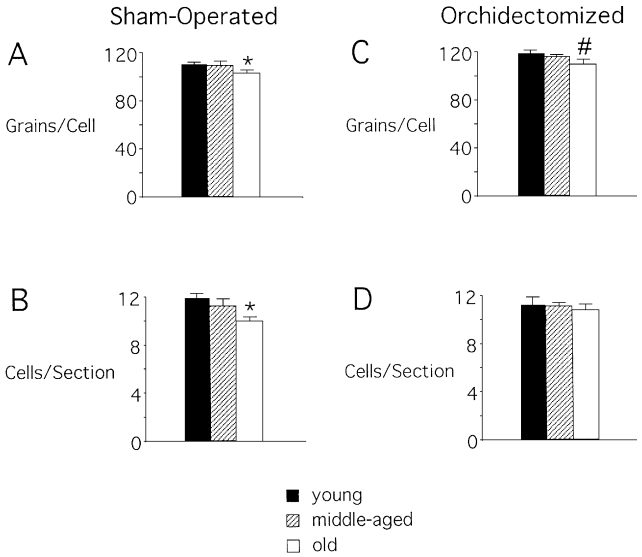

FIG. 57.5. ppGnRH mRNA content measured by *in situ* hybridization histochemistry in the medial preoptic area (MPOA) and diagonal band of Broca (DBB) of sham-operated (A, B) and orchidectomized (C, D) young (3-month-old, solid bars, $n = 8$ and 8, respectively), middle-aged (13-month-old, hatched bars, $n = 8$ and 7, respectively), and old (23-month-old, open bars, $n = 7$ and 7, respectively) male Brown Norway rats. ppGnRH mRNA content was quantitated by measurement of the number of silver grains per cell (A, C) and the number of labeled cells per section (B, D). Values shown are means ± SEM. The number of grains per cell was significantly reduced in old compared to young and middle-aged rats in both the sham-operated and orchidectomized groups. The number of labeled cells per section was significantly decreased in old compared to young and middle-aged sham-operated, but not orchidectomized animals (*$P < 0.05$ vs young and middle-aged rats). Used with permission (Gruenewald *et al*., 1999).

Thus, the reduction in GnRH gene expression with aging is not dependent on testicular feedback factors in the male Brown Norway rat. These finding suggest that excessive progesterone secretion in aging F344 rats may have confounded our earlier studies.

We also found that ppGnRH mRNA levels were not markedly affected by orchidectomy in young rats. However, with aging, both the cellular ppGnRH mRNA content and the number of neurons expressing the GnRH gene were increased with orchidectomy, suggesting that testicular factors may play a greater role in regulating GnRH gene expression in old than in younger animals. This increased effect of orchidectomy on GnRH gene expression with aging as well as the age-related decline in GnRH gene expression itself could be explained by an increase in testosterone negative feedback sensitivity with aging. Additional studies to determine the dose–response effects of testosterone replacement on hypothalamic ppGnRH mRNA levels in aging orchidectomized Brown Norway rats will be required to test this hypothesis.

III. Modulation of GnRH Neuronal Activity by Other Neurotransmitters and Neuropeptides

Our understanding of reproductive system aging must account not only for intrinsic alterations in GnRH neuronal function and changes in gonadal feedback, but also for alterations in other neuromodulatory influences that affect GnRH secretion. In this regard, our findings in Brown Norway rats suggest that the age-related decline in gonadotropin secretion is not fully accounted for by changes in GnRH gene expression. ppGnRH mRNA levels in intact male Brown Norway rats decreased by 20 to 25% between young and old animals, if changes in both the cellular ppGnRH mRNA content and the number of neurons expressing the GnRH gene are combined (Gruenewald *et al*., 1999). In contrast, GnRH peptide content in the MPOA and median eminence declined by 35–40% in old Brown Norway rats, suggesting that factors other than altered GnRH gene expression contribute to the age-related dysregulation of reproductive axis function. At the same time, pituitary responsiveness to GnRH stimulation is intact with aging in male Brown Norway rats (Bonavera *et al*., 1998; Gruenewald *et al*., 1999), indicating a defect in brain regulation rather than at the pituitary level.

Pulsatile GnRH secretion is thought to be governed by an interactive network of neurons secreting a variety of neurotransmitters and neuromodulators (Kalra *et al*., 1997). The list of candidate substances that may mediate the effects of aging on GnRH neurons includes (but is not limited to) neuropeptide Y, the excitatory amino acid glutamine, the endogenous opioid peptide β-endorphin, and the diffusable gas nitric oxide, among many others. However, demonstration of an age-related change in neurons that are thought to affect GnRH neurons does not prove that the impairment in GnRH synthesis and secretion is due to the change in these ''upstream'' neurons. Rather, it seems likely that as the final common pathway of hypothalamic regulation of reproduction, age-related changes in GnRH neuronal function reflect the integration of all changes in neuromodulatory systems impacting GnRH neurons, together with intrinsic changes in GnRH neurons themselves. Sorting out the relative contributions of each of these elements is a formidable challenge indeed.

A. Neuropeptide Y

Neuropeptide Y (NPY) has been implicated in the control of gonadotropin secretion. In adult male rats, intracerebroventricular administration of NPY stimulates LH release (Allen *et al*., 1985), although chronic intracerebroventricular NPY infusion results in a marked inhibition of pituitary–testicular axis function (Pierroz *et al*., 1996). Furthermore, NPY neurons synapse on GnRH neuron perikarya (Tsuruo *et al*., 1990), suggesting that these stimulatory and inhibitory effects of NPY on LH are mediated in part by corresponding actions of NPY on GnRH neurons. The actions of NPY on the hypothalamic/pituitary/gonadal axis appear to depend on the presence of sex steroids. For example, NPY readily stimulates GnRH release *in vitro* from the mediobasal hypothalamus or the median eminence of intact adult male rats (Kalra *et al*., 1990), and intracerebroventricular (or intravenous) NPY induces an increase in GnRH gene expression in preoptic area neurons of adult male rats (Li *et al*., 1994). However, GnRH responsiveness to NPY is reduced in tissues obtained from orchidectomized rats (Urban *et al*., 1996), and in contrast to intact rats, NPY administered intravenously or icv decreases circulating LH levels in orchidectomized rats (Kerkerian *et al*., 1985).

NPY neurons appear to be an important target of sex steroid feedback (Sar *et al*., 1990; Kalra *et al*., 1997). NPY release and gene expression in the arcuate nucleus is modulated by testosterone, with castration decreasing NPY release and arcuate nucleus prepro-NPY messenger RNA (ppNPY mRNA) levels, and testosterone replacement increasing ppNPY mRNA back to levels observed in intact rats (Sahu *et al*., 1992; Urban *et al*., 1993).

Based on the foregoing, it has been proposed that decreased LH and GnRH secretion in aging rats is due at least in part to declining NPY neuronal activity and that decreased circulating testosterone levels with aging may contribute to declining NPY neuron secretory activity (Sahu *et al*., 1988; Kalra *et al*., 1993). An initial study to assess age-related changes in hypothalamic NPY activity involved the measurement of NPY peptide content in discrete hypothalamic nuclei and the ability of potassium-induced depolarization to cause NPY release from the mediobasal hypothalamus of male Sprague–Dawley rats *in vitro* (Sahu *et al*., 1988). Compared to 2.5-month-old rats, 8- and 13-month-old rats released significantly less NPY from the mediobasal hypothalamus after potassium-induced depolarization *in vitro*, and NPY content was reduced in several hypothalamic nuclei containing the perikarya and nerve terminals of NPY neurons, including the arcuate nucleus, MPOA, median eminence, and other nuclei.

A subsequent study of the effects of aging, orchidectomy, and testosterone replacement on NPY peptide content in hypothalamic nuclei revealed that in young rats, orchidectomy was associated with a decrease in NPY content in the ventromedial nucleus, arcuate nucleus, and median eminence that was prevented with testosterone replacement (Sahu *et al*., 1990) (Fig. 57.6). However, no effect of orchidectomy was observed in four other nuclei (MPOA, suprachiasmatic nucleus,

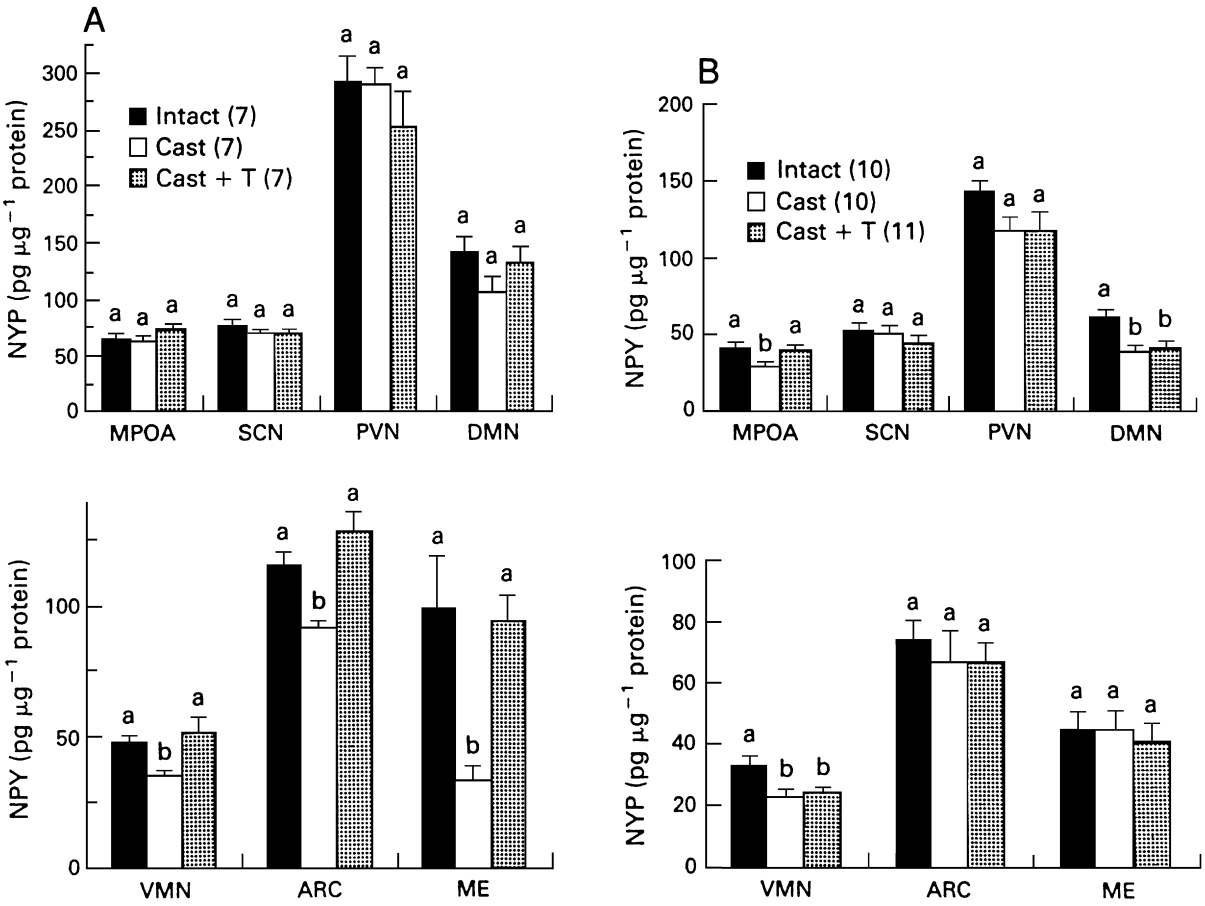

FIG. 57.6. Effects of orchidectomy (Cast) and testosterone (T) replacement on the neuropeptide Y (NPY) content by radioimmunoassay in various hypothalamic sites of (A) 2.5-month- and (B) 15-month-old male Crl:CD(SD)Br rats. ARC, arcuate nucleus; DMN, dorsomedial nucleus; ME, median eminence; MPOA, medial preoptic area; PVN, paraventricular nucleus; SCN, suprachiasmatic nucleus; VMN, ventromedial nucleus. Figures in parentheses denote number of rats. Values shown are means ± SEM. Bars with dissimilar superscripts are significantly different from each other for that nucleus ($P < 0.05$). Used with permission (Sahu *et al*., 1990).

paraventricular nucleus, and dorsomedial nucleus). In contrast, old rats did not exhibit a decrease in NPY content with orchidectomy in the median eminence or the arcuate nucleus, whereas a decrease was observed in the ventromedial nucleus, MPOA, and dorsomedial nucleus. Furthermore, with the exception of the MPOA (the site of most GnRH neuron cell bodies), testosterone replacement did not prevent the decrease in NPY content with orchidectomy in old rats. These findings suggested regional specificity in the effects of orchidectomy on NPY neurons and loss of NPY responsiveness to testosterone action with aging.

As noted previously, it is not possible to determine whether a change in peptide content is due to an effect on peptide synthesis or an opposite effect on peptide release or degradation. Therefore, we performed additional studies in our laboratory in aging male Brown Norway rats to determine whether the decreased NPY content and *in vitro* release with aging were associated with a decrease in hypothalamic NPY synthetic capacity (Gruenewald *et al*., 1994b). Furthermore, we assessed the potential role of testicular feedback in contributing to age-related alterations in NPY synthetic capacity.

We hypothesized that reduced NPY secretion with aging is due to decreased NPY gene expression and that this decrease is independent of testicular feedback. To test this hypothesis, arcuate nucleus ppNPY mRNA levels measured by *in situ* hybridization and serum gonadotropin and testosterone levels determined by radioimmunoassay were compared in sham-operated and orchidectomized young (3 month), middle-aged (13 month), and old (23 month) male Brown Norway rats. Hybridization area and average optical density were used as indices of arcuate nucleus ppNPY mRNA content. In sham-operated rats, both ppNPY mRNA hybridization area and optical density decreased progressively with aging (Fig. 57.7), while serum testosterone levels were decreased in old compared to middle-aged and young rats. In orchidectomized rats, ppNPY mRNA hybridization area also decreased significantly with aging, although optical density did not change significantly (Fig. 57.8). This observation of an age-associated reduction in ppNPY mRNA levels in both sham-operated and orchidectomized rats suggested that NPY synthetic capacity is decreased with aging independently of the effects of testicular feedback. Furthermore, ppNPY mRNA levels were

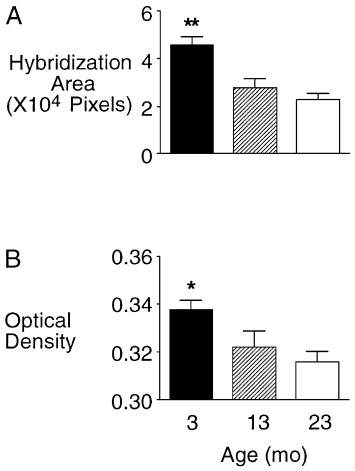

FIG. 57.7. ppNPY mRNA content measured by *in situ* hybridization histochemistry in the arcuate nucleus of sham-operated young (3-month-old, $n=8$, solid bars), middle-aged (13-month-old, $n=6$, hatched bars), and old (23-month-old, $n=7$, open bars) male Brown Norway rats. ppNPY mRNA levels were quantitated by film autoradiography over the entire arcuate nucleus of each rat brain. Total hybridization area (A) and average optical density (B) were used as indices of total arcuate nucleus ppNPY mRNA levels. Values shown are means ± SEM. Note that optical density is a logarithmic function, and that optical density scale does not include zero. Both hybridization area and optical densities were significantly decreased in old and middle-aged compared to young rats (**$P<.001$ vs middle-aged and old; *$P<0.05$ vs middle-aged and old). Used with permission (Gruenewald *et al*., 1994b).

lower in orchidectomized than in sham-operated young and middle-aged rats, while they were similar in orchidectomized and sham-operated old rats, indicating a lack of effect of orchidectomy upon ppNPY mRNA levels in older animals.

Our findings are consistent with the hypothesis that declining NPY synthetic capacity and secretion contributes to a decrease in GnRH and LH secretion with aging. Although ppNPY mRNA levels were markedly decreased in middle-aged animals, we found that LH and testosterone levels at a single time point were not decreased in middle-aged compared to young intact Brown Norway rats, (Gruenewald *et al*., 1994b), suggesting a lack of concordance between ppNPY mRNA levels on the one hand and circulating gonadotropin and testosterone levels on the other. However, we subsequently found that circulating levels of LH and testosterone determined over a 24-hr period decreased progressively with aging, apparently the result of an age-related decrease in diurnal variation of these hormones in male Brown Norway rats (Gruenewald *et al*., 1999). These recent findings indicate that the age-related reductions in NPY synthetic capacity are associated with reductions in GnRH, LH, and testosterone secretion in this model.

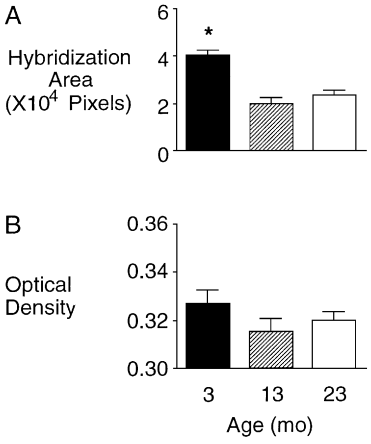

FIG. 57.8. ppNPY mRNA content measured by *in situ* hybridization histochemistry in the arcuate nucleus of orchidectomized young (3-month-old, $n=8$, solid bars), middle-aged (13-month-old, $n=7$, hatched bars), and old (23-month-old, $n=7$, open bars) male Brown Norway rats. Values shown are means ± SEM. In these orchidectomized rats, total hybridization area (A) was significantly decreased in old and middle-aged compared to young rats (*$P<.001$ vs middle-aged and old), while average optical density (B) was unchanged with aging. Used with permission (Gruenewald *et al*., 1994b).

Some of our findings suggest that declining testosterone levels may not be a major cause of decreased NPY synthetic capacity with aging. First, NPY hybridization area decreased with aging in both orchidectomized and in sham-operated animals (Figs. 57.7 and 57.8). Second, the reduction in NPY gene expression we observed with orchidectomy (10–32% depending upon age group) was not as marked as the decline occurring with aging (40–50%), even though the reduction in testosterone levels was much greater with orchidectomy than aging. Therefore, the mechanisms underlying the decreases in NPY gene expression with aging and orchidectomy may be different, and the effects of aging upon ppNPY mRNA levels are not due only to declining testosterone levels with aging.

A subsequent study of aging and ppNPY gene expression in male F344 × Brown Norway rats by Li *et al*. (1998) reported that ppNPY mRNA levels did not decrease from 3 to 24 to 31 months of age. However, Li *et al*. sacrificed their rats at a different time in the light–dark cycle, 2 hr after lights-off, in contrast to our practice of sacrificing animals during the light phase. ppNPY mRNA levels in young adult animals exhibit circadian variation, with a sustained increase during the second half of the light phase and a sharp decrease at the time of lights off (Akabayashi *et al*., 1994). When rats were killed during the light phase, Li *et al*. were able to confirm a decrease in ppNPY mRNA with aging, similar to our results (unpublished data, see Li *et al*., 1998). Based on these findings, future studies of NPY gene expression should take careful account of this circadian variation in ppNPY mRNA (and circulating hormone) levels, and further studies are indicated to determine whether the circadian variation observed in young adult animals is affected by aging.

B. Excitatory and Inhibitory Amino Acids

Acidic amino acids such as glutamate and aspartate activate central nervous system neurons and are thought to be important excitatory neurotransmitters in the mammalian central nervous system. Moreover, excitatory amino acids are thought to have an important role in the regulation of GnRH and LH secretion. For example, *N*-methyl-D-aspartate (NMDA), an analog of the putative neurotransmitter aspartate, increases LH secretion in male rats after systemic or central administration (Schainker and Cicero, 1980; Ondo *et al*., 1988). This

effect of NMDA on the hypothalamic–pituitary–gonadal axis is thought to be mediated by specific receptors within the central nervous system rather than at the pituitary level (Schainker and Cicero, 1980; Ondo *et al*., 1988; Brann and Mahesh, 1994), with NMDA administration stimulating hypothalamic GnRH release that in turn leads to LH release. Furthermore, ppGnRH mRNA levels increase rapidly following NMDA administration (Petersen *et al*., 1991), suggesting that NMDA stimulates GnRH neuron synthetic capacity.

With aging, decreases have been reported in binding to and number of hippocampal NMDA receptors in various rodent models (Ingram *et al*., 1992; Magnusson and Cotman, 1993). To determine whether alterations in excitatory amino acids acting through NMDA receptors could in part explain alterations in GnRH release with aging, GnRH release from hypothalamic explants from young (3- to 6-month-old) and old (20- to 22-month-old) male Wistar-Kyoto rats was measured *in vitro* after administration of the excitatory amino acids NMDA, glutamate, and kainate (Sortino *et al*., 1996). These different glutamate receptor agonists were administered because although the role of glutamate in the control of GnRH release is well-established, the involvement of various subtypes of glutamate receptors (e.g., NMDA, kainate and D,L-α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors) in this process is more controversial. GnRH release in response to glutamate was similar in young and old rats, whereas NMDA elicited a greater GnRH response in young than in old rats. In contrast, GnRH release after kainate administration was greater in the old than in the young animals. These findings suggest that the involvement of the various excitatory amino acid receptor subtypes in the regulation of GnRH secretion may vary with aging.

The role of excitatory amino acids in mediating age-related changes in reproductive axis regulation was further evaluated by Bonavera *et al*. (1998) in young (3- to 4-month-old), middle-aged (12- to 13-month-old), and old (21- to 22-month-old) male Brown Norway rats. The increase in circulating LH levels after NMDA administration *in vivo* was less in old than in younger rats (Fig. 57.9), and GnRH release from mediobasal hypothalamus/preoptic area fragments *in vitro* after NMDA was also decreased in old compared to younger rats (Fig. 57.10). Finally, glutamine content in mediobasal hypothalamus/preoptic area fragments was decreased in old compared to younger rats. These findings support an important role for excitatory amino acids acting through NMDA receptors in mediating the age-related decline in GnRH secretion and extend these observations to the aging male Brown Norway rat model.

This group further investigated the potential mechanisms underlying hypothalamic–pituitary dysregulation of reproductive function, by evaluating age-related changes in nitric oxide synthesis in the preoptic area and hypothalamus of male Brown Norway rats (Vernet *et al*., 1998). Nitric oxide (NO) is a neurotransmitter that is thought to play a physiological role in stimulating the release of a number of hypothalamic neuropeptides including GnRH. Under normal conditions, NO is thought to mediate the effects of glutamate acting through NMDA receptors in the hypothalamus; glutamate stimulates neuronal NO synthase, and NO synthase inhibitors block the ability of glutamate to stimulate GnRH release

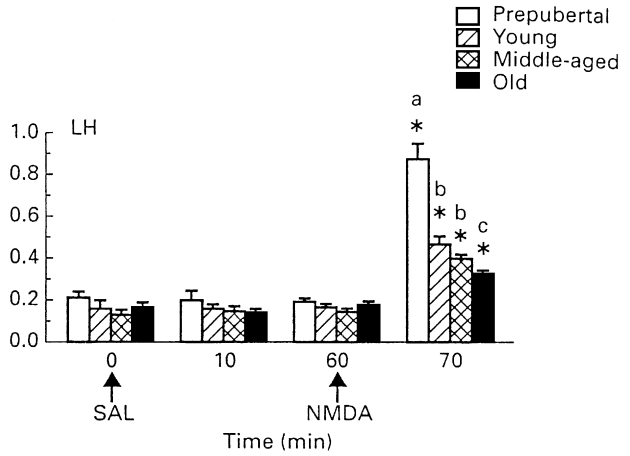

FIG. 57.9. Effect of NMDA on LH secretion in prepubertal (35-day), young (3- to 4-month), middle-aged (12- to 13-month) and old (21- to 23-month) male Brown Norway rats *in vivo*. Saline (SAL) and NMDA (5 mg/kg) were injected iv at 0 and at 60 min, respectively. Note that NMDA but not SAL produced significant increases in LH at 70 min (denoted by an asterisk, $P < 0.05$ vs SAL). Different superscripts above the bars denote significant differences ($P < 0.05$) among different age groups at the same time point. Used with permission (Bonavera *et al*., 1998).

(Rettori *et al*., 1994). Thus, an aging-related decrease in NO synthesis due to reduced excitatory amino acid binding to NMDA receptors could contribute to decreased GnRH secretion with aging. On the other hand, if glutamate stimulation of NO synthesis were excessively increased with aging, this could lead to accumulation of NO metabolites, possibly resulting in cytotoxic effects on hypothalamic neurons and impairment of GnRH neuronal function.

To determine whether aging is associated with alterations in NO synthesis in the hypothalamus that could contribute to reproductive axis dysfunction, hypothalamic NO synthase activity was measured in 3- and 24-month-old male Brown Norway rats using the arginine/citrulline assay (Vernet *et al*., 1998). A relatively modest (67%) increase in hypothalamic neuronal NO synthase activity was observed in old compared to young rats, but there was no change in neuronal NO synthase content by Western blot with aging, and hypothalamic NMDA receptor content and binding were decreased by 34 and 66%, respectively, in old rats. In contrast, hypothalamic activity of inducible NO synthase, the isoform induced in inflammatory or degenerative processes, was increased nearly fourfold in old compared to young adult rats. Thus, hypothalamic NO production appears to increase with aging, but there is no corresponding increase in the number of NMDA receptors. These findings argue against the hypothesis that reduced GnRH secretion with aging is due to a decrease in excitatory amino acid binding to NMDA receptors and subsequent reduction in NO synthesis. Furthermore, it is unlikely that excessive excitatory amino acid stimulation acting through the NMDA receptor is the cause of elevated NO synthase activity with aging, and NMDA receptors are probably not a major participant in the degenerative hypothalamic changes occurring in aging rats. However, the marked increase in inducible NO synthase activity with aging suggests that elevated NO levels could contribute to neurotoxicity by other mechanisms, possi-

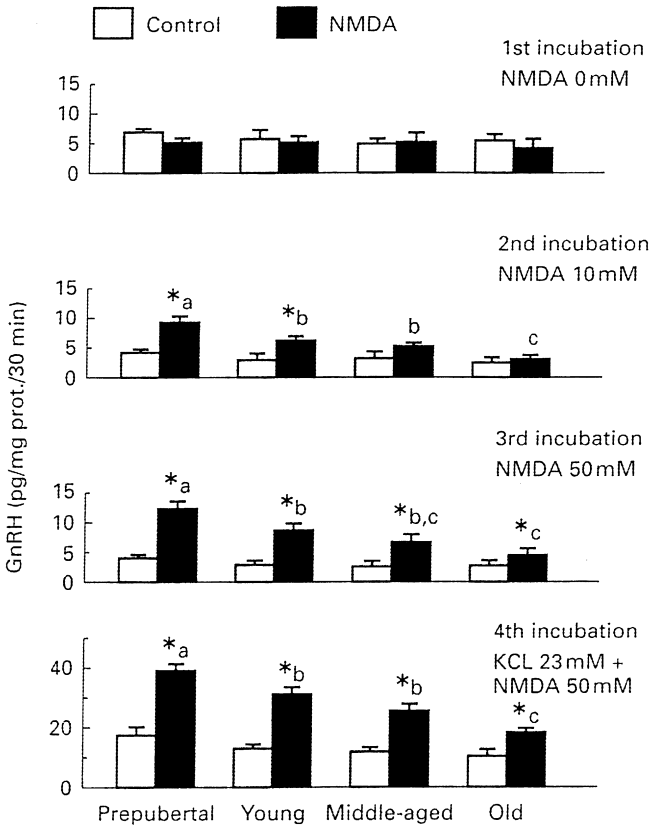

FIG. 57.10. Effect of NMDA on basal and KCl-induced GnRH release *in vitro* by fragments of preoptic area/mediobasal hypothalamus (POA-MBH) from prepubertal (35-day), young (3- to 4-month), middle-aged (12- to 13-month), and old (21- to 23-month) male Brown Norway rats. Each treated fragment (filled bars) was incubated consecutively with medium containing 0 mM (basal, first incubation), 10 mM (second incubation), 50 mM NMDA (third incubation), and 50 mM NMDA + 23 mM KCl (fourth incubation). Control POA-MBH fragments (clear bars) were incubated with Krebs-Ringer phosphate bicarbonate in the first three incubations and with Krebs-Ringer containing 23 mM KCl in the fourth incubation. Significant differences between control and NMDA treated fragments within each age group at the same incubation time are denoted by an asterisk ($P < 0.05$; unpaired student t test). Bars with different superscripts indicate significant differences ($P < 0.05$) among NMDA-treated fragments from different age groups at the same incubation time. Used with permission (Bonavera *et al.*, 1998).

bly leading to impairment in GnRH neuronal function in old animals.

Alterations in inhibitory acids may also play a role in mediating aging-related changes in GnRH and gonadotropin secretion. GABA is thought to be important in the regulation of gonadotropin secretion in young adult male rats. In studies *in vitro*, for example, the GABA-A and GABA-B receptor agonists muscimol and baclofen, respectively, decreased GnRH and glutamate release from hypothalamic perfusates, whereas the GABA-A and GABA-B receptor antagonists bicuculline and phaclofen, respectively, enhanced GnRH and glutamate release (Feleder *et al.*, 1996). With aging, concentrations of GABA in the hypothalamus are significantly decreased in male Brown Norway (Bonavera *et al.*, 1998) and F344 (Banay-Schwartz *et al.*, 1989) rats, and a reduction in [^{3}H]muscimol binding to GABA-A receptors was observed in all brain areas examined in male F344 rats (Araki *et al.*, 1996). However, the effects of these age-related changes in brain GABA on GnRH and LH secretion are unknown.

C. β-Endorphin

β-Endorphin is an endogenous opioid peptide that is thought to exert a tonic inhibitory influence upon GnRH secretion and to be an important regulator of reproductive function (Cicero *et al.*, 1979; Delitala *et al.*, 1983). β-Endorphin is derived from a larger precursor peptide, proopiomelanocortin (POMC), and is produced by neurons located in the arcuate nucleus, many of which synapse onto GnRH neurons in the MPOA.

Administration of the opiate antagonist naloxone in male Sprague–Dawley rats was found to induce a marked increase in serum LH levels in young animals, which was attenuated with aging (Steger *et al.*, 1980b). However, more recently, *in vitro* studies in males of the same rat strain found that less naloxone was needed to induce GnRH release from hypothalami of older compared to young adult rats (Nazian *et al.*, 1998). The reasons for this apparent discrepancy are unclear. Hypothalamic β-endorphin content decreases with age in various rat strains such as Wistar (Dax *et al.*, 1988), Sprague–Dawley (Gambert *et al.*, 1980; Barden *et al.*, 1981; Forman *et al.*, 1981), and Long–Evans (Dorsa *et al.*, 1984) rats, which could represent either a decrease in β-endorphin production, or an increase in β-endorphin release or metabolism. Alterations in posttranslational processing of hypothalamic POMC occur in aging male F344 rats, with increased amounts of acetylated β-endorphin peptides and shorter forms of β-endorphin (βE_{1-27} and βE_{1-26}) (Wilkinson and Dorsa, 1986; Dax *et al.*, 1988). β-endorphin is thought to be an endogenous ligand for μ-opioid receptors, which are thought to be involved in the regulation of LH secretion (Panerai *et al.*, 1985), and the number of hypothalamic μ-opioid receptors was found to decrease with aging in male Sprague–Dawley rats (Piva *et al.*, 1987). However, the effects of decreased hypothalamic β-endorphin content, altered posttranslational processing of β-endorphin and reduced μ-receptor binding with aging on opiate tone and GnRH and gonadotropin secretion are unclear.

We tested the hypothesis that the age-related decrease in GnRH secretion in male rats is due to increased β-endorphin synthesis, by comparing prepro-POMC (ppPOMC) mRNA levels in the arcuate nucleus of intact young (3-month-old), middle-aged (11-month-old), and old (23-month-old) male F344 rats. ppPOMC mRNA levels were quantified by *in situ* hybridization histochemistry. We found a significant decrease in both cellular ppPOMC mRNA content and in the number of labeled POMC neurons in old compared to younger rats.

These findings in male F344 rats suggest that β-endorphin synthetic capacity is decreased with aging. However, as for the effects of aging on GnRH, these observations in aging male F344 rats are potentially confounded by elevated progesterone levels. To our knowledge, no studies of aging effects on POMC gene expression in the arcuate nucleus or other aspects of β-endorphin regulation of reproductive axis aging have been performed in aging male Brown Norway rats, but our results in the F344 model suggest that the decline in GnRH secretion in old male rats is not a result of increased β-endorphin synthesis.

D. Catecholamines and Serotonin

Dopamine is a catecholamine neurotransmitter synthesized from tyrosine. The rate-limiting step in dopamine biosynthesis is tyrosine conversion to L-dopa, which is catalyzed by tyrosine hydroxylase. Tuberoinfundibular dopaminergic neurons in the periventricular and arcuate nuclei and dopaminergic neurons of the rostral periventricular nuclei that project to the MPOA and other hypothalamic nuclei are thought to regulate reproductive function (Kalra and Kalra, 1983). However, the role of dopamine in the regulation of gonadotropin secretion is controversial, because dopamine has been found to both stimulate and inhibit GnRH and gonadotropin secretion (Schneider and McCann, 1969; Kamberi *et al*., 1970; Fuxe *et al*., 1976; Negro-Vilar *et al*., 1979; Gallo, 1980).

Dopamine released by tuberoinfundibular dopaminergic neurons tonically inhibits pituitary prolactin secretion. In turn, prolactin stimulates dopamine secretion from tuberoinfundibular dopaminergic neurons, forming a feedback loop (Moore, 1987; Toney *et al*., 1991). Increased prolactin levels occur in aging male rats of several strains, including F344 (Bethea and Walker, 1979; Turek and Desjardins, 1979), Wistar (Simpkins *et al*., 1977), and Long–Evans (Riegle and Meites, 1976), but not Brown Norway (Gruenewald *et al*., 1994a) or Sprague–Dawley (Amoroso *et al*., 1987) rats. Some investigators have found that chronic hyperprolactinemia occurring in some aging animal models is associated with suppressed tuberoinfundibular dopaminergic activity (Sarkar *et al*., 1984; Simpkins and Gabriel, 1984), suggesting that the hyperprolactinemia is caused by age-related reduction in the activity of tuberoinfundibular dopaminergic neurons in these rat strains. However, elevated PRL levels inhibit gonadotropin secretion (McNeilly, 1987; Fox *et al*., 1987) and ppGnRH mRNA levels (Selmanoff *et al*., 1991), therefore, excessive prolactin is a potentially confounding variable in reproductive aging studies in these rat strains. Furthermore, clinically significant hyperprolactinemia does not occur with normal aging in humans; therefore, studies performed in rats that do not develop hyperprolactinemia with aging may provide information more analogous to the situation in aging humans.

Most studies have reported a decrease in dopamine content in the hypothalamus and median eminence of aging male rats, including Long–Evans (Demarest *et al*., 1980), Sprague–Dawley (Carfagna *et al*., 1985), F344 (Steger *et al*., 1985) and Wistar (Simpkins *et al*., 1977; Bhaskaran and Radha, 1983) rats and C57BL/6J mice (Finch, 1973), although levels of hypothalamic dopamine were found to be similar in young and old Brown Norway rats (Gilad *et al*., 1993). Measurements of hypothalamic dopamine turnover rates, which provide more information about dopaminergic neuron activity than content measurements, were found to decrease with aging in Long–Evans (Demarest *et al*., 1980) and Wistar (Simpkins *et al*., 1977) rats, but were unchanged with aging in Sprague–Dawley rats (Carfagna *et al*., 1985). Diminished dopamine release *in vitro* with aging has also been reported (Goldman *et al*., 1987; Gregerson and Selmanoff, 1990), although no age-related changes were found in Sprague–Dawley rats (Amoroso *et al*., 1987). *In vivo*, secretion of dopamine into hypophysial portal blood has been found to decrease with aging (Gudelsky *et al*., 1981) or to increase with aging (Hotta *et al*., 1991) in Wistar rats that were hyperprolactinemic. Hypothalamic tyrosine hydroxylase activity appears to be unchanged with aging (Ponzio *et al*., 1982; Fernandez-Ruiz *et al*., 1992). Moreover, tyrosine hydroxylase gene expression in the hypothalamus was unchanged with aging in male Long–Evans rats (Kedzierski and Porter, 1990). However, activity of hypothalamic monoamine oxidase, an enzyme involved in catecholamine removal, increases with aging (Bhaskaran and Radha, 1983).

Few studies have assessed the effects of these age-related changes in dopamine secretion on reproductive axis function. L-Dopa-induced hypothalamic LH release in young adult female rats is attenuated with aging, but in male rats L-dopa injections failed to increase serum LH in either young or old rats (Riegle and Meites, 1976). Administration of pergolide, a D2 dopamine receptor agonist, throughout adult life in male F344 rats prevented the age-related decline in circulating FSH levels typically seen in this rat strain (Felten *et al*., 1992). Intriguingly, long-term (12 months) testosterone replacement in 24-month-old male Wistar rats increased dopamine release in the MPOA, while at the same time restoring sexual behavior nearly to levels observed in 3-month-old rats (Sato *et al*., 1998). These findings suggest that dopamine may be involved in the age-related decline in male reproductive function, and that this impairment is reversible with chronic testosterone replacement therapy. To our knowledge, the effect of age-related changes in hypothalamic dopamine function on GnRH secretion have not been directly determined, nor are data available regarding the effects of aging on hypothalamic dopamine turnover and release, or tyrosine hydroxylase activity in male Brown Norway rats. Finally, it is important to note that many of the studies of age-related effects on dopamine activity mentioned above were performed in rats that either developed hyperprolactinemia with aging or in whom prolactin levels were not measured, raising questions regarding potential confounding effects of chronic hyperprolactinemia on hypothalamic dopamine activity and/or GnRH secretion.

Levels of hypothalamic norepinephrine have been found either to decrease (Miller *et al*., 1976; Simpkins *et al*., 1977; Bhaskaran and Radha, 1983; Steger *et al*., 1985) or to remain unchanged (Lorens *et al*., 1990; Rodriguez-Gomez *et al*., 1995) with aging in male rats. Most studies have found a decrease in hypothalamic norepinephrine turnover with aging in male rats (Simpkins *et al*., 1977; Ponzio *et al*., 1978) and mice (Finch, 1973), although some have reported no change in norepinephrine turnover with aging (Carfagna *et al*., 1985). Noradrenergic neurons are thought to stimulate GnRH release (Kalra and Kalra, 1983), suggesting that a decline in noradrenergic stimulation with aging could contribute to the age-related decline in GnRH secretion.

The effects of serotonin or 5-hydroxytryptamine on gonadotropin secretion are controversial, with reports of stimulatory, inhibitory, or no effects (Vitale and Chiocchio, 1993). Many studies have reported that serotonin levels in the hypothalamus are unchanged in aging male rats (Simpkins *et al*., 1977; Ponzio *et al*., 1982; Bhaskaran and Radha, 1983), although others have found increased (Steger *et al*., 1985; Rodriguez-Gomez *et al*., 1995) or decreased (Gozlan *et al*., 1990) levels with aging. These inconsistencies may be due in part to a marked circadian variation in hypothalamic serotonin neuronal activity, especially in the suprachiasmatic nucleus (Simpkins and Mill-

ard, 1987). However, hypothalamic serotonin turnover has been more consistently reported to increase with aging (Simpkins *et al*., 1977; Gozlan *et al*., 1990; Rodriguez-Gomez *et al*., 1995).

The reader is referred elsewhere for more in-depth reviews of aging and hypothalamic neurotransmitters (Simpkins and Millard, 1987; Meites, 1991).

E. Other Neuromodulators

Corticotropin-releasing hormone (CRH) is thought to inhibit the secretion of gonadotropins through both an endogenous opioid-dependent inhibition of GnRH secretion and a direct, opioid-independent effect on GnRH neurons (Almeida *et al*., 1988; MacLusky *et al*., 1988). With aging, hypothalamic CRH content has been found to decrease in male Wistar (Kowalski *et al*., 1992) and F344 × Brown Norway F1 hybrid (Cizza *et al*., 1994) rats, and was decreased in the median eminence of F344 × Brown Norway F1 hybrid rats (Hauger *et al*., 1994). CRH binding was decreased in the hypothalamus of old male F344 rats (Heroux *et al*., 1991). CRH mRNA levels in the paraventricular nucleus of the hypothalamus was found to decrease (Cizza *et al*., 1994) or to be unchanged (Hauger *et al*., 1994) in aging male F344 × Brown Norway F1 hybrid rats, and was decreased with aging in male F344 rats (Kasckow *et al*., 1999). Based on these data that generally indicate a decrease in hypothalamic CRH activity with aging, together with the findings of an inhibitory effect of CRH on GnRH and gonadotropin secretion, it seems unlikely that CRH plays a major role in the age-related impairment in reproductive axis regulation in the male rat.

Galanin is a neuropeptide that stimulates LH release, apparently by potentiating the effect of GnRH (Lopez *et al*., 1991). Galanin and GnRH are colocalized in a subset of preoptic neurons in the rat brain, and in adult female rats galanin gene expression in GnRH neurons is induced by ovarian steroids in association with the LH surge (Rossmanith *et al*., 1996), suggesting an important role for galanin in the regulation of reproductive functions in females. However, less attention has been paid to its role in the regulation of male reproductive function. The number of galanin-immunoreactive cells in the medial septal nucleus and the diagonal band of Broca is decreased in 16- to 30-month-old compared to 3- to 6-month old male rats (de Bilbao *et al*., 1991). However, no studies have determined whether the number of neurons colocalizing galanin and GnRH declines, nor has the effect of declining numbers of galanin-immunoreactive neurons on reproductive function been assessed in aging male rats.

The effects of Substance P on gonadotropin secretion are controversial. Dees *et al*. (1985) reported that injections of either a substance P antagonist or an antiserum into the lateral ventricle suppressed circulating LH levels in orchidectomized male rats. In contrast, Picanco-Diniz *et al*. (1990) found that injection of substance P into the MPOA of either intact or orchidectomized male rats significantly decreased circulating gonadotropin levels. Hypothalamic substance P content has been reported to decline with aging in male Sprague–Dawley rats (Z. P. Wang *et al*., 1993), but the role of substance P in mediating age-related changes in male reproductive axis function has not been determined.

IV. Experimental Approaches to "Reversal" of Age-Related Hypothalamic Reproductive Dysfunction

A. Hormone Supplementation

There has recently been considerable interest in the potential role of declining levels of hormones such as testosterone, growth hormone, dehydroepiandrosterone (DHEA), and melatonin in causing or contributing to the adverse effects of aging. In contrast to aging-related estrogen deficiency in females, the age-related decreases in the levels of these other hormones occur gradually, and the rate of decline is often highly variable between individuals. Indeed, it is unclear whether declining hormone levels with aging constitute a hormone "deficiency" state or whether the decrease in hormones may protect against other adverse effects of aging.

It has been hypothesized that the age-related decline in hormones such as the ones described above may contribute to the age-related decrease in GnRH neuronal activity with aging, and that replacement of these hormones may at least in part reverse the age-related decline in reproductive function (Li *et al*., 1997a,b). For example, although melatonin has been observed to have antigonadotrophic effects in some species, particularly those with marked seasonal variations in gonadal function, in young adult male rats, melatonin was found to stimulate GnRH gene expression as determined by ISHH (Li and Pelletier, 1995). Based on observations that administration of melatonin to female rodents increased the longevity of these animals, Li and Pelletier determined the effect of melatonin administration on age-related changes in ppGnRH mRNA levels in male Sprague–Dawley rats (Li *et al*., 1997b). Either vehicle or 24 mg/kg melatonin was administered intraperitoneally twice a day for 2.5 days to 50- to 54-day-old and 18-month-old rats, followed by sacrifice and measurement of cellular ppGnRH mRNA content (number of silver grains per labeled cell) by ISHH in the basal forebrain. Cellular ppGnRH mRNA content declined by 13% in old compared to young vehicle-treated rats, similar to results we reported in both F344 and Brown Norway rats (Gruenewald and Matsumoto, 1991; Gruenewald *et al*., 1999). In young rats, melatonin administration increased cellular ppGnRH mRNA content by 11% compared to vehicle-treated rats (Fig. 57.11). In old rats, melatonin administration increased cellular ppGnRH mRNA content by 17% compared to old vehicle-treated rats, restoring mRNA levels to the level of young vehicle-treated rats but not reaching levels observed in young melatonin-treated rats.

A similar study methodology was used to determine the effect of DHEA administration (12 mg/kg body weight sc twice a day) for 2.5 days in 50- to 54-day-old and 18-month-old male Sprague–Dawley rats. As in the melatonin study, a 10% decrease in cellular ppGnRH mRNA content was observed in old compared to young control rats. Whereas DHEA administration resulted in an 18% decrease in cellular ppGnRH mRNA content in young rats, in older animals DHEA restored cellular ppGnRH mRNA content to levels slightly higher than those in young vehicle-treated rats.

Based on the foregoing, it was suggested that declining melatonin levels may be involved in the reduction in GnRH neuronal activity with aging, and that melatonin or DHEA

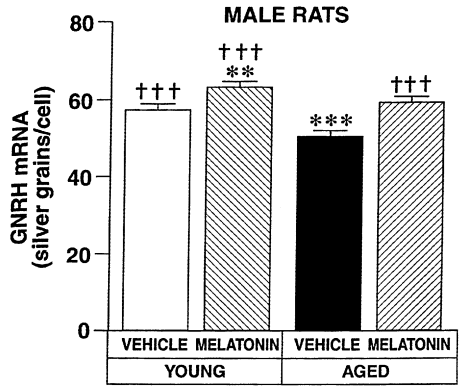

FIG. 57.11. Effect of five injections of melatonin (24 mg/kg body weight) administered intraperitoneally every 12 hr on ppGnRH mRNA levels as measured by the number of grains overlying labeled neurons by *in situ* hybridization histochemistry in young (50- to 54-day) and aged (18-month) male Sprague–Dawley rats (***$P<0.001$, **$P<0.01$ vs vehicle-treated young rats; $^{+++}P<0.001$ vs vehicle-treated old rats). Control animals received vehicle (0.9% NaCl and 5% ethanol) instead of melatonin. Rats were sacrificed 6 hr after the last injection. Used with permission (Li *et al*., 1997b).

administration might be useful in preventing or reversing age-related deficits in reproductive function. However, the dose of melatonin administered to these animals was pharmacological rather than physiological; by comparison, in humans, administration of 0.1 to 0.3 mg in the daytime results in peak serum concentrations that are within the normal nighttime range (Brzezinski, 1997). In these rat studies, no data were provided regarding circulating endogenous melatonin levels, nor were circulating LH and testosterone levels measured. It is possible that melatonin treatment decreased testosterone levels, which could in turn increase GnRH synthesis and secretion as a result of reduced testosterone negative feedback. Therefore, the physiological role of melatonin in the aging process cannot be determined from these studies alone. This will require further investigation.

As for DHEA, in contrast to humans, rodents have negligible production of adrenal androgens such as DHEA. Indeed, DHEA concentrations are so low in rodents that it is unknown whether they decline with aging as in humans (Baulieu, 1996). Therefore, the role of this compound is purely pharmacological in rodents, and these results have limited applicability to the human condition. In addition, as in the melatonin study, the dose of DHEA that was used is large; human studies involving 100 mg per day or more have been associated with increased circulating concentrations of androgenic and estrogenic steroids (Yen *et al*., 1995). Furthermore, because DHEA is metabolized to active androgenic and estrogenic steroids such as testosterone and estradiol, including within the brain, it is unclear whether the effects of DHEA are due to a direct effect of DHEA or to the actions of one or more of its metabolites. Finally, in both the melatonin and the DHEA studies, the experimental protocol involved administering these substances for only 2.5 days; therefore the relevance of these findings to longer term changes of hypothalamic aging is unclear.

Finally, as noted above, long-term testosterone replacement from 12 to 24 months of age in orchidectomized male rats was found to restore the mount rate of these 24-month-old rats nearly to levels observed in 3-month-old rats (Sato *et al*., 1998). Furthermore, dopamine release in the MPOA after infusion of *N*-methyl-D-aspartate was increased in testosterone-replaced old rats. These findings suggest that the aging-related impairment in sexual functioning is reversible with chronic testosterone replacement and that dopamine may play a role in mediating the effects of aging on reproductive function in the male.

B. Grafting of Fetal Neurons

Another potential experimental strategy to reverse the decline in hypothalamic regulation of reproductive axis function with aging is to surgically implant juvenile neuronal tissues in the hypothalamic area of experimental animals. Huang *et al*. (1987) transplanted the anterior hypothalamus from male Long–Evans rat fetuses at 17–19 days of gestation into the third ventricles of 18- to 20-month-old impotent male rats. Compared to control rats of the same age that were either untreated or that received grafts of cerebral cortex, 7 of 10 hypothalamic grafted rats experienced restoration of sexual function and were able to father pups when placed together with a proestrous female rat, whereas 0 of 7 untreated and 1 of 4 cortex-grafted rats experienced restoration of sexual function. Furthermore, circulating LH and testosterone levels were significantly higher 2 to 3 months after hypothalamic grafting in animals that exhibited increased sexual functioning (Table 57.2), whereas hormone levels declined in rats whose sexual activity was not increased with hypothalamus grafting and in untreated and cortex-grafted rats. Histological evaluation demonstrated that well-vascularized hypothalamic (and cortex) grafts were growing in the third ventricle of the host brains, apparently in all grafted rats. These findings indicate

TABLE 57.2 Circulating Luteinizing Hormone (LH) and Testosterone (T) Levels by Radioimmunoassay in Impotent 18- to 20-Month-Old Male Long–Evans Rats before and 2 to 3 Months after Receiving Third Ventricular Transplantation of Anterior Hypothalamus from Male Long–Evans Rat Fetuses at 17–19 Days of Gestation

	Transplanted rats		Untreated controls	
	Baseline	After grafting	Baseline	Baseline +2–3 months
LH (ng/ml)	0.68 ± 0.13	0.98 ± 0.09*	0.76 ± 0.16	0.45 ± 0.07*
T (ng/ml)	0.29 ± 0.04	1.04 ± 0.16*	0.67 ± 0.26	0.24 ± 0.07*

Note. Control rats of the same age that did not receive surgery are included for comparison. The experimental data shown are for the subset of rats that exhibited increased sexual functioning after transplantation. In contrast, rats that received third ventricular transplantation of fetal hypothalamus grafts but that did not exhibit increased sexual functioning after the grafts exhibited reduced LH and testosterone levels after 2 to 3 months (data not shown). Furthermore, another group of control rats that received third ventricular transplantation of cortex grafts from fetal rats exhibited declining LH and testosterone levels after 2 to 3 months, similar to that seen in untreated controls (data not shown). Values are expressed as the mean ± SEM. Data from Huang *et al*., 1987, used with permission.

*$P<0.05$ vs baseline for the same experimental group.

that transplantation of fetal hypothalamic grafts can survive and develop in the brains of aging rats and that these grafts can restore reproductive hormone levels and sexual function at least partially toward normal young adult levels. However, no young control rats were included for comparison, to determine whether full restoration of hormonal status or sexual functioning was achieved.

A similar study was subsequently performed by Hung *et al*. (1997), who grafted fetal preoptic area neurons into the preoptic area of 19- to 24-month-old male Long–Evans rats. Similar to the previous study, most of the grafted rats exhibited improved sexual motivation and copulatory activity, whereas sexual performance did not improve in rats grafted with cortex neurons or who received preoptic grafts into the ventromedial hypothalamus. Grafted rats that exhibited improved sexual performance also showed normalization of serum testosterone and LH levels that were not significantly different than levels in intact 6-month-old rats used as controls. These findings suggest that age-related alterations in reproductive neuroendocrine functions and sexual activity are due at least in part to loss of preoptic area function with aging.

C. Calorie Restriction

Chronic dietary calorie restriction has been shown to delay or prevent a wide variety of aging-associated pathologies in a number of rodent strains. In fact, it has been suggested that calorie-restricted rodents be used as a standard model for aging research (Masoro, 1993). Calorie restriction throughout adult life has been found to prevent aging-related reductions in circulating LH, FSH, and testosterone levels in male Sprague–Dawley and F344 rats (Merry and Holehan, 1981; Stokkan *et al*., 1991). Furthermore, 22-month-old male F344 rats that were calorie-restricted throughout adult life exhibited decreased hypothalamic dopamine, norepinephrine, and serotonin content compared to *ad libitum*-fed age-matched control rats (Kolta *et al*., 1989). However, the effects of chronic calorie restriction on aging-related changes in GnRH synthesis and secretion are unknown, and studies of the effects of calorie restriction on reproductive axis function have not been performed in aging male Brown Norway or F344 $\times$ Brown Norway F1 hybrid rats.

V. Conclusion

Based on the studies described above, it is apparent that age-related alterations in reproductive axis function in male rats are due in part to alterations in hypothalamic function. These changes are manifested at the level of GnRH gene expression in preoptic area GnRH-containing neurons. An important unresolved issue in reproductive neuroendocrinology is whether the decrease in GnRH gene expression with aging is due to an intrinsic change in GnRH neuronal function, to altered neuromodulatory input onto GnRH-containing neurons, or both. Currently available studies indicate that the activities of some of the neurons that synapse onto GnRH-containing neurons undergo important changes with aging that could account for decreased GnRH secretion, such as the NPY-containing neurons. Thus, there is probably an important role for altered neuromodulatory input affecting GnRH-containing neurons in contributing to aging-related reproductive decline. However, the data are not yet complete enough to construct a meaningful ''circuit diagram'' describing the effects of aging on a majority of the neuromodulatory influences affecting GnRH secretion that have been described in young adult male rodents. Clearly, further studies are needed to determine the relative importance of changes in the milieu of circulating hormones such as testosterone and alterations in neurotransmitter and neuropeptide input in mediating the effects of aging on GnRH secretion. These studies should use models of aging such as the male Brown Norway rat, in which the physiology of aging related changes in reproductive function is similar to the human, and in which the potential for confounding age-associated pathologies is minimized. Finally, remarkably few studies of the hypothalamic regulation of reproductive aging in the male have been performed in rodent models other than the aging rat. It would be beneficial to validate the findings from rat studies in other rodent models, especially the mouse, to determine whether these results are more broadly generalizable. It is likely that this research will ultimately provide important clues that will add to our understanding of the effects of aging on neuroendocrine regulation in humans.

Regulation of Energy Intake in Old Age

Unexplained weight loss is common in late old age due to a decrease in energy intake relative to energy expenditure and is given the term ''anorexia of aging.'' There is evidence from multiple studies that a loss of the ability to accurately regulate food intake may be an important contributing factor, especially when combined with the adverse social and medical problems that are common in old age. The underlying reasons for the age-associated loss of the ability to regulate food intake are not well understood. However, likely candidates exist at all points in the cascade of mechanisms thought to be involved in energy regulation, including impaired taste and smell, delayed gastric emptying, and altered digestion-related hormone secretion and central responsiveness to those hormones. Further research is needed to identify which of the suspected mechanisms are quantitatively important and whether a loss of the ability to accurately regulate food intake can be offset by dietary or other lifestyle interventions. © 2001 Academic Press.

I. Introduction

Aging is known to be associated with alterations in body fat that have an important impact on health. Through middle age there is a doubling in body fat in men and women living in developed countries (Steen, 1988; Shimokata *et al*., 1989) which is associated with increased morbidity and mortality [U.S. Department of Health and Human Services (USDHHS), 1990]. In contrast, in late old age, body fat typically decreases even in healthy individuals (Steen *et al*., 1979; Chumlea *et al*., 1988; Steen, 1988; Shimokata *et al*., 1989) and unexplained weight loss leading to energy protein malnutrition becomes increasingly common in diverse groups of human subjects and also animal models (Fig. 58.1 and 58.2) (Mason, 1970; Fischer and Johnson, 1990; Miller *et al*., 1990; Coroni-Huntley *et al*., 1991; Fleming-Moran *et al*., 1991; Williamson, 1993; Launer *et al*., 1994; Scarlett *et al*., 1994; Armstrong and Lund, 1996; Ryan *et al*., 1996). Among the institutionalized elderly, as many as 30–50% are reported to suffer from protein-energy malnutrition (Rudman *et al*., 1990; Lipschitz, 1991). This loss of body fat is associated with premature death, micronutrient deficiencies, frailty, increased hospital admission, an increased risk of disability from falls, and it is also known to delay recovery from injury (Delmi *et al*., 1990; Tayback *et al*., 1990; Pamuk *et al*., 1992; Mowe *et al*., 1994).

Although negative energy balance, resulting from low energy intake relative to energy expenditure, is thought to be the usual cause of the loss of body fat in old age, the underlying causes of weight loss and negative energy balance in old age are not well understood. Nationwide studies have suggested that low dietary energy intake is widespread even among healthy elderly adults (USDHHS, 1983), while studies of total energy expenditure in the elderly (Prentice, 1992; Roberts, 1995; Roberts and Dallal, 1998) suggest low rather than high values. The combination of these findings suggest that inadequate energy intake, rather than increased energy expenditure, is the primary cause of weight loss in old age. However, whether this low energy intake is primarily due to social changes that decrease dietary intake or whether there are underlying metabolic changes that impair energy regulation in old age is still under investigation. This review and others (Doty *et al*., 1984; Morley *et al*., 1985; Leibowitz, 1988; Morley and Silver, 1988; Schiffman and Warwick, 1989; Morley, 1997; Schiffman, 1997; Blanton *et al*., 1999; Finkelstein and Schiffman, 1999; Roberts, 2000a–d) examines current evidence on the factors leading to late-life weight and fat loss.

II. Biobehavioral and Social Determinants of Energy Regulation in Older Adults

Many social changes associated with aging have been suggested to cause weight loss. As summarized in Table 58.1, adverse factors ranging from poverty and bereavement to poor dentition, chronic disease, and the use of multiple prescription medications may all potentially be important (Doty *et al*., 1984; Morley and Silver, 1988; Schiffman and Warwick, 1989; Morley, 1990, 1996, 1997; Gorbien, 1994). In addition, depression has been suggested as an important cause of weight loss among the elderly, a finding that has been confirmed in an analysis of cohort data (DiPietro *et al*., 1992). It is interesting to note that the study of DiPietro *et al*. (1992) showed that depression was associated with weight loss only in individuals ages 55 years or older and was actually associated with weight

gain in younger adults. One potential explanation for this finding (Roberts *et al*., 1994) is that social factors are potential catalysts for weight loss only when there is an underlying impairment in the regulation of food intake (see below) that allows impediments to eating to be expressed.

Two related social factors that may potentially reduce energy intake in old age and which have received relatively greater study are reduced dietary variety and social isolation.

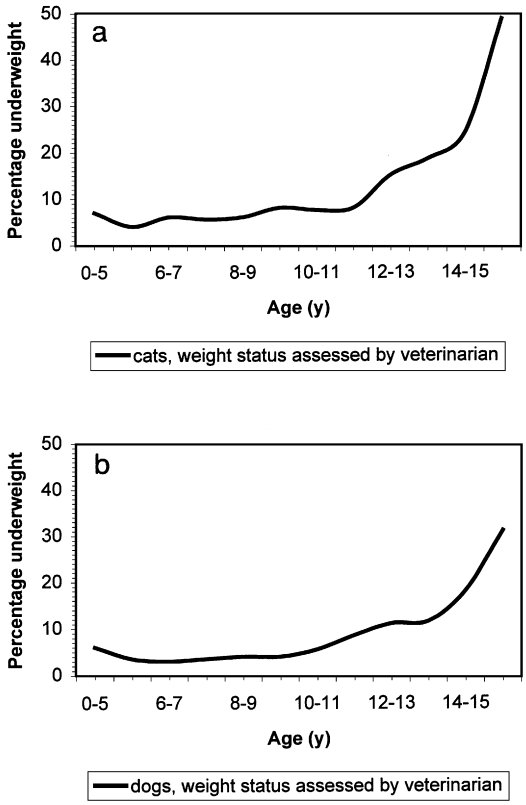

FIG. 58.2. Percentage of underweight cats (a) and dogs (b) by age group (Adapted from Armstrong and Lund, 1996, © Veterinary Practice Publishing Company).

Concerning variety, studies in laboratory rats, cats, and hamsters have shown that energy intake is greater when a variety of foods is provided compared to when only a single food is provided (McCrory *et al*., 1999b, 2000). Numerous single-meal studies in humans also show this phenomenon (Rolls, 1985; McCrory *et al*., 1999b). While two longer term studies have shown that laboratory rats have greater body fat and body fat gain when fed a variety of foods compared to when only a single food is fed (Rolls *et al*., 1983; Louis-Sylvestre *et al*., 1984), long-term studies in humans have been lacking until recently. Our laboratory recently reported on the long-term association between dietary variety and body fatness in healthy adult men and women (McCrory *et al*., 1999b), using 6 month dietary intake reports from a food frequency questionnaire (Block *et al*., 1986) and accurate measurements of body fatness by underwater weighing. In multiple regression analyses controlled for age and sex, dietary variety from a combined group of sweets, snacks, condiments, entrees, and carbohydrates was positively associated with body fatness and in the same model dietary variety from vegetables was negatively associated with body fatness. In other words, individuals who consumed a wide variety of higher energy foods coupled with a low variety of vegetables were relatively fat. The opposite was also true: individuals who consumed a low variety of sweets, snacks, condiments, entrees, and carbohydrates and a high variety of vegetables were relatively lean.

Although it was not possible to specifically examine the effects of age in that study, the results are relevant to aging because dietary variety comes primarily from high-energy

items, and there are reports suggesting that dietary variety typically decreases in old age (Brown, 1976; Fanelli and Stevenhagen, 1985). The reason for why dietary variety may decrease in old age is not known, but social factors such as poverty and living alone may be important. In addition, a study by Rolls and McDermott (1991) suggested that older adults have reduced "sensory specific satiety," a term used to describe the phenomenon of declining pleasantness of food as it is consumed. As summarized in Fig. 58.3, the adolescent and young adult subjects of Rolls and McDermott (1991) responded in the expected manner to a yogurt preload (i.e. decreased desire to eat yogurt but not other offered foods). However, older subjects did not respond and in fact reported an equivalent desire to eat yogurt and other test foods after the preload. Although necessarily short-term and requiring confirmation in a larger study, these data suggest that older adults lack normal patterns of sensory specific satiety that encourage wide dietary variety and thus provide a potential explanation for the observed reduction in dietary variety in old age (Brown, 1976; Fanelli and Stevenhagen, 1985). The underlying reason for decreased sensory specific satiety in old age requires investigation, but potentially may be traced back to the widely reported declines in taste and smell sensitivity associated with aging (Schiffman *et al*., 1976; Schiffman, 1977, 1994, 1997; Schiffman and Pasternak, 1979; Weiffenbach *et al*., 1982; Doty *et al*., 1984; Schiffman and Gatlin, 1993; Finkelstein and Schiffman, 1999). Most studies (Schiffman *et al*., 1976; Schiffman, 1977,1994,1997; Schiffman and Pasternak, 1979; Weiffenbach *et al*., 1982; Doty *et al*., 1984; Schiffman and Gatlin, 1993; Finkelstein and Schiffman, 1999) suggest that detection and recognition thresholds for salt and other specific tastes increase with age, in part because of a loss of functional taste buds and alterations in taste bud structure (Arey *et al*., 1936) and in part because of impaired olfaction (which contributes to the sensation of taste). In consequence, and as shown by Schiffman (1977), elderly individuals have a reduced ability to identify individual foods in blinded tests. If foods taste more similar, the pleasure of a diverse diet will presumably be reduced, thus tending to decrease dietary variety in the absence of social factors working in the opposite direction.

Concerning social isolation, de Castro and de Castro (1989) reported that less energy is eaten at meals taken alone compared to meals eaten in company, with the difference in energy intake between the two situations being a substantial 30%. Although such data are generally used to suggest that social eating is disadvantageous because it promotes overeating and obesity, the opposite (namely that eating alone leads to undereating and weight loss) may be an equally correct interpretation. This is especially true when it is considered that humans are a gregarious animal species, and naturally eat in social groups. This is directly relevant to the issue of low energy intake in older population, because bereavement and functional disabilities can limit social contact (Markson, 1997). Thus, an increased frequency of eating alone may be

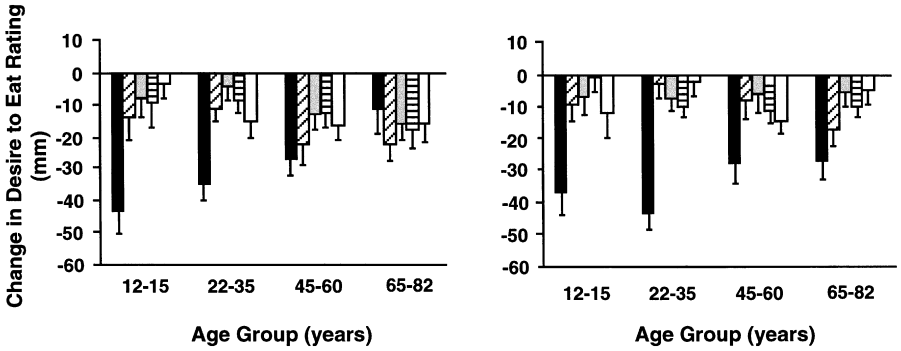

FIG. 58.3. Mean (± SEM) changes in ratings for each of the foods sampled of desire to eat that food from just before to just after eating either 300 g (left) or *ad libitum* (right) amounts of yogurt by the different age groups (years) (From Rolls and McDermott, 1991, © American Society for Clinical Nutrition). ■ Yogurt; ▨ tuna; ▩ cracker; ▤ carrot; □ pretzel.

one of the factors contributing to low energy intake in older adults. Furthermore, there is a positive association between the frequency of eating restaurant food and body fatness (McCrory *et al*., 1999a) and for reasons of social isolation and functional disabilities, older adults may eat out less frequently. The combination of these different observations and findings suggests a potentially important role for reductions in social meals and eating out in the low energy intake and body weight loss of older adults.

III. Impaired Regulation of Food Intake in Older Adults

The question of whether there might be a loss of the ability to regulate energy intake specifically associated with old age, rather than the adverse social factors and diseases common in the elderly, was investigated by our group (Roberts *et al*., 1994,1995; Saltzman and Roberts, 1996; Moriguti *et al*., 2000) and others (Rolls *et al*., 1995; Clarkston *et al*., 1997; Cook *et al*., 1997; Morley, 1997).

In our own studies, we tested the hypothesis that aging is associated with a reduced energy expenditure response to overfeeding or underfeeding and also an impaired subsequent regulation of food intake. As predicted, there were clear differences between age groups in both energy expenditure during the intervention and subsequent energy intake. Young men had a significant increase in basal metabolic rate during overfeeding and a significant decrease in resting energy expenditure during underfeeding, whereas elderly men did not (Saltzman and Roberts, 1996). Moreover, although body weight change during overfeeding or underfeeding was similar in the two age groups, young men subsequently tended to lose all the excess weight following overfeeding while the weight of the elderly men did not decrease significantly (Fig. 58.4). This difference was apparently due to the fact that the young men significantly decreased their voluntary energy intake following overfeeding, while the energy intake of the elderly men did not decrease significantly and indeed remained elevated relative to their previous weight-maintenance requirement (Fig. 58.5). Comparable results were obtained in the underfeeding component of the study. As with overfeeding, there was a similar weight loss during underfeeding in the young and elderly subjects (Fig. 58.6) but subsequently, young men gained back the weight lost during underfeeding while elderly men did not (Fig. 58.6). Again, this difference was apparently due to differences in voluntary food intake following the cessation of underfeeding, because the young men significantly increased their energy intake following underfeeding, although

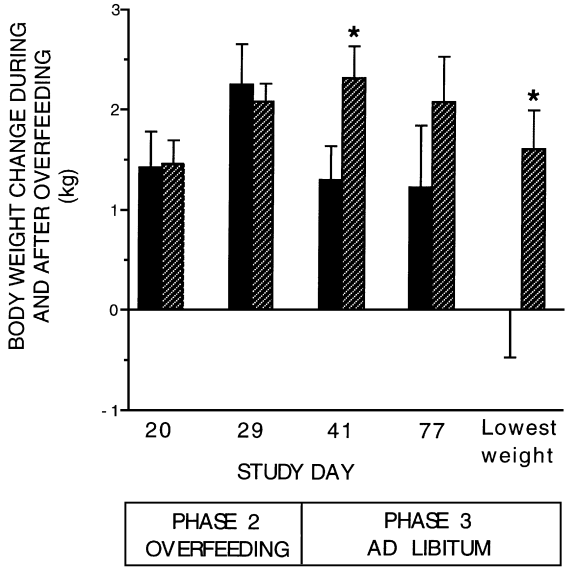

FIG. 58.4. Body weight change during 21 days of overfeeding and a subsequent 46-day period of *ad libitum* diet (From Roberts *et al*., 1994, © 1994 American Medical Association). Values are mean ± SEM for young (■) and older (▨) men. *$P<0.05$ relative to the young men.

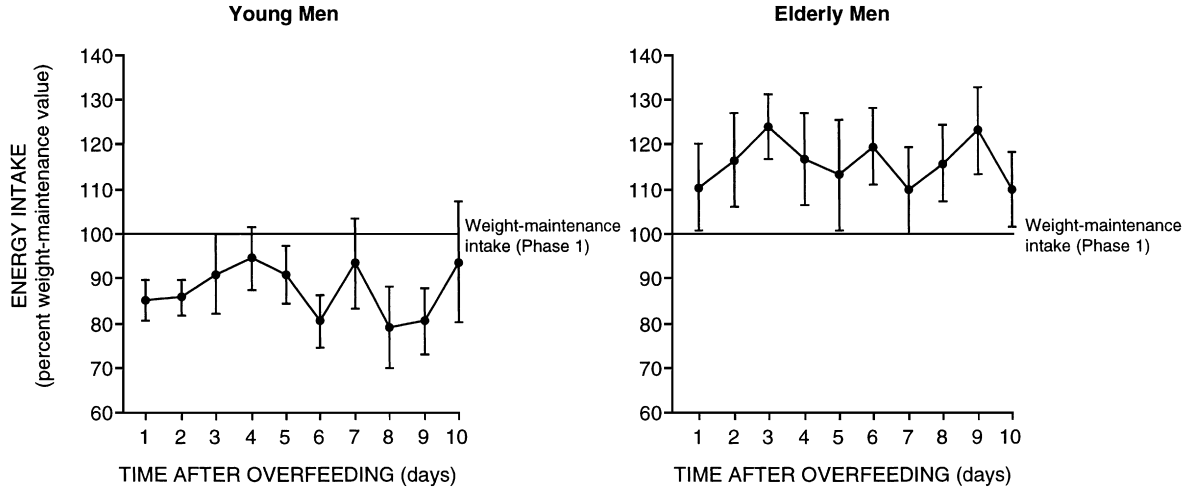

FIG. 58.5. Voluntary energy intake during a 10-day period following overfeeding in young and older men (From Roberts *et al*., 1994, © 1994 American Medical Association). Values are means ± SEM in comparison with initial weight maintenance energy requirements. The change in energy intake relative to initial weight maintenance requirements were significantly different between the age groups ($P = 0.006$).

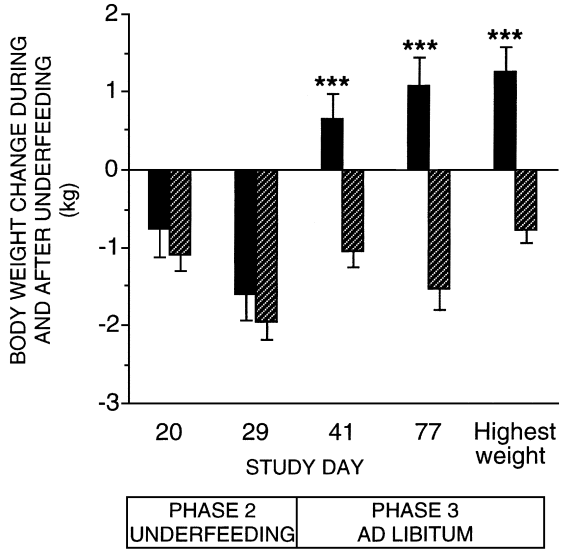

FIG. 58.6. Body weight change during 21 days of underfeeding and a subsequent 46-day period of *ad libitum* diet (From Roberts *et al*., 1994, © 1994 American Medical Association). the energy intake of the elderly men did not increase significantly and actually remained somewhat depressed relative to their previous weight-maintenance requirement (Fig. 58.7).

Thus, in two separate protocols involving opposite, experimentally imposed changes in energy balance, older men had a substantial reduction in their ability to maintain a constant energy balance compared to young men. The fact that the same result was obtained under opposite experimental conditions (overfeeding and underfeeding) suggests a basic difference between age groups rather than an experimental artifact, and implies that aging is indeed associated with an impaired ability to accurately regulate food intake.

Consistent results have recently been reported in other studies. Rolls *et al*. (1995) and Morley (1997) both observed that elderly subjects are less able to accurately compensate for preloads at a subsequent meal than young subjects and report less desire to eat postprandially (Clarkston *et al*., 1997) and less hunger but not greater fullness (Clarkston *et al*., 1997). Intraduodenal nutrient infusion has also been reported to reduce hunger in young but not elderly adults (Cook *et al*., 1997). Finally, we have also obtained recent data (Moriguti 2000) suggesting that elderly men and women experience less frequent hunger during dieting than young individuals.

When interpreting these combined results, it is important to recognize that most of the studies were conducted in older men and women who reported having no problems with their appetite, and thus the extent to which an elderly individual with impaired energy regulation loses or gains weight may depend on social factors. For example, factors that have previously been thought to cause anorexia and weight loss (such as loss of teeth and depression) may precipitate a long-term reduction in body weight only when the metabolic signals that drive adaptive variations in energy intake are absent or reduced as they appear to be in the older subjects in the above investigations. In support of this suggestion, depression is associated with weight gain in young adults but weight loss in the elderly (DiPietro *et al*., 1992). Elderly individuals may also have an impaired ability to regain weight after periods of weight loss precipitated by disease.

IV. Mechanisms Underlying the Decreased Ability to Regulate Food Intake in Old Age

The mechanisms underlying successful energy regulation in young adults are poorly understood. It is generally believed that multiple overlapping mechanisms exist to regulate energy balance in young adults, with hunger and satiety being moni-

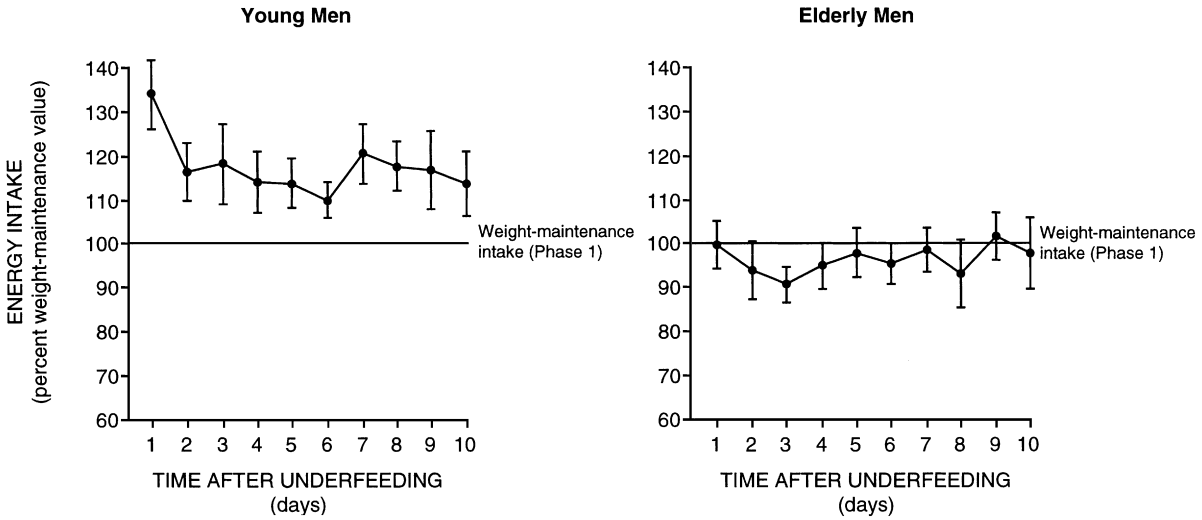

FIG. 58.7. Voluntary energy intake during a 10-day period following underfeeding in young and older men (From Roberts *et al*., 1994, © 1994 American Medical Association). Values are means ± SEM in comparison with initial weight maintenance energy requirements. The change in energy intake relative to initial weight maintenance requirements were significantly different between the age groups ($P = 0.016$).

tored both peripherally and centrally by several systems. As such, there are multiple candidates for age-related changes that could contribute to the anorexia of aging, and several of these have been outlined in recent reviews (see Morley *et al*., 1985; Blundell, 1988; Morley and Silver, 1988; Morley, 1997; Blanton *et al*., 1999). It is important to recognize that the likely redundancy in energy regulation mechanisms implies that multiple pathways need to fail before a measurable impairment in energy regulation is seen. Thus, quite a large number of candidate mechanisms may potentially be shown to be impaired in old age and work is needed to identify which mechanisms are quantitatively important. The strongest candidates based on current knowledge are summarized below, and are combined in a suggested model in Fig. 58.8.

Gastric emptying is one potentially important factor in the anorexia of aging. Most studies examining gastric emptying in relation to age have reported a decreased rate of gastric emptying in the elderly. In some cases delayed emptying of both liquids and solids has been observed (Richey and Bender, 1977; Horowitz *et al*., 1984; Wegener *et al*., 1988; Clarkston *et al*., 1997), while in other studies only delayed emptying of liquids (Evans *et al*., 1981; Moore *et al*., 1983) or normal emptying of solids (van Liere and Northup, 1941) has been reported. This is relevant because delayed gastric emptying has been linked to reduced hunger and increased satiety in several studies (Shafer *et al*., 1987; Sepple and Read, 1989; Bergmann *et al*., 1992; Horowitz *et al*., 1993; Clarkston *et al*., 1997) and thus may potentially contribute to increased satiety and satiation and/or decreased hunger.

The mechanisms by which reduced gastric emptying could directly cause alterations in energy regulation are not known, but there are several possibilities that require further study. For example, delayed gastric emptying presumably prolongs the period during which nutrients are absorbed, and this may translate into a prolonged period during which energy substrates (glucose, free fatty acids) remain in the circulation. Several models of energy regulation (Mayer, 1953; Flatt, 1987; Friedman, 1995) postulate a central role for substrate availability in energy regulation, and recent work on blood glucose and hunger has supported the concept of a role for low blood glucose in initiation of hunger signals in young adults (Campfield *et al*., 1996; Ludwig *et al*., 1999; Melanson *et al*., 1999). Although some aspects of the central detection and response to alterations in blood glucose (such as during hypoglycemia) seem to be impaired in elderly individuals (Brierley *et al*., 1995), the hunger response to hypoglycemia is reportedly intact (Brierley *et al*., 1995), and a prolonged age-associated elevation of blood glucose following consumption of meals has been reported in one recent study (Melanson *et al*., 1998). Gastric emptying presumably also results in a prolonged period of stomach distention, which may additionally prolong satiation directly through afferent vagal signals.

Concerning the underling causes of delayed gastric emptying in the elderly, more work in this area is needed, but several mechanisms have been suggested, including increased phasic pyloric pressure waves in response to nutrients in the duodenum (Cook *et al*., 1997) and impaired autonomic nervous system function which is common in the elderly (see Clarkston *et al*., 1997 and Chapter 64). Morley (1997) has also suggested that a reduction in nitric oxide production by the stomach in elderly adults may increase satiation by reducing relaxation of the fundus. In addition, the age-associated alterations in taste sensitivity (Schiffman *et al*., 1976; Schiffman, 1977, 1994, 1997; Schiffman and Pasternak, 1979; Weiffenbach

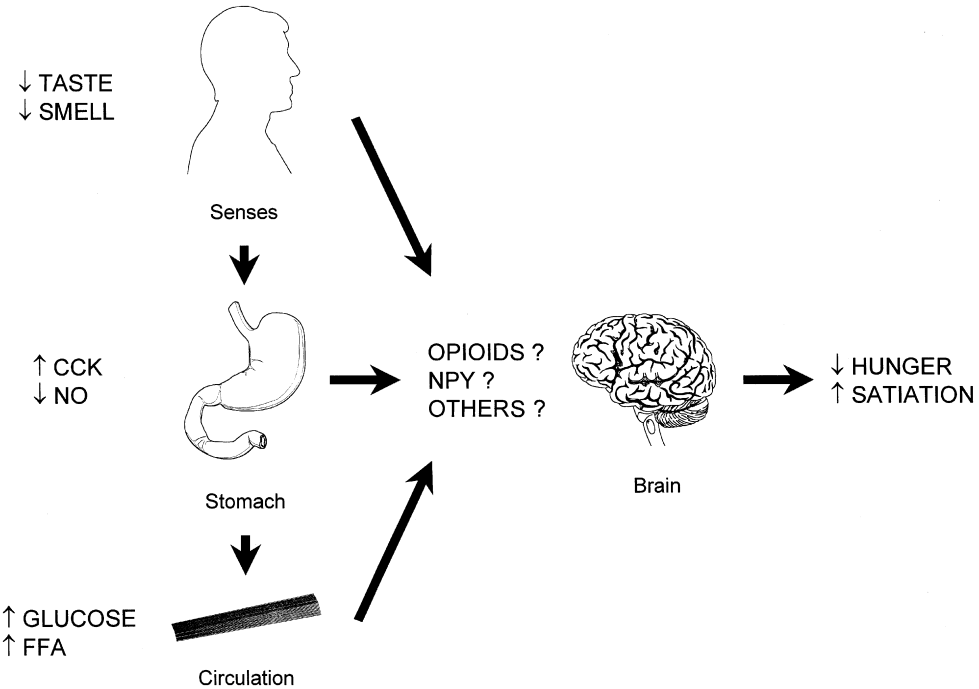

FIG. 58.8. Suggested model of metabolic impairments in the normal cascade of energy regulation mechanisms that could help explain impaired regulation of energy leading to an increased risk of weight loss in old age. FFA, free fatty acids; NO, nitric oxide; CCK, cholecystokinin; NPY, neuropeptide Y. Life ART Images © 1989-2000 by Lippincott Williams & Wilkins.

et al., 1982; Doty *et al*., 1984; Finkelstein and Schiffman, 1999), detailed above, may play a more central role than currently recognized. As reviewed elsewhere (Schiffman, 1997), intact senses of taste and smell are necessary for the celphalic phase of digestion, which includes the initial increases in salivary, gastric, pancreatic, and intestinal secretions designed to initiate digestion. We recently obtained preliminary evidence (Sawaya *et al*., 2000) suggesting that consumption of bland foods decreases the glycemic response to test meals compared to palatable meals of the same macronutrient composition, presumably as a result of a reduced rate of gastric emptying and hence digestion. If the losses in taste and smell associated with aging have an equivalent effect (i.e., making food seem more bland, as commonly reported), the decreased gastric emptying and delayed absorption of nutrients could help explain the reported increase in satiation and decrease in hunger in old age. Consistent with this suggestion, elderly individuals eat more of individual foods if they are flavor-enhanced (Schiffman and Warwick, 1993), and in another study smell was significantly correlated with hunger and appetite (de Jong *et al*., 1999). It should be noted that, in this latter study, there was no association between smell and energy intake; however, recognized inaccuracies in the measurement of energy intake (Schoeller and Fjeld, 1991) make the validity of such correlations uncertain.

In addition to its effects on taste, gastric emptying, and related variables, old age may also influence the production and detection of several digestion-related hormones thought to be involved in satiety and satiation. For example, glucagon has long been suggested to be one of the signals of satiation (Stunkard *et al*., 1955; Schulman *et al*., 1957; Geary, 1990), with its action mediated at least in part through vagal afferent signals from the liver and perhaps also by increasing blood glucose (which is another postulated signal, see above). Melanson *et al*. (1998) recently reported that elderly women have significantly elevated levels of glucagon in response to consumption of meals of 500 kcal or greater, suggesting a potential role for glucagon in the enhanced satiation associated with old age.

There is also evidence of both altered synthesis and impaired central responsiveness to gut hormones. For example, fasting levels of the postulated satiety hormone cholecystokinin are typically higher in elderly individuals than in young adults (Smith and Gibbs, 1988; Martinez *et al*., 1993; MacIntosh *et al*., 1999) and rise more in response to an isocaloric rate of intraduodenal fat infusion than in young adults (MacIntosh *et al*., 1999). Concerning evidence for impaired detection of gut hormone signals, the rise in cholecystokinin, glucagon-like peptide 1 and polypeptide YY associated with intraduodenal lipid infusion were significantly correlated with a decrease in hunger in young but not elderly individuals (MacIntosh *et al*., 1999). Consistent data were also obtained in animal models, with administration of exogenous cholecystokinin, bombesin, and calcitonin having a greater suppressing effect on food intake in young than in elderly mice (Silver *et al*., 1988).

Leptin (Zhang *et al*., 1994; Halaas *et al*., 1995) has also been proposed as a candidate hormone that may contribute to the anorexia of aging, but current data are conflicting. For example, there is a significant correlation between leptin and body fat in young adults (Considine *et al*., 1996; Roberts *et al*., 1997; Moller *et al*., 1998) and some (Moller *et al*., 1998) but not all (Roberts *et al*., 1997; Wolden-Hanson *et al*., 1999) investigations have suggested no similar correlation in elderly adults.

The fact that a variety of peripheral satiety signals, including cholecystokinin, leptin, and perhaps blood glucose are suggested to be imperfectly detected in old age may be related to several central mechanisms responsible for coordination of energy regulation signals. One potential candidate is neuropeptide Y (NPY), an integrator of metabolic endocrine and behavioral systems (Leibowitz, 1988, 1991) that acts through various hypothalamic nucleii, affects release of hormones that modulate energy metabolism such as insulin, and stimulates feeding behavior (Leibowitz, 1991). Currently, however, the data are conflicting. The finding of high levels of NPY in both plasma and cerebrospinal fluid of elderly anorectics implies that NPY expression does not relate to the anorexia of aging (since high NPY is predicted to increase feeding in young, see Martinez *et al*., 1993). On the other hand, the fasting-induced increases in both food intake and NPY gene expression normally seen in young rats are attenuated in aging rats (Gruenewald *et al*., 1996), suggesting that responsiveness to NPY may be impaired in old age. Consistent with this suggestion, the feeding and drinking responses to NPY injection in the paraventricular hypothalamic nucleus are attenuated in aged rats (Pich *et al*., 1992) but more work in this area is needed.

Finally, opioid peptides (Morley, 1980; Sanger, 1981; Morley and Levine, 1982) are also indirectly implicated in the anorexia of aging by the observation that the opioid agonist butorphanol increases feeding in young rats, and the effect is attenuated in elderly rats (Gosnell *et al*., 1983). Similarly, the opioid antangonist naloxone suppresses feeding in young rats but not in elderly rats (Gosnell *et al*., 1983).

V. Summary

Even healthy older adults appear to exhibit a significant loss of the ability to regulate food intake. When combined with a reduction in sensory specific satiety and disadvantageous social factors such as chronic illness, functional limitations and depression, this loss of the regulation of food intake may contribute to unexplained weight loss in elderly adults. Further research is needed to determine the quantitative importance of the different mechanisms (both biological and psychological) that are suggested to underlie age-related changes in the regulation of food intake, and to determine what practical steps can be taken to prevent weight loss and associated declines in physical function.

Thermoregulation during Aging

Old mammals exhibit alterations in their thermoregulatory system that compromise their ability to maintain homeothermy when encountering hot or cold environments. Despite the difficulties in obtaining consistent data on humans, there are now numerous examples of age-related changes in both behavioral and physiological responses, the latter involving heat production as well as heat conservation/dissipation. Studies on old laboratory rodents provide further evidence for blunted thermoregulatory effectiveness with age, for gender differences in cold tolerance, for individual variation (even in in bred strains), and for the concept that the mechanisms underlying age-related changes in thermal responses do not occur in a linear manner. This chapter discusses studies evaluating the effects of age on specific thermal responses/effectors in humans as well as studies on laboratory rodents where mechanistic questions have been addressed.

I. Introduction

The maintenance of homeothermy depends on the balance between heat loss/heat conservation and metabolic heat production (Fig. 59.1). Behavioral strategies are a first line of defense in maintaining core temperature. In humans this includes adding or removing clothing or seeking alternate thermal environments. In other mammals, behavioral responses to cold exposure include group huddling, tucking of tail and paws, and seeking warmer shelter where possible; responses to warm include increasing surface area by adopting a more prone position, spreading saliva for evaporative cooling, and seeking cooler temperatures. Physiological mechanisms are elicited as a second line of defense when behavioral approaches are insufficient to maintain appropriate core temperature. Mammals, in general, respond to temperatures outside their thermal neutral zone with three types of physiological adjustments: (i) peripheral vasoconstriction to minimize heat loss (cold exposure) or vasodilation, panting, and sweating to increase heat loss (heat exposure); (ii) shivering thermogenesis in skeletal muscle (cold exposure), and (iii) nonshivering thermogenesis in sites such as brown adipose tissue (cold exposure).

There is substantial evidence indicating that the ability to maintain homeothermy in the face of either cold or warm temperatures is blunted in older mammals. However, the mechanisms that underlie this attenuation are not well defined. This chapter reviews the evidence for age-related changes in the thermoregulatory responses of older humans to heat and to cold. In addition, because most of the mechanistic studies dealing with cold-induced responses have utilized rodents as model systems, it also includes a discussion of the effects of age on thermoregulatory responses to cold in laboratory rats and mice.

II. Thermoregulation in Elderly Humans

A. Heat-Induced Thermal Responses in the Elderly

1. Overview

Although there are numerous reports that heat-induced failure of thermal homeostasis in old individuals increases morbidity and mortality to a greater extent than it does in younger adult populations (Levine, 1969; Lye and Kamal, 1977; Mirchandani *et al*., 1996), the degree to which aging itself contributes to this dysfunction is difficult to quantify because uncontrolled external factors, including socioeconomic status, disease, physical fitness, and lack of prior heat acclimatization, can confound the results. For example, hyperthermia-related deaths of aged individuals reported in Philadelphia during 1993 more closely reflected preexisting natural diseases in persons who lived alone without air conditioning in upstairs bedrooms with windows shut than it did age per se (Mirchandani *et al*., 1996). Imprecise measurement and definition of core temperature, hydration state of the individual, and a reliance on cross-sectional analysis (i.e., measurement of variables in different groups of individuals at two or more ages) rather than longitudinal investigations (repeated measurements of variables on the same individuals as they age) also introduce significant confounding variables. Nonetheless, taken as a whole, several studies have provided considerable insight into the effects of chronological aging on specific physiological variables (e.g., core temperature, sweat rate, skin blood flow) and on cardiovascular adjustments that are critical to the maintenance of heat tolerance in the elderly.

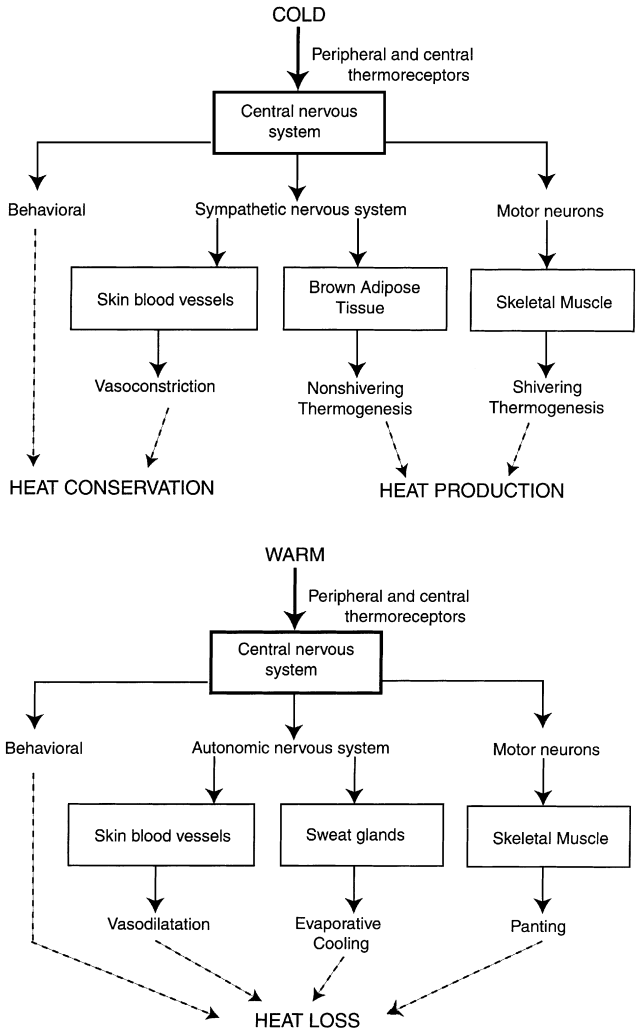

FIG. 59.1. Diagram of the central and peripheral components of the thermoregulatory system that are regulated when mammals are exposed to cold or to warm temperatures.

2. Aging, Heat Tolerance, and Sweat Gland Function

Early investigations comparing young (16–30 years of age) to older (greater than 65 years of age) individuals reported significantly higher aural and tympanic temperatures at the onset of sweating in older compared to younger age cohorts (Fennell and Moore, 1973; Crowe and Moore, 1974). However, there is no indication in these reports that young and old subjects were matched for heat acclimation, body composition, or physical fitness. Yousef *et al*. (1984) noted that younger and older men and women (ages 17–88) that were matched for level of heat acclimation had similar rectal and skin temperatures, heart rate, and total sweat loss after a 1 hr desert walk (40–44°C) at a work intensity of 40% VO_{2max}. These investigators concluded that heat acclimation influences the ability for heat tolerance in the elderly much more so than does age. This conclusion is consistent with several other investigations that have observed similar responses to heat exposure in younger and older subjects (Kenney, 1997). That is, when younger and older individuals were matched for fitness levels, body composition, prior acclimation, and other morphological factors, fewer differences in their response to passive heat exposure were observed.

Sweat rates of older men and women during passive heat exposure (i.e., during exposure to warm temperatures) are significantly less than those of younger individuals (Fennell and Moore, 1973; Crowe and Moore, 1974; Shoenfeld *et al*., 1978; Inoue *et al*., 1995). Age-related declines in sweat rate can reflect several anatomical and physiological factors but have been evaluated primarily from the perspective of sweat gland density and/or sweat rate per gland. Most investigations that have used localized injections of methylcholine, a cholinergic analog, to induce sweating in older men and women, have found that age-related reductions in sweat rate reflect lower output per gland rather than decreased sweat gland density. For example, in cross-sectional analysis comparing three age groups, 22–24, 33–40, and 58–67 years of age, methylcholine injection (10 μM) into the thighs of men produced the greatest localized sweat rate (65 nl/sweat gland/2 min) in the youngest group and the least in the oldest (22 nl/sweat gland/2 min); the sweat rate (41 nl/sweat gland/2 min) of the middle aged group, 33–40 years, was intermediate to the youngest and oldest groups (Kenney and Fowler, 1988). Sweat gland density was not affected by age in this investigation. Results from other studies evaluating sweat gland density and sweat rate as a function of age are consistent with these results (Yousef *et al*., 1984; Tankersley *et al*., 1991; Ferrer *et al*., 1995). However, Inoue (1996) reported significant variation in both density and rate that was dependent on the anatomical site sampled. Altered heat-activated sweat rates and sweat gland densities at five different anatomical locations were determined longitudinally in men who were 65–75 years of age at the first test period. Five years later, these men were retested. Although they had no changes in physical characteristics such as percentage body fat or VO_{2max}, their total body sweat output was significantly less. This decrease reflected significantly lower sweat rates per gland on sites sampled on the back, but no such differences on the thighs. In contrast, sweat gland density did not differ with age on the back, but was significantly less on the thigh. Thus, depending on the site, both density and output/gland appears to be blunted with age.

3. Thermoregulatory Cardiovascular Responses to Heat in the Elderly

The dissipation of heat during active (exercise-induced) or passive (non-exertional-induced) warming is accomplished primarily through an increase in the amount of cardiac output to the skin plus the degree of vasodilatation. Age-related reductions in either variable could result in insufficient heat dissipation and an inappropriate rise in core temperature (hyperthermia). There is general consensus that skin blood flow during passive and active heat stress is significantly less in the elderly compared to younger subjects matched for body weight and VO_{2max} (Kenney *et al*., 1990, 1991, 1997; Armstrong and Kenney, 1993; Kenney and Zappe, 1994; Kenney and Ho, 1995; Kenney and Armstrong, 1996). In a series of investigations performed by Kenney and colleagues, skin blood flow was evaluated in men and women (ages 50–75 and 20–30 years) during exercise in a hot environment. In each of the investigations, the subjects were matched for

VO_{2max}. Although there were differences in the protocols for each experiment, the results showed that the increase in skin blood flow at a given core temperature was less in the older than in the younger subjects (see review by Kenney, 1997). A subsequent investigation further suggested that this blunted heat-induced increase in skin blood flow in the elderly reflected altered cutaneous vasodilatation (Martin *et al*., 1995). In this study, forearm blood flow was measured by venous occlusion plethysmography and by laser Doppler flowmetry in subjects ranging in age from 5 to 85 years. A continual spray of fine water heated to 42°C elevated skin temperature, and resistance to flow was calculated as maximal forearm blood flow/mean arterial pressure. This resistance was significantly greater in the older individuals, resulting in a significant reduction in maximal vasodilatation (Martin *et al*., 1995).

The mechanisms underlying the blunted heat-induced vasodilatation remain to be elucidated. One hypothesis is that increased sympathetic nervous system activity, a finding often reported to occur in aged humans, may enhance vasoconstrictor tone, making a given thermal signal less effective in stimulating dilation. Although this hypothesis is attractive, direct testing of the hypothesis has not been supportive. That is, skin blood flow of younger and older individuals during 1 hr of moderate cycle exercise at 36°C increased similarly before and after administration of prazosin, an α_1-adrenergic antagonist which should inhibit sympathetic-induced vasoconstriction (Kenney *et al*., 1991). Along similar lines, bretylium tosylate, an agent that blocks release of norepinephrine from sympathetic nerve terminals, did not prevent the attenuated increase in skin blood flow in older (66 years) vs younger (22 years) male subjects (Martin *et al*., 1995) exercising at 50% VO_{2max} in a 36°C environment. Based on the results of these two investigations, Kenney and his colleagues have suggested that the age-related decrease in heat-induced vascular conductance reflects alterations in the active vasodilator (rather than constrictor) system. That this reduction in vasodilatation suggested by the skin blood flow studies involves age-related alterations in the structure of the vasculature is supported by reports of age-related increases in vascular wall stiffness (Lakatta, 1995). Such increases would decrease the distensibility of the vessels which, in turn, would result in enhanced resistance to dilation. While the mechanisms underlying increased vessel wall stiffness are unknown, decreased elastin and increased concentrations of collagen cross-links are common findings in vessels collected from aging humans.

Another potential contributor to the age-related attenuation of heat-induced increases in skin blood flow is decreased cardiac output. Here, the data are inconsistent. Sawka (1988) reported that healthy unacclimated elderly men (61–73 years) had cardiac outputs, heart rates, and total sweat outputs during whole body passive heat at 40°C and 40% relative humidity that were comparable to those of younger adult males (21–39 years). Similar results (i.e., no difference in cardiac output or heart rate) were seen in older and younger men and women (17–88 years) who walked for 1 hr in desert heat of 40–44°C (Yousef *et al*., 1984). In contrast, Kenney *et al*. (1997) reported that older (61–73 years) vs younger (21–33 years) men had significantly lower cardiac output and heart rate at all work intensities tested (up to about 60% VO_{2max}) during incremental cycle exercise in the heat (36°C). While stroke volume was higher in the older men, it was not enough to increase cardiac output to the same level as in younger individuals.

Attenuated heat-induced redistribution of cardiac output from splanchnic and renal beds to the skin has also been evaluated as a potential contributor to reduced heat loss in the elderly. Renal blood flow and renal vascular conductance were estimated during exercise (50% VO_{2max}) in a warm environment (30°C) in fit older and younger men matched for body size and VO_{2max} (Kenney and Zappe, 1994). The decrease in renal blood flow induced by heat/exercise was significantly greater in the young men (down 45%) compared to that in the older individuals (down 12%). Decreased renal vascular conductance was also significantly greater in the young (-52%) than in the old (-15%) men. Subsequent work by Kenney *et al*. (1997) has demonstrated that a similar age-related attenuated redistribution of flow occurs in the splanchnic vascular bed.

The extensive studies by Kenney and colleagues support the hypothesis that the blunted heat/exercise-induced skin blood flow of older vs younger men reflects reduced active vasodilatation within the skin and attenuated redistribution of blood flow from renal and splanchnic vascular beds. However, the inclusion of exercise as a modality to increase core temperature could be a confounding variable. That is, the age-related effects on the physiological adjustments to acute and chronic exercise, independent of ambient temperature, are not well understood, raising the concern that the outcomes reported by Kenney and colleagues reflect responses to exercise per se rather than simply alterations in heat dissipation mechanisms. To deal with these concerns, these investigators evaluated the central and peripheral hemodynamic responses of young (19–28 years) and old (64–81 years) men during direct passive heating (Minson *et al*., 1998). Cardiac output in young individuals was significantly greater than that observed in old men at their limit of thermal tolerance (11.1 ± 0.7 and 7.4 ± 0.2 liters/min for young vs old men, respectively; the limit of thermal tolerance was defined as the time at which the subject was unable to continue, esophageal temperature reached 39.5°C, or the subject was unable to control hyperventilation). Furthermore, the older men redistributed less blood flow from the combined splanchnic and renal beds at the limit of thermal tolerance (960 ± 80 vs 720 ± 100 ml/min in young and old subjects, respectively). These data indicate that less blood flow is indeed directed to the skin during non-exertional heating in older vs younger individuals.

4. Summary

Clinical evidence suggests that elderly individuals are at greater risk for the development of hyperthermia than are younger cohorts. Several investigations have shown that in many cases, hyperthermia and the associated increased mortality rate observed in the elderly are more closely correlated with lower socioeconomic status, preexisting disease, low physical fitness, and lack of prior heat acclimatization than with aging per se. Nonetheless, experimental evidence has described specific age-related alterations in thermal homeostatic mechanisms. Localized sweat rates (nl/min/sweat gland) appear to decline with age, but the changes are not uniform at all anato-

mical sites, with some sites displaying no age-related changes. The data describing age-related cardiovascular adjustments to heat exposure are inconsistent. Several investigations using older and younger individuals matched for body composition and fitness levels find reduced heat-induced blood flow to skin, but no reduction in cardiac output, heart rate, or oxygen consumption. However, a series of investigations by Kenney and colleagues suggest that the reduction in heat-induced blood flow to skin of older vs younger individuals reflects an attenuated increase in cardiac output, significantly less redistribution of blood to skin from the renal and splanchnic vascular beds, and resistance to dilation of the skin vasculature.

B. Cold-Induced Thermal Responses in the Elderly

1. Overview

Older humans (as well as laboratory rodents) have been reported to regulate core temperature more poorly than younger adults in cold environments. This impairment may account for the higher than normal mortality rate among elderly humans during winter months (e.g., Collins, 1987; Macey and Schneider, 1993) and for the decreased survival of older laboratory rodents maintained in cold environments for days (e.g., Grad and Kral, 1957; Trujillo *et al*., 1962; Kiang-Ulrich and Horvath, 1979, 1985a; Owen *et al*., 1991). However, unlike data obtained on laboratory rodents, seasonal survivability statistics for old humans may be confounded by many of the same factors that influence heat tolerance in the elderly (i.e., socioeconomic status, disease, physical fitness, body composition, and lack of prior temperature (in this case cold) acclimatization). Nonetheless, as was the case with thermal tolerance to heat, several lines of investigation in humans suggest that the elderly have lower thermogenic capacity, changes in sensory perception, and altered vascular characteristics that could influence heat conservation. Examples of each of these changes are discussed briefly below, followed by an extensive consideration of information regarding underlying mechanisms derived from studies of cold-exposed laboratory rodents. [For a more detailed discussion of some of the difficulties in interpreting the data from humans studies, see the review by Young (1991).]

2. Aging, Thermogenesis, and Thermal Perception

As depicted in Fig. 59.1, thermoregulatory heat production can occur via shivering and nonshivering mechanisms. The major site for the latter is brown adipose tissue, the amount of which is negligible in older humans (Heaton, 1972; Ito *et al*., 1991). Thus, shivering in skeletal muscle is the major contributor to cold-induced thermogenesis in the elderly, and there are several studies which indicate that the magnitude of shivering (cold-induced thermogenesis) is less in old vs young individuals (e.g., Horvath *et al*., 1955; Wagner *et al*., 1974). In addition, although the elderly were shown to maintain the ability to shiver, their bursts of muscle contraction did not peak as high as in the young (Collins *et al*., 1981a; Collins, 1987). This resulted in lower shivering intensity. Collins and his colleagues (1981a; Collins, 1987) also noted that there was a long latent period before maximal shivering occurred in the older cold-exposed subjects. This was in contrast to the rapid onset of maximal shivering in younger individuals. Hence, the characteristics of shivering may change with age. Moreover, since many elderly individuals have lost significant skeletal muscle mass and motor units, their capacity to generate heat is diminished. It should be noted, however, that not all cross-sectional studies have shown significant differences in cold-induced heat production between old and young subjects (e.g., Wagner and Horvath, 1985a), emphasizing the difficulty in drawing general conclusions from selected populations that may not be well matched in terms of variables other than age.

It has also been reported that the ability to discern cold is compromised in many of the elderly. In a behavioral experiment, Collins *et al*. (1981b) measured the preciseness, over a 2.5 hr period, with which comparably dressed male subjects manually controlled the temperature of the room in which they were seated (initial temperature was 19°C). The mean preferred temperatures of these 13 young (18–39 years) and 17 old subjects (70 years and above) did not differ significantly ($23 \pm 2.3°$ vs 22.7 ± 1.2°C, respectively). However, on average, the older subjects showed poorer control of the room temperature than did the young males as indicated by greater peak temperatures and a greater range of temperatures. The young subjects initially allowed the temperature to vary by 3°C but by the end of the experimental period, this variation averaged near 1°C. In contrast, the old subjects increased the amplitude of oscillations from about 3°C initially to 4.5°C by the end of the experimental period (Collins and Exton-Smith, 1986). When hand-skin temperature discrimination was measured in these subjects, it was found that all of the young males could discriminate temperature differences of about 1°C, 12 of the elderly could discriminate temperatures of 2°C or less, but 5 of the elderly men were unable to discriminate differences greater than 2°C. Although no differences were observed between the latter 5 and the 12 other old subjects with respect to preferred temperature or comfort rating, the 5 poor temperature discriminators had the lowest frequency of temperature change/h as well as the highest temperature range (Collins and Exton-Smith, 1986). These data are consistent with the earlier work of Watts (1972) who reported that some (but not all) elderly women (74–86 years old) experienced the sensation of cold only at considerably low ambient temperatures. Thus, it appears that at least some old people perceive ambient temperature changes less accurately than do the young, contributing to their greater vulnerability.

3. Thermoregulatory Cardiovascular Responses to Cold

Heat conserving mechanisms invoked during cold exposure include peripheral vasoconstriction and decreased skin blood flow to the skin. Several investigators have reported age-related alterations in these cold-induced changes. For example, in a longitudinal study of elderly males, Collins and colleagues found that the proportion of individuals who showed little or no vasoconstrictor response to acute cold ($\sim$15°C) increased with age. In their initial measurements, 37 of 43 old subjects (greater than 69 years of age) showed cold-induced decreases in hand blood flow (as compared to 39 of 41 subjects younger than 45 years old). Four years later, only 29 of the 43 old subjects exhibited a vasoconstrictor response and 8 years later, the

number was further reduced (Collins *et al*., 1977, as cited by Young, 1991). Whether this diminished responsiveness reflects changes in the sensitivity of the vasculature or changes in the neural regulation associated with vasoconstriction has not yet been determined.

4. Gender Differences

Epidemiological statistics indicate that the majority of cold-related deaths among the elderly are in men (e.g., Macey and Schneider, 1993). Other investigations have shown that during acute cold exposure, older females are able to maintain core temperature as well as younger females and do so better than older males (e.g., Wagner and Horvath, 1985a). The gender effect in humans may involve differences in body size and composition [i.e., a smaller body surface area relative to mass and more subcutaneous body fat in older females vs older males (Wagner and Horvath, 1985a,b)]. There may also be differences in the peripheral vasoconstrictor response to cold, as indicated by the moderately higher skin temperature of older males vs older females exposed to 10°C for 2 hr (Wagner and Horvath, 1985a) although gender differences in finger or forearm blood flow during acute cold exposure have not always been seen (e.g., Wagner and Horvath, 1985b). Differences in metabolic heat production may also play a role. For example, Wagner and Horvath (1985a) reported that older women have a larger early metabolic increase than do older males and younger females upon exposure to cold (2 hr at 10°C).

5. Summary

Although the sometimes contradictory results reported by various investigators render it difficult to make sweeping generalizations about the effects of age on thermoregulatory ability of cold-exposed humans, there are numerous examples of age-related alterations in both behavioral and physiological responses. The fact that within a given age cohort, there is often considerable variability in individual responses to thermal perturbations emphasizes the dichotomy between chronological age and ''functional'' or biological age and the need to be alert to individual differences as well as group responses. This is further illustrated by the age of onset of senescence in F344 rats (section IV).

III. Cold-Induced Thermoregulatory Responses in Laboratory Rodents

A. Overview

Numerous investigators have examined cold-induced responses in laboratory rodents. As is the case with humans, old mice and rats have a greater mortality rate when exposed to cold than do their younger counterparts. Age-related decrements in cold tolerance have been reported in female C57BL mice (Grad and Kral, 1957), female RF mice (Trujillo *et al*., 1962), male Sprague–Dawley rats (Kiang-Ulrich and Horvath, 1979), and male F344 rats (Kiang-Ulrich and Horvath, 1985a; Owen *et al*., 1991). While there are some strain differences with respect to the degree of cold tolerance in these animals, in all cases, heat production was insufficient to overcome heat loss and subsequent hypothermia.

B. Age-Related Changes in Thermoregulation in Rodents

Various strains of laboratory mice and rats have been used for aging studies of thermoregulation. The majority of these studies have been cross-sectional where age comparisons are made using different groups of animals usually at two or three different ages. Typically, they include an age group that is sexually mature and past the exponential growth phase (young adults) and one that approximates or exceeds the median survival age for the respective population (old). In contrast, longitudinal studies (e.g., Balmagiya and Rozovski, 1983; Reynolds *et al*., 1985; Talan *et al*., 1985) make repeated measurements on the same rats over a given age span.

A summary of laboratory studies (mainly cross-sectional) on changes in body temperature during acute cold exposure in mice and rats is presented in Table 59.1. Those demonstrating that aging negatively alters the ability to regulate core temperature far exceed those finding no aging effect. There are, however, several factors which influence these results—these include strain, gender, age, and severity of cold (exposure time and temperature). Other confounding factors are health status, body size and composition, feeding conditions (fed vs fasted), surgical procedures or anesthetics used, disturbance/handling of the animal during the cold test (e.g., blood collections, insertion of colonic temperature probe, etc.), and physical restraint.

1. Cold Tolerance in Mice

The mouse, with its high body surface area-to-mass ratio that favors rapid heat exchange with the environment (Dawson, 1967; Schmidt-Nielsen, 1984), is especially prone to body temperature imbalances when exposed to low ambient temperatures. Even moderate impairments in physiological and/or behavioral mechanisms that reduce heat loss or increase heat production can result in rapid drops in core temperature to levels that threaten survival. A significant number of aging studies on cold-induced thermoregulation in mice have used males from the C57BL/6J genotype of *Mus musculus*, a relatively short-lived rodent species that does not undergo torpor (an adaptive physiological phenomenon in which core temperature is lowered to less than 34°C for 2 hr or longer (Duffy *et al*., 1987) when there is a need for energy conservation (e.g., during food restriction)). The mean life span of the *ad libitum*-fed C57BL/6J mouse strain has been estimated to be 26–27 months (Goodrick, 1975).

In an early study by Finch *et al*. (1969), young (10-month-old) and old (30-month-old) male C57BL/6J mice were placed individually into 2-quart glass jars and exposed to 3 hr of cold (9–10°C). Rectal temperatures of all the old mice decreased in a steady and progressive manner while those for the young mice changed only slightly. In addition, there was a much higher degree of variability in temperature responses of old vs young mice (range of cold-induced hypothermia values of 3–13°C vs 0–1.5°C, respectively). Similarly, Hoffman-Goetz and Keir (1984) found that partially restrained old (19- to 20 month-old) male C57BL/6J mice had significantly lower rectal

Note: Data are for first cold exposure and without any intervention protocol (e.g., prior cold exposure, exercise training, drugs) unless indicated otherwise. ΔTc, cold-induced change in core (rectal or colonic) temperature; ΔTsk, cold-induced change in skin temperature. For ΔTc and ΔTsk: ø, no difference between old and young animals; ↑, greater change in old animals; ↓, smaller change in old animals; NA, not available. Cold-induced ΔTc (°C) values in parenthesis were estimated from bar or line graph data; values not in parentheses are based on table/text data. Values shown for Talan and coworkers were calculated from temperature slopes (drop in Tc/min). However, mice in these studies were removed from the cold if core temperature fell below 24°C (thus, declines in Tc greater than ∼11°C did not actually occur).

temperatures (~2.2°C) than did young (6- to 7-month-old) mice after 3 h at 15°C. The restraint system consisted of a flexible polyethylene neck tether which allowed for lateral movement as well as behavioral thermoregulation. The less severe hypothermia developed by old mice in this study compared to that of old mice in the study by Finch *et al*. (1969) can be explained in part by the 10-month age difference of older mice as well as by the less severe cold exposure. Talan and Engel (1984) also noted a significant age-related decline in cold tolerance of male C57BL/6J mice when physical restraint was imposed (in order to minimize behavioral influences on body temperature responses) by placing the animals singly into small (30 mm internal diameter) Plexiglas tubes with perforations for ventilation. This restraint procedure prevented gross physical movement but did not inhibit shivering. The average rectal temperature of the restrained young (10-month-old) and old (30-month-old) mice exposed to 10°C for 3 hr decreased by approximately 3 and 11.5°C, respectively. In contrast, in unrestrained mice, the average loss of rectal temperature was similar in both age groups (~3°C), indicating a strong reliance of old mice on behavioral thermoregulation in maintaining homeothermy. Subsequent investigations by Talan and coworkers have confirmed a poorer cold tolerance of old vs young mice to this same restraint–cold stress test (Table 59.1).

2. Cold Tolerance in Rats

The larger size of the rat compared to the mouse makes it relatively more resistant to passive heat loss because of its lower ratio of body surface area to mass. However, the ability of rats to effectively cope with acute and chronic cold still deteriorates with advanced age. An early investigation by Hügin and Verzár (1957) involving 1 hr exposure to −0.5 to −14°C showed that with increasing age (from 3 to 31 months), groups of male rats exhibited significantly greater drops in rectal temperature. With exposure to colder temperatures, the age difference became even more pronounced (Verzár, 1958). As summarized in Table 59.1, subsequent studies have reported age-related alterations of cold-induced thermoregulation in male Long–Evans male rats, male and female Sprague–Dawley rats, female EMD:Wi-AF/Han rats, female Iva:WIWU rats, and male F344 rats. In contrast, the aging male Osborne–Mendel rat remains cold tolerant up to at least 24 months of age (McDonald *et al*., 1989b), and aging F344 females are more cold-resistant than are males at a comparable age (McDonald *et al*., 1989a).

The fact that different strains of mice and rats often exhibit different degrees of age-related decline in cold-induced thermoregulatory abilities (Kiang-Ulrich and Horvath, 1984a, 1985b; Martin *et al*., 1985; Talan and Ingram, 1986a; McDonald *et al*., 1989b) may be correlated with strain-specific life span, as suggested by Talan and Ingram (1986a), who observed greater age-related loss of cold tolerance in relatively short-lived A/J (mean life span of 22 months) vs longer-lived B6/AF_1/J (mean life span of 29 months) males of an inbred strain of *M. musculus*. Cold-induced thermoregulation may also be influenced by the level of domestication, as indicated by the far better cold tolerance of old mice of a pen-bred strain of *M. musculus* captured from the wild than that seen in old mice of the domesticated strains A/J, C57BL/6J, and B6/AF_1/J (Talan and Ingram, 1986a). In some cases, there are also strain differences in cold-induced thermoregulatory abilities of younger animals. For example, Kiang-Ulrich and Horvath (1984a) reported that 3- to 4-month-old male F344 rats better maintained core temperature during exposure to −10°C for 3 hr than did male Sprague–Dawley rats of the same age; in fact, even non-cold-acclimated older (24-month-old) male F344 rats exhibited greater tolerance to cold than did cold-acclimated young Sprague–Dawley rats (Kiang-Ulrich and Horvath, 1985b). The strain effect in younger rats reflected a blunted cold-induced increase in oxygen consumption in Sprague–Dawley vs F344, indicating that differences in heat production were partly responsible (Kiang-Ulrich and Horvath, 1984a). In other cases, strain differences in cold tolerance do not appear until later age. For example, at 12 months of age, both Osborne-Mendel and F344 male rats maintained colonic temperature during exposure to cold (6 hr at 6°C); at 24 months of age, however, only the Osborne-Mendel rats remained cold-tolerant, whereas the F344 rats developed a hypothermia of ~5°C (McDonald *et al*., 1989b). This hypothermia occurred in spite of thermogenesis equivalent to that of older Osborne-Mendel rats, indicating that the older F344 rats had experienced greater heat loss and had a poorer ability to compensate for it metabolically. The primary cause of heat loss was unclear, but did not appear to be due simply to differences in body size and composition. The F344 rat is much smaller in size than the Osborne-Mendel rat (carcass mass of 311.8 gas in grams vs 460.7 g at 24 months), which suggests a greater body surface area-to-mass ratio and thus an increased potential for passive heat loss. However, the higher percentage carcass fat of F344 vs Osborne-Mendel rats (20.6% vs 15.1% at 24 months) implies a greater relative tissue insulation capacity to offset some of the body size effect. It thus seems that the peripheral vasoconstrictor response to cold, which leads to augmented thermal resistance of the body shell (Kenney and Buskirk, 1995), is attenuated in older F344 vs Osborne-Mendel rats. However, the involvement of other heat conservation mechanisms cannot be excluded. The percentage lean body mass and brown adipose tissue thermogenic capacity also differed with strain—both were significantly higher in Osborne-Mendel vs F344 rats (young and old) (McDonald *et al*., 1989b). These data suggest that Osborne-Mendel rats have a greater capacity for shivering and nonshivering thermogenesis than do F344 rats. The finding that cold-induced oxygen consumption did not differ between the two strains could reflect a greater reliance on shivering in the F344 than in the Osborne-Mendel rats (thermogenesis from brown fat is more effective than is shivering in warming the core of the animal because a greater proportion of the heat generated by shivering is lost to the environment due in part to increased blood flow to peripheral muscles and in part to the generation of heat closer to the animal's surface). It could also indicate that the two strains used their thermogenic capacities to different degrees—submaximally in the Osborne-Mendel rats and maximally (or closer to maximal) in the F344 rats (McDonald *et al*., 1989b).

3. Nonlinearity of the Age-Related Decrement in Thermoregulation

Numerous observations suggest that thermoregulation does not decline at a single linear rate over the entire life span of the rodent. One of the earliest is that by Hügin and Verzár

(1957) who studied groups of male rats between ages 3 and 26 months, with measurements made at ~3-month age intervals. They found a gradual loss of cold-induced thermoregulation between ages 3 and 24 months as reflected in the observation that the average hypothermia of the 24 month-old rats was only about 1°C greater than that of the 3-month-old rats. This was followed by a more rapid loss of regulation between ages 24 to 26 months (development of an approximately 2°C greater cold-induced hypothermia). The physiological basis for this acceleration in the rate of loss of function in later life was unclear. We too have found that older rats separated in age by only a few months can exhibit marked differences in their ability to cope with cold. For example, after 6 hr at 6°C, the drop in core temperature in very old (27-month-old) vs old (23-month-old) F344 rats was 2.9°C vs 1.8°C in males and 0.7°C vs 0°C in females (McDonald *et al*., 1989a). Cold-exposed 5-month-old rats of both genders maintained a constant core temperature. These data support the idea of a time-independent component of thermoregulatory decline that is expressed in later life. This was most evident in F344 females, who exhibited no deficit in thermoregulation until some time between ages 23 and 27 months. This study also demonstrated the influence of gender on thermoregulatory loss—that is, while males developed considerable hypothermia by 23 months of age, females at this age still maintained homeothermy. The rate of cold-induced mass-independent oxygen consumption did not differ significantly between the 23- and the 27-month-old rats (McDonald *et al*., 1989a), suggesting that the blunted ability of very old vs old rats to maintain core temperature in response to cold was due to less effective heat conservation rather than attenuated heat production. Although carcass mass was about 10–13% less in the 27-month-old vs 23-month-old males and females (a difference that did not reach statistical significance), the percentage values for the body composition variables (fat, lean body mass, etc.) remained comparable. Thus, rats in both age groups appear to have had the same relative tissue insulation capacity for minimizing heat loss, implicating other heat conservation mechanisms (peripheral vasoconstriction, behavioral adjustments, fur coat). Although increased heat loss rather than reduced heat production seems to have been the direct cause of the greater hypothermia in the 27-month-old vs 23-month-old rats, the fact that this greater heat loss was not compensated for in the very old rats indicates that they also had problems inducing further increases in thermogenesis.

This nonlinearity in the rate of loss of thermoregulatory ability is also reflected in survival rates during long-term cold exposure. For example, Kiang-Ulrich and Horvath (1985a) reported that only 46% of 25-month-old male F344 rats survived 3 weeks of exposure to 5°C compared to 100% survival of 3-, 12-, and 21-month-old rats maintained for 7 to 9 weeks. The 25-month-old rats (survivors and nonsurvivors) lost considerably more body weight in the cold compared to 21-month-old rats, but this was not due simply to differences in food intake, which increased by about the same magnitude in both age groups (Kiang-Ulrich and Horvath, 1985a). The authors speculated that the chronologically older rats may have had problems utilizing glucose, and thus a poorer ability to provide the fuels for thermogenesis required to survive the cold (Kiang-Ulrich and Horvath, 1985a). However, since heat production and core temperature were not measured in this study, the metabolic state of the 25-month-old vs 21-month-old rats is only speculative.

4. Effects of Gender

As with the human studies, work with rats has shown that older females are often less prone to develop hypothermia during cold exposure than are comparably aged males (e.g., McDonald *et al*., 1989a, 1994; Gabaldón *et al*., 1995). Our understanding of the physiological mechanisms underlying this gender difference has been limited by the fact that few investigations have used females. In several of our studies, we have evaluated the effects of age on both females and males. For example, we have shown that cold exposure of 27-month-old rats to 6°C for 6 hr resulted in a 2.9°C decrease in colonic temperature in males compared to only a 0.7°C decrease in females and no significant decrease in 5-month-old rats regardless of gender (McDonald *et al*., 1989a). The 27-month-old females in this study had a significantly higher percentage carcass fat compared to males (25.7 vs 21.3), and this may have provided greater protection against passive heat loss. There were no gender differences in cold-induced mass-independent oxygen consumption of older rats (McDonald *et al*., 1989a), but females may have derived a greater percentage of total heat production from nonshivering thermogenesis in brown adipose tissue than did males. The latter is suggested by the ~1.5-fold greater total amount of purine nucleotide (GDP) binding to brown fat mitochondria isolated from 2 hr cold-exposed older females than that seen in older males (McDonald *et al*., 1989a), this binding being an *in vitro* index of the thermogenic state of brown fat mitochondria. In a subsequent study, we found that sympathetic stimulation to brown fat (as measured by norepinephrine turnover in the tissue) was not diminished more in older male than in female F344 rats, indicating that diminished cold-induced neural signals could not explain the gender difference in the ability to maintain homeothermy (McDonald *et al*., 1994)

C. Mechanisms Underlying the Hypothermia in Older Rodents

The ability to maintain thermal homeostasis depends upon the functional state of the neural pathway (Fig. 59.2) as well as that of the peripheral effectors (Fig. 59.1). As discussed below, age-related alterations at several steps in this regulatory pathway have been suggested to occur.

1. Heat Conservation Mechanisms

Retention of metabolic heat during exposure to low ambient temperatures is dependent upon the effectiveness of the insulation provided by the body shell and coat. Subcutaneous fat and skeletal muscle both contribute to total tissue insulation (Kenney and Buskirk, 1995). A poorly perfused body shell provides a more effective insulation, and this is accomplished by vasoconstriction of the peripheral vasculature. This is especially important in minimizing heat loss from the poorly insulated and highly vascularized regions of the body (the tail, ears, and paws in rodents).

Age-related changes in body composition of rats show strain differences. For example, the cross-sectional study by

McDonald *et al*. (1987) on female Sprague–Dawley rats ages 5 and 26 months indicated a decrease with age in the percentage of lean carcass mass and a significant increase in the percentage of fat. In contrast, there were no major age-related alterations in the carcass composition of male and female F344 rats between ages 5–7 and 23–27 months (McDonald *et al*., 1988a,b, 1989a,b). There were also no major age-related changes in the body composition of male Osborne-Mendel rats between ages 12 and 24 months (McDonald *et al*., 1989b). Thus, the insulative capacity due to adipose tissue does not appear to be diminished with age.

In studies with rodents, measurement of skin temperature is often used as an index of peripheral circulation. In response to cold, sympathetic nervous activity to peripheral blood vessels increases, resulting in vasoconstriction, reduced skin blood flow, rapid lowering of skin temperature, and decreased heat loss. Although it has been suggested that there may be blunted vasoconstriction in old rodents, several studies suggest that this is not the case, and in fact, that vasoconstriction is greater in older rats and mice (Cox *et al*., 1981; Balmagiya and Rozovski, 1983; Talan, 1997; Shefer and Talan, 1997). For example, Cox *et al*. (1981) showed that the tail temperature of male Sprague–Dawley rats decreased comparably in young and old rats in response to cold and that there were no age differences in the rate at which tail temperature fell. Balmagiya and Rozovski (1983), using male Sprague–Dawley rats, showed that the total drop in tail temperature in response to cold (1.5 h at 18–19°C) was two times greater at 13 and 24 months of age than at 3–9 months, and the time for tail temperature to return to baseline after cold became progressively longer with increasing age (i.e., 50 min at 24 months vs 10 min at 3 months). These age-related changes in tail temperature coincided with the changes in rectal temperature (greater cold-induced decrease in older vs younger rats and slower recovery time). This implies that the older rats maintained a more intense vasoconstriction as compensation for insufficient heat production. These findings support the idea that the vasoconstrictor response is intact and functional in at least some strains of older rodents. However, when exposed to chronic cold (6 weeks at 10°C), older (22-month-old) male F344 rats developed tail pathologies which were speculated to have been caused by intense vasoconstriction resulting in a complete shutdown of blood flow to the tail (Owen *et al*., 1991). Thus, the vasoconstrictor response, although present in older animals, may not be regulated well over the entire time course of cold exposure—sometimes there appears to be excessive responsiveness that is detrimental to tissue health.

2. Heat Production Mechanisms

Lower cold-induced heat production, as measured by oxygen consumption, has been observed in several strains of older vs younger mice [e.g., Grad and Kral, 1957 (female C57BL); Estler, 1971 (female NMRI); Tatelman and Talan, 1990a,b, 1993 (male C57BL/6J); Schaefer *et al*., 1996 (male C57BL/6J)] and rats [e.g., Kiang-Ulrich and Horvath, 1985b (male F344); Lee and Wang, 1985 (male Sprague–Dawley); McDonald *et al*., 1987 (female Sprague–Dawley); McDonald *et al*., 1988a (male F344); Wang *et al*., 1992 (male Sprague–Dawley)]. Not all studies, however, have shown diminution in cold-induced thermogenesis with age in rats [e.g., Balmagiya and Rozovski, 1983 (male Sprague-Dawley); McDonald *et al*., 1988b (male F344); McDonald *et al*., 1989a (male/female F344); McDonald *et al*., 1989b (male F344 and Osborne-Mendel rats)]. Cold-induced heat production occurs in skeletal muscle and in brown fat depots which are located at various sites in rodents. From blood flow studies, it has been estimated that warm-acclimated (28°C) younger rats acutely exposed to cold (6°C) derive as much as 33% of their total heat production from skeletal muscle and 37% from brown adipose tissue (Foster and Frydman, 1979). Nonshivering thermogenesis in brown fat continues to play an important role in thermoregulation in old rats and mice; and some studies have shown that brown fat thermogenic capacity is reduced with aging. There is also evidence that shivering ability may be diminished with aging.

A significant loss of lean body mass (and thus diminished shivering capabilities) sometimes occurs in old mammals that have reduced thermal homeostasis. Reduction of oxidative enzyme activity in skeletal muscle or in the availability/handling of substrates that fuel thermogenesis could also decrease the potential for shivering. Studies which suggest an age-related loss of shivering thermogenesis in rodents include those by Balmagiya and Rozovski (1983), Lee and Wang (1985), and Wang *et al*. (1992). Lee and Wang (1985) reported that older (23- to 26-month-old) Sprague–Dawley male rats treated with the drug aminophylline, a phosphodiesterase inhibitor which enhances intracellular cAMP levels, had greater heat production and smaller drops in core temperature during acute cold exposure compared to controls. In contrast, aminophylline did not enhance norepinephrine-induced nonshivering thermogenesis, i.e., brown fat thermogenesis. These results were interpreted as indicating that the primary disruption in cold-induced heat production in older rats was blunted skeletal muscle shivering thermogenesis resulting from decreased substrate availability (due to impaired mobilization or utilization mechanisms regulated by cAMP). The apparent inability of cold-exposed older rats to raise their cAMP levels in skeletal muscle may be due to enhanced adenosine stimulation (Wang *et al*., 1992). This is based on the observation that the endogenous adenosine deaminase activity in neck muscle, a key site of shivering thermogenesis, was significantly lower in older vs younger rats, and that administration of adenosine deaminase greatly improved thermogenesis and cold tolerance of older rats (Wang *et al*., 1992). The ability to sustain shivering thermogenesis is dependent to a large degree on the availability of substrate, but the glycolytic and oxidative capacities of skeletal muscle tissue determine the rate of substrate utilization, and thus the rate of production of the ATP required for sustaining shivering. Oxidative enzyme activity in hindlimb skeletal muscle is increased significantly by several weeks of moderate intensity physical exercise training in older (and younger) rats (and mice). This may account, at least in part, for the improved cold tolerance that occurs after exercise training in some rodents (e.g., McDonald *et al*., 1988b; Shefer and Talan, 1998), albeit not all (Talan and Ingram, 1986b).

Although brown adipose tissue disappears almost entirely by about the eighth decade of human life (Heaton, 1972; Ito *et al*., 1991), it remains an important component of regulatory thermogenesis throughout the life of rats and mice. Some data sug-

gest that brown fat thermogenic capacity does not decrease with age in male rodents (Kirov, *et al*., 1996; Scarpace, 1997; Talan, 1997). However, many other investigations have shown that cold-, norepinephrine-, and β-adrenergic agonist-induced thermogenesis and/or components of the thermogenic pathway in this tissue are attenuated with age (Balmagiya and Rozovski, 1983; Kiang-Ulrich and Horvath, 1984b; Lee and Wang, 1985; McDonald *et al*., 1988a, 1989a; Scarpace *et al*., 1988, 1992; Hamilton *et al*., 1990), with older males retaining less brown fat thermogenic capacity than older females (McDonald *et al*., 1989a). The proliferative response of brown fat to chronic cold is also attenuated with age, at least in male F344 rats (Florez-Duquet *et al*., 1998). On the other hand, there appears to be no age-related decrease in ability to generate the thermogenic signal (i.e., norepinephrine) to brown fat during acute cold exposure (Kawate *et al*., 1993; McDonald *et al*., 1993; Talan, 1997); and although sensitivity of brown adipocytes to the sympathetic signals could be reduced (Scarpace *et al*., 1996; Scarpace, 1997), we have found that brown adipocytes isolated from old (26-month) vs younger (12- and 6-month) F344 rats (males and females) did not show any decrement in their responsiveness to norepinephrine or CL 316,243 (a β_3 adrenergic agonist) with respect to cAMP generation, lipolysis, or oxygen consumption (Gabaldón *et al*., 1998). Thus, it appears that the blunted brown fat thermogenesis generated by the old F344 rats is more reflective of reduced amounts of brown adipocytes than of changes in the adipocytes themselves (Gabaldón *et al*., 1998).

3. Sympathetic Nervous System Response to Cold Stress

Various techniques have been used to assess the functional state of the sympathetic nervous system in the old rodents. Among these are measurements of circulating levels of norepinephrine (which derives primarily from post-ganglionic sympathetic nerve endings); firing rates of nerves innervating specific tissues; and measurement of norepinephrine turnover in target tissues. Acute cold increases the activity of the sympathetic nervous system, and in rodents the effect is typically more pronounced in older vs younger individuals as evidenced by higher plasma norepinephrine concentrations (Avakian *et al*., 1984; McCarty, 1985; Gabaldón *et al*., 1995). Cold-induced sympathetic outflow to the interscapular brown adipose depot has also been shown to be greatly enhanced rather than attenuated with aging in rodents. Kawate *et al*. (1993) recorded the efferent electrical activity from sympathetic nerves to interscapular brown fat in C57BL/6J male mice and found that artificial lowering of body temperature resulted in a significantly greater increase in firing rate in 30-month-old vs 10-month-old animals. In a separate investigation of a similar design, Talan (1997) showed that sympathetic firing rate to interscapular brown fat was greater in 24- to 26-month-old vs 10- to 12-month-old C57BL/6J male mice during artificial lowering of body temperature. This occurred when the mice were acclimated to room temperature (22°C) and to thermoneutrality (29°C); the cold-induced sympathetic activity in old mice became even stronger when they were acclimated to the cooler temperature, but it was not enhanced significantly in adult mice (Talan, 1997). Sympathetic outflow to brown fat is also higher in cold-exposed older vs younger F344 male rats

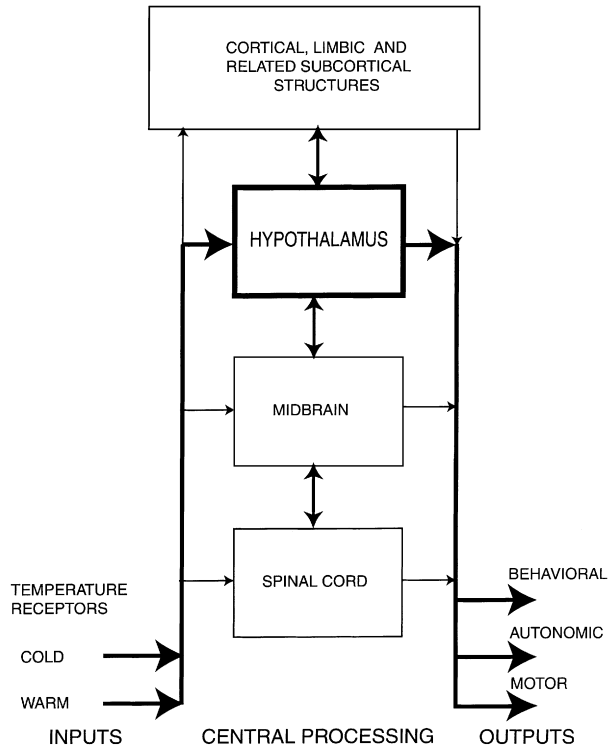

FIG. 59.2. Potential sites of age-dependent neural changes in temperature regulation. The hierarchical control of parallel systems (as indicated by the double arrows) is based on a review by Satinoff (1978) on the neural organization and evolution of thermal regulation in mammals. Warm and cold thermoreceptors in the periphery (Pierau, 1996) and in the central nervous system (Boulant, 1996) send signals to parallel systems within the brain. The dominant role of neural networks in the hypothalamus (Boulant, 1996) controlling autonomic outputs is indicated by darkened lines. Potential sites of age-related thermoregulatory changes can thus occur in a variety of brain areas as well as in the periphery.

(and vs older females) as evidenced by higher norepinephrine turnover rates (McDonald *et al*., 1993). Thus, cold-induced sympathetic neural activity in male rodents appears to be enhanced rather than attenuated with age. In the case of brown fat, this may reflect an attempt to compensate for the diminished amount of thermogenically competent tissue.

4. Central Nervous System

There is evidence to suggest that central nervous control of thermoregulation (Fig. 59.2) is altered with aging in rodents. The findings of Cox *et al*. (1981) suggest that the inability of old rats to respond to temperature changes as effectively as young rats is due, in part, to alterations in concentrations of and/or sensitivity to putative central neurotransmitters involved in hypothalamic thermoregulatory pathways, such as dopamine. These investigators found that intraperitoneal injection of apomorphine (a dopamine agonist) or amphetamine (which causes the release of endogenous dopamine) induced a significant drop in core temperature in young (2-month-old) and old (24-month-old) Sprague–Dawley male rats, but the response was significantly blunted in the old rats. There is also evidence that hypothalamic dopamine content is reduced in old rats (Carfagna *et al*., 1985), and that there

is degeneration of catecholamine terminals in the anterior region of the hypothalamus in old mice (Masuoka *et al*., 1979). Other investigators have also reported age-related alterations in central sensitivity to neurotransmitters/neuromodulators which influence the regulation of body temperature (e.g., Frolkis, 1976; Clark and Lipton, 1981). The possibility of an altered central control mechanism of thermoregulation in older rodents is further supported by the observation that electrical self-stimulation of ''reward'' areas of the hypothalamus improves cold tolerance of old male C57BL/6J mice (Talan *et al*., 1984). The mechanism of this effect is unclear, but it was postulated that electrical stimulation might activate a hypothalamo–hypophyseal regulatory axis which resulted in increased metabolic level which, in turn, facilitated the ability of older mice to increase heat production during cold (Talan *et al*., 1984).

Notwithstanding the above observations, our data showing that 26-month-old male F344 rats respond to acute cold by increasing sympathetic activity to brown fat to a greater extent than do young rats indicate that the circuitry from thermoreceptor to hypothalamic integrator to sympathetic nerves is intact and is functioning appropriately (McDonald *et al*., 1993). Rather, the rate-limiting factor(s) for thermogenesis might instead involve blunted end-organ function and/or reduced substrate availability/handling. This idea is further supported by Tatelman and Talan (1993), who showed that old C57BL/6J male mice were capable of increasing heat production in response to acute cold (3 hr at either 18, 12, or 6°C), but not in proportion to the intensity of the cold stimulus as did young mice. Specifically, maximal thermogenesis in old mice was reached between 18 and 12°C, while maximal thermogenesis in young mice was not reached until 6°C (or lower). The net effect was greater heat production in young vs old mice at 12 and 6°C ($\sim$37 and $\sim$56%, respectively) but comparable heat production at 18°C. This was interpreted as indicating that the lower cold-induced metabolic heat production of old vs young mice reflected reduced capacity for thermogenesis rather than reduced ability to induce it. Thus, while altered central control of thermoregulation may occur with aging, this is probably not the primary mechanism underlying the cold-induced hypothermia in older rodents.

5. Behavioral Thermoregulation

Although age-related alterations in behavioral thermoregulation have been implicated in humans (e.g., Watts, 1972; Collins *et al*., 1981b), the available evidence does not support analogous changes in rodents. In an investigation by Jakubczak (1966), young (7- and 12-month-old) and old (28-month-old) Sprague–Dawley male rats were placed in the cold (16 hr at 2°C) with access to a lever that turned on a heat lamp (250 W, 2 s heat burst/lever press). The young and old rats worked for heat equally well by lever pressing and exhibited comparable amounts of heat loss as measured by rectal temperature. Hence, the mechanisms involved in regulating this heat-seeking behavior are not altered with age. In line with this, Owen *et al*. (1991) found no age-related differences in preferred ambient temperature of F344 male rats placed in a thermocline (7–37°C linear gradient). This was observed regardless of whether the rats were cold-acclimated or not: the preferred ambient temperature of non-cold-acclimated younger and older rats was about 23.7°C; and after 6 weeks at 10°C, rats in both groups selected cooler temperatures (about 7 and 5°C cooler than preacclimation values, respectively).

6. Summary

Old laboratory mice and rats of various strains exhibit an attenuated ability to maintain homeostasis when cold exposed, this decrement being greater in males than in females of the same chronological age. The decrease in cold tolerance does not occur linearly with age but rather, is markedly enhanced in animals as they approach the end of their natural life. Increased heat loss and blunted heat production contribute to the age-related decrease in thermal homeostasis. With respect to heat loss, currently available evidence argues against diminished cold-induced vasoconstriction as a primary cause. Alternative mechanisms such as lower insulative effectiveness of fur have not yet been evaluated. On the heat production side, both shivering and nonshivering thermogenesis appear to be decreased in older rodents, although not to the same degree in the various strains. As in humans, decreased shivering is most apparent in old animals that have lost lean body mass. Similarly, the decrease in nonshivering thermogenesis is most closely related to lower amounts of brown adipose tissue and UCP1, although in some cases there may also be altered β-adrenergic receptor density. Reduced cold-induced sympathetic signaling to brown fat does not appear to play a role in the lower nonshivering thermogenesis of older rodents. Notably, the observation that cold exposure results in increased sympathetic signaling to brown adipose tissue in old presenescent rats (i.e., body weight stable) indicates that the thermoregulatory circuitry is intact and functional. Nonetheless, reports of morphological and neurochemical changes in the brain suggest the possibility of altered hypothalamic regulation of thermoregulation—an area that clearly needs further study.

IV. Senescence and Thermoregulation in Rats

Some older rodents (as well as humans) exhibit spontaneous and relatively rapid weight loss near the end of their life. We have referred to this phase of aging as senescence. It is associated with reduction of food intake (Everitt, 1957, 1958; Blanton *et al*., 1998) as well as a changes in several other physiological variables. As described below, we have found that transition of F344 rats from gradual aging, i.e., chronological aging, to senescence is accompanied by pronounced deterioration of at least two components of the thermoregulatory system. Specifically, senescent rats develop very poor tolerance to cold (McDonald *et al*., 1996) and exhibit weak circadian rhythms of core temperature (McDonald *et al*., 1999).

In the F344 male rats that we obtain from the National Institutes on Aging colony (median life span of $\sim$25 months), senescence, as identified by the period of rapid body weight loss, generally occupies about the last 2–7 weeks of life. Notably, the age of onset of senescence varies from 23 to 30 months of age, indicating that even in an inbred strain such as the F344 rat, chronological age is a poor indicator of this change in functional state. At necropsy following natural death, we have found no consistent pathology that could account for

the rapid loss of body weight (Murtagh-Mark *et al*., 1995); nor were there significant differences in the incidence of leukemia, nephropathy, or pituitary lesions (age-related pathologies characteristic of the F344 rat) between senescent and age-matched presenescent rats (Blanton *et al*., 1998). We also found no evidence of disease-associated cachexia, which is characterized by reduced food intake, increased resting metabolic rate, decreased protein synthesis, and increased whole-body protein degradation. Our rats did not exhibit enhanced resting metabolic rates, higher body temperatures, lower concentrations of serum protein or albumin levels (indices of protein synthesis), or increased amounts of urinary creatinine or urea nitrogen (indices of protein catabolism) (McDonald *et al*., 1996). Thus, senescence appears to be a distinct functional state from chronological aging, but one which cannot be explained by any single pathology.

The senescent F344 rats have severely impaired cold-induced thermoregulation (McDonald *et al*., 1996). When exposed to 6°C for up to 4 hr, they exhibited a rapid decline in core temperature during the first hour of cold (total drop of 2.7°C), followed by a more gradual but significant decline in the hours thereafter; by hour 4, rats completing the cold challenge had dropped their colonic temperature an average of 5.5°C. In contrast, these same rats maintained a more constant core temperature throughout the period of cold exposure before they entered senescence (i.e., when they were body weight stable). This attenuation of thermoregulation in senescent rats was accompanied by 50% lower total amounts of UCP1 in interscapular brown fat depots, indicating decreased potential for nonshivering thermogenesis. To determine if the increased susceptibility to hypothermia resulted from the weight loss per se, we measured the responses of 26-month-old presenescent rats (weight stable) that were food restricted to the same weight loss ($\sim$10%) as the senescent rats. When these food restricted rats were cold exposed under the same conditions as the senescent rats, they did not develop severe hypothermia (McDonald *et al*, 1996). Thus, the loss of body weight of the senescent rats is an indicator that the rats had entered a different functional state—it is not the cause of this state.

The fact that altered circadian rhythms of core temperature (McDonald *et al*., 1999), attenuated cold-induced thermoregulation (McDonald *et al*., 1996), and reduced food intake (McDonald *et al*., 1996, 1999) all occur at approximately the same time suggests that transition from gradual aging to senescence is accompanied by hypothalamic dysfunction. The deterioration of brown fat in senescent rats further supports the possibility of altered neural/hormonal signaling. Brown fat UCP1 levels are highly regulated by the sympathetic nervous system, with modulatory influences from hormones such as triiodothyronine and insulin. The lower UCP1 levels in brown adipose tissue from senescent vs presenescent older rats (McDonald *et al*., 1996) thus suggest possible blunting of neural and/or hormonal signals that regulate its synthesis. We have found significantly lower serum thyroxine concentrations in senescent vs presenescent rats (Blanton *et al*., 1998). This may lessen the capacity of brown adipocytes to generate, via the action of thyroxine 5′-deiodinase, the amount of triiodothyronine necessary to fully enhance norepinephrine-induced UCP1 synthesis. Current studies are examining potential mechanisms for these thermoregulatory changes.

V. Conclusions and Future Directions

Although not all inferences made from studies on thermoregulation in elderly humans have stood the test of time, they have played a valuable role in setting the stage for a series of recent investigations that are more carefully controlled and where data are more conservatively interpreted. It is now recognized that to evaluate the role of aging in the altered thermal responses of the elderly requires consideration of a variety of confounding factors, including physical fitness, socioeconomic status, disease, and prior heat or cold acclimation, if any. Results from longitudinal studies, which allow comparison of changes in a single subject over time, combined with the more variable results from cross-sectional studies, have provided insight into some of the factors contributing to altered thermoregulation in the elderly as well as identification of gender differences. This insight has been greatly advanced by examination of the role of various effectors important in human thermoregulation. These include sweat gland function, vasodilatation, and skin blood flow in warm environments and temperature perception, peripheral vasoconstriction, and skin blood flow in cold environments. However, while these studies have created a framework for describing thermoregulatory changes in elderly humans, a more complete understanding of how age exerts these effects requires further work.

Aging studies on thermoregulatory mechanisms in laboratory rodents have also progressed to a stage where confounding factors have been identified and age-dependent changes in effector mechanisms have been described. Valid comparisons of results in studies on rodents require the recognition that different strains of mice and rats have different life spans, and that chronological age may not represent the same biological age in individuals within the same strain let alone animals of different strains. Nonetheless, studies of laboratory rodents allow analyses that cannot be done in humans. Initial studies on neurotransmitter changes in the central nervous system of aged rats are opening the way for a more complete evaluation of aging and hypothalamic thermoregulation. The rat also is also an excellent model for future neural studies on the hierarchical thermoregulatory system, an area as yet relatively unexplored in aging research; and despite their small size, transgenic mice offer the possibility of testing the role of candidate genes modulating/mediating age-related changes in thermal responses.

Taken as whole, studies on mice, rats, and humans show that age differentially affects various components of the thermoregulatory system. Even though caution must be used in drawing general conclusions across species, studies on different species are contributing to an emerging picture of the mechanisms underlying compromised thermoregulation with age. Additional work is needed to precisely delineate the detailed nature of these mechanisms.

Sleep and Hormonal Rhythms in Humans

In the human, sleep and hormonal secretions are under the dual control of circadian rhythmicity and of a homeostatic process relating the depth of sleep to the duration of prior wakefulness. The circadian clock plays a major role in the timings of sleep onset and offset, sleep consolidation, and the distributions of rapid eye movement (REM) sleep. The temporal organization of the secretions of a number of hormones such as melatonin and the hormones of the hypothalamo–pituitary–adrenal axis are also primarily controlled by the circadian pacemaker. On the other hand, the temporal profile of non-REM sleep, in particular slow-wave sleep, and a number of hormones such as prolactin and growth hormone are primarily controlled by the homeostatic process. Normal aging is commonly associated with profound alterations of both the homeostatic process and the circadian pacemaker, which are, however, chronologically dissociated. Alterations of the homeostatic process, as assessed by exponential decreases in slow-wave sleep and in nocturnal growth hormone secretion, are essentially complete by midlife. In contrast, alterations of the circadian pacemaker, as assessed in particular by modifications of REM sleep and of the glucocorticoid secretory profiles, occur essentially from 50 years onward. Strategies for preventing or limiting such alterations should take into account this dissociated chronology of aging. Pharmacological approaches to restore normal sleep could represent an indirect form of hormonal therapy with possible beneficial health effects.

I. Mechanisms Subserving Sleep and Hormonal Rhythms

In the human as in all mammalian species, reproducible changes of essentially all physiological and behavioral variables occur over the course of the 24 hr day, in synchrony with the 24 hr periodicities in the physical environment. However, these daily or diurnal rhythms are not simply a response to the environmental periodicities imposed by celestial mechanics, but instead are generated by an internal time-keeping system, generally referred to as the circadian clock or pacemaker (Turek, 1998). Two small bilaterally paired nuclei in the anterior hypothalamus, called the suprachiasmatic nuclei, function as a master circadian pacemaker (Rusak and Zucker, 1979; Moore-Ede, 1982; Miller *et al*., 1996). In the absence of any environmental time cues, the intrinsic period of this master pacemaker, which is primarily responsible for the generation and entrainment of all circadian rhythms of the body, is rarely exactly 24 hr. In the human, this period is slightly longer than 24 hr. Estimations from early studies of subjects maintained for extended periods of time in temporal isolation, either in underground bunkers or in specially designed units, averaged 24.5–25.0 hr (Wever, 1979; Aschoff, 1981). A recent reevaluation using a different experimental strategy has, however, suggested that the endogenous period of human circadian rhythmicity is actually very close to 24 hr, i.e. 24.18 hr (Czeisler *et al*., 1999). The endogenous pacemaker needs to be synchronized and entrained by environmental signal(s) to ensure adequate adaptation of physiological and behavioral functions to environmental conditions. Otherwise, a clock with a period only a few minutes shorter or longer than 24 hr would soon be totally desynchronized from the environment. The light–dark cycle is the most important synchronizing environmental agent (Turek, 1998). Light–dark information is transmitted from the retina to the suprachiasmatic nuclei and then to the pineal gland, where it regulates melatonin secretion. In turn, melatonin exerts synchronizing effects on the circadian pacemaker as an indirect photic zeitgeber. There is increasing evidence that the rest–activity cycle may also participate in the synchronization of endogenous circadian rhythmicity independently of photic inputs (Turek, 1998).

In the human, sleep is under the dual control of circadian rhythmicity and of a homeostatic process relating the depth of sleep to the duration of prior wakefulness. Thus, circadian rhythmicity plays an important role in the timings of sleep onset and offset, sleep consolidation, and the distribution of rapid eye movement (REM) sleep and sleep spindle activity (Czeisler *et al*., 1980; Dijk and Czeisler, 1995). On the other hand, non-REM sleep, in particular slow-wave sleep, is primarily controlled by the homeostatic process, which is thought to involve a putative neural sleep factor which increases during waking drops and exponentially during sleep (Achermann and Borbély, 1990; Borbély, 1998).

Both sleep and the circadian clock are major regulators of endocrine function. Their relative contributions in the temporal organization of hormonal release differ from one endocrine

axis to another. For most pituitary hormones, the 24 hr profiles result from the interaction of the circadian clock with sleep–wake homeostasis and reflect the superposition of 24 hr periodicities on an ultradian, or pulsatile, pattern of release.

Morphological and neuroanatomical alterations have been evidenced in the suprachiasmatic nuclei of older animals in some, but not all, studies (Wise *et al*., 1987, 1988; Swaab *et al*., 1988; Weiland and Wise, 1990). These alterations could, at least partially, be responsible for age-related changes in 24 hr rhythms which are primarily driven by the circadian pacemaker, such as reduced amplitude and earlier phase. It has been suggested that the phase-advance of circadian rhythmicity in the elderly could result from a shortening of the intrinsic period of the circadian pacemaker (Pittendrigh and Daan, 1974; Weitzman *et al*., 1982; Czeisler *et al*., 1986, 1992). However, a recent study performed under conditions of forced desynchrony—where the subjects are maintained on a sleep–wake and dark–light cycle with a period outside the range of entrainment of the circadian system—found similar durations of intrinsic periods of the circadian pacemaker in healthy young and older individuals (Czeisler *et al*., 1999). It is possible, however, that the relatively short duration of the protocol did not allow for the expression of the endogenous period and of a possible impact of age. Studies in blind subjects who have no photic input to their circadian system and therefore ''free-run'' naturally have indeed provided estimations of the human circadian period around 24.6 hr (Lewy and Newsome, 1983). Alternatively, changes in 24 hr rhythms could reflect age-related modifications in entrainment mechanisms or exposure to entrainment agents, e.g., absence of constraining professional and social schedules and decreased exposure to the synchronizing effects of the dark–light and rest–activity cycles. Indeed, some older individuals maintain well-preserved circadian function into the later stages of adulthood (Monk *et al*., 1995). It has been suggested that individual differences in circadian function in the elderly could reflect individual differences in degree of exposure and responsivity to the synchronizing effects of both photic and nonphotic inputs in the course of aging (Campbell *et al*., 1988; Van Cauter *et al*., 1998). Decreased sleep quality is also a hallmark of aging and is likely to contribute to the development of hormonal alterations in the elderly (Van Cauter *et al*., 1998).

The characteristics and the chronology of age-related changes in sleep duration and quality will be reviewed in the first section of the present chapter. The following sections will be devoted to a review of age-related alterations in a number of hormonal rhythms classically considered to be mainly dependent on sleep–wake homeostasis (growth hormone, prolactin), on circadian rhythmicity (cortisol, melatonin), or on both processes (thyrotropin). Particular emphasis will be put on two hormones for which the chronology of aging has been clearly defined, namely growth hormone and cortisol.

II. Sleep

REM sleep and non-REM sleep both correlate with specific changes in brain activity, muscle tone, and autonomic activity. Non-REM sleep is subdivided, relatively arbitrarily, into four precisely defined stages: stages 1, 2, 3, and 4. Stage 1 sleep is a transitional stage between wakefulness and sleep, and is followed after a few minutes of sleep by stage 2 sleep, which is generally considered to be the onset of true sleep. This is successively followed by stages 3 and 4, which are generally referred to as slow-wave sleep or ''deep sleep.'' During stages 3 and 4, the electroencephalogram is characterized by slow waves in the range 0.5–4.0 Hz, often referred to as ''delta waves.'' REM sleep, also referred to as ''paradoxical sleep,'' is a state in which the brain is highly activated but the body is paralyzed, and is preferentially associated with dreaming and eye movements. Under normal conditions, sleep starts with non-REM stages, followed by the first period of REM sleep. As the night progresses, REM sleep increases in duration with each successive cycle, which lasts approximately 90 min, while slow-wave sleep decreases (Fig. 60.1, top). Thus, in a young normal adult, normal sleep architecture typically consists of four to five alternating non-REM and REM cycles, with REM sleep occupying approximately 25% and non-REM sleep approximately 75% of the total sleep time.

Profound disruptions of the daily sleep–wake cycle are commonly observed in normal aging. Elderly individuals frequently complain of sleep problems, usually reporting shallow, unrefreshing sleep, frequent awakenings during the night, early morning awakenings and unwanted daytime naps (Prinz, 1995). Consistent with this decrease in sleep quality with aging, regular use of sedative and hypnotic medications also increases in elderly.

Numerous studies have demonstrated that these age-related changes in subjective sleep quality reflect marked alterations in polysomnographically defined sleep architecture (Prinz *et al*., 1990; Bliwise, 1993, 1994; Prinz, 1995). While the sleep period (i.e., the interval separating sleep onset from final morning awakening) remains relatively constant across adulthood, significant sleep fragmentation occurs after 50 years of age, resulting in a decrease in total sleep time (i.e., the sleep period minus the total duration of awakenings) and therefore in a reduction of sleep efficiency. Morever, aging exerts differential effects on the different sleep stages (Fig. 60.1). The most spectacular age-related change is the decrease in slow-wave (stages III and IV) sleep and in delta wave activity. This decrease appears to be more pronounced in men than in women. The decline in REM time, while less marked, is accompanied by a redistribution of REM stages across sleep. Indeed, REM stages are shifted toward the early part of the night. This is illustrated in Fig. 60.2, which shows that following sleep onset, the time necessary to accumulate 50% of the total amount of REM sleep is 75 min shorter in normal old men than in young controls. Since the distribution of REM sleep is mainly controlled by the circadian pacemaker, these alterations suggest that a phase advance of the circadian clock could be a hallmark of aging.

The chronology of age-related changes in sleep quality is illustrated in Fig. 60.3. From young adulthood (16–25 years) to midlife (35–50 years), the duration of slow-wave sleep decreases rapidly (almost 30 min per decade) so that by midlife slow-wave sleep represents less than 10% of the sleep period, with practically no more stage IV sleep. This decrease in deep sleep is compensated by an increase in light non-REM sleep (i.e., stages I and II) while the durations of REM sleep and

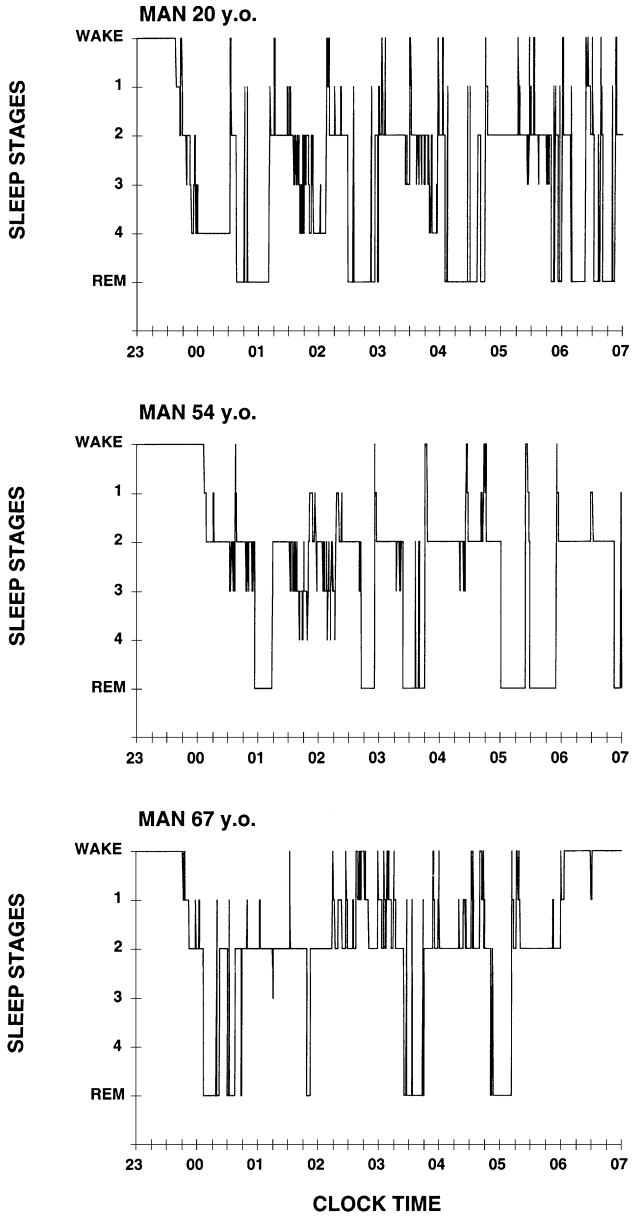

FIG. 60.1. Sleep scores at 30 sec intervals throughout the night in three normal men ages 20 years (top), 54 years (middle), and 67 years (bottom).

of wake and the total sleep time remain stable. In contrast, from midlife to old age (70–83 years), there is no additional decline in slow-wave sleep, but the duration of REM sleep decreases and the duration of wake increases, resulting in a progressive decline in total sleep time.

This differential pattern of age-related changes in slow-wave sleep, primarily controlled by the homeostatic process, and in REM sleep, mainly dependent on the circadian pacemaker, suggests that an alteration in sleep–wake homeostasis may constitute an early biological marker of aging in normal men.

III. Hormones Primarily Controlled by Sleep–Wake Homeostasis: Prolactin and Growth Hormone

A. Prolactin

In normal young adults, the 24 hr profile of circulating prolactin levels is characterized by a major nocturnal elevation starting shortly after sleep onset and culminating around midsleep (Sassin *et al.*, 1972, 1973; Van Cauter *et al.*, 1981). Sleep onset has a stimulatory effect on prolactin release, irrespective of the time of the day, but the amplitude of the prolactin rise associated with daytime sleep may be dampened as compared with nocturnal sleep (Van Cauter and Refetoff, 1985). Conversely, modest elevations of prolactin levels may persist during waking around the time of the usual sleep onset, particularly in women. Thus, prolactin secretion appears to be also modulated by circadian rhythmicity, and maximal stimulation occurs only when sleep and circadian effects are superimposed (Desir *et al.*, 1982; Spiegel *et al.*, 1994; Waldstreicher *et al.*, 1996). The circadian component of prolactin secretion is much more pronounced in women than in men (Waldstreicher *et al.*, 1996). In addition, two studies have indicated that elevations of nocturnal prolactin levels in the absence of sleep could also depend on other factors. In one study, prolactin increased when the subjects were kept awake in total darkness but not in the presence of light (Okatani and Sagara, 1993). Therefore, the authors suggested that the nocturnal elevation of prolactin may be partially dependent on melatonin. Indeed, administration of low doses of melatonin during the daytime results in an

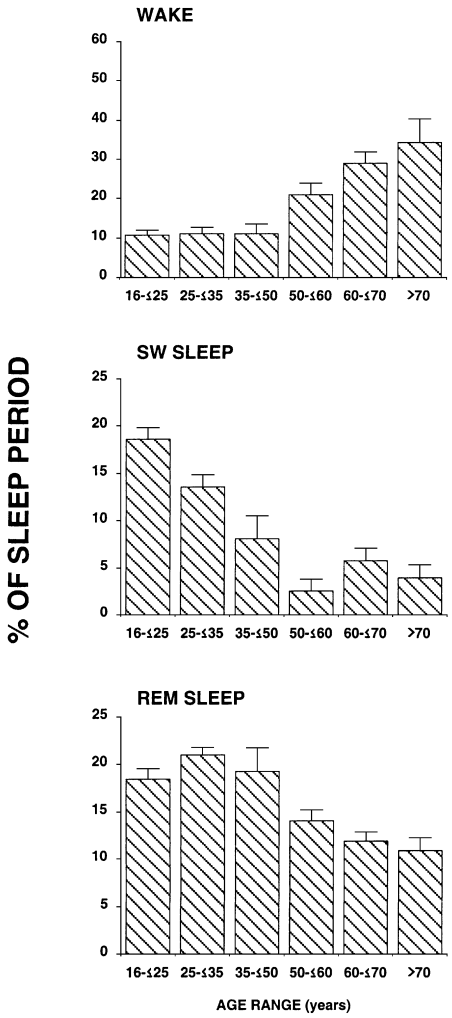

FIG. 60.3. Percentages of the sleep period spent in wake, slow-wave (SW) sleep, and REM sleep as a function of age in normal men (mean ± SEM). Data source: Van Cauter *et al*. (2000).

elevation of plasma prolactin concentrations. In the other study, elevations of prolactin during nocturnal wakefulness occurred only when subjects were in a state of "quiet rest" but not if they expected to be disturbed (Wehr *et al*., 1993).

The relationship between sleep stages and prolactin release has been investigated in a few studies. A close temporal relationship has been evidenced between slow-wave activity (estimated by spectral analysis) and sleep-associated prolactin secretion (Spiegel *et al*., 1995). Conversely, awakenings inhibit nocturnal prolactin release (Spiegel *et al*., 1995). Thus, fragmented sleep will generally be associated with lower nocturnal levels of prolactin.

As illustrated in Fig. 60.4, the night time prolactin rise is generally dampened in elderly subjects (van Coevorden *et al*., 1991). This could be due to increased sleep fragmentation. When considered in relation to the time of the sleep onset, the timings of the nocturnal rise and of the early morning decline are not modified (van Coevorden *et al*., 1991). Daytime levels remain essentially unchanged. No data are available concerning the time course of the occurrence of prolactin alterations with aging.

B. Growth Hormone

It was recognized more than 30 years ago that GH secretion is markedly stimulated during sleep (Quabbe *et al*., 1966; Takahashi *et al*., 1968; Honda *et al*., 1969; Sassin *et al*., 1969). In normal young adults, the 24 hr profile of circulating GH levels consists of stable low concentrations abruptly interrupted by secretory pulses. In normal young adult males, the largest and most reproducible pulse occurs shortly after sleep onset (Takahashi *et al*., 1968; Sassin *et al*., 1969; Van Cauter *et al*., 1992), while in normally cycling young women, this sleep-onset-associated pulse, while also present, does not generally account for the majority of the 24 hr secretion, since daytime pulses are far more frequent and of higher amplitude than in men. The increased daytime GH secretion in women appears to be correlated with circulating free estradiol levels (Ho *et al*., 1987). The close association between sleep onset and GH secretory bursts is still present in subjects submitted

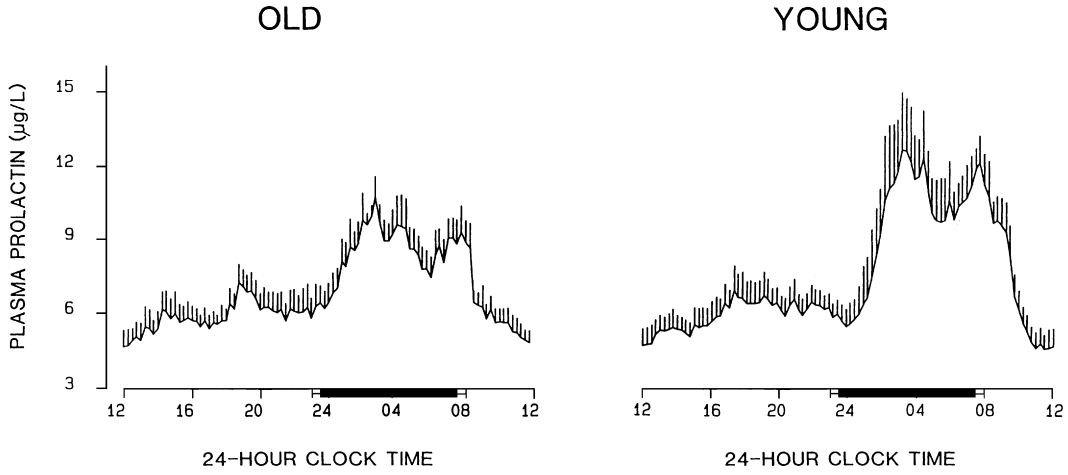

FIG. 60.4. Mean 24 hr (± SEM) profiles of plasma prolactin in normal men ages 67–84 years (left) and 20–27 years (right). Black bars denote the bedtime periods. Adapted from van Coevorden *et al*. (1991).

to various manipulations of the sleep–wake cycle, including recovery sleep following sleep deprivation, sleep interruptions followed by reinitiations of sleep, phase advances, and phase delays (Takahashi *et al*., 1968; Sassin *et al*., 1969; Beck *et al*., 1975; Golstein *et al*., 1983; Davidson *et al*., 1991; Van Cauter *et al*., 1991, 1992; Pietrowsky *et al*., 1994; Weibel *et al*., 1997). Thus, shifts of the sleep–wake cycle are immediately followed by parallel shifts of the GH rhythm. This is observed after transmeridian shifts (Golstein *et al*., 1983), in shift work conditions (Weibel *et al*., 1997), and in subjects living in free-running conditions, i.e., in temporal isolation without any environmental time cues (Weitzman *et al*., 1981; Moline *et al*., 1986). However, modest GH secretory pulses may persist during waking in the late evening and in the early part of the night following abrupt delays of the sleep period, indicating the existence of a modulation of the somatotropic axis by circadian rhythmicity (Aschoff, 1979; Van Cauter *et al*., 1992). It has been shown that during nocturnal sleep, the major GH pulse occurring following sleep onset is caused by a sleep-associated surge of hypothalamic GH-releasing hormone (GHRH) which coincides with a circadian period of relative somatostatin disinhibition (Jaffe *et al*., 1995; Ocampo-Lim *et al*., 1996).

The relationship between sleep stages and nocturnal GHRH surges—resulting in GH secretory bursts—can be investigated using a deconvolution procedure to estimate GH secretory rates. This procedure provides an accurate estimation of the amount of GH released during each secretory pulse and allows to delineate precisely the temporal limits of each pulse. A robust relationship has been evidenced between slow-wave sleep and nocturnal GH secretion (Holl *et al*., 1991; Van Cauter *et al*., 1992). Thus, maximal GH release occurs within minutes of the onset of slow-wave sleep; the longer the slow-wave episode, the more likely it is to be associated with a GH pulse; the amount of GH secreted during pulses occurring during slow-wave sleep is quantitatively correlated with the duration of the slow-wave episode. Similar correlations have been evidenced between GH secretion and concomitant values of spectral power density of the electroencephalogram in the delta range, i.e., 0.5–4.0 Hz (Gronfier *et al*., 1996). However, this relationship between slow-wave sleep and GH secretion, although strong and consistent, is not obligatory, since nocturnal GH secretion may also occur in the absence of slow-wave sleep, and approximately one-third of the slow-wave periods are not associated with detectable GH secretion (Van Cauter *et al*., 1992). These dissociations could reflect variations in the somatostatinergic tone which exerts an inhibitory action on GH secretion (Jaffe *et al*., 1995).

The mechanisms underlying the relationship between slow-wave sleep and GH release are still a matter of speculation. Based on rodent data, it has been suggested that the promotion of slow-wave sleep and the stimulation of GH release are two separate processes which involve GHRH neurons situated in two distinct areas of the hypothalamus (Obál *et al*., 1991; Krueger and Obál, 1993; Bredow *et al*., 1996). Daytime pituitary GH release would primarily involve GHRH neurons in the arcuate nucleus, while promotion of slow-wave sleep would implicate GHRH neurons of other hypothalamic area(s) (Meister and Hökfelt, 1992; Toppila *et al*., 1997). The association between slow-wave sleep and GH release would reflect synchronous activity of GHRH neurons in these distinct regions. However, the existence of a quantitative relationship between various measures of slow-wave activity and the amount of GH secreted (Van Cauter *et al*., 1992, 1997; Gronfier *et al*., 1996) suggests that the GHRH neurons which are implicated in the promotion of slow-wave sleep also participate in the control of nocturnal pituitary GH secretion.

Aging is associated with dramatic decreases in circulating levels of GH and insulin-like growth factor I (IGF-I) (Ho *et al*., 1987; van Coevorden *et al*., 1991; Landin-Wilhelmsen *et al*., 1994). This is illustrated in Fig. 60.5, which shows individual 24 hr GH profiles in young, middle aged, and old adult men. In normal men over 65 years, daily GH secretion is only about one-third of the amount secreted by young adults (Finkelstein *et al*., 1972; Ho *et al*., 1987; Vermeulen, 1987; Iranmanesh *et al*., 1991; van Coevorden *et al*., 1991; Frank

et al., 1995). This reduction is achieved by a decrease in amplitude, rather than in frequency, of GH pulses (Vermeulen, 1987; Veldhuis *et al*., 1995). Moreover, it has recently been suggested that the orderliness of GH secretion decreases with aging (Veldhuis *et al*., 1997). Interestingly, it has been shown that in men aging affects GH release —both during sleep and during wake—with a similar chronology to that observed for slow-wave sleep (Fig. 60.6, top), the age-related GH decrease is exponential, and despite the persistence of high levels of sex steroid hormones, circulating GH concentrations and pulsatile GH secretion rates fall in midlife to less than half the values achieved in young adulthood. This decrease is followed by further more progressive decrements from midlife to old age. In a cross-sectional study performed in 114 normal men (Van Cauter *et al*., 2000), the 24 hr GH secretion for ages 25–35 years and 60–70 years averaged around 50 and 30%, respectively, of the secretion for ages 16–25 years. These age effects are independent of modifications in the body mass index. Decreases in GH secretion rates and circulating levels are followed by a more gradual decline in plasma IGF-I levels (Clemmons and Van Wyk, 1984; Landin-Wilhelmsen *et al*., 1994). In the elderly, IGF-I levels are about 50% of the values in young adults, but there is a wide individual variation. About 20% of normal men beyond 60 years old have IGF-I values within the normal range of young (20–30 years old) men. Conversely, there is a considerable overlap between healthy elderly subjects and patients with GH deficiency due to pituitary disease.

The origin of this decrease in GH-IGF-I axis activity in aging is very probably multifactorial but the underlying mechanisms remain largely speculative. The major primary alteration appears to be an increase of hypothalamic secretion of somatostatin (Muller *et al*., 1995). The ability of the hypothalamus to synthesize and release GHRH and the intrinsic secretory capacity of somatotroph cells do not appear to be altered, but the secretion rate of GHRH is decreased, at least partly, because of the increased somatostatinergic tone (Martin *et al*., 1997). Thus, the reduction of GH secretion would result from increased somatostatin inhibitory activity and decreased GHRH responsiveness (Martin *et al*., 1997). In addition, the decrease in the orderliness of GH pulses suggests that the fine coordination of the GHRH–somatostatin interaction at the pituitary level may be impaired in the elderly and contribute to the blunting of GH secretion (Veldhuis *et al*., 1995). A possible increased negative feedback by GH and/or IGF-I in the elderly has been evoked to explain the increase in somatostatin, but a recent study suggests on the contrary that the negative feedback exerted by IGF-I on GH secretion is blunted in old age (Chapman *et al*., 1997). It has also been suggested that diminished cholinergic tone could be, at least partly, responsible for the somatostatin increase (Martin *et al*., 1997). The parallelism between GH and slow-wave sleep alterations in the elderly suggests the involvement of common mechanisms. Decreased physical activity as well as decreased sex steroid hormone concentrations in older men and women certainly contribute to the reduction in GH secretion (Veldhuis *et al*., 1997).

Normal elderly subjects display a number of features similar to those observed in young adults with GH deficiency due to pituitary disorders: increased body fat, reduced protein synthesis and protein turnover, reduced lean body mass, muscle strength and exercise capacity, decreased bone mass and bone mineral content, reduced renal blood flow and glomerular filtration, reduced cellular immunity (Cuneo *et al*., 1992; Corpas *et al*., 1993; Rosen *et al*., 1993). Since in young adults with GH deficiency, these features can be partly reversed by long-term treatment with GH (Marcus and Hoffman, 1998), it has been suggested that in older healthy subjects, they may result from relative GH-IGF-I deficit and represent a syndrome that has been named somatopause (Hoffman *et al*., 1993). However, the causal link between decreased GH-IGF-I activity and these somatic features in the elderly has not been proven.

Nevertheless, the effects of sustained recombinant human GH therapy in healthy older subjects have been investigated in a limited number of clinical trials, with mixed results (Rudman *et al*., 1991; Holloway *et al*., 1994; Papadakis *et al*., 1996). Though circulating IGF-I values were restored within the normal range for young adults and despite significant increases in lean body mass, no consistent improvement in functional capacities, as assessed by grip strength and endurance, could be demonstrated. Similarly, there was no consistent improvement in cognitive performances. Only slight beneficial effects on bone mineral density were evidenced. Moreover, there was a high prevalence of side effects, mainly edema, carpal tunnel syndrome, gynaecomastia, and hyperglycemia, possibly because the recombinant human GH dosages used were excessive.

Treatment with rhGH, which needs daily—or at least three weekly—subcutaneous injections, does not actually restore a

physiological GH-IGF-I profile, even if circulating IGF-I levels are carefully monitored and rhGH doses adjusted accordingly. Indeed, because of the very broad range of normal IGF-I values, the goal to be reached in each individual cannot be defined with precision. Morever, it is impossible to preserve the normal pulsatile pattern of GH secretion. In addition, GH injections inhibit GHRH secretion and are therefore likely to have detrimental effects on slow-wave sleep, since GHRH is involved in the generation of slow-wave sleep (Kerkhofs *et al*., 1993).

Preliminary investigations suggest that orally active pharmacological GH secretagogues might potentially be used during the somatopause to both stimulate GH secretion and enhance slow-wave sleep. Prolonged oral administration of an experimental GH secretagogue, MK-0677, was found to stimulate pulsatile GH release and to increase IGF-I levels in normal young and old subjects (Chapman *et al*., 1996; Copinschi *et al*., 1996). Moreover, it was also found to have beneficial effects on sleep, with significant increases in the duration of stage IV and of REM sleep (Copinschi *et al*., 1997). Interestingly, in normal young subjects, the rise in GH levels appeared to be less important than the enhancement of IGF-I values (Copinschi *et al*., 1996), possibly because elevated IGF-I levels exert a negative feedback effect on GH secretion. This relative dissociation between increases in GH and IGF-I levels might reduce the occurrence of negative side effects of the treatment, although MK-0677 had an adverse effect on glucose tolerance in older subjects (Chapman *et al*., 1996).

Two recent studies indicate that compounds known to stimulate slow-wave sleep could represent a novel class of GH secretagogues and be potentially useful for the treatment of somatopause. Reliable stimulation of both slow-wave sleep and GH secretion has been obtained in normal young subjects with oral administration of ritanserin, a selective serotonin 2 receptor antagonist (Gronfier *et al*., 1996), as well as with low doses of γ-hydroxybutyrate (Van Cauter *et al*., 1997), a simple four-carbon fatty acid which is used as an investigational drug for the treatment of narcolepsy.

Thus, experimental approaches which might mimic natural GH secretory patterns and improve sleep quality would appear more promising than recombinant human GH administration. The question still remains, however, as to whether the aim of restoring GH and IGF-I levels to the normal young range is legitimate. If that was the case, such interventions should target early midlife rather than subjects over 60 years of age, in whom peripheral tissues have been continuously exposed to very low GH and IGF-I levels for at least two decades. Indeed, initiating in subjects over 60 years old a treatment aiming at restoring GH secretion to the normal young range of may be compared to starting an estrogen replacement therapy in postmenopausal women when they are 70 years old.

IV. Thyrotropin: A Hormone Controlled by Both Sleep–Wake Homeostasis and Circadian Timing

The 24 hr pattern of circulating thyrotropin levels appears to be generated by frequency as well as amplitude modulation of secretory pulses (Veldhuis *et al*., 1990). Daytime levels are low and relatively stable. In normal young adults, the nocturnal rise starts in the early evening and the maximum occurs around the beginning of the sleep period. This presleep elevation is interrupted by sleep onset and levels progressively decline throughout the sleep period toward low daytime values (Brabant *et al*., 1990). Because the onset of the nocturnal rise occurs well before sleep onset, it is considered to reflect a circadian effect. Conversely, the decline in thyrotropin levels observed following sleep onset is thought to reflect an inhibitory influence of sleep on thyrotropin secretion (Parker *et al*., 1976). Indeed, during sleep deprivation, the nocturnal decline does not occur and thyrotropin levels continue to increase until the middle of the usual sleep period, as illustrated in Fig. 60.7, left). The sleep-related thyrotropin inhibition appears to be associated with slow-wave stages (Goichot *et al*., 1992). Conversely, awakenings are frequently associated with thyrotropin increments (Hirschfeld *et al*., 1996). Interestingly, thyrotropin levels are not suppressed significantly below normal daytime levels when sleep occurs during daytime hours (Hirschfeld *et al*., 1996). Thus, the inhibitory action of sleep on thyrotropin secretion appears to be operative only when the circadian elevation has occurred. While the onset of the thyrotropin nocturnal rise may be considered as a robust marker of the circadian clock, the diurnal thyrotropin profile appears to be a good illustration of the interaction between sleep and circadian rhythmicity.

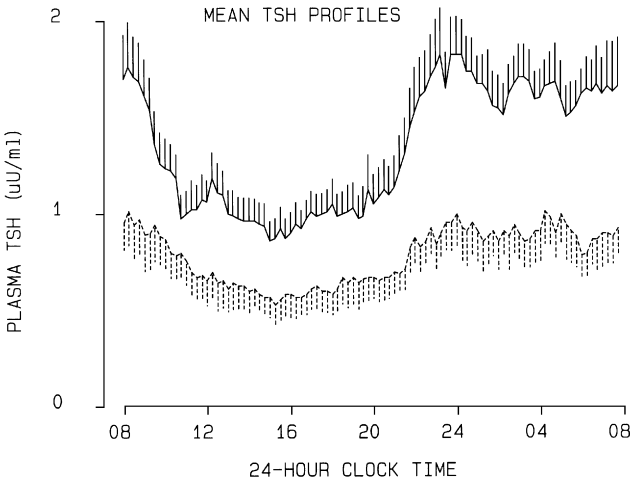

FIG. 60.7. Mean ($\pm$ SEM) thyrotropin profiles in normal young men ages 22–27 years and normal old men ages 59–72 years during a 52 hr period including 8 hr of nocturnal sleep, 28 hr of sleep deprivation, and 8 hr of daytime sleep. Black bars denote the bedtime periods.

Aging is associated with a progressive decrease in overall thyrotropin secretion (which is achieved by a decrease in amplitude, rather than in frequency, of secretory pulses) and in circulating thyrotropin levels, and with a dampening of the amplitude of the circadian variation (van Coevorden *et al*., 1991). This is illustrated in Fig. 60.7 (right) and 60.8. Figure 60.7 shows a comparison of thyrotropin profiles obtained during a 53 hr study period including 8 hr of nocturnal sleep, 28 hr of sleep deprivation, and 8 hr of daytime sleep in normal young men ages 22–27 years and normal old men ages 59–72 years, while Fig. 60.8 shows a comparison of 24 hr thyrotropin profiles in normal young men ages 20–27

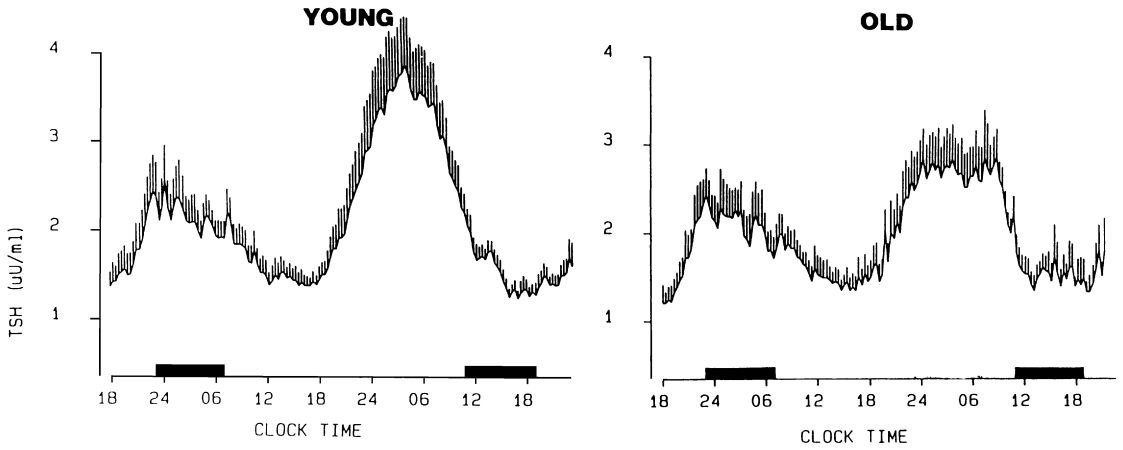

FIG. 60.8. Mean (± SEM) 24 hr thyrotropin profiles in normal young men ages 20–27 years (solid lines) and normal old men ages 67–84 years (dashed lines). From van Coevorden *et al.* (1991).

years and normal old men ages 67–83 years. In the older elderly (Fig. 60.8), thyrotropin levels are clearly lower than in young adults thoughout the 24 hr span, although the difference is more marked during sleep than during the daytime period. In the younger elderly (Fig. 60.7), age-related decreases in thyrotropin levels are apparent only during the period of nocturnal sleep deprivation. Thus, it appears that the thyrotropin secretory capacity declines progressively with aging.

The timing of the onset of the nocturnal rise was found to be advanced by approximately 1.5 hr in a group of normal old men ages 67–84 years, as compared to subjects under 20 years of age (van Coevorden *et al.*, 1991). This finding is consistent with a phase advance of the circadian clock in the elderly.

V. Hormones Primarily Controlled by the Circadian Clock

A. Melatonin

Not surprisingly, in view of the neuroanatomical connection between the hypothalamic suprachiasmatic nuclei and the pineal gland, the 24 hr profile of plasma melatonin is a robust marker of the human circadian clock (Rosenthal, 1991). During daytime, circulating levels are low and stable. In normal young adults, the circadian rise starts in the evening, between 21:00 and 23:00 hr, and the maximum occurs around the middle of the sleep period. Thereafter, melatonin levels progressively decrease to return to low daytime values in the morning, between 08:00 and 09:00 hr. Although a recent study indicated that high-intensity exercise may have acute stimulatory effects on melatonin secretion when applied during the night (Buxton *et al.*, 1997), melatonin rhythmicity is otherwise primarily dependent on the circadian pacemaker and does not appear to be directly affected by sleep and nonphotic stimuli (Geoffriau *et al.*, 1998). In contrast, exposure to light of sufficient intensity (>200–500 lux) exerts immediate direct inhibitory effects on the melatonin secretion, resulting in a dose-dependent suppression of nocturnal melatonin levels (Lewy *et al.*, 1980).

Daytime levels of melatonin are similar in young and old normal adults as illustrated in Fig. 60.9. The nocturnal elevation is markedly dampened in the elderly (van Coevorden *et al.*, 1991), although some old people may have melatonin peak values within the normal range for young adults. This is illustrated in Fig. 60.8. Moreover, as shown in Fig. 60.10, the circadian rise occurs almost 1.5 hr earlier in older than in young adults (van Coevorden *et al.*, 1991).

B. Cortisol

Diurnal profiles of plasma cortisol reflect the circadian pattern of adrenocorticotropic activity (which, in turn, results from periodic changes in level of pituitary stimulation by corticotropin-releasing hormone). The 24 hr rhythm of plasma cortisol is a good model for estimating the circadian temporal organization of the corticotropic axis because of its reproducibility and large amplitude. Mathematical procedures (Cleveland, 1979; Van Cauter, 1979) have been used to quantify the 24 hour profile of plasma cortisol and to determine times of occurrence and values of the maximum (acrophase) and the minimum (nadir) of the circadian rhythm as well as its amplitude. In young normal adults, plasma cortisol profiles show an early morning maximum around 07:00–08:00 hr, declining levels during the daytime, followed by a prolonged period of minimal levels (sometimes referred to as the quiescent period) centered around midnight and an abrupt elevation (referred to as the circadian rise) during the later part of the night (Fig. 60.11) (Van Cauter and Spiegel, 1999). This pattern is primarily controlled by the circadian pacemaker and is produced by modulation of the height of successive secretory pulses (Veldhuis *et al.*, 1989). However, modulatory effects are also exerted by sleep–wake homeostasis. Indeed, sleep onset is consistently associated with a short-term inhibition of cortisol secretion (Weitzman *et al.*, 1983; Born *et al.*, 1988; Van Cauter *et al.*, 1991; Bierwolf *et al.*, 1997). This inhibitory effect of sleep appears to be related to slow-wave stages (Follenius *et al.*, 1992). Conversely, during the second part of the night, awakenings—and particularly the final morning awakening—are consistently followed by bursts of cortisol secretion (Van Cauter *et al.*, 1990, 1991; Spath-Schwalbe *et al.*, 1991; Pruessner *et al.*, 1997). Nevertheless, adaptation of the 24 hr pattern of cortisol to abrupt shifts of the sleep–

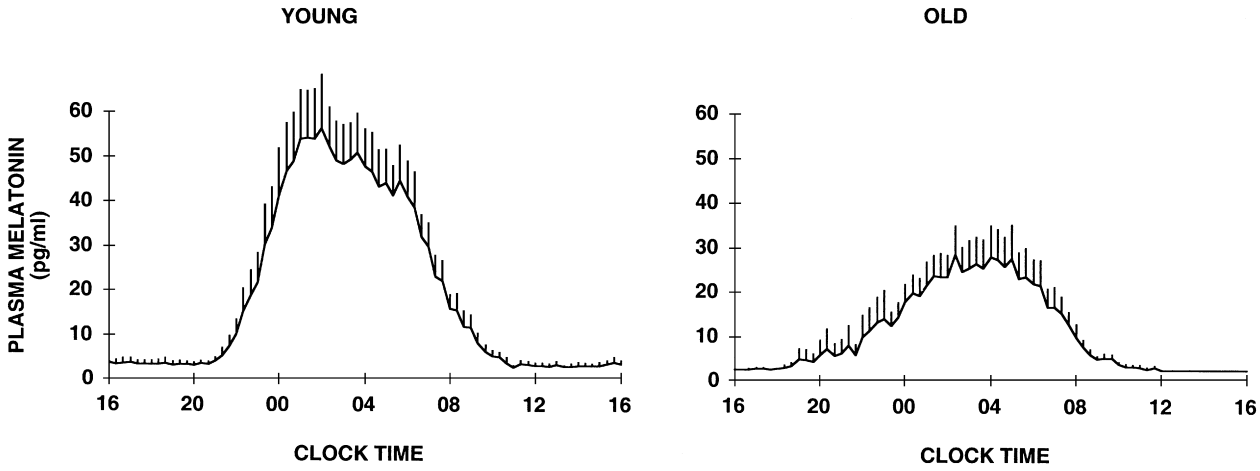

FIG. 60.9. Mean (± SEM) 24 hr profiles of plasma melatonin in normal men ages 20–27 years (left) and 67–84 years (right). Adapted from van Coevorden *et al.* (1991).

wake cycle needs several days to be complete and therefore the 24 hr profile of plasma cortisol, especially the timing of the onset of the early morning circadian rise, may be considered as a robust marker of circadian timing (Van Cauter and Turek, 1995). This morning rise represents a response to an endogenous stimulatory signal timed by the circadian clock. On the other hand, the subsequent decline of cortisol levels and the occurrence and the maintenance of the quiescent period all partially reflect the recovery of the corticotropic axis from this endogenous challenge.

Aging is associated with marked gender-specific effects on the levels and diurnal variation of plasma cortisol. This was examined in a retrospective analysis of 24 hr cortisol profiles recorded in 90 normal men and 87 normal women, with ages spanning seven decades, from 18 to 83 years (Van Cauter *et al.*, 1996). This study indicates that although diurnal rhythmicity is preserved in old age, alterations of the cortisol profiles, which essentially develop from 50 years of age onward, are present in the elderly, as illustrated for men in Fig. 60.11. A modest but significant increase in 24 hr cortisol levels from young adulthood to old age is observed for both sexes. Between 20 and 80 years of age, basal cortisol levels increase by 20–50%, more in women than in men, so that cortisol levels, which are slightly higher in young men than in young women, become

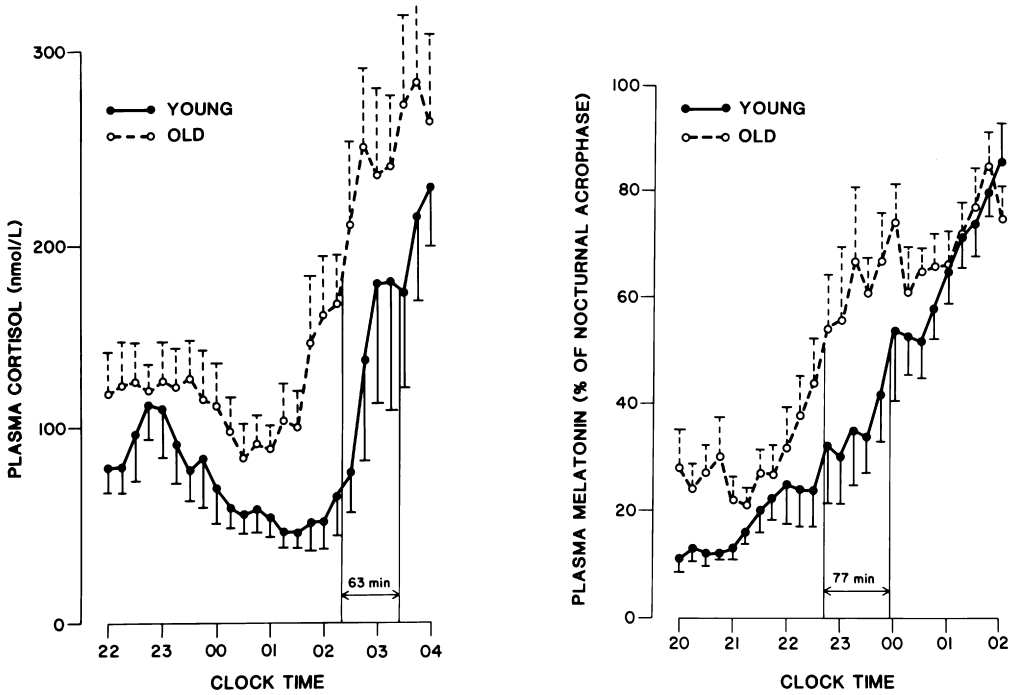

FIG. 60.10. Mean (± SEM) profiles of the circadian rises of cortisol (left) and melatonin (right) in normal men ages 20–27 years (solid lines) and 67–84 years (dashed lines). Adapted from van Coevorden *et al.* (1991).

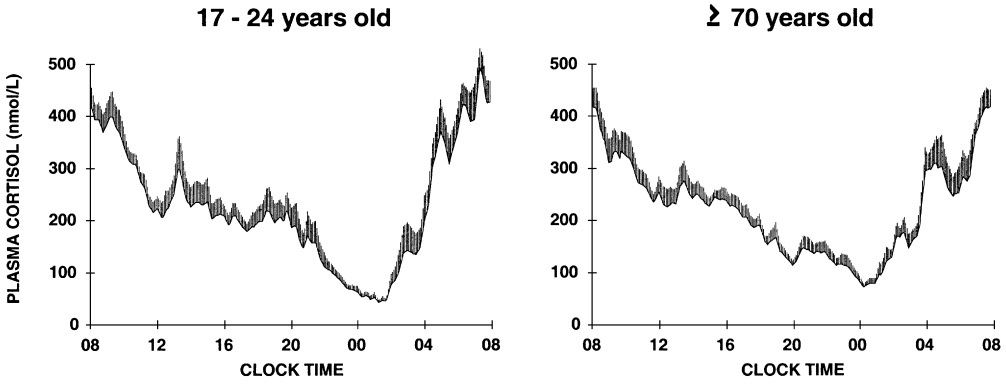

FIG. 60.11. Mean (± SEM) 24 hr profiles of plasma cortisol in normal men ages 17–24 years (left) and over 70 years (right).

similar in older men and women. With advancing age, both evening and morning cortisol levels increase in women, while only evening levels rise in men. Typically, the cortisol nadir in a subject over 70 years of age is three- to four-fold higher than in a young adult. As a result, a dampening of the amplitude of the circadian variation is observed with aging in both sexes. While there is no effect of age on the timing of the morning acrophase, the timing of the nadir and the timing of the onset of the circadian rise advance markedly with aging, similarly in men and in women. Between 20 and 80 years of age, the timing of the onset of the circadian rise—a marker of the circadian phase—advances 1.5 to 3 hr, as illustrated in Fig. 60.11. The quiescent period starts later and ends earlier in older subjects than in young adults. As a result, the duration of the quiescent period is markedly shortened and increasingly fragmented, as illustrated in Fig. 60.12. Between 25 and 65 years of age, the reduction in the duration of the quiescent period averages almost 3 hr in men and approximately 4.5 hr in women, so that the quiescent period, which is somewhat longer in young women than in young men, has a similar duration in older men and women.

These data confirm that in late adulthood, aging is associated with an advance of circadian phase and a dampening of the amplitude of the circadian variations which suggests that the strength of the signal originating from the hypothalamic pacemaker decreases with advancing age. The major and

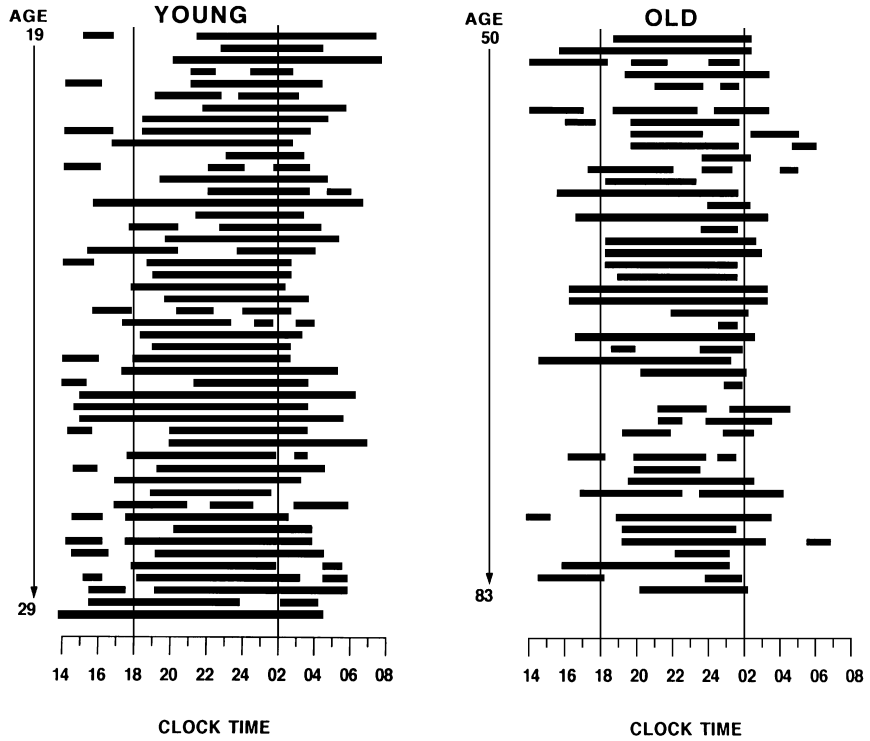

FIG. 60.12. Individual quiescent periods (represented by black bars) in young (ages 19–29 years; left) and old (ages 50–83 years; right) normal men. Vertical lines at 18:00 and 02:00 hr serve to facilitate the visual estimation of onsets and offsets of quiescent periods. Note the later onset, the earlier offset, and the increased fragmentation of quiescent periods in older subjects. Adapted from Van Cauter *et al*. (1996).

most consistent age-related alteration in cortisol levels is an elevation of the evening nadir. Both animal and human studies have indicated that deleterious effects of hyperactivity of the hypothalamo–pituitary–adrenal axis, especially at the hippocampal level, are more pronounced at the time of the nadir of the rhythm than at the time of the peak (Dallman *et al*., 1993; Plat *et al*., 1999). Thus, even modest elevations in evening cortisol levels could facilitate the development of central and peripheral disturbances associated with glucocorticoid excess, such as insulin resistance and memory deficits (McEwen and Stellar, 1993; McEwen, 1998a). The age-related increase in evening cortisol levels is likely to reflect a loss of resiliency of the hypothalamo–pituitary–adrenal axis (i.e. ability to recover from challenge), consistent with the concept of ''wear and tear'' of lifelong exposure to stress, and is likely to reflect neuronal loss in the hippocampus (McEwen, 1998b). Such hippocampal defects may underlie some of the memory deficits that occur in many older adults. In addition, the loss of resiliency could also contribute to the increased sleep fragmentation in the elderly, since elevated cortisol levels promote awakenings.

Interestingly, REM sleep is characterized by highly synchonized electroencephalographic activity in the 4- to 10-Hz ''theta frequency'' range in the hippocampus (Siegel, 1994). Whether hippocampal theta waves during REM sleep reflect a restorative action on neuronal mechanisms underlying the negative feedback regulation of glucocorticoid secretion is not known, but this hypothesis would be consistent with the fact that age-related alterations in REM sleep and in evening cortisol levels occur in a mirror image, as illustrated in Fig. 60.6 (bottom). Thus, decreased sleep quality could contribute to the allostatic load, i.e. to the wear and tear resulting from overactivity of stress-responsive systems (McEwen, 1998b).

VI. Conclusion

The transition from early adulthood to midlife is associated with profound alterations of sleep–wake homeostasis, resulting in particular in exponential decreases in slow-wave sleep and in GH secretion. Statistical analysis of the data shown in Fig. 60.6 indicates that the reduction in GH secretion was significantly associated with the reduction in amount of slow-wave sleep, independently of age. In contrast, alterations of the circadian pacemaker exert their effects more progressively, essentially during the transition from midlife to old age, resulting in particular in modifications of REM sleep and of the glucocorticoid profiles. Reduced amounts of REM sleep could be related to increased evening cortisol levels. Strategies for preventing or limiting such alterations should take into account this dissociated chronology. Pharmacological approaches to restore normal sleep could represent an indirect form of hormonal therapy with possible beneficial health effects.

Circadian Rhythms and Sleep in Aging Rodents

Circadian rhythms are found many aspects of animal physiology. The efficacy of input pathways to and output pathways from central nervous system circadian pacemakers change with advancing age, as does the functioning of the central pacemaker itself. While the timing of sleep is partly under the control of the circadian clock, other brain regions are involved in the timing of sleep and the homeostatic sleep mechanism. Many sleep parameters also undergo age-related changes. The scientific literature on the aging of the circadian timing and sleep systems is reviewed here, along with data from experiments that suggest some of the mechanisms underlying these changes and interventions that may attenuate their severity. © 2001 Academic Press.

I. General Introduction

One of the fundamental assumptions underlying the study of physiology is that organisms are driven to keep their internal milieu as constant as possible. Thus, under the classical model of the negative feedback loop, a perturbation to a physiological system will be detected and the organism's effector systems will be mobilized to return the system to a set point. While this model is generally valid, it is complicated by the presence of a circadian clock. That is, physiological systems do not in fact keep their internal milieu constant, but rather vary it daily in a rhythmic fashion.

Why should an organism complicate its physiology so? Circadian clocks are thought to have evolved for several purposes. First, they regulate an organism's behavioral state. By keeping activity confined to one portion of the day an animal can forage under optimal conditions and avoid predation. Animals whose circadian pacemakers have been disrupted are more susceptible to predation in the field (DeCoursey *et al*., 1997; DeCoursey and Krulas, 1998). Second, circadian clocks allow an animal the ability to go beyond simply responding to periodic changes in the environment and instead predict such changes and begin to alter physiology and behavior before the changes even occur.

Finally, circadian clocks provide a degree of internal synchronicity; that is, the master circadian pacemaker can keep the rhythms of various internal systems in the proper phase relationships with one another. The rest–activity state is by no means the only physiological parameter under the control of the circadian clock. In fact, variables such as heart rate, blood pressure, acid production, and body temperature are all under circadian clock control (Zee and Turek, 1999). By keeping many oscillating systems coordinated, the circadian clock promotes a healthy internal environment. In fact, maintaining organisms as diverse as tomatoes (Hillman, 1956), blowflies (Saint Paul and Aschoff, 1978), *Drosophila* (Pittendrigh and Minis, 1972), rats (Kort and Weijma, 1982; Kort *et al*., 1986; Nelson and Halberg, 1986), hamsters (Penev *et al*., 1998b), and humans (Kawachi *et al*., 1995) in altered light:dark cycles can result in health disturbance or even decreased longevity. Clearly the circadian clock is crucial in maintaining an appropriate internal physiological environment.

Sleep, too, is under the control of the circadian clock, as well as the influence of a homeostatic mechanism and at least one ultradian pacemaker (Zee and Turek, 1999). Recent evidence, which will be discussed further herein, suggests that the homeostatic components of the sleep mechanism are also influenced by the circadian clock. Thus any problem in the circadian system could have consequences for a wide number of physiological systems, including sleep and the restorative role it is thought to play.

Aging itself is one source of such disruption. There are profound changes in both sleep and circadian rhythms in advanced age. These changes are seen both in humans (Carrier *et al*., 1996) and in a large number of laboratory animals (van Gool and Mirmiran, 1983; Welsh *et al*., 1986; Van Reeth *et al*., 1992; Whealin *et al*., 1993; Turek *et al*., 1995a; Valentinuzzi *et al*., 1997; Naylor *et al*., 1998a). Using animal models of rhythms, sleep, and aging, we can begin to understand the mechanisms of how these systems age. In mammals, the master circadian clock is housed in the suprachiasmatic nuclei of the anterior hypothalamus (Klein *et al*., 1991). No single sleep center has been found, but certain areas including the pons, and the cholinergic basal forebrain are implicated in the control of

sleep. By understanding how sleep and circadian rhythms change in advancing age, and by finding the anatomical and biochemical alterations underlying such changes, we can also learn the importance of the components of these physiological systems to their normal functions.

II. Effects of Aging on Circadian Rhythmicity

A. Introduction

In 1974, Pittendrigh and Daan first described systematic age-related changes in the circadian timing system of rodents. They observed that old animals' circadian clocks run at a different speed than when those same animals were young. When animals are placed in an environment devoid of time cues (e.g., constant darkness), the daily changes once associated with the light:dark cycle, for example the increase in wheel-running in the early evening by nocturnal rodents, persist. This suggests that the animals have an internal time-keeping mechanism. Those rhythms that persist in the absence of time cues with a period of approximately 24 hr are referred to as circadian rhythms; the period with which they persist is referred to as τ. Pittendrigh and Daan (1974) showed that golden hamsters and two species of mice have shorter τ, or faster-running clocks, when they are old. While any oscillating system is composed of inputs to the oscillator, which synchronize it with external cues, the central pacemaker, and outputs, τ is a fundamental property of the central oscillator. Thus the consistent shortening of circadian period in old hamsters and deer mice suggested that the central oscillator's function changes with age (Pittendrigh and Daan, 1974). This was the first piece of evidence that the circadian system changes with age and the picture has become considerably more complex as more data have been collected. These changes include, but are not limited to, a change in the timing of the active phase under a light:dark cycle, changes in the phase-resetting properties of both photic and nonphotic stimuli, an increase in rhythm fragmentation, and a decrease in the amplitude of overt rhythms (Morin, 1988; Rosenberg *et al*., 1991; Zee *et al*., 1992; Van Reeth *et al*., 1993; Mrosovsky and Biello, 1994; Penev *et al*., 1995, 1998a; Benloucif *et al*., 1997a; Valentinuzzi *et al*., 1997). While some of these changes can be partly explained by changes in the inputs and outputs of the circadian timing system, it also appears that the central pacemaker itself changes with advanced age. The recent discovery of a molecular mechanism of the circadian clock in mammals (Dunlap, 1999) and similar mechanisms in *Drosophila* (Young, 1998) and *Neurospora* (Bell-Pedersen *et al*., 1996; Dunlap, 1996) as well as information gleaned from the complex relationships between inputs, outputs, and the central pacemaker offer hints as to how clocks might be breaking in old age and what we can do to fix them.

Since Pittendrigh and Daan (1974) first described the change in τ with advancing age a large body of data has been collected on age-related changes in circadian behavior in laboratory animals, primarily in rats, mice, and hamsters. First we will examine the evidence from experimental animals that circadian rhythms change with age. We will explore the possibility that changes in either the inputs to or the outputs from the clock can explain the phenomena observed. We will examine why these explanations are inadequate and the evidence for a change in the central pacemaking mechanism. Finally, we present evidence that it may be possible to intervene to delay the onset or reduce the severity of these changes.

B. Changes in Inputs to the Circadian Clock

1. Photic Inputs

The rotation of the earth on its axis provides a dynamic yet predictable environment. This environmental light:dark cycle is the major entraining cue, or *zeitgeber*, to the circadian timing system. Shifts in the light:dark cycle lead to gradual reentrainment, as can occur when people move rapidly across time zones. It is thought that the mechanism by which entrainment occurs is through daily adjustments of the circadian clock, whose endogenous period is rarely exactly 24 hr. By delaying this internal clock slightly each evening or advancing it slightly each morning, the environmental light:dark cycle keeps the animal's physiology and behavior synchronized to Earth's 24 hr rotation.

Information about the light:dark cycle has access to the circadian system by two routes. Retinal ganglion cells project directly to the suprachiasmatic nuclei via the retino-hypothalamic tract and indirectly through the thalamic intergeniculate leaflet (Morin *et al*., 1992). Light changes the phase of the circadian clock by a cascade of events within suprachiasmatic nucleus cells, including the activation of the *mPer1* gene (Akiyama *et al*., 1999) and immediate–early genes (Kornhauser *et al*., 1990), the phosphorylation of the cyclic AMP response element binding protein (Zhang *et al*., 1996), and ultimately *de novo* protein synthesis (Inouye *et al*., 1988; Khalsa *et al*., 1992). Old animals are less sensitive to changes in the light:dark cycle, as measured by either biochemical or behavioral means. Old rats fail to show a shift in the rhythm of pineal *N*-acetyl transferase, an enzyme in the melatonin synthesis pathway under strict suprachiasmatic nucleus control, 4 days after an advance of the light:dark cycle, whereas young adult rats show a clear phase shift (Buresová *et al*., 1990). Old hamsters (Rosenberg *et al*., 1991; Zhang *et al*., 1996), rats (Sutin *et al*., 1993), and mice (Benloucif *et al*., 1997a) all show smaller phase shifts to light pulses than young animals, indicating that either the visual transduction system or the suprachiasmatic nucleus's ability to respond to such a signal has been modulated by age. It is important to note that this phenomenon is true only at relatively dim light intensities, i.e., those that produce a submaximal shift in the phase of the circadian rhythm of locomotor activity in young animals (Rosenberg *et al*., 1991; Zhang *et al*., 1996). Old hamsters also have reduced photic induction of c-*fos*, a gene that is necessary for photic phase shifting in young rodents, and CREB phosphorylation (Zhang *et al*., 1996). Old mice show a reduced induction of both *c-fos* and *Jun*-B mRNA after phase-shifting light pulses (Benloucif *et al*., 1997a). Together, these studies show that the deficit in shifting the phase of the circadian rhythm of locomotor activity is not simply a failure of outputs from the circadian system, but rather a failure of the circadian system to respond to the light pulse. While the aging process can compromise visual function through disease processes such as cataracts, these phenomena do not fully account for

the loss of sensitivity to photic *zeitgebers* that accompanies aging (Zhang *et al*., 1996, 1998). Compared to young hamsters, old hamsters' lenses transmit only about 75% of 500-nm light (the wavelength involved in photic phase-shifting of the circadian clock). However, this fails to fully explain the fact that the phase shifts induced by light at this wavelength in old animals are only 5% as large as in young animals (Zhang *et al*., 1998). Additionally, tract-tracing studies indicate that there is no effect of age on either the size of or degree of retinal innervation of the suprachiasmatic nucleus (Zhang *et al*., 1998). Therefore, there appears to be a change in either the efficacy of the retina to transmit photic information or a change in the suprachiasmatic nucleus's response to this information.

2. Nonphotic Inputs

While light is the major *zeitgeber*, it is not the only stimulus that can entrain the circadian clock. For example, social interaction, food availability, and even maternal signals to a fetus can entrain the circadian clock. Stimuli that induce a large amount of activity (including, but not limited to, the benzodiazapine triazolam, pulses of darkness on a background of constant light, and access to a novel running wheel) induce robust phase advances in hamsters when administered during the subjective day (Van Reeth and Turek, 1989; Mrosovsky, 1996). Activity, or its neural correlate, is necessary for these phase shifts (Van Reeth and Turek, 1989). Like photic stimuli, nonphotic *zeitgebers* also lose their efficacy to induce phase shifts in old rodents. Even though these stimuli induce a similar amount of activity in old hamsters, the subsequent phase shifts are attenuated (Van Reeth *et al*., 1992, 1993; Mrosovsky and Biello, 1994). Activity-inducing stimuli, such as triazolam, are thought to induce phase advances by stimulating the intergeniculate leaflet to release neuropeptide Y (NPY) from terminals in the suprachiasmatic nucleus (Huhman and Albers, 1994; Wickland and Turek, 1994). A change in the efficacy of the intergeniculate leaflet in either integrating nonphotic information or transmitting such information to the suprachiasmatic nucleus, or in the suprachiasmatic nucleus' efficacy in interpreting these signals could result in a decreased response to all these stimuli. These data do not permit us to distinguish the effect of aging on the input pathways from the effect of aging on the central pacemaker (the suprachiasmatic nucleus); both may be compromised in old age.

The serotonergic system may also mediate nonphotic phase shifts. When injected peripherally during the subjective day, the serotonin receptor agonist 8-OH-DPAT induces large phase shifts in young hamsters and smaller phase shifts in old hamsters (Penev *et al*., 1995). 8-OH-DPAT most likely exerts its effects by activating both the dorsal and medial raphe nuclei, which send projections to the intergeniculate leaflet and the suprachiasmatic nucleus, respectively (MeyerBernstein *et al*., 1997). Old hamsters show smaller phase advances in response to injections of 8-OH-DPAT and a decreased ability of light to attenuate 8-OH-DPAT-induced phase shifts (Penev *et al*., 1995, 1997). The effects of age on the circadian system, including changes in τ and decreased sensitivity to triazolam injections and subsaturating light pulses, are mimicked by monoamine depletion in young hamsters, suggesting that a loss of serotonergic input to the suprachiasmatic nucleus and/or the intergeniculate leaflet is responsible for some of the age-related changes in circadian rhythmicity (Penev *et al*., 1993, 1994).

Clearly physiological inputs cannot convey information to the circadian clock in old animals as they can in young animals. While the inputs to the circadian clock are by definition separate from the central oscillating mechanism, they do comprise an important part of the overall physiological system. Proper function of the input mechanisms is necessary for the organism to synchronize its internal timekeeping mechanism with the appropriate environmental cues. Thus the age-related changes observed in input efficacy may partly underlie the age-related changes in circadian physiology. However, the changes in circadian timing system with age are likely to also occur at the level of the central pacemaker as well.

C. Changes in the Central Pacemaker

Many of the changes observed in circadian rhythms with advancing age can be attributed to changes in the function of the central pacemaker. Current evidence points to a change in the amplitude of the circadian oscillator as an important component of the aging circadian phenotype. Here we review the literature supporting the hypothesis that the circadian pacemaker itself is altered in advanced age and fails to operate as robustly as in young adults.

Perhaps the most consistent age-related change in circadian rhythmicity is the one first noticed by Pittendrigh and Daan (1974), the change in τ. While their paper reported a consistent decrease in τ, data gathered over the past 25 years show that there can be both increases and decreases in τ, and the direction of the change seems to be species-dependent. Some laboratories have failed to find a change in τ across the life span in golden hamsters (Davis and Viswanathan, 1998), but many other studies have shown an age-related shortening of the free-running period of the locomotor activity and body temperature rhythms in rats (Witting *et al*., 1994), hamsters (Rosenberg *et al*., 1991; Morin, 1993, 1988; Penev *et al*., 1995, 1997), and field mice (*Mus booduga*) (Sharma and Chandrashekaran, 1998). In contrast, C57BL/6J, DBA/2J, and SWR mice (*Mus musculus*) show increases in τ with advanced age, as determined from the circadian rhythm of locomotor activity (Mayeda *et al*., 1997; Valentinuzzi *et al*., 1997). Whereas the direction of the change is species-specific, a change in τ in constant darkness is one of the most consistent effects of age on the circadian clock. Frequency is a fundamental property of any oscillating system, and a change in frequency most likely indicates that the oscillator itself is changing. That such changes are seen in advancing age by several laboratories working with several species suggests that these changes are a fundamental part of circadian aging. Figure 61.1 presents actograms from young and old hamsters and mice. Note that the free-running period sometimes, but not always, changes with advancing age.

Behavioral data on the phase-shifting effects of light suggest that aging changes the amplitude of the pacemaker. While Zhang *et al*. (1996) found that subsaturating light pulses induce smaller phase shifts in older animals, Rosenberg *et al*. (1991) reported that old animals in fact show larger phase shifts to saturating (i.e., when an increase in either intensity or duration of light fails to further increase the magnitude of

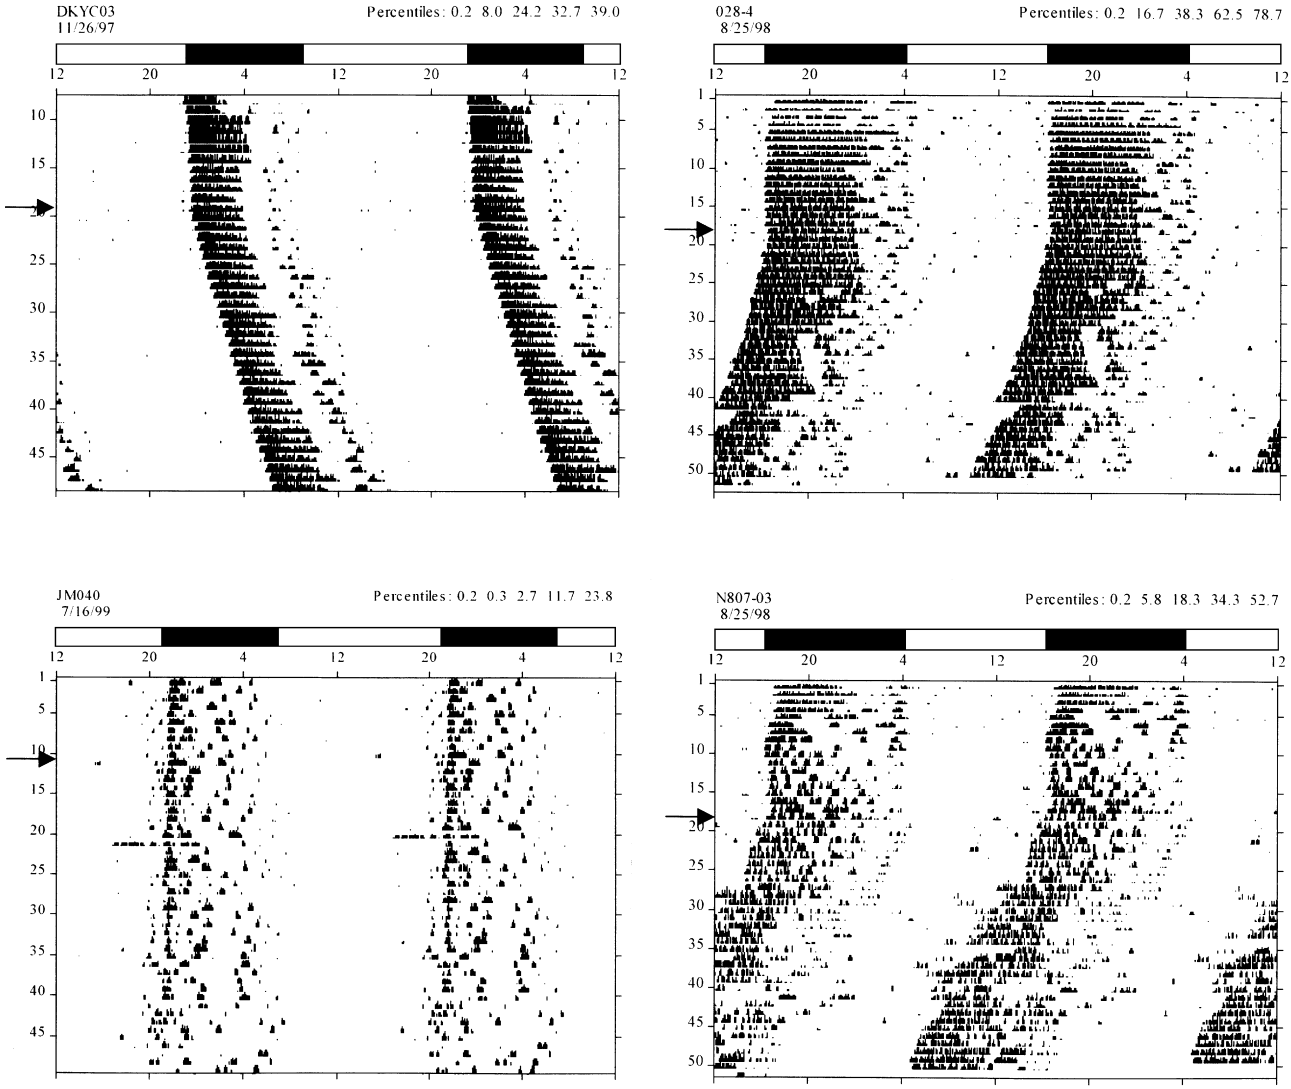

FIG. 61.1. Actograms of representative young (top) and old (bottom) golden hamsters (left) and mice (right). Tick marks indicate periods of wheel-running activity. Forty-eight hours are plotted across the horizontal axis to ease visualization. Successive days are plotted beneath one another. The dark bars above each activity record indicate times of darkness when the animals were maintained in a light:dark cycle. The arrows indicate the time of transfer to constant darkness. Note the increase in fragmentation of the activity pattern in both species and the shortening of the free-running period in hamsters.

the phase shifts in young animals) light pulses, a seemingly contradictory result. However, this is true only when the light pulses are administered around circadian time 16[1]; at this time old animals show phase shifts three times as large as those seen in young animals (Rosenberg *et al*., 1991). These large phase shifts have two possible explanations. Either light has a greater salience in old animals and is therefore able to exert a larger effect (i.e., an age-related change in potency) or the oscillator's amplitude is decreased such that the same stimulus that perturbs the system slightly in young animals drastically perturbs it in old animals (Rosenberg *et al*., 1991). However, the former is not likely since subsaturating light pulses have an attenuated effect on phase shifting, gene induction, and protein phosphorylation in the suprachiasmatic nucleus of old hamsters, and this is not due to decreased lens transmittance alone (Zhang *et al*., 1996, 1998). Clearly light does not have an increased salience in old hamsters; thus the large phase shifts seen with saturating light pulses are more likely due to reduced oscillator amplitude.

The rhythms generated by the central circadian pacemaker are often observed to damp out in old age. For the circadian rhythm of locomotor activity, the most commonly measured overt rhythm in rodents, this damping in the rhythm is seen as a reduced difference between the amount of activity during the subjective day and the subjective night. It is also visible as an increase in fragmentation of the pattern of activity. Penev *et al*. (1998b) report quantitative results showing that old hamsters have significantly more bouts of activity per day than

[1]Circadian time 12 is defined in a nocturnal animal as the time of the onset of the activity rhythm in the absence of time cues, such as when the animal is placed in constant darkness or constant light.

young hamsters. This confirms visual inspection of old hamsters' actograms, which clearly show more bouts of activity in the night and the day. Similar qualitative and quantitative results have also been reported in C57BL/6J mice (Valentinuzzi *et al*., 1997). While the increase in the number of bouts of activity during the night might be explained by factors independent of the circadian timing system, including decreased muscle tone and respiratory problems, an age-related increase in the number of bouts of activity during the day indicates an inappropriately timed signal to become active and/or difficulty in maintaining sleep or rest states.

Results from experiments looking at suprachiasmatic nucleus function more directly support the hypothesis that the amplitude of the circadian pacemaker is decreased in old age. While each suprachiasmatic nucleus is composed of approximately 8000 neurons (van den Pol, 1991), it appears that each neuron within the nucleus is capable of generating circadian rhythms independently; the synaptic connections between the individual neurons probably serve to coordinate the pacemakers into a unified entity (Welsh *et al*., 1995; Liu *et al*., 1997). In young rodents there is a robust circadian rhythm of the suprachiasmatic nucleus' firing rate *in vitro*, with a peak in firing rate during the subjective day. Compared to those of young hamsters, the suprachiasmatic nuclei of old hamsters have a significantly lower firing rate during the subjective day and a decreased difference between the firing rate during the day and the night (Watanabe *et al*., 1995). In old rats, the amplitude of the firing rhythm is damped, without a change in mean firing rate (Satinoff *et al*., 1993). The authors of this study suggest that this is not due to a disappearance of cells capable of firing at fast rates, but rather can be attributed to either a change in the individual oscillators' ability to generate circadian rhythms or a decrease in the coupling strength between these oscillators (Satinoff *et al*., 1993). Interestingly, there is not a decrease in the number of neurons within the suprachiasmatic nucleus (Roozendaal *et al*., 1987; Woods *et al*., 1993; Madeira *et al*., 1995), so the age-related changes in circadian rhythms cannot be explained by cell death. Rather they appear to be due to changes in either the individual oscillators that comprise the circadian clock or the connections between them. In addition, old rats have a change in the rhythm of glucose use in the suprachiasmatic nucleus without a change in overall glucose use (Wise *et al*., 1988), again suggesting a change in the function of the oscillators or the coupling between them. These are all examples of decreases in the amplitude of the circadian pacemaker's oscillation. They are best explained by a decrease in the coupling between individual oscillators or by a decreased function of many of these oscillators while their synaptic couplings remain intact.

Gene expression plays an important role in the generation of circadian rhythms. Many neurons in the suprachiasmatic nucleus are thought to be capable of generating and maintaining circadian rhythms individually through an autoregulatory feedback loop. This loop contains both positive elements that start transcription and negative elements that inhibit it (see Dunlap, 1999, for a review of the molecular machinery comprising the circadian clock). In the suprachiasmatic nucleus, many genes, both within and outside of this loop, are transcribed on a circadian basis and can serve as indicators of the clock's function. In aging, the rhythmic expression of some of these genes in the suprachiasmatic nucleus is altered. Two independent research groups have shown that old rats have a reduced rhythm of vasoactive intestinal peptide in the suprachiasmatic nucleus; in fact this rhythm is absent by the time the animals are middle-aged (Kawakami *et al*., 1997; Krajnak *et al*., 1998). While there is no change in the rhythm of argenine-vasopressin expression on old rats, there is a decrease in the number of argenine-vassopressin-producing cells in the suprachiasmatic nucleus (Roozendaal *et al*., 1987; Krajnak *et al*., 1998). As argenine-vasopressin may serve as a diffusible output of the circadian clock (Silver *et al*., 1996), this finding suggests that the signal from the suprachiasmatic nucleus to the rest of the body may be attenuated in old age. However, the decrease in the number of cells producing an output signal without a change in its rhythmicity would not explain all the changes observed in overt circadian rhythmicity, both behavioral and biochemical (e.g., electrophysiological firing rhythms in the suprachiasmatic nucleus *in vitro*). Production of the immediate–early gene product Fos, which is produced in response to photic stimuli that phase shift the circadian clock (Kornhauser *et al*., 1990; Wollnik *et al*., 1995), is attenuated in middle-aged and old rats (Cai *et al*., 1997a) and old hamsters (Zhang *et al*., 1996). The amount of Jun-B protein induced by photic stimuli is attenuated in old rats (Cai and Wise, 1996). Several of the genes that are responsible for either generation or phase-shifting of circadian rhythms cease to function properly in old rodents.

Transplant studies also suggest that *in vivo* the aging of circadian rhythms are due in part to changes within the suprachiasmatic nucleus itself. Transplanting fetal suprachiasmatic nucleus tissue into old host hamsters restores the sensitivity to the phase-shifting effects of triazolam; this effect is not obtained with control (cerebellar) fetal tissue, indicating that it is an suprachiasmatic nucleus specific effect (Van Reeth *et al*., 1994). Suprachiasmatic nucleus transplants have also been reported to increase the amount of wheel-running activity and the length of survival of the hosts compared to those animals that received control transplants (Hurd and Ralph, 1998). In rats, transplanting fetal suprachiasmatic nucleus tissue restores the diurnal pattern of Fos expression in the host suprachiasmatic nucleus (Cai *et al*., 1997a,b) as well as the ability of light to induce Jun-B protein production (Cai and Wise, 1996). Other studies have shown that fetal suprachiasmatic nucleus transplants into old animals can restore the diurnal rhythms of corticotropin-releasing hormone and proopiomelanocortin gene expression in nuclei driven by the suprachiasmatic nucleus clock (Cai *et al*., 1997b). Together these data suggest that the age-related changes in overt circadian rhythms and the underlying changes in gene expression are in part due to changes within the suprachiasmatic nucleus tissue itself; changes that alter the ability of the suprachiasmatic nucleus to generate rhythms and to respond to external stimuli.

D. Changes in Function of Effector Systems

In addition to the changes in the efficacy of the inputs to the circadian clock and the changes in the central pacemaker, aging also alters the function of at least some of the outputs of the clock. Locomotor activity is one of the most commonly observed circadian outputs of laboratory animals. Old hamsters

(Penev *et al*., 1995, 1997; Davis and Viswanathan, 1998), and mice (Wax, 1975; Valentinuzzi *et al*., 1997) both run fewer revolutions in their running wheels than young animals. A weakening of the muscles could easily explain this difference. Similarly, aging reduces pineal (Reiter *et al*., 1980) and serum (Pang and Tang, 1983) melatonin content in hamsters and sometimes reduces mean body temperature in rats (Satinoff, 1998). The point is that many effector systems *do* break down in old age; the decrease in mean levels of either pineal melatonin or body temperature need not be explained by changes in the circadian system, rather the outputs of the circadian system could have begun to fail in their own right. Care should be taken not to confuse breakdowns of the central pacemaker with breakdowns of the organ that produces the observed rhythm. In order to infer the health of the pacemaker it is important to not only observe the mean level of any driven rhythm, but also parameters specific to its timing: the period, phase, and amplitude of the rhythm, as well as its degree of fragmentation.

Some of the systems downstream of the circadian system have feedback effects on the clock and therefore the age-related changes in these systems have the potential to further alter circadian clock function. For example, the fact that old hamsters run less than their young counterparts (Penev *et al*., 1995, 1997; Davis and Viswanathan, 1998) could reduce the efficacy of activity feedback as a synchronizing agent.[2] Similarly, the age-related decrease in pineal (Reiter *et al*., 1980) and serum (Pang and Tang, 1983) melatonin levels might alter animals' sensitivity to either melatonin or other *zeitgebers*. While one study found no effect of age on the phase-shifting effects of melatonin (Benloucif *et al*., 1997b), other species have not been studied in this manner. Since melatonin can act as both an input to and an output of the circadian clock, its age-related decline may be important in modulating responses to other phase-shifting agents. Whereas the outputs of the clock are often thought to merely reflect the position of the hands (i.e., the phase of the clock contained within the suprachiasmatic nuclei), they do in fact have effects on the clock itself. Thus the effects of age on the circadian system can be magnified by changes in feedback of the outputs back onto the clock.

E. Can Age-Related Changes in Circadian Rhythms Be Attenuated or Reversed?

Since the clock is less responsive to inputs, one way to enhance its oscillations might be to provide it with stronger inputs. As light is the major *zeitgeber*, an obvious remedy would be to increase the intensity of the light:dark cycle. Two such experiments have shown promising results. First, Witting *et al*. (1993) increased the light intensity from 3.5 to 445 lux during the light phase of the light:dark cycle. They found that the brighter intensities were able to reverse some of the age-related changes in rats' sleep–wake cycle (Witting *et al*., 1993). For example, the bright light intensities increased the day:night differences in the amount of quiet sleep; viewed in circadian terms the bright light increased the amplitude of the diurnal rhythm (Witting *et al*., 1993). Interestingly all of the improvement in rhythm amplitude was due to changes in behavioral states during the light phase (Witting *et al*., 1993). This suggests that the bright light can suppress inappropriate timing of activity in this nocturnal species.

In a second study, Labyak *et al*. (1998) found that after increasing the light intensity from 300 to 1500 lux, middle-aged hamsters, which already show many of the signs of aging discussed above, showed fewer daily bouts of activity during the light phase and an increase in the daily number of wheel revolutions. However, the same increases in light intensity failed to significantly affect old hamsters' rhythms, suggesting that interventions to the aging of the circadian system must be made during middle age. There are two possible explanations for the failure of light to reverse the effects of aging in the oldest hamsters. First, Labyak *et al*. (1998) used 300 lux as their lowest light intensity; this is almost as bright as the Witting *et al*. (1993) brightest intensity. The lack of significant improvement in diurnal rhythmicity by old hamsters exposed to bright light in the Labyak *et al*. study could be due to a ceiling effect. Second, the two experiments examined different outputs of the circadian timing system. The coupling strength of the circadian clock could be more strongly coupled to the sleep–wake system than to the networks underlying locomotor activity.

While there are not yet convincing data on an age-related change in melatonin sensitivity (see previous section), the age-related decline in melatonin levels are well-documented (Reiter *et al*., 1980). Experiments with melatonin and its analogs, indicating that melatonin can act as a *zeitgeber* (Kumar *et al*., 1997), raise the possibility that increasing the melatonin signal might reverse some of the effects of aging on the circadian system. It has been suggested that melatonin may be useful in treating a number of human circadian disorders, including age-related insomnia (Arendt and Deacon, 1997). The melatonin agonist S20242 significantly increased a measure of rhythm stability, the χ^2 value of the periodogram, when administered to middle-aged and old rats (Koster-van Hoffen *et al*., 1993). This treatment also increased the amplitude of the circadian rhythm of body temperature in middle-aged, but not old rats (Koster-van Hoffen *et al*., 1993). Daily feeding of a different melatonin agonist (S20098) to old hamsters restored their sensitivity to a dark pulse; when the treated food was removed, dark pulses once again failed to phase-shift the old hamsters (Van Reeth *et al*., 1997). Together, these two studies suggest that exogenous melatonin can restore some of the youthful properties to the circadian systems of old animals.

If the age-related changes in circadian rhythmicity are due to changes in the function or expression patterns of circadian clock genes, then genetic interventions might be able to modulate the onset or severity of these changes. Senescence-accelerated mice are a series of inbred strains selected for short longevity and rapid onset of biomarkers of aging. Senescence-resistant mice serve as genetic controls. A brief study investigating the role of the senescence-accelerated mouse genotype on the aging of the circadian timing system examined only two strains, one senescence-accelerated mouse and one senescence-resistant mouse. The authors found that there was no difference in the overall pattern of circadian activity, free-running period, or time to reentrain following a 6 hr delay

[2]Recall that the decreased efficacy of non-photic phase-shifting agents in old animals is independent of the amount of activity induced (Van Reeth *et al*., 1992, 1993).

of the light:dark cycle (Sanchez-Barcelo *et al*., 1997). There was no difference in either the overall morphology or number of vasopressin-producing neurons in the suprachiasmatic nucleus (Sanchez-Barcelo *et al*., 1997). However, this failure to find changes related to senescence-accelerated mouse genotype is not conclusive, as only one strain from each of the selected lines was tested. In theory, the exact genetic makeup of each of the selected senescence-accelerated mouse lines could differ. More thorough experimentation involving multiple senescence-accelerated mouse and senescence-resistant mouse lines are necessary to determine the role of genetic background on the acceleration of circadian aging. Additionally, classical genetic techniques such as quantitative trait loci analysis could help to elucidate genetic components to the aging of the circadian timing system.

In summary, with advanced age there are changes in several components of the circadian timing system and each may play a role in the age-related decline in efficacy of the system as a whole. While a decreased strength of input signals to the circadian system may explain some of the age-related decline in sensitivity to both photic and pharmacological stimuli, concurrent changes in the function of the central pacemaking mechanism itself may account for some changes in sensitivity. Changes in the suprachiasmatic nucleus itself may occur at the level of the intracellular loop of transcription and translation that has been recently elucidated, although the experiments that would test this hypothesis have yet to be performed. In addition, some of the decline in overt circadian rhythmicity may be due to deteriorating function of the body's aging effector systems.

III. Effects of Aging on Sleep

A. Introduction

Age-related changes in the sleep patterns of animals have not been as well-studied as the effects of age on circadian rhythmicity. Only a few studies on each of several species have been carried out, almost always with differing methodologies, experimental protocols, and analysis techniques. Indeed, the experiments are often sufficiently different from one another that the results, which can seem contradictory, cannot always be meaningfully compared. Combined with the rapidly changing technology for the collection and analysis of electroencephalographic (EEG) waveforms, the results reported in one paper cannot necessarily be compared to those reported earlier. Both the mechanisms underlying the sleep process and its functional significance are not nearly so well understood as those underlying circadian rhythmicity. Nevertheless, there are some trends which emerge from the literature on age-related changes in rodent sleep that may help us understand analogous changes in humans.

Since the physiological sleep mechanism is poorly understood, our discussion of the age-related changes in sleep are placed within the framework of a theoretical model. Borbély's two-process model provides a theoretical backdrop upon which to understand both the buildup and diminution of sleep need (Borbély, 1982, 1998). He posits two processes, one circadian (termed process C) and the other homeostatic (termed process S). As an animal stays awake, process S accumulates in a logarithmic fashion with a slow time constant. When an animal sleeps, process S decreases exponentially with a much faster time constant until it reaches a certain point, determined by the interaction of the endogenous setpoint the sinusoidal nature of process C. The drive, or pressure, to sleep is determined by the difference between the level of process S and that of process C. Thus the duration of sleep is determined by both the amount of time previously spent awake and the phase of the circadian cycle at which sleep occurs; the model predicts that a sleep-deprived subject will sleep less if he begins to sleep in the afternoon than if he begins to sleep in the evening after an equal amount of sleep deprivation (Borbély, 1982). Changes in the duration of sleep can be caused by changes in the set point (i.e., the level to which process S must decrease before the animal awakes), the phase of process C, which varies in a circadian fashion, changes in the rate of accumulation of S, or changes in the kinetics with which S decreases. This model makes certain predictions that have been borne out by experiments in both humans and animals [see Borbély (1998) for a review of agreement between predictions of the model and empirical data].

Because the duration of sleep is dependent on the interaction between these two processes, the amount of sleep that an animal exhibits does not necessarily tell us anything about process S. As will be described in the following sections, many species of animals show age-related changes in the duration of sleep, and some experiments have shown age-related changes in the fragmentation of sleep. However, it is important to keep in mind that these changes can be explained fully by the well-documented changes in circadian rhythmicity described above. To be able to conclude that age has an effect on process S, the homeostatic sleep mechanism, one must measure it in action (i.e., by studying the intensity of sleep as opposed to the duration). In most species, this is best reflected by the power of electroencephalograph waves in the delta range (Borbély, 1982; Dijk *et al*., 1990; Franken *et al*., 1991) (generally defined as 0.5–4 Hz, but varying slightly by laboratory and species studied). Waveforms of this nature generally occur during deep, non-rapid-eye-movement (non-REM) sleep. Rapid eye movement (REM) or paradoxical sleep is characterized by EEG waves that are similar to those seen during the waking state [see Rechtschaffen and Kales (1968) for a complete description of sleep stages and the corresponding waveforms].

In aging humans, there are clear changes in both circadian rhythmicity (process C) and sleep (process S) (Copinschi and Van Cauter, 1995; Turek *et al*., 1995b; Bundlie, 1998). There are decreases in both slow-wave and REM sleep, with the changes in slow-wave sleep occurring earlier than those in REM sleep (Van Cauter *et al*., 1998). As the changes in sleep in aging humans are described elsewhere in this volume, they will not be detailed here. While the data from experimental animals are often contradictory, there do appear to be some general changes in both the amount and the qualitative nature of sleep in old animals.

B. Changes in Sleep Due to Changes in the Circadian Clock

Since the timing of sleep is under the control of the circadian clock, anything that affects the stability of the pacemak-

ing mechanism may affect sleep. As reviewed earlier in this chapter, old age causes a general loss of function of the circadian clock, which results in increased fragmentation and decreased rhythm amplitude, among other changes. Since sleep is an output of the clock, one would expect to see changes in sleep fragmentation and the amplitude of the sleep–wake cycle in advancing age. This phenomenon has been observed in several species, suggesting that the mechanisms that underlie the age-related fragmentation in other circadian rhythms may also underlie some of the age-related changes in sleep in animals.

1. Rats

While measuring EEGs in young and old animals, some studies detected a change in circadian, but not sleep-related parameters (Rosenberg *et al*., 1979; Li and Satinoff, 1995). For example, Li and Satinoff (1995) measured sleep parameters and the diurnal body temperature rhythm in young and old female Long–Evans rats. They found that some old rats maintained their stable daily temperature rhythms and others had unstable temperature rhythms. In contrast, all young animals had robust temperature rhythms. Those old rats that had unstable body temperature rhythms had significantly less REM sleep during the light phase and significantly more REM sleep during the dark phase (Li and Satinoff, 1995). However, there was not a difference between young and old rats with robust body-temperature rhythms in any of the sleep parameters measured (Li and Satinoff, 1995). This suggests that the effects on REM sleep that they observed were not due to direct effects of age on REM sleep centers in the brain, but could be due to either a breakdown of the circadian timing system[3] or the secondary disruptions of the thermoregulatory system. These results are entirely consistent with a breakdown in the circadian pacemaker driving the timing of sleep.

Van Gool and Mirmiran (1983) found that compared to young adult Wistar rats, 22 month old rats had increased amounts of wake and decreased amounts of REM sleep during the light phase (van Gool and Mirmiran, 1983). The old rats showed a decreased light:dark ratio of wakefulness and of active (REM) sleep (van Gool and Mirmiran, 1983). However this is not necessarily reflective of a change in process S, as it can be explained by the decreased amplitude of the circadian pacemaker detailed above. In fact, the Wistar rats showed no age-related change in the maximum EEG frequency in the delta or theta (5–9 Hz) ranges, nor was there a change in the theta:delta ratio (van Gool and Mirmiran, 1983). These data suggest that sleep is another overt rhythm whose amplitude changes in old age. The age-related changes in circadian sleep parameters (i.e. fragmentation of sleep and decreased day: night differences in the duration of sleep) of male Wistar rats and the absence of such an effect in female Long–Evans rats suggests that there may be an interaction between sex and aging of the circadian control of sleep in rats (van Gool and Mirmiran, 1983; Li and Satinoff, 1995).

Additionally, an early study by Rosenberg *et al*. (1979) measured activity in the delta (2–4 Hz) range in young and old Fischer 344 rats but failed to detect a difference. However, this study did find a decreased amplitude of the diurnal sleep–wake rhythm, which is consistent with a breakdown of the circadian timing system (Rosenberg *et al*., 1979). Old rats slept significantly more than young rats, and did show more REM sleep as a percentage of total sleep time (Rosenberg *et al*., 1979). This suggests that process S is changing in old age, but absent a significant change in EEG, it is not clear whether the differences in sleep architecture are due to changes in process S, process C, or both. However, the increased amount of total sleep time seen in this strain of old rats is similar to the increase recently reported in old hamsters (see below) (Naylor *et al*., 1998a).

2. Mice

A study by Welsh and colleagues (1986) looking at the aging of sleep phenotypes in the mouse found changes similar to those in rats (Rosenberg *et al*., 1979; van Gool and Mirmiran, 1983) and hamsters (Naylor *et al*., 1998a). Compared to young mice, old C57BL/10 and C57BL/6 mice showed an increased fragmentation of sleep and wake over several circadian cycles (Welsh *et al*., 1986). As described above, these differences could be reflective of changes in either process C, process S, or both. The authors did not report data on EEG spectra and thus no information on the effect of age on delta power was obtained.

One particular advantage of mice as laboratory animals is their use in understanding the genetics of physiology and behavior. To this end, Eleftheriou *et al*. (1975) studied the effects of age on sleep in two inbred strains of mice. They found that both C57BL/6J and DBA/2J mice showed significant age-related increases in time spent awake and decreases in time spent in both non-REM and REM sleep (Elefthériou *et al*., 1975). This is in contrast with the age-related increases seen in sleep in hamsters (Naylor *et al*., 1998a) and several strains of rats (Rosenberg *et al*., 1979; van Gool and Mirmiran, 1983; Tani and Ishihara, 1988). Significant age-by-strain interactions were found on the amount of time spent in REM and non-REM sleep as well as REM sleep time as a percentage of total sleep time (Eleftheriou *et al*., 1975), indicating that at least some sleep parameters and age-related changes in sleep patterns are genetically determined. Hopefully, the wealth of genetic information available on mice will enable future research to identify genes involved in the aging of sleep phenotypes.

C. Changes in the Homeostatic Sleep Mechanism

In addition to changes in the circadian clock control of sleep, process S, the homeostatic drive for sleep, also changes in old age. This is best measured by EEG power, and age-related changes in EEG, particularly in the delta range associated with deep, slow-wave sleep, have been observed in a number of species.

1. Rats

While Rosenberg *et al*. (1979) found only changes in the diurnal rhythm of sleep of Fischer 344 rats and not in the amount of activity in the delta frequency range (2–4 Hz), a later study in the same strain found significant age-related dif-

[3]The age-related changes in the circadian timing system of female rats have been described in detail by Wise and her colleagues. See Wise *et al*., (1997) for a review.

ferences in EEG power (Tani and Ishihara, 1988). Tani and Ishihara (1988) measured EEG of both frontal cortex and the dorsal hippocampus. They found that awake older rats showed decreased power of alpha (8.0–12.8 Hz) waves in both brain regions, and also showed higher delta (2.0–3.6 Hz) activity in the hippocampus. This indicates that even while the animals are behaviorally awake, they have intrusions of delta waves, which suggests that they are chronically sleep-deprived. The age-related differences in EEG were more pronounced during sleep. In the first few hours of EEG recording, which the researchers termed the ''drowsy period,'' all old animals showed bursts of activity at 8–9 Hz and 15–16 Hz in the frontal cortex; none of the young animals showed this pattern (Tani and Ishihara, 1988). During sleep, old rats showed significantly more hippocampal theta (4.0–7.6 Hz) and less alpha-2 (10.0–12.8 Hz) activity than young animals. The sleeping old rats also showed significantly less power in the delta range than did young rats (Tani and Ishihara, 1988). This suggests that the old rats are not sleeping as efficiently as the young ones, perhaps reflecting a deficit in process S, and could account for the increase in delta power during wake. Unfortunately, Tani and Ishihara (1988) did not report total sleep time or percentage of time spent in REM and non-REM sleep. Thus, their data preclude any conclusions about the importance of the observed shifts in EEG power spectra to changes in total sleep time and sleep fragmentation previously reported in this strain (Rosenberg *et al*., 1979).

Old Sprague–Dawley rats have significantly less REM sleep and a blunted day:night difference in the amount of time spent sleeping (Stone *et al*., 1989). Compared to young Sprague–Dawleys, old rats have significantly less REM sleep, shorter bouts of REM sleep, and spend less of their time during the light period sleeping (Stone *et al*., 1989). The increase in the number of bouts of REM sleep suggests that process C has caused an increase in fragmentation. However, the change in the amount of REM sleep without a change in total sleep time (Stone *et al*., 1989) suggests that process S has changed, as this is independent of the timing of sleep or the amplitude of the ?tlsb> sleep rhythm. Like hamsters, this strain of rat shows evidence of changes in both components of Borbély's model of sleep.

Fisher rats show no change in total sleep time with age, but the amount time spent in deep non-REM sleep, as defined by amplitude of EEG waveforms greater than the mode of all non-REM waves, was decreased in middle-aged and old rats, when compared to young animals (Mendelson and Bergmann, 1999). However, these animals showed an increase in the lighter stages of non-REM sleep, so total non-REM sleep time was not affected by age (Mendelson and Bergmann, 1999). While there was no effect of age on the day:night differences in sleep and wake time, there was an age-related shortening of the length of each sleep bout; again this difference was apparent by middle age. However, the total number of sleep and waking bouts was not altered by age. Together these data suggest as this strain ages, the homeostatic sleep process (process S) is affected but process C is spared. However, these researchers used a relatively crude measure of circadian amplitude (data were averaged into 12 hr bins); studies specifically designed to examine circadian rhythms, as opposed to sleep, in aging rats have found effects of age (see data presented in the first section of this chapter).

2. Hamsters

Recent data from our laboratory show that as Syrian hamsters age they show an increased amount of non-REM sleep (Naylor *et al*., 1998a). The difference in daily non-REM sleep duration between young and old animals is entirely due to a difference in the amount of non-REM sleep during the dark phase, which is the active phase in this nocturnal species (Naylor *et al*., 1998a). While this could be attributed to a decreased circadian amplitude, EEG power in the delta (0.5–4 Hz) range, during non-REM sleep epochs, was decreased in old hamsters (Naylor *et al*., 1998a). This change is unlikely due to a change in process C and is more likely due to a change in process S. Since delta sleep is thought to be the restorative sleep (i.e., the component of sleep which decreases the level of process S in Borbély's model), by having delta sleep of decreased efficacy, the old animals may not able to break down process S as effectively during the light (inactive) phase and thus must sleep more during the dark (active) phase. This hypothesis is suggested by the observations made in two independent studies of old Fischer 344 rats mentioned above. While neither study reported both EEG power and percentage of time spent in sleep and wake, the data suggest that old rats show both decreased delta power during sleep (Tani and Ishihara, 1988) and increased time spent sleeping (Rosenberg *et al*., 1979). Additionally, old rats showed increased delta power while awake (Tani and Ishihara, 1988), suggesting that they may be trying to sleep more during the light phase to compensate for a decreased efficiency of process S. Thus the decreased delta power and concomitant increased sleep time seen in old hamsters (Naylor *et al*., 1998a) may apply to rodents in general.

D. Potential Mechanisms of the Age-Related Changes in Sleep and Implications for Treatment

1. Humoral and Metabolic

Although the suprachiasmatic nucleus has been identified as the master circadian pacemaker in mammals, no single brain structure has yet been found to have an analogous role for sleep. Thus it is difficult to study the physiological mechanisms behind either sleep or its age-related changes. Nevertheless, some intriguing results have been reported which suggest either potential mechanisms for these age-related changes or ways to prevent these changes from occurring.

The relationships between peripheral glucose regulation, sleep, and cognitive function point to the importance of the former in advancing age. Stone *et al*. (1990) found that old Sprague–Dawley rats with poor tolerance of a 500 mg/kg intraperitoneal bolus injection of glucose had significantly shorter bouts of REM sleep. There was no significant correlation in young animals (Stone *et al*., 1990), suggesting that as rats age, some animals lose their ability to regulate glucose, and those with compromised glucose regulation are subject to more fragmented REM sleep. Low doses of glucose (100 mg/kg) into old rats attenuated the age-related shortening of REM sleep bouts (Stone *et al*., 1992). This effect is age-specific, that is, glucose injections of this magnitude have no effect on REM bout duration in young rats (Stone *et al*., 1992).[4] This

[4]Significantly higher doses (2.5 g/kg) of glucose can alter REM duration in young rats (Sangiah and Caldwell, 1988).

has practical implications for both rat and human health, as other experiments have shown that sleep fragmentation is also associated with impairments on cognitive tasks in both species (Markowska *et al*., 1989) (see Stone *et al*., 1990, for a brief review of the relationship between glucose regulation and cognitive function, especially in diabetics). Since memory scores in middle-aged rats can predict their glucose tolerance, cognitive ability, and REM bout length when they are old (Stone *et al*., 1997), there are opportunities to intervene in youth or middle age to prevent some of the age-related changes. The finding that glucose can diminish the age-related shortening of REM sleep bouts suggests that the age-related changes are not due to permanent structural brain changes, but rather are due to shortages in energy or activity of neurons and could be secondary to problems with peripheral glucose regulation (Stone *et al*., 1992). Although decreased glucose tolerance (often associated with insulin resistance) and decreased amount of REM sleep have been observed in older adult people, the precise relationship between these manifestations and memory and cognitive deficits has not yet been investigated (Frank *et al*., 1995).

Sleep parameters are also correlated with brain neurochemical levels. Cortical serotonin is negatively correlated with total sleep time and non-REM sleep time in old rats; REM sleep time is positively correlated with serotonin in the caudate nucleus (Markowska *et al*., 1989). However, this study only examined aging rats and thus no conclusions can be drawn as to whether these neurotransmitters are involved in the regulation of sleep in young adult animals or in the aging of the sleep systems. Nevertheless, as the serotonergic system may also underlie the aging of the circadian timing system (Penev *et al*., 1993, 1994, 1995; Turek *et al*., 1995b), it is possible that therapies which restore the function of the serotonergic system might influence both the homeostatic sleep process (process S) and the circadian timing system (process C).

Other age-related changes in sleep and cognitive function can be mimicked by lesions of the nucleus basalis magnocellularis in animals (Stone *et al*., 1989). Old Sprague–Dawley rats have significantly less REM sleep and a decreased day:night difference in the amount of time spent sleeping (Stone *et al*., 1989). They also perform significantly worse on a passive-avoidance memory task and have decreased choline acetyltransferase activity in both the frontal cortex and the striatum (Stone *et al*., 1989). Nucleus basalis magnocellularis lesions of young rats also change sleep in similar ways. For instance, these lesions cause a decrease in the number and length of REM sleep bouts, which is also apparent in old intact rats (Stone *et al*., 1989). Similarly, young nucleus basalis magnocellularis-lesioned and old intact rats both show a decrease in the percentage of time spent sleeping during the light phase (Stone *et al*., 1989). They also show similar changes in passive-avoidance learning and cortical choline acetyltransferase activity, compared to young intact rats (Stone *et al*., 1989). These data suggest that some of the age-related changes in REM sleep and memory[5] are caused by the decreases in cholinergic function, perhaps at the level of the nucleus basalis magnocellularis or the frontal cortex.

There is good evidence for age-related declines in the function of cholinergic neurotransmission in general and in the basal forebrain in particular (Gallagher and Rapp, 1997). As adenosine levels in the basal forebrain have recently been implicated in the regulation of slow-wave sleep in cats (Porkka-Heiskanen *et al*., 1997), it is an obvious candidate for investigations into the mechanisms underlying age-related changes in slow-wave sleep. Future studies of old animals in species showing age-related changes in process S (e.g., hamsters, Fischer 344 rats) should examine adenosine levels in brain regions associated with sleep, especially the basal forebrain, as well as the efficacy of these cholinergic pathways in transmitting neural impulses to their targets.

There is also tentative evidence that the GABAergic system is involved in age-related changes in both REM and non-REM sleep regulation. Systemic administration of the $GABA_B$ antagonist CGP 35348 to old Wistar rats during the early portion of the night increased both REM and non-REM sleep duration and decreased the latency to REM onset (Puigcerver *et al*., 1996). However, due to limitations in the experimental design (no young control animals were studied), it is not possible to conclude if this effect is specific to aging animals (as is the effect of glucose on REM duration; see Stone *et al*., 1992) or is a general enhancer of REM (as is the effect of auditory stimulation, see below). Additionally, this study did not take into account the potential phase-shifting effects of this GABAergic compound; other GABAergic drugs [e.g., benzodiazepines (Turek and Losee-Olson, 1986)] can alter the phase of the circadian clock. GABA is a major neurotransmitter within the suprachiasmatic nucleus itself (Moore and Speh, 1993). Thus apparent changes in sleep may be the result of change in the phase of the circadian clock. Finally, no age-related changes in REM have been reported in Wistar rats, the strain used in this study. In fact, the authors cite data from other strains to support their claim that old rats show changes in REM sleep, when there seems to be an effect of genetic background on aging of sleep systems (Eleftheriou *et al*., 1975). Yet, the finding that a $GABA_B$ antagonist might increase REM suggests that this particular subclass of receptors is involved in sleep regulation and points to another possible mechanism underlying age-related changes in sleep.

2. Environmental Manipulations

Some data suggest that nonpharmacological environmental manipulations can influence age-related changes in sleep. For example, auditory stimulation (2 kHz, 75–80 dB, delivered for 100 msec every 20 sec) was delivered to both young and old rats. In young rats, stimuli were programmed to coincide with REM sleep bouts. In old rats, which show significantly shorter bouts of REM sleep, stimuli were presented for 10 min every 25 min (Arankowsky-Sandoval *et al*., 1992). On the day of stimulation both young and old rats showed increased time spent in REM sleep (Arankowsky-Sandoval *et al*., 1992); this effect is similar to that seen in both cats and humans (cf. Arankowsky-Sandoval *et al*., 1992). While the authors of this study suggest that auditory stimulation may increase REM sleep via the pons, they do not present data to show its involvement in this

[5]The relationship between REM sleep and long-term memory is beyond the scope of this review. Generally, preventing REM sleep inhibits consolidation and both sleep and memory disturbances are common in old age.

study (Arankowsky-Sandoval *et al*., 1992). Future studies are needed to determine if this relatively benign intervention can be used as a tool to explore the mechanisms of both age-related changes in REM bout duration, their functional significance, and ways to reverse them.

Interestingly, housing in an enriched environment also seems to offer the ability to counter some of the age-related changes in sleep. Van Gool and Mirmiran (1986) found that housing animals in an enriched environment for approximately 1 month following the baseline sleep-recording session led to an increase in both slow-wave (non-REM) and REM sleep during the light period in both young and old animals (van Gool and Mirmiran, 1986). This finding is particularly exciting because it suggests that the age-related changes in sleep quality are not necessarily permanent. Since the authors did not report delta power during non-REM sleep, it may be that the effect of the enriched environment is on circadian amplitude and not sleep *per se*. However, by increasing the circadian amplitude of the old rats, this intervention may be able to effect an output rhythm, i.e., the day:night difference in sleep duration.

3. Genetics

The severity of age-related changes in sleep parameters is at least partly under genetic control. As described above, males from two inbred strains (C57BL/6J and DBA/2J) of mice show a differential effect of aging on sleep parameters (Eleftheriou *et al*., 1975). In general, sleep in the DBA/2J mice ages faster, as measured by the age-related decrease in both REM and non-REM sleep. In fact, by the time they are 2 years old, DBA/2J mice show no REM sleep at all (Eleftheriou *et al*., 1975). Since the mice in a given strain are genetically identical, and all mice were maintained in the same environment, differences in the rate of aging are due to genetic differences between strains. Interestingly there is no difference between the two strains when they are young, suggesting that these strains have allelic differences in the way gene products underlying sleep change with age.

Little progress has been made in discovering genes that contribute to the aging of the sleep phenotype. However, two preliminary reports suggest the involvement of specific genes in the age-related changes of sleep. One report suggests that *Clock* plays an important role in regulating the set point of process S. *Clock* mutant mice were discovered in a screen for animals with altered circadian rhythms. Animals that are heterozygous for this mutation have long a circadian period (approximately 25 hr) and those that are homozygous for the mutation have a 28 hr period before losing circadian rhythmicity (Vitaterna *et al*., 1994). Compared to wild-type C57BL/6J mice, *Clock* mutants have decreased total sleep time without a change in power in the delta range (Naylor *et al*., 1998b). Most of the difference between the genotypes over a 24 hr period is due to decreased sleep time during the light phase. This suggests that the *Clock* mutation, which clearly alters process C (see Vitaterna *et al*., 1994; King *et al*., 1997; Antoch *et al*., 1997, and Jin *et al*., 1999, for a complete description of the effects and molecular basis of *Clock*), also has effects on process S. Further research will elucidate whether the difference in the homeostatic sleep mechanism is due to effects of the mutation on the circadian timing system or if there are other brain areas that are also affected by the mutation. It is not yet known if the CLOCK protein is expressed in brain regions that are thought to control sleep. A second report indicates that old rats have significantly less non-REM sleep during recovery from sleep deprivation, and that they also had less c-Fos and AP-1 production compared to young rats (Shiromani *et al*., 1998). Of course, *c-fos* and *Clock* are probably not the only genes involved in the age-related changes in sleep regulation. As new mutants and knockouts become available, they will serve as tools with which one can dissect the interactions between process C, process S, and aging.

Acknowledgments

The authors thank Drs. Etienne Challet and Eve Van Cauter for their helpful comments on the manuscript. This work was supported by National Institutes of Health Grants AG18200, AG11412, HD09885, and HL59598 to F.W.T. and a Glenn scholarship from the American Federation for Aging Research to D.E.K.

Glucocorticoids and the Aging Brain: Cause or Consequence?

In this review we discuss if changes in corticosteroid levels are the cause or consequence of the aging process and age-related brain pathology. Accumulating evidence suggests that corticosteroid levels are not consistently elevated in aging. However, if corticosteroid levels circulate in aberrant concentrations, they do increase the vulnerability to cognitive decline and disease, rather than aging *per se*. Corticosteroid hormone action is mediated through mineralocorticoid (MR) and glucocorticoid receptors (GR) that are colocalized in hippocampal neurons. The high-affinity MR operates in a proactive mode, limiting homeostatic disturbance and promoting neuronal stability. The low-affinity GR on the other hand, facilitates, in a reactive manner, the recovery of homeostasis following perturbation by stress. Together, steroid hormone-mediated MR and GR actions involve the expression of specific target genes that control brain processes like neuronal excitability, calcium homeostasis, energy metabolism, and cell division in discrete hippocampal regions. Given this capacity, MR and GR are critical for the set point regulation of many homeostatic processes during aging. Depending on additional environmental and genetic factors, an imbalance in their actions can therefore result in altered stress regulation, cognitive decline, and impaired behavioral adaptation, through dysregulation of the same genes that are otherwise essential for maintaining neuronal homeostasis and health. Corticosteroid receptors and their responsive genes are thus not only critical for successful aging, they form at the same time excellent drug targets, through which homeostasis can be reestablished and the restorative capacity still present within the diseased aging brain, promoted.

I. Introduction

Many changes associated with aging are experienced as deleterious, leading to slow, but progressive deterioration of peripheral organs, physical, and mental functions. In particular the senescent central nervous system (CNS) displays many neurophysiological, neurochemical, and neuroanatomical changes that are not only different from each other in nature, but also affect different parts of the brain to a different extent (Price *et al*., 1991; Mouton *et al*., 1994; Morrison and Hof, 1997; Braak *et al*., 1998).

Since many of our brain and bodily functions are governed by hormones, impaired endocrine control has been implicated in the etiology of several age-related dysfunctions and disease. A well-known definition of aging in this respect is a decreased ability to maintain homeostasis (Dilman *et al*., 1979; Everitt and Meites, 1989). Frolkis *et al*. (1972a,b), Landfield (1978), Finch (1979), and Sapolsky (1996, 1999) have studied this concept in more detail and implicated one class of steroid hormones, the glucocorticoid hormones, as major contributors to age-related pathology.

Glucocorticoids (GCs) are essential in mediating survival from stressors that threaten an organism's homeostasis. As such, they are involved in almost all aspects of peripheral physiology, such as energy metabolism, growth, immune function, but also in such diverse CNS processes as cognition, learning, memory, and behavioral adaptation. Small disruptions in their homeostatic control yield an altered neuroendocrine set point that, through aberrant hormone levels, induces slowly evolving functional changes, that can eventually accumulate in pathology and cognitive decline in senescence. Critical for neuroendocrine control of the GC set point are corticosteroid receptors localized in brain and anterior pituitary, through which the well-known classical action of these steroid hormones on gene transcription is mediated.

In this review we will focus on just that class of hormones and review changes in and consequences of GC action observed during mammalian brain aging. We further discuss to what extent structural and behavioral changes with aging are induced by GC alterations and at what point the central action of GCs shifts from a predominantly protective one to an endangering and damaging condition. This discussion is embedded in a

literature review of the role of GCs and the hypothalamic-pituitary-adrenal (HPA) axis in the adaptation to stress, which may be impaired with age.

II. Normal Physiology

A. The Hypothalamic-Pituitary-Adrenal (HPA) Axis and Hippocampus

Aging has been defined as a decreased ability to maintain homeostasis and a consequent failure to adapt to environmental changes and challenges. The view has evolved that the impact of age-related degeneration, in particular in higher organisms, is far more dramatic when the integrative and homeostatic communication and control systems are affected too (Everitt and Meites, 1989). Key elements in the communication of these adaptive changes within the organism are the autonomic nervous system with its sympathetic and parasympathetic components and the HPA axis, which uses amines, peptides, and steroids to integrate and exert complex homeostatic control functions.

The main function of the HPA axis is basically to mediate responses to environmental stressors and challenges, and to coordinate daily activities and sleep-related events. With a strong circadian rhythmicity, or after stimulation by stress, the release of the hypothalamic hormones corticotrophin-releasing hormone (CRH) and vasopressin (VP), is increased, leading in turn to the release of ACTH and endorphins from the pituitary. The latter peptides are end products of the proteolytic processing of the proopiomelanocortin (POMC) precursor. ACTH subsequently stimulates the adrenocortical release of the glucocorticoids, i.e., corticosterone in rodents and cortisol in primates. Peak levels of corticosterone, rising about 40-fold after stress, are usually reached within 15–30 min and return to prestress levels 60–90 min later. Through negative feedback action, glucocorticoids control their own release by downregulating the increases of CRH, vasopressin, and POMC peptides, whereas the secretion of mineralocorticoids is only slightly affected.

The primary sites of this negative feedback action are the pituitary corticotrophs and the parvocellular neurons of the paraventricular nucleus (PVN), where corticosteroids block stress-induced activation of the HPA axis. An extensive literature also points to the hippocampus as an additional site of control of HPA activity (Herman *et al*., 1989; Sapolsky *et al*., 1991b). Under basal conditions, however, the hippocampus exerts an overall inhibitory influence, whereas following stress, the hippocampus appears to be involved in the magnitude, onset, and termination phase of the HPA response. This hippocampal influence is mainly transsynaptic and occurs predominantly via the bed nucleus of the stria terminalis, from which an inhibitory GABAergic input innervates the PVN (see Fig. 62.2). This input is then integrated with input from several other areas, that, together, determine the composition of the secretagogue cocktail released to the pituitary (Herman *et al*., 1994, 1995, 1996; Herman and Cullinan, 1997). Glucocorticoid control of this neuroendocrine stress system is mediated by nuclear receptors that will be discussed below.

B. Brain Corticosteroid Receptors

Two types of corticosteroid receptors are expressed in brain: the mineralocorticoid receptors (MR), which bind corticosterone and cortisol with high affinity, and the glucocorticoid receptors (GR), with an approximately 10-fold lower affinity (Reul and De Kloet, 1985). Neurons in the hippocampus contain both receptor types in high densities, whereas cells in most other brain regions, including glia, mainly express GRs, and the anterior pituitary contains them as well (Van Eekelen *et al*., 1991; Drouin *et al*., 1993). Since synthetic steroids like dexamethasone, poorly penetrate the blood–brain barrier (De Kloet *et al*., 1975; De Kloet, 1997; Meijer *et al*., 1998; De Kloet *et al*., 1998), the pituitary GRs are the main site where these steroids exert their feedback action. The naturally occuring GCs on the other hand, are highly lipophylic and readily pass the blood–brain barrier, where their principal sites of action are the CRH neurons of the paraventricular nucleus where GRs are also found in high densities.

Due to the high affinity of MR, these hippocampal receptors are already largely occupied when corticosteroid levels are low, for example during rest. Under these conditions, GRs are, however, only partially occupied and do not become fully activated until corticosteroid levels rise considerably, such as after stress. Although, classically, homodimers of MR or GR are known to bind to glucocorticoid responsive elements on the DNA, and from there affect gene transcription, many additional genomic steroid actions require protein–protein interactions between corticosteroid receptor monomers and other transcription factors: see Fig. 62.1, and also coactivators have been implicated (Meijer *et al.*, 2000). The effects of steroids on brain cells and their function therefore critically depend also on the nature and timing of other inputs that acti-

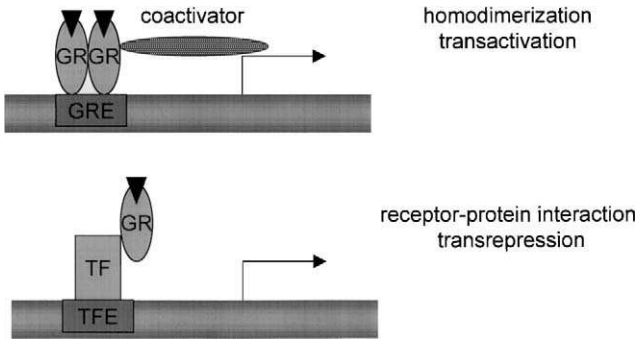

FIG. 62.1. Corticosteroid receptor-mediated actions on gene transcription. The interaction of the steroid receptors with other proteins in the cell constitutes a molecular basis for the conditional or context-dependent effects of corticosteroid hormones and consists of two modes of action. (Top) Transactivation: Upon ligand binding, corticosteroid steroid receptor can form homodimers, that bind to glucocorticoid response elements (GRE) in the DNA and recruit RNA polymerase II that contains a pre-initiation complex of multiple proteins and can subsequently stimulate the synthesis of mRNA. This mode of steroid action requires interaction of the receptor with additional coactivator proteins. (Bottom) Transrepression: In this mode of action, GRE-dependent target genes in the nucleus are left unstimulated, but transcription factors (TF) can bind specific response elements (TFE) and stimulate transcription. The receptor interferes in its monomeric form with transcription, that is activated by interactions with other TFs (transrepression).

vate transcription factors, like cyclic AMP response element binding protein (CREB) or other immediate–early genes (Vreugdenhil and DeKloet, 1998; Reichardt *et al*., 1999).

A wide variety of cellular and molecular actions by corticosteroids has been described, particularly for cells of the hippocampus. In general, situations where mostly MRs, but few GRs, are activated, are associated with small calcium currents, and thus a reduced spike frequency accommodation, stable responses to repeated stimulation of glutamatergic pathways, and relatively small responses to biogenic amines (Joëls and De Kloet, 1990, 1992; Joëls *et al*., 1991; Karten *et al*., 1999). MR activation thus seems to guarantee a stable background of neuronal firing which has been described as a proactive mode with respect to its role in maintaining neuronal homeostasis (De Kloet *et al*., 1998, 1999).

Activation of GR, in addition to MR, as occurs after exposure to a stressor or during the circadian peak, results in enhanced calcium influx, stronger spike frequency accommodation, changes in ion channel conductances, and marked responses to biogenic amines like serotonin (Joëls and De Kloet, 1989; Nair *et al*., 1998; Joëls *et al*., 1991; Karten *et al*., 1999). GR activation thus reduces cellular activity after acutely stressful situations, which is in accordance with their proposed reactive mode of action by which corticosteroids facilitate the recovery from disturbances in homeostasis (De Kloet *et al*., 1998).

Interestingly, in the absence of corticosteroids, many cellular properties and synaptic plasticity related events, resemble the situation as seen after high corticosteroid levels with simultaneous MR and GR activation. The effects of stress exposure on synaptic plasticity thus seems to follow essentially the same pattern in the two conditions (Diamond *et al*., 1992), revealing an (inverted) U-shaped, dose dependency for the action of these steroids (Joëls and De Kloet, 1990, 1992; De Kloet, 1991). The properties of the entire neuronal network may either change in parallel with or result from the steroid effects on individual cell characteristics, such as calcium influx and responsiveness to glutamatergic input.

C. Behavior

Steroid actions on hippocampal cells and the circuits they form also modulate learning and memory processes. For example, it has become clear that predominant MR activation results in completely different actions on these processes than concomittant MR and GR activation. Recent studies have shown that MR plays a role in behavioral reactivity during novel situations, whereas GR is involved in the consolidation of learned information (Fig. 62.2). This is partly based on studies using the Morris water maze. Intracerebroventricular administration of selective GR antagonists before or immediately after the first training session in a water maze resulted in impaired retention of the task 24 hr later (Oitzl and De Kloet, 1992; Oitzl *et al*., 1994, 1997b). Since treatment before the retrieval test was ineffective, GR blockade apparently interferes with the consolidation rather than the retrieval of acquired spatial information. MR blockage did not influence the latencies to find the platform, irrespective of the timing of the treatment. However, MR blockade significantly changed the search strategy in the free swim trial. The rats still headed directly to the former platform location (hence retention is undisturbed), but subsequently explored other areas of the pool as well, rather than remaining in the platform quadrant, which the controls did (Fig. 62.2 and Oitzl *et al*., 1994, 1995, 1997b, 1998a,b).

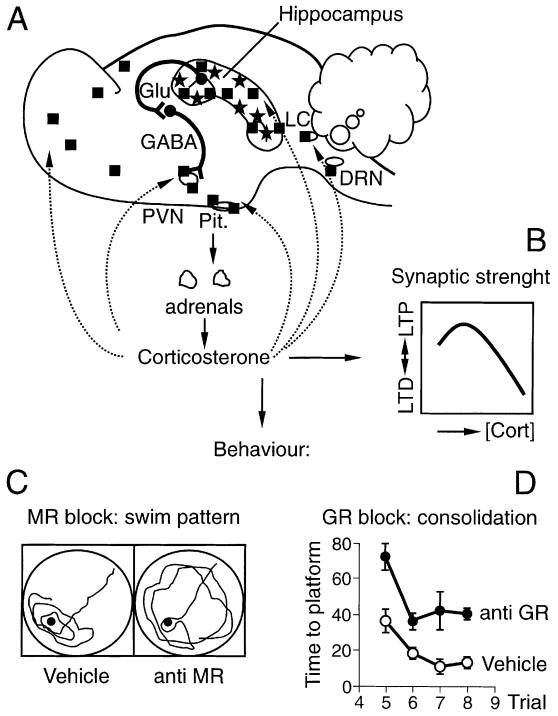

FIG. 62.2. MR and GR-mediated corticosteroid regulation of HPA-activity, of synaptic strength in hippocampus, and spatial learning behaviour. (A) HPA-axis: Schematic view of the HPA-axis comprising the hippocampus with mineralocorticoid receptors (MR, stars) and glucocorticoid receptors (GR, squares), the CRH neurons in the paraventricular nucleus (PVN), the corticotrophs in the anterior pituitary gland and the adrenal cortex. A major inhibitory GABAergic input to the PVN is formed by excitatory glutamatergic input originating from the hippocampus. Stress-induced rises of corticosteroids exert a negative feedback following binding to GRs in the pituitary corticotrophs and the CRH neurons of the PVN. The MR is involved in potentiation of the hippocampal output and thus enhances neural inhibition of the HPA-axis, whereas GRs in the hippocampus mediate opposite actions of corticosteroids, and dampen hippocampal output. GRs also mediate corticosteroid activation of ascending aminergic inputs to the PVN coming from the brain stem (LC, locus coeruleus; DRN, dorsal raphe nucleus) (De Kloet *et al.*, 1998). (B) Synaptic strength: LTP is induced in an optimal manner when corticosteroid levels are mildy elevated, that is, when MR and some GR are activated. High levels of corticosteroids in contrast, occupying most GRs, not only inhibit long term potentiation (LTP), but also induce long term depression (LTD). These data point to a bell-shaped dose-dependency for the formation of LTP in the hippocampus (De Kloet *et al.*, 1990). (C and D) Spatial learning behavior: (C) Following testing in the Morris water maze, the application of an MR antagonist i.c.v., 30 min prior to the retrieval test 24 hr later, clearly influenced the swim pattern and interfered with the selection of a behavioral response (left panel, MR block: swim pattern). Although treated rats (anti MR) approach the former platform position directly they subsequently spend less time searching in the vicinity of the platform quadrant, and rather search for an escape route elsewhere in the pool. (D) Inhibition of GR (anti GR) immediately during the consolidation process on day 1, resulted in an impaired performance when tested 24 hr later, indicating the role of GR in memory consolidation. These MR- and GR-mediated effects on information processing facilitate behavioral adaptation (Oitzl and de Kloet, 1992).

Specific MR- and GR-mediated effects can thus be disentangled by administration of selective agonists and antagonists for one of the receptor types, at specific stages of information processing. This should be done with care, in view of the possibility of changed blood–brain barrier kinetics for synthetic steroid receptor agonists, like dexamethasone (Meijer *et al*., 1998). The resulting suppression of HPA activity after dexamethasone takes place at the level of the pituitary, but leaves hormone receptors within the brain unoccupied. This explains why systemic administration of corticosterone to adrenalectomized rats, which activates both MR and GR, can reinstate contextual fear conditioning, whereas dexamethasone failed to do so (Bohus and De Kloet, 1981). These behavioral studies underscore the notion that MR activation appears essential for the correct interpretation of environmental stimuli and selection of a proper behavioral response. The MR- and GR-mediated effects are different, but interact and proceed in a coordinative manner, linked in time to the particular stage in information processing (De Kloet *et al*., 1998, 1999).

D. Neuroendocrine Regulation

Observations on the selective effects of glucocorticoids on HPA regulation have often been made without considering their additional effects on higher brain functions involved in arousal and information processing. GR-mediated effects on brain areas projecting to the PVN, for example, can have profound and long-lasting consequences for glucocorticoid feedback regulation of the HPA axis. First, the ascending aminergic inputs excite the PVN, an action that is potentiated by glucocorticoids and stress. Inputs from other nuclei, such as the suprachiasmatic nucleus and an intrahypothalamic GABAergic network, are also under control of glucocorticoids (Herman *et al*., 1996; Herman and Cullinan, 1997; De Kloet *et al*., 1998).

Limbic inputs into the intrahypothalamic GABAergic network, coming from the hippocampus, can be either excitatory, and thus enhance the inhibitory GABAergic tone, or inhibitory, when they originate from the amygdala, in which case they reduce the inhibitory tone (Fig. 62.2). This implies that with an enhanced exitatory input from the hippocampus, the HPA axis becomes relatively more suppressed. MR-mediated actions in the hippocampus maintain a high excitatory tone in the hippocampal circuit (Deuschle *et al*., 1998b), which, via the subsequent activation of the GABAergic input to the paraventricular nucleus, are expected to suppress HPA activity. Consistent with this hypothesized mechanism, central administration of an MR antagonist indeed disinhibited the HPA axis, and elevated basal levels of corticosterone were observed (Ratka *et al*., 1989; Oitzl *et al*., 1995; Spencer *et al*., 1998).

GR-mediated effects generally oppose those mediated by MRs in the hippocampus (Joëls and De Kloet, 1992). Accordingly, during a rise in GC levels after stress, GR activation suppresses hippocampal excitatory output, which results in disinhibition of the GABAergic input to the paraventricular nucleus. This disinhibitory influence persists as long as adaptation to the stressor fails, and both HPA activity and GC levels remain elevated. Behavioral adaptation eventually eliminates the HPA hyperdrive and is facilitated by GC action in the hippocampus. Accordingly, GC action in higher brain regions like the hippocampus, appears to be primarily concerned with behavioral adaptation and only secondarily with the neuroendocrine consequences of information processing (De Kloet *et al*., 1998).

III. Aging

A. Glucocorticoid Changes in Aging Mammals

A vast and already somewhat older literature has generally demonstrated elevated basal GC and ACTH levels in aged rodents, frequently accompanied by a flattened circadian GC rhythm. Following stress, HPA reactivity displays a profoundly different pattern in young and old animals. Peak levels of ACTH and/or corticosterone are elevated, but there are large variations between individuals and between strains. It has been reported that aged animals furthermore generally display a reduced ability to terminate the stress response (Sapolsky, 1992, 1996) and hence are exposed to increased cumulative GC levels as compared to young animals (Landfield *et al*., 1978, 1981; Angelucci *et al*., 1987; Brodish and Odio, 1989; Dellwo and Beauchene, 1990; Erisman *et al*., 1990; Sabatino *et al*., 1991; Sapolsky, 1992, 1996; Hauger *et al*., 1994). Exceptions exist as well, as several studies failed to find elevations in basal GC levels, reported on decreases in GC or ACTH levels, or, such as found an enhanced ACTH rather than GC response to an emotional stressor, in old as compared to young animals (Fig. 62.3 and Sonntag *et al*., 1987; Issa *et al*., 1990; Lorens *et al*., 1990; Scaccianoce *et al*., 1990, 1995; Van Eekelen *et al*., 1991, 1992; Dhabhar *et al*., 1993; Morano *et al*., 1994; Cizza *et al*., 1995; Seckl and Olsson, 1995).

Following exposure to a prolonged or repeated stressor, GC-mediated feedback of the HPA axis is reduced. This may in part be due to decreases in the number or affinity of the GR, that were found in at least some rat and mouse strains and may reflect functional alterations as well (Nicholson *et al*., 1987, 1988; Eldridge *et al*., 1989a,b; Patacchioli *et al*., 1989, 1990; Zoli *et al*., 1991; Meaney *et al*., 1992; Sapolsky, 1992, 1996, 1999; Talmi *et al*., 1993). However, many of these binding studies did not discriminate between MR and GR. Moreover, they considered the hippocampus as a sole and primary neuroendocrine feedback site through which GR-mediated effects suppress HPA activity, and failed to include GR expression in the hypothalamic paraventricular nucleus or the pituitary corticotrophs.

In old Brown Norway rats, differential changes in MR and GR number in hippocampus and hypothalamus have been reported (De Kloet *et al*., 1991; De Kloet, 1992; Van Eekelen *et al*., 1991, 1992). One consistent finding is that regardless of the strain of rats examined, a reduction in MR binding capacity at senescence is found (Lorens *et al*., 1990; De Kloet, 1992). In addition, both MR mRNA and GR mRNA levels in the hippocampus as well as GR mRNA in the PVN and frontal cortex were found to be reduced in aged rats, which suggests a decreased transcriptional activity in these areas (Plotsky *et al*., 1993; Morano *et al*., 1994; Makino *et al*., 1995; McEwen, 1996; Workel *et al*., 2000). These observations are further supported by reductions in GR immunoreactivity in the CA1 and CA2 fields of the hippocampus (Van Eekelen *et al*., 1991, 1992; Zoli *et al*., 1991). However, with immuno-

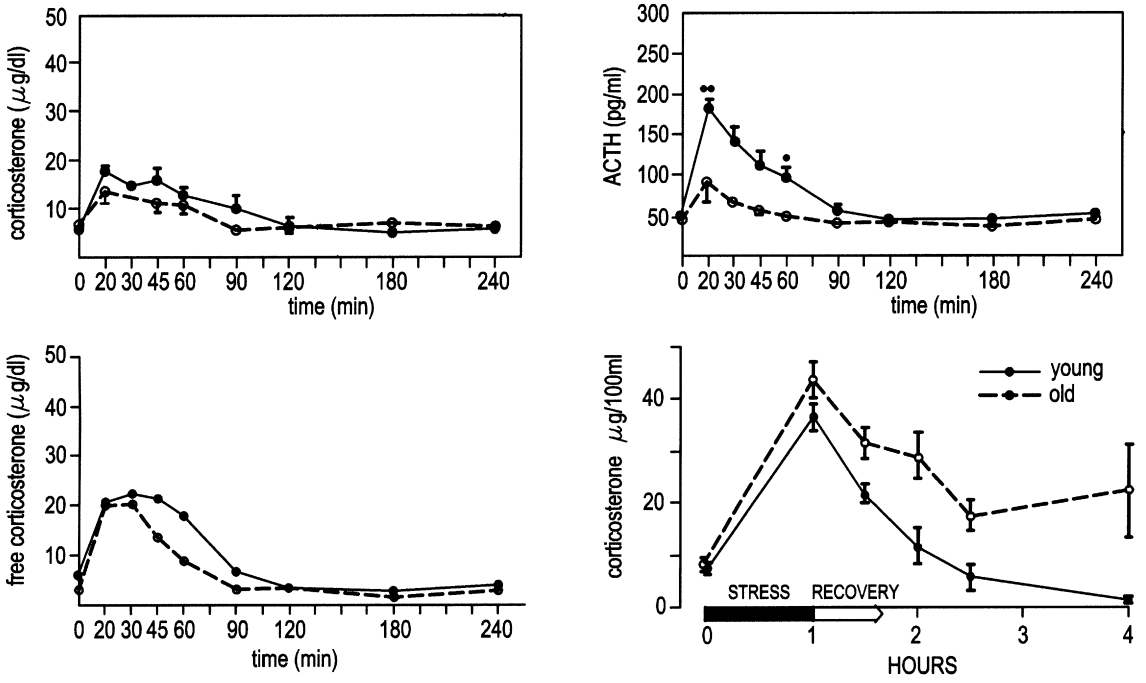

FIG. 62.3. Effect of stress on the plasma ACTH and corticosterone levels of the senescent rat. (Upper right and left) Effects of a conditional emitional response on corticosterone and ACTH levels in young (open circles, n=8, dashed line) and aged (closed circles, n=6, continous line) male Brown Norway rats. Note that corticosterone levels are not significantly different, whereas the ACTH response to stress is significantly enhanced (from Van Eekelen *et al.*, 1991, with permission). (Lower left) Effect of a conditional emotional response on free corticosterone levels in plasma of the male Brown Norway animals shown above (open circles, young; and closed circles, old animals). Plasma corticosteroid binding is suppressed during aging and the small differences in free corticosterone levels between the groups indicate a delayed recovery from stress (from Van Eekelen *et al.*, 1991, with permission). (Lower right) Corticosterone levels in young and aged Fisher rats during 60 min of immobilization stress during the light period, monitored for 3 subsequent hr of recovery. In contrast to the Brown Norway rat, corticosterone levels of aged subjects of the Fisher strain did not recover to basal values after this stressor (from Sapolsky *et al.*, 1984, with permission).

cytochemistry for the MR in these old animals, no consistent changes could be found, either in number of MR immunopositive cells or in MR immunoreactivity per cell (Bhatnagar *et al.*, 1997). MR mRNA was altered in the hippocampus, but only in discrete areas, like the dentate gyrus (Workel *et al.*, 2000). This discrepancy concerning the age-related downregulation of MR binding vs MR mRNA levels and immunoreactivity may be due to translation, receptor processing, or posttranslational events.

Another mammal that is relatively well studied in relation to the effects of stress and GC exposure is the day-active tree shrew, which is highly sensitive to social hierarchy differences (Fuchs and Flügge, 1998). When two males are confronted with each other in a dominant–subordinate setting, profound changes in several behavioral and physiological parameters of HPA axis activity are induced. The resulting psychosocial, rather than physical, stress induces many changes like elevated GC levels in the subordinate animal, dendritic atrophy of CA3, downregulation of GR mRNA in the hippocampus as well as suppression of neurogenesis (Johren *et al.*, 1994; Fuchs *et al.*, 1995; Magarinos *et al.*, 1996; Jamieson *et al.*, 1997; Fuchs and Flügge, 1998). In a recent aging study in this species, gradual increases were reported until adulthood, after which no further rise was found in basal urinary free cortisol concentrations, or after reaching senescence (7–8 years) (Van Kampen and Fuchs, 1998). Interestingly, no indications could be found for amyloid pathology in the brain of the old tree shrew, which contrasts with the situation in all other aged non-human primates studied to date and may possibly relate to the absence of increased GC levels in aging (Pawlik *et al.*, 1999).

B. Aging Studies in Rodents: General Considerations

As is clear from the above, HPA axis activation in aging rats has been reported in many, but not all studies (Sonntag *et al.*, 1987; Issa *et al.*, 1990; Lorens *et al.*, 1990; Van Eekelen *et al.*, 1991, 1992; Dhabhar *et al.*, 1993; Morano *et al.*, 1994; Cizza *et al.*, 1995; Sapolsky, 1996). These differences largely depend on differences in strain and sex or experimental design (see Sapolsky, 1992, 1996). Spraque–Dawley, Long–Evans, Fisher, and Wistar rats, furthermore, generally show increased basal and prolonged stress-induced GC levels during aging. However, in aged Brown–Norway rats, neither basal plasma GC levels nor GC rises induced by a novel environment or a conditioned emotional response were altered (Fig. 62.3 and Van Eekelen *et al.*, 1991, 1992; Gomez *et al.*, 1998). In the latter strain, the capacity of GC-binding globulin was strongly reduced, which yields an increased free fraction of nonbound GC. Together with the increased peak values, but not the duration of the ACTH response, and without clear changes in adre-

nocortical GC secretion, this suggests a reduced adrenal sensitivity to ACTH or a reduced bioactivity of ACTH in old animals of this particular strain.

When comparing aging studies in rodents, clear differences in the 50% survival age are apparent between rat strains (Masoro, 1980a,b). Criteria formulated for an animal model for aging include an almost rectangular survival curve and thus a high estimated 50% survival age, which should be accompanied by the occurrence of age-related, multiple pathologies, rather than inbred strain specific diseases like the high prevalence of testis or pituitary tumors in F344 or Wistar rats (Masoro, 1980a,b). The animals used in many of the previous aging studies in fact either fail to meet these criteria for a good model for aging or should be considered middle-aged rather than old (i.e., less than the lowest estimate of the 50% survival age for the strain) which can have important consequences when studying age-related changes (Coleman *et al*., 1990). The Brown Norway strain does meet these criteria and is as such generally accepted as a good rodent model to study aging.

Another important consideration in this type of studies is the individual variation within a genetically homogeneous cohort of animals, which becomes much more pronounced at old age. With respect to many behavioral and neurobiological parameters such as memory performance, individual animals can often be classified in an impaired, an intermediate, and a nonimpaired subgroup (Gage *et al*., 1984b; Rots *et al*., 1996b,c; Oitzl *et al*., 2000a,b; Workel *et al*., 2000). In a large group of aged rats, approximately 30% appeared to be unaffected in their memory performance, whereas the rest had severe impairments, notably in relation to their GC levels (Issa *et al*., 1990).

Interestingly, individual differences in cognitive decline that appear at old age, are subject to manipulation by early life events. Procedures like maternal deprivation or postnatal handling during the first 3 weeks of the rat's life, for example, can alter the animal's stress responsiveness permanently. Animals handled postnataly showed lower basal GC levels at old age than non-handled, aged animals, as well as reduced rises in plasma GC levels following stress, less age-related hippocampal cell loss and less cognitive impairment (Levine *et al*., 1991; Meaney *et al*., 1991, 1992; Van Oers *et al*., 1998, 1999; Workel *et al*., 2000).

Another example of the long-lasting effects of early life events is maternal deprivation, which influences several aspects of HPA axis reactivity during development, adulthood, and aging. The outcome of maternal deprivation, however, depends on the frequency and age at which separation occurs, while also strain and sex are important variables (Levine *et al*., 1991; Meaney *et al*., 1991; Rots *et al*., 1996a; Workel *et al*., 1997, 2000). Deprivation for 24 hr at day 3 of the rat pup's life was recently shown to cause a striking pattern of endocrine and behavioral changes during life. The stress-induced corticosterone output of the deprived animals showed a pronounced increase at midlife, but senescent animals displayed attenuated corticosterone responses as compared to their control, mother-reared littermates. At midlife they showed a transient increase in expression of MR mRNA in the hippocampal dentate gyrus prior to downregulation at senescence and age-related changes in GR expression as well (Workel *et al*., 2000).

The most striking effect of maternal deprivation was on cognitive performance at senescence. Based on current ideas, it was expected that an early traumatic life event would cause cognitive decline in *every* individual. This was, however, not observed and maternal deprivation was found to amplify the individual differences present at old age and gave rise to a complete shift in the percentages of animals classified as good, intermediate, and bad learners, on the basis of their performance in the Morris water maze. The large group of average performers in the mother-reared rats, fell apart in two extremes of cognitive performance in the maternally deprived group. The senescent, mother-reared animals were mostly partially impaired, whereas deprived littermates were either very poor, or very good performers in terms of cognition. Notably, senescent animals that were maternally deprived in the first days after birth were either good or impaired learners at old age, with only a few animals showing intermediate performance. Their frequency distribution, consequently, resembled a ''U-shaped'' curve. In contrast, the learning ability of nonhandled, control animals at old age showed a bell, or ''inverted U-shaped'' distribution, with the majority of the animals showing intermediate performance. This dichotomy of cognitive performance in the deprived animals developed in association with attenuated corticosterone responses to stress, but was preceded by a midlife surge in stress reponsiveness and hypercorticism. Whether such a ''midlife'' crises in the rat programs the subsequent aging trajectory remains to be established (Oitzl *et al*., 2000a,b; Workel *et al*., 2000).

Regarding handling of newborn animals, this procedure in female animals resulted in consistent increases in GR binding (Meaney *et al*., 1991, 1992) and probably also involves changes in serotonin metabolism and in sensitivity to antidepressants. Both restraint stress induced atrophy of the dendritic tree in CA3 as well as the parallel memory impairment could be prevented by serotonin uptake enhancers in nonhandled adult rats (Magarinos *et al*., 1998, 1999). The antidepressant amitriptyline also significantly improved spatial memory in young rats and increased hippocampal MR, but not GR mRNA expression, whereas in aged rats, this antidepressant had no effect on spatial memory or hippocampal corticosteroid receptor gene expression, either in cognitively unimpaired or cognitively impaired animals (Yau *et al*., 1995). Amitriptyline did not influence basal morning plasma corticosterone levels in either young or aged rats, but significantly decreased evening corticosterone levels in aged rats, consistent with a selective activation of hippocampal MR. In addition, age-related decreases in various hippocampal 5HT transporter sites could be upregulated by 10 weeks of antidepressant treatment, which may contribute to the general lower effectiveness of tricyclic antidepressants with aging (Yau *et al*., 1995, 1999). In another study, administration of antidepressants reversed the age-related changes in corticosterone and feedback function in old animals, but not in GR levels or cognitive decline (Rowe *et al*., 1997), whereas *in vitro* treatment of cultured hippocampal neurons increased both GR binding as well as GR gene expression (Okugawa *et al*., 1999).

Together, this suggests that early life events can permanently alter the responsiveness of the serotonergic and the HPA systems throughout life. These changes may have important consequences for the development of differential sensitivity to adult and senescent cognitive decline, but are very difficult

to influence or correct once steady-state conditions have been reached in adulthood.

In conclusion, on the basis of animal studies, several scenarios have been put forward that link rises in GC levels to aging. First, stress and hypercorticism were proposed to promote cognitive aging. Second, aging may cause initial hypercorticism, which then, in a feedforward cascade of increasing feedback insensitivity, would further promote the aging process. Third, stress together with hypercorticism would amplify the individual variation in cognitive aging. The evidence for these three scenarios will be discussed below in different species.

C. Glucocorticoid-Related Changes in Aging Primates and Humans

Similar to rodents, increased HPA activity is not a universal feature of human aging either, although these species also differ in several respects. Aging does not seem to lead to a change in basal HPA activity as measured by morning cortisol levels that were not different between young or old subjects, nor did cortisol-binding globulin levels change with age, and no changes in the sensitivity of the feedback system to dexamethasone were observed with human age (Huizenga *et al*., 1998). The circadian release pattern of cortisol also appears intact in terms of rhythmicity and pulsatile hormone release, but a reduced amplitude and a phase-advance in the cortisol peak have been reported as well (Colucci *et al*., 1975; Touitou *et al*., 1983; Huizenga *et al*., 1988; Van Cauter *et al*., 1996; Deuschle *et al*., 1997, 1998a). Following a (prolonged) challenge, furthermore, the stress response seems to remain intact, as does adrenal sensitivity to ACTH and feedback sensitivity to dexamethasone with age (Cartlidge *et al*., 1970; Riegle and Hess, 1972; Zimmerman and Coryell, 1987; Roberts *et al*., 1990; Gotthardt *et al*., 1995). A few studies reported an increased ACTH and corticosterone response in aged individuals, that was sex dependent in some but not all studies. A sex difference was also found in the cortisol response in aged females that was larger compared to males, which may represent an enhanced age-related decline in feedback inhibition of the HPA axis of females (Heuser *et al*., 1994; Wilkinson *et al*., 1997; Deuschle *et al*., 1998a).

In addition, in studies on the postmortem human hypothalamus, increased numbers of CRH expressing neurons, and increased CRH-vasopressin colocalization in the paraventricular nucleus were found with aging in males indicative of an increased chronic CRH activation during human aging (Raadsheer *et al*., 1994, 1995). Related activational changes, like activation of vasopressin neurons, increases in cortisol concentrations in the cerebrospinal fluid (Swaab *et al*., 1994), were also observed during aging, in Alzheimer's disease, and in depression (Raadsheer *et al*., 1993, 1994, 1995; Swaab, 1995; Lucassen *et al*., 1994, 1997a; Swaab *et al*., 1999).

As most of the human studies are done retrospectively and many different paradigms and criteria for the definition of "aged" have been used, it is difficult to draw final conclusions on the effects of aging on human HPA parameters or vice versa. Two studies, however, followed a prospective approach in which cortisol was related to cognitive function. First, Lupien observed that individuals with increased cortisol levels over a period of 4 years, showed impaired performance in explicit memory and selective attention tasks. However, when these individuals were classified into three subgroups (low, medium, and high cortisol levels), only individuals with rising corticosterone levels over the 4-year period, showed impairment in cognition, indicating a relation between basal corticosterone and cognitive deficits at old age, that seems to be predicted by early changes in GC levels (Lupien *et al*., 1997; Lupien and McEwen, 1997). Furthermore, stress responsiveness was involved, since a (stressful) public speech task revealed that the subgroup with an early (anticipatory) increase in cortisol in response to the stimulus, was impaired in declarative memory, whereas elderly without this early rise in cortisol showed no memory deficits (Lupien *et al*., 1997, 1998) (Fig. 62.4).

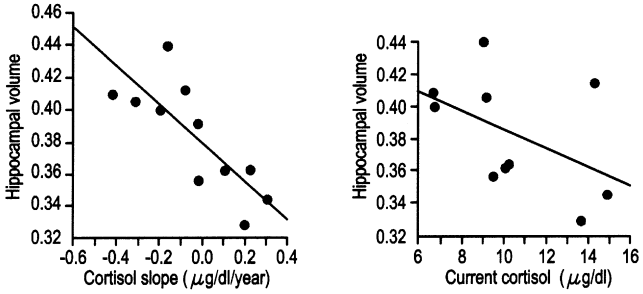

FIG. 62.4. Cortisol and hippocampal volume in aged human subjects. (Left) Correlations between cortisol slope (i.e., the change in average amount of circulating cortisol per year) and (Right) current cortisol levels with the volume of the hippocampus, as measured by MRI, in 11 elderly subjects (from Lupien *et al.*, 1998, with permission).

Second, in another prospective follow-up study in Rotterdam, the ratio of free cortisol over dehydroepiandrosterone (DHEA) was significantly related to cognitive impairment, which confirms the notion that changes in basal free cortisol influence cognitive decline (Kalmijn *et al*., 1998). Regarding the possible inverse relationship between another important adrenal steroid, dehydroepiandrosterone sulfate (DHEA-S) and cognitive changes in aging, no final conclusions can yet be drawn (Kalmijn *et al*., 1998; Wolf *et al*., 1998, 1999; Wolf and Kirschbaum, 1999).

These data suggest that some of the results from rat studies, especially those showing that long-term GC overexposure in later life can accelerate aspects of brain aging and may initiate memory disturbance and cognitive decline, can be partly extrapolated to the human situation. However, it should be realized that the design and extent of the stressors compared have been quite different.

1. Memory and Cognitive Changes in Aging Humans

Studies in humans and primates suggest a similar sensitivity of brain and hippocampal functioning to aberrant GC exposure, as occurs in aging rodents (Issa *et al*., 1990; Geinisman *et al*., 1995; McEwen and Sapolsky, 1995; Van Cauter *et al*., 1996; Wilkinson *et al*., 1997; Newcomer *et al*., 1999b; Ward *et al*., 1999). First, declines in cognitive function frequently accompany normal aging in human and nonhuman primates and are often paralleled by gradual increases in GC levels (Luine, 1997; Lupien *et al*., 1997, 1998). In addition, exogen-

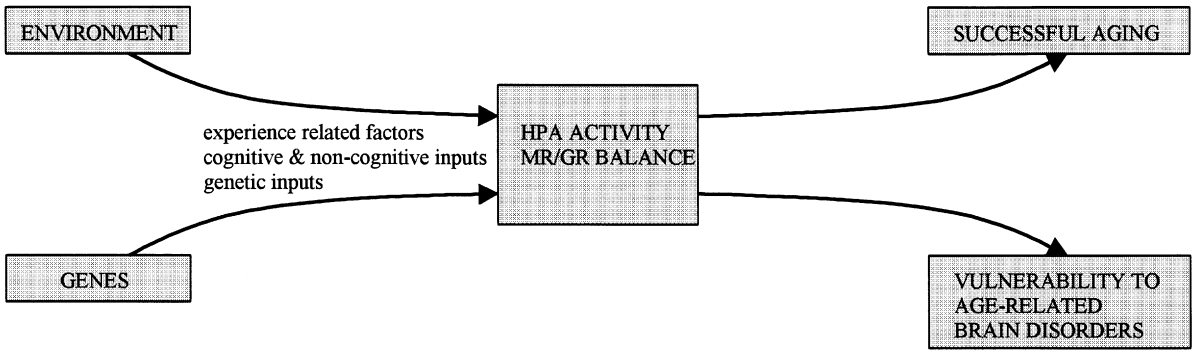

FIG. 62.5. Stress and aging. Scheme depicting genetic and environmental factors in relation to the set point of HPA activity and the balance of MR- and GR-mediated effects in hippocampal cells. Dysregulation of HPA activity and MR/GR imbalance are thought to be critical factors determining the individual vulnerability to age- and stress-related disorders in senescence (see also de Kloet *et al.*, 1998).

ous application of high doses of GCs to humans, for example, by oral administration, causes acute cognitive impairment of declarative memory and disruption of memory formation (Newcomer *et al*., 1994; Luine, 1997; Lupien *et al*., 1997; McEwen *et al*., 1999). Furthermore, women exhibiting increases in cortisol excretion over a 2.5-year follow-up period, preferentially showed declines in memory performance, that were, however, reversible upon normalization of their cortisol levels (Seeman *et al*., 1997). Moreover, in human conditions associated with prolonged cortisol elevation or activation, such as Cushing's disease, following (synthetic) steroid treatment, aging, Alzheimer's disease or in major depression, memory disturbances are frequently observed as well (Starkman *et al*., 1992; Newcomer *et al*., 1994, 1999b; Kirschbaum *et al*., 1996; Lupien *et al*., 1997; Lupien and McEwen, 1997; Wolf *et al*., 1998; McEwen, 1999; McEwen *et al*., 1999).

A word of caution is required regarding the interpretation of GC application in human studies. First, often synthetic glucocorticoids are given, that, at least in rat, can have rather the opposite effect, as they deplete the brain MRs of their endogenous ligands, and thus create a condition resembling that of chemical adrenalectomy, which is expected to affect neuronal viability (De Kloet, 1997; De Kloet *et al*., 1998; Meijer *et al*., 1998; Sousa *et al*., 1999). Furthermore, steroids given to humans are often administered out of context with respect to the particular stage of information processing as outlined in the behavioral studies above (Oitzl *et al*., 1994, 1995, 1998a,b). This can exert differential, and even opposite effects regarding the selective MR- or GR-mediated modes of action (De Kloet *et al*., 1999; see above). Accordingly, altered cognitive performance and behavior is redirected under such conditions to a more opportune response that may be quite unrelated to the original test situation (Fig. 62.5).

2. Hippocampal Volume Changes

Interestingly, changes in hippocampal function are often associated with reductions in hippocampal volume as measured by, for example, MRI in live persons. These are already apparent in elderly individuals who display still only mild cognitive or memory impairment. Such changes have also been observed in many of the GC-associated conditions mentioned above (Convit *et al*., 1995; De Leon *et al*., 1995, 1997a,b; Double *et al*., 1996; Sheline *et al*., 1996, 1999; Bobinski *et al*., 1998; Kumar *et al*., 1998; McEwen, 1999; McEwen *et al*., 1999; Bremner *et al.*, 2000). Although direct correlations with learning deficits in the same animals were not described in this species, studies on tree shrews subjected to a 4 week treatment with cortisol, also showed a significant reduction in hippocampal volume in relation to memory performance (Ohl and Fuchs, 1998, 1999; Ohl *et al*., 1999).

Furthermore, in a prospective study in man, increased basal cortisol levels correlated with reductions in explicit memory and attention tasks (Lupien and McEwen, 1997) that were paralleled by a 14% decrease in hippocampal volume (Lupien *et al*., 1998) (Fig. 62.4). Significant correlations have furthermore been found between hippocampal formation size and delayed, but not primary or immediate memory performance, that was independent of sex, generalized cerebral atrophy, or age. The extent of these early atrophic changes of the hippocampus that was found to be a risk factor for accelerated memory dysfunction in normal aging (Golomb *et al*., 1993, 1994, 1996; Lupien *et al*., 1998; Reiman *et al*., 1998), appeared to correlate with the neurofibrillary pathology in Alzheimer's disease (Bobinski *et al*., 1996), and was even proposed to predict the decline in memory performance (Golomb *et al*., 1996).

Notably, in aged but cognitively normal individuals, changes in hippocampal volume were preceded by changes in glucose metabolism. Both changes depended on the genotype of the patients. For example, both hippocampal volume and hippocampal metabolism were strongly reduced in carriers of the apolipoprotein E (ApoE) epsilon 4 allele, which is a well-known risk factor for age-related cognitive deficits and Alzheimer's disease (Reiman *et al*., 1996, 1998; Haan *et al*., 1999). Furthermore, clear changes in hippocampal or even entire cerebral volume were found in conditions associated with altered HPA functioning, such as aging (Golomb *et al*., 1994; Double *et al*., 1996), depression (Sheline *et al*., 1996, 1999; Kumar *et al*., 1998; Lupien *et al*., 1998; Bremner *et al.*, 2000), or Cushing's disease (Starkman *et al*., 1992). In some reports on the effect of high-dose GC exposure, the consequences appeared reversible once the steroid exposure had decreased or stopped, suggesting that the atrophy observed is in fact transient and may relate to atrophy or changes in water content rather than to actual cell loss (Starkman *et al*., 1992; Sapolsky, 1996; Seeman *et al*., 1997).

D. Age-Related Glucocorticoid Changes in Mice

The current generation of many transgenic mice models has allowed the detailed analysis of several genes or proteins in isolation that are relevant to neurodegenerative or cognitive changes during aging. The actual phenotype of these mice in terms of cognitive or learning capacities, is, however, heavily influenced by the genetic background, that in many of them result in non-specific cognitive deficits that are not related to the manipulated gene (Ingram and Jucker, 1999). One explanation is that behaviors like learning and cognition are so complex that their genetic regulation probably involves many interrelated genes and gene products. Changes in any one of these single genes may consequently lead to a perturbation of the behavioral aspect under study (Keverne, 1997; Nelson and Young, 1998; Picciotto, 1999).

In spite of these considerations, unbiased analysis of the related anatomical substrates or studies on the relation between cognition and glucocorticoid levels in aging (transgenic) mice have been limited so far (Bernstein *et al*., 1985; Fordyce and Wehner, 1993a,b; Talmi *et al*., 1993; Ammassari-Teule *et al*., 1994; Barkats *et al*., 1996). Calhoun *et al*. (1998) failed to find age-related deficits in learning performance, number of synaptophysin-positive boutons, or total neuron number of the DG or CA1 area of aged C57BL/6J mice, although a significant relationship between DG synaptophysin-positive bouton number and water maze performance was found. Other studies in a substrain of aged B6 mice reported some impairment in water maze performance, but this finding has not been related to cell numbers (Fordyce and Wehner, 1993a,b). Similarly, radial arm maze performance tested in young and old mice in two studies was found not to differ either (Bernstein *et al*., 1985; Ammassari-Tuele *et al*., 1994). Furthermore, in old β-amyloid precursor protein knockout mice, learning deficits were clearly apparent, but could not be related to hippocampal neuron numbers (Phinney *et al*., 1999), whereas in aging mice lacking neurotrophin receptor p75 or high-affinity nicotine receptors, significant central neuronal loss was found, associated with (Peterson *et al*., 1999) as well as without behavioral impairment (Zoli *et al*., 1999).

Another major risk factor for age-related cognitive deficits, hippocampal volume reductions as well as the development of Alzheimer's disease, is apolipoprotein E (ApoE), a lipoprotein that plays an important role in peripheral fat metabolism, which is found in three variants, ApoE ϵ 2, 3, and 4 (Soininen and Riekkinen, 1996; Roses, 1997). In the brain, where a separate ApoE population appears to be present, this lipoprotein is thought to play a role in repair and lipid redistribution in response to damage or insults. Some cues as to the function of ApoE in the brain are becoming clear from studies in ApoE knockout mice. For example, adult ApoE knockout mice display a severe learning deficit when tested in a Morris water maze and also show electrophysiological changes in hippocampal function (Gordon *et al*., 1995, 1996a; Krugers *et al*., 1997; Oitzl *et al*., 1997a; Anderson *et al*., 1998; Veinbergs *et al*., 1998). Furthermore, some indications for neurodegenerative alterations in these mice have been observed at old age (Masliah *et al*., 1995; Montine *et al*., 1999) that may relate to changes in ApoE expression during life (Masliah *et al*., 1996; Robertson *et al*., 1998) and appear isoform specific (Raber *et al*., 1998; Buttini *et al*., 1999; Teter *et al*., 1999). Also neurotrophic alterations were found (Veinbergs *et al*., 1999). In adult ApoE knockout animals, tau alterations also have been described (Genis *et al*., 1995) while reintroduction of ApoE in these knockout mice was shown to prevent the cognitive deficit as well as the neurodegenerative changes from occurring (Masliah *et al*., 1997).

Interestingly, ApoE knockout mice appear increasingly sensitive to subsequent damage or insults, like ischemia or kainic acid injections. These treatments induce ApoE expression in neurons, the same cell type in which ApoE is found in the Alzheimer brain (Masliah *et al*., 1996; Boschert *et al*., 1999; Horsburgh *et al*., 1999; Grootendorst *et al*., 2000a). Furthermore, in addition to the learning impairment, these mice show aberrant basal GC levels and alterations in stress responsiveness which suggests a reduced adrenocortical synthetic capacity (Gordon *et al*., 1996b; Zhou *et al*., 1998; Grootendorst *et al*., 2000b), and thus decreased dynamics in the corticosterone response. Furthermore, the observed learning deficit in ApoE knockout mice could be reversed by either GC suppletion or the application of chronic stress, whereas in wild-type littermates, this induced learning impairment (Grootendorst *et al.*, 2000b) indicating that the ApoE genotype is apparently crucial for the direction of the effects of aberrant GC levels in mice.

IV. Corticosteroid Exposure and Hippocampal Damage

A. Rat Studies

The hippocampus has frequently been implicated in the negative feedback regulation of corticosterone and is thought to exert a tonic inhibitory control on HPA axis activity (see above, and Ratka *et al*., 1989; Herman *et al*., 1989; Sapolsky *et al*., 1991b; Jacobson and Sapolsky, 1991). More recent studies have revealed that this inhibition is exerted through several, often indirect neural pathways to which also frontal cortical regions and the ventral subiculum contribute (Herman *et al*., 1994, 1995, 1996; Herman and Cullinan, 1997). On the other hand, GC feedback of the HPA axis, takes place primarily at the level of the paraventricular nucleus in the hypothalamus (De Kloet and Joëls, 1998; Kretz *et al*., 1999). Also this structure may thus be involved in a gradual insensitivity to feedback signals, slowly causing a loss of control over vital homeostatic processes as proposed before (Frolkis *et al.* 1972b; Dilmean *et al.*, 1979). Nevertheless, the hippocampus remains an important brain region involved in modulating aspects of learning and memory processing, mood, affect, and adaptation, each with their own associated effects on neuroendocrine regulation.

In spite of the indirect connections between hippocampus and PVN, glucocorticoid or stress-induced damage to either area can impair HPA axis inhibition, as was shown before after mechanical or pharmacological intervention studies (negative feedback Herman *et al*., 1989, 1996; Jacobson and Sapolsky, 1991; Herman and Cullinan, 1997). It has thus been proposed that this glucocorticoid neuronal damage can give rise to an altered negative feedback set point and a feedforward cascade of cumulative GC overexposure, from which the entire brain and body suffer. With the rapid effects on memory and cogni-

tion in mind, establishing the impact of (acute or chronic) GC overexposure on function and structure of an important neuroendocrine control center like the hippocampus, has become a highly relevant subject of study in recent years.

Regarding GC-related damage, it is important to note that a clearly differential vulnerability is apparent between the main hippocampal subareas with respect to different GC concentrations. First, GCs are essential for neuronal viability in the dentate gyrus, since GC absence, induced after adrenalectomy, induces widespread apoptotic cell death throughout the granule cell layer of the dentate gyrus (Sloviter *et al*., 1989, 1993a,b; Sapolsky *et al*., 1991a; Adem *et al*., 1994; Sousa *et al*., 1997; MacLennan *et al*., 1998) to which also androgens contribute (Frye and McCormick, 2000). The cell loss appears specific for the dentate gyrus since pyramidal cells, calbindin or somatostatin containing hippocampal interneurons, and areas outside the dentate gyrus remain intact (Sapolsky *et al*., 1991a; Sloviter *et al*., 1993a,b; Adem *et al*., 1994; MacLennan *et al*., 1998).

As part of the trisynaptic circuit in the hippocampus, the dentate gyrus is important for information processing to CA1 and subsequent cortical regions. Indeed, adrenelectomy-induced dentate gyrus apoptosis is accompanied by abnormal electrophysiological responses to perforant path stimulation, calcium currents, and learning performance (Armstrong *et al*., 1993; Karst *et al*., 1997; Stienstra *et al*., 1998; Phan *et al*., 1999). These effects are thought to be mediated through the MR, since the effects of adrenelectomy-induced apoptosis can be prevented by low doses of corticosterone that occupy only MR and not GR. Furthermore, treatment with the MR agonist, but not with GR agonists like dexamethasone, prevents the occurrence of apoptosis. Treatment with the latter even seems to increase hippocampal damage in primates (Uno *et al*., 1994), whereas in rat, shorter periods are already effective and reveal changes within anatomical subregions (Hassan *et al*., 1996; Hornsby *et al*., 1996; Sousa *et al*., 1997, 1999). As outlined earlier, this dexamethasone effect is likely to be indirect, depleting MR of its endogeneous ligand. Aging rats in particular, were reported to have an increased sensitivity to dexamethasone (Hassan *et al*., 1996, 1999). In addition to hypercorticism, hypocorticism can thus be deleterious for rat hippocampal viability as well. For many human somatic and CNS functions, reduced glucorticoid concentrations and hypocorticism are indeed considered endangering (Heim *et al*., 1999).

Elevated GC levels, on the other hand, primarily affect pyramidal neurons in the CA layers and are thought to induce hippocampal dysfunction predominantly through GR action (Sapolsky *et al*., 1985, 1990; Uno *et al*., 1989; Virgin *et al*., 1991; Diamond *et al*., 1992; Dachir *et al*., 1993; Arbel *et al*., 1994; Levy *et al*., 1994; Stein-Behrens *et al*., 1994; Bodnoff *et al*., 1995; Fuchs *et al*., 1995; Hassan *et al*., 1996; De Kloet *et al*., 1998, 1999; Sousa *et al*., 1998a, 1998b, 1999). Consequences of hypercorticism are dependent on the duration and concentration applied, and range from early functional deficits and selective, but still transient, changes in neuronal morphology, via an increased vulnerability to subsequent insults, to eventually neuropathology and cell death under extreme conditions. More specifically, atrophy of the apical dendrites of neurons in the CA3c subarea is observed first, in association with reversible memory impairment (Magarinos *et al*., 1996, 1997; Luine, 1997; Lupien and McEwen, 1997), which is influenced by excitatory amino acid transmission (Armanini *et al*., 1990; McEwen, 1996, 1999). Even short exposures to aberrant GC levels or stress can endanger hippocampal neurons in their response to subsequent insults and effects of, for example, ischemia or kainic acid, which are much more severe when applied following stress or high GC exposure than under low corticosterone conditions, both *in vivo* and *in vitro* (Sapolsky and Pulsinelli, 1985; Koide *et al*., 1986; Morse and Davis, 1990; Tombaugh *et al*., 1992; Elliott *et al*., 1993; White-Gbadebo and Hamm, 1993; Lawrence and Sapolsky, 1994; Stein-Behrens *et al*., 1994; Bodnoff *et al*., 1995; Krugers *et al*., 1998; Porter and Landfield, 1998).

When stress becomes severe and prolonged or hypercorticism has been chronic, the atrophy of CA3 neurons has been proposed to eventually lead to cell death, which may, through subsequent anterograde degeneration, partly affect CA1 as well (Sapolsky *et al*., 1985, 1990; Uno *et al*., 1989; Kerr *et al*., 1991; Stein-Behrens *et al*., 1994; Sapolsky, 1996, 1999). The extent of the deleterious effects of high glucocorticoid exposure during the course of aging (Sapolsky and Altmann, 1991; Sapolsky, 1992), for example, the hippocampal volume changes in rat (Rapp *et al*., 1999), also seems to depend on additional factors like neuronal energy metabolism (see below) and sex steroids (McEwen, 1996, 1999; Luine, 1997; Rivier, 1999). For example, castration significantly worsened the extent of the cell loss in CA3 and CA4 after severe restraint stress (Mizoguchi *et al*., 1992; Phan *et al*., 1999).

On the basis of observations on adrenocortical activity and GC levels, that positively correlated with hippocampal pathology, the relationship between increased GC levels and hippocampal function has been causally implicated in aging. This was judged from increased numbers of reactive astrocytes, activation of microglia, and changes in membrane conductances of hippocampal neurons (Landfield *et al*., 1978, 1981; Kerr *et al*., 1991; Nichols *et al*., 1993; Seckl and Olsson, 1995; Sugaya *et al*., 1996; Rozovsky *et al*., 1998). In later studies in Long–Evans rats, also other markers like superoxide dismutase, β-amyloid precursor protein, and nitric oxide synthase were found to be increased in the aged hippocampus, which paralleled the extent of the age-related learning impairment (Sugaya *et al*., 1996).

Importantly, adrenalectomy of rats at middle age, attenuated hippocampal degeneration and cognitive decline later in life, when compared to aged, intact animals (Landfield *et al*., 1981). Although the latter study seems to confirm that elevated basal GC levels contribute to the development of age-related cognitive impairment and pathology, it should be noted that these animals were supplemented from midlife onward with low levels of corticosterone. This indeed excludes GR effects, but, in view of the above-mentioned differential receptor affinities for cortisol (De Kloet, 1991; De Kloet *et al*., 1998), still allows for a predominant MR occupation, a condition known to promote stability, which may explain the lack of deleterious effects on neuronal viability (De Kloet *et al*., 1998, 1999).

1. Functional Changes

Hypercorticism in young and middle-aged rats frequently results in senescent-like neurophysiological patterns that are

characterized by a general failure to regulate intracellular calcium levels properly. Spatial learning deficits are further found in aged rats, suffering from hypercorticism which often parallels the extent of pathology. Such deficits can also be induced following corticosterone injections, which cause altered electrophysiological function (Gage *et al*., 1984b; Issa *et al*., 1990; Gallagher and Holland, 1992; Dachir *et al*., 1993; Gallagher and Nicolle, 1993; Geinisman *et al*., 1995; Sapolsky, 1996, 1999; Conrad *et al*., 1999; Hebda-Bauer *et al*., 1999). Interestingly, in one study, elevated plasma GC levels were found only in aged rats with spatial memory deficits but not in animals without such deficits, suggesting that not age itself, but rather the extent of the associated hypercorticism, is crucial for alterations in hippocampal function (Issa *et al*., 1990). As was pointed out above, this notion is being disputed, since in aged individuals of the Brown Norway rat strain cognitive decline occurs in the absence of hypercorticism (Van Eekelen *et al*., 1991), while in Fisher 344 × Brown Norway rats, spatial learning impairment was not found even in the very old animals group (32 months), except when changes were made in the environment. Furthermore, after injections with corticosterone, very old Fisher 344 × Brown Norway rats even demonstrated enhanced spatial learning (Hebda-Bauer *et al*., 1999).

Previous studies have already revealed that GCs act via a GR-mediated mechanism to increase the voltage-dependent calcium influx into hippocampal neurons. Hypercorticism induces prolonged and increased calcium dependent after hyperpolarizations, reduced thresholds for eliciting excitatory postsynaptic potentials (EPSP), reduced EPSP amplitudes, and overall increased calcium currents, all conditions know to hamper proper synaptic transmission. The importance of altered calcium regulation in aging is also supported by changes observed in aged animals and associated with neuronal degeneration, in factors involved in intracellular calcium buffering, such as calbindin, calretinin, calmodulin, etc. Furthermore, spatial learning was found to be related to changes in calcium-dependent protein kinases (Fordyce and Wehner, 1993a,b; Colombo *et al*., 1997; Krugers *et al*., 1997b). Pharmacological manipulation of intracellular calcium was further shown to be effective in influencing aspects of cognition in the aged brain (Landfield *et al*., 1978, 1981; Joëls and de Kloet, 1989; Kerr *et al*., 1991; Nair *et al*., 1998; Vekhratsky and Toescu, 1998).

Glucocorticoids also influence long-term potentiation (LTP), an electrophysiological model for memory formation. Interestingly, this also seems to follow a U-shaped dose–response relationship, since in hippocampal slices the long-term potentiation response is impaired only when GC concentrations are either too high or too low (Joëls and De Kloet, 1992; De Kloet *et al*., 1999). The inability to generate LTP in the hippocampus of aged rats, has been attributed to aberrant, high GC exposure in these animals (Kerr *et al*., 1991). A similar dose–response relationship of GCs exists for voltage-dependent ion conductances such as calcium and serotonin 1a-receptor-mediated hyperpolarization (Joëls and De Kloet, 1992; Joëls, 1997; De Kloet *et al*., 1998).

2. Structural Changes

Persistently elevated GC exposure, either resulting from stress or from exogenous application, has been reported to lead to reactive glial cell proliferation, a reduction of the dendritic branching in the CA3 area, reductions in volume, and reduced cell numbers in CA1 and CA3 (Landfield *et al*., 1978, 1981; Sapolsky *et al*., 1985, 1990; Sapolsky, 1996, 1999). Chronic exposure for 6 months to foot shock stress for 4 hr per day resulted in endogenous hypercorticism and induced CA1 pyramidal neuronal loss, but only in senescent rats (Kerr *et al*., 1991). Also, increases in glial fibrillary acidic protein and astrocytic activation have been reported in aged rats quite consistently and in parallel to the extent of the learning deficit (Nichols *et al*., 1993; Sugaya *et al*., 1996). Most studies on high GC exposure, stress, hippocampal viability, and aging, however, were done in rats, applying either rather extreme, often physical, stressors or pharmacologically high GC concentrations (Sapolsky *et al*., 1985; Sapolsky, 1996, 1999; see also Seckl and Olsson, 1995). Studies performed under less extreme, more physiologically relevant conditions, or, for example, in nonrodent species, have so far provided conflicting data (see below).

In most older studies, shrinkage-sensitive density measures were used to assess structural changes, which may cause bias when counting numbers of cells. In order to study the true extent and localization of structural alterations in, for example, the aged hippocampus and neocortex, modern stereology has been a powerful tool, that has modified some of the earlier views considerably (Gundersen *et al*., 1988; Korbo *et al*., 1990; Morrison and Hof, 1997; West, 1999; Long *et al*., 1999). When assessed by means of these tools, rat hippocampal neuron numbers or volume remain relatively stable with age, nor do they seem to be related to cognitive deficits, or be influenced by stress or GC treatment (Rapp and Gallagher, 1996; Rasmussen *et al*., 1996; Sousa *et al*., 1998b, 1999). Also, in both young and aged rats subjected to stress as well as to several steroid treatments, no changes could be found in neuron number after high GC exposure, although some volume reductions were measured in specific (neuron-sparse) subareas of the hippocampus and some loss in DG and CA3 after dexamethasone (Sousa *et al*., 1998a,b, 1999; Rapp *et al*., 1999). Volumetric analysis of the main circuits in the aged rat hippocampus revealed regionally selective and circuit-specific effects of aging, that, for example, were shown to spare the temporal hippocampus (Rapp *et al*., 1999).

Whether the age-related GC changes in conditions of GC overexposure in rodents (Sapolsky, 1996), have indeed structural or neuropathological consequences for the human and primate hippocampus, has been addressed only to a limited extent, and a structural basis for the observed age-related declines in volume and cognition, remains, therefore, so far unclear (Gallagher and Holland, 1992; Convit *et al*., 1995; Gallagher *et al*., 1996; Hyman and Gómez-Isla, 1996; Landfield *et al*., 1996; Reagan and McEwen, 1997; Lupien *et al*., 1998). In humans, the reduction in neuron numbers in the brain during normal aging and in Alzheimer's disease, as assessed with stereological methods, is relatively small and appears to occur only in specific subregions of the cortex, hippocampus, and locus coeruleus (West, 1993; Mouton *et al*., 1994; Hoogendijk *et al*., 1995; Gómez-Isla *et al*., 1996; Morrison and Hof, 1997; Simic *et al*., 1997). The number of neurons in the CA1–3 hippocampal regions, is also relatively preserved during human aging, in spite of the changes in hippocampal

volume as measured by magnetic resonance imaging (West, 1993; Simic *et al*., 1997). Interestingly, the latter changes are in fact related to reductions in memory, which in turn, are preceded by reductions in glucose metabolism in this area (West, 1993; Convit *et al*., 1995; De Santi *et al*., 1995; De Leon *et al*., 1997b; McEwen *et al*., 1999), while also genetic factors like ApoE contribute to this effect (Reiman *et al*., 1998). Furthermore, recent studies using disector methodology to count neuron numbers in the hippocampal of chronical cortisol treated and control, aged rhesus monkeys, failed to find any difference between the groups (Leverenz *et al*., 1999), consistent with similar studies on the tree shrew and rat hippocampus (Vollmann-Honsdorf *et al*., 1997; Sousa *et al*., 1998a,b, 1999).

In major depression, a condition generally associated with an activated HPA axis, GC feedback resistance, hypercorticism as well as a decreased volume of the hippocampus (Raadsheer *et al*., 1994, 1995; Holsboer and Barden, 1996; Sheline *et al*., 1996; Rowe *et al*., 1997; Deuschle *et al*., 1998a; Bremner *et al*., 2000) and reductions in prefrontal lobe and whole brain volume (Kumar *et al*., 1998), detrimental effects on hippocampal viability may be expected as well (Chan *et al*., 1996; Landfield *et al*., 1996; Sapolsky, 1996; Reagan and McEwen, 1997). However, in a well characterized cohort of depressed and steroid-treated patients, no indications could be found for gross anatomical changes nor any obvious neuronal loss or damage was observed using various histological markers, although only very few apoptotic cells were present suggesting that in spite of the enhanced HPA activity, at least large structural changes were not induced in areas at risk for SL over-exposure (Lucassen *et al*., 1997b, 2000; Muller *et al*., 1998, 2000).

These and other studies seem to suggest that hippocampal cell loss does not account for the behavioral or cognitive impairments observed following prolonged stress or hypercorticism, but that these changes are more likely to be reflected by changes in the neuronal network function, its dendrites, or its synapses, rather than in structural changes, like neuronal number (Rapp and Gallagher, 1996; Rasmussen *et al*., 1996; Sousa *et al*., 2000). This conclusion is also consistent with the transient nature of GC-induced brain or neuronal atrophy that appears to allow for recovery or reversal, once the treatment is stopped (Starkman *et al*., 1992; Sapolsky, 1996; Seeman *et al*., 1997). Should massive neuronal loss have been induced, this would be difficult to explain. Stereological studies addressing the extent of synaptic loss, at least in man, are just beginning to appear and also fail to suggest neuronal loss (DeKosky *et al*., 1996; Sze *et al*., 1997; West, 1999). An alternative possibility is that structural degenerative hippocampal changes are induced indirectly, in subcortical neuronal populations, that project to and regulate the function of the hippocampal and cortical circuitry (Arbel *et al*., 1994; Aubert *et al*., 1995; Bodnoff *et al*., 1995; Geinisman *et al*., 1995; Calhoun *et al*., 1998; Dawson *et al*., 1999; Nicolle *et al*., 1999; Phinney *et al*., 1999; West, 1999).

B. Possible Mechanisms Underlying Glucocorticoid-Related Damage

In the previous sections, MR- and GR-mediated GC effects on membrane permeability for ions such as calcium were described. While changes in ion regulation have important consequences for cell function and viability in aging, the underlying mechanisms are not known. Glucocorticoids may induce genes encoding specific membrane proteins, receptors, and subunits of ion channels, but these genomic effects rarely explain the electrophysiological changes in a direct way. Glucocorticoid-induced genes may instead be, for example, kinases involved in activation of ion channel function, but presently there is no evidence for this assumption. In the course of the research on GCs and aging a number of factors and processes have been proposed that could be implicated in the cascade of degenerative changes that accompany the aging process.

1. Metabolic Factors

In terms of possible underlying mechanisms, acute and chronic increases in cortisol suppress hippocampal glucose metabolism, which is known to reflect learning and memory capacity (Gage *et al*., 1984a; Newcomer *et al*., 1994, 1999b; De Leon *et al*., 1997a; Ouchi *et al*., 1998). In rat, GC overexposure accelerated ATP loss (Lawrence and Sapolsky, 1994), inhibited glucose transport in neurons and glia *in vitro*, as well as glutamate uptake in hippocampal astrocytes (Horner *et al*., 1990; Virgin *et al*., 1991). Consistent with these observations, memory impairment was found to be associated with decreased glucose metabolism, appearing most pronounced in the hippocampus compared to the proisocortex and neocortex (Stein *et al*., 1998). Positron emission tomography measurements of cerebral glucose metabolism showed that elderly subjects, as well as individuals at risk for Alzheimer's disease, were characterized by a generalized hypometabolism in the cortical and hippocampal areas, that preceeded subsequent hippocampal volume reductions and reduced performance on a long-term memory test (Convit *et al*., 1995, 1996; De Santi *et al*., 1995; De Leon *et al*., 1997a; Ouchi *et al*., 1998). Furthermore, unlike healthy elderly, no effect of cortisol on the inhibition of glucose metabolism could be demonstrated in patients with Alzheimer's disease (De Leon *et al*., 1997a).

Furthermore, restoration of energy levels, by means of glucose supplementation, could protect the brain and hippocampus from various insults, and improved memory when the brain was exposed to aberrant GC conditions as occurs during aging (Gage *et al*., 1984a; Fordyce and Wehner, 1993a; Sapolsky, 1996; Winocur and Gagnon, 1998; Newcomer *et al*., 1999a). Also, genetic overexpression of the glucose transporter (Lawrence *et al*., 1995, 1996) was shown to protect against stroke or seizure induced cell loss. Similarly, growth-promoting factors, like insulin-like growth factor I expression, which can have beneficial effects on neuronal viability, are suppressed in socially stressed monkeys, attenuated after deafferentiation in aged rats, and modulated by GCs as well (Sapolsky and Spencer, 1997; Islam *et al*., 1998; Woods *et al*., 1998; Sonntag *et al*., 1999). *In vitro* data on cortical neurons further demonstrate similar beneficial effects of high glucose protection against *N*-methyl-D-aspartate, free radicals, and oxygen deprivation (Seo *et al*., 1999). The beneficial effects not only of glucose, but also of insulin supplementation on aspects of rat and human memory and cognition, are interesting to mention here, although this effect is not unequivocal (Winocur and Gagnon, 1998; Craft *et al*., 1999; Newcomer *et al*., 1999a). Together, these observations suggest that inhibition of energy utilization is a critical feature of GC action, and may be a possible mechanism mediating the deleterious consequences of high glucocorticoid exposure.

2. Neurogenesis

Another possibility relates to a unique feature of the dentate gyrus, in which ongoing neurogenesis persists in a large number of rodent species as well as in adult tree shrew, marmosets, rhesus monkey, and human brain (Eriksson *et al*., 1998; Gould *et al*., 1999; Kornack and Rakic, 1999). In contrast to other brain areas, neurogenesis persists from development into old age only in this part of the hippocampus and in the lateral ventricle well. The former is thought to allow the dentate gyrus to continuously rejuvenate its neuronal population in order to adapt to changing situations or demands. Interestingly, not only does stress or enhanced GC levels suppress the frequency of neuronal birth in young, adult (Cameron and Gould, 1994; Gould *et al*., 1998; Gould and Tanapat, 1999), and aged rats, but a number of steroid- and non-steroid-mediated conditions modulate neuronal birth in the adult brain as well. These include enriched environmental housing, increased physical activity through voluntary running, estrogen treatment, amygdala kindling, or training in a hippocampal dependent learning task (Kempermann *et al*., 1998; Parent *et al*., 1998; Tanapat *et al*., 1999; Van Praag *et al*., 1999). Newborn cells were further shown to become functional, as increases in synaptic plasticity, learning performance, long-term potentiation and have been demonstrated (Patel *et al*., 1997; Lee *et al*., 1998; Nilsson *et al*., 1999; Palmer *et al*., 1999).

In aged rats and mice, neuronal birth persists, but at a considerably slower pace. As aging is associated with increased GC levels in some strains, reduction of GC levels in old rats by adrenalectomy was found to restore the rate of cell proliferation to that observed in young animals and resulted in increased numbers of new granule neurons (Cameron and McKay, 1999). These data require scrutiny, however, since these studies were actually performed in middle-aged animals, no information was given on the circulating corticosterone levels, and the data analysis was based on a small number of animals showing substantial individual variation.

Recently, serotonin metabolism, which is regulated by GCs as well (Meijer and De Kloet, 1998; Brezun and Daszuta, 1999), has also been implicated in controlling hippocampal neurogenesis that consequently, may also influence changes in hippocampal volume. This evidence suggests that increased serotonin levels enhance the production of new neurons, that may be mediated via activation of the serotonin 1a receptor (Gould, 1999). This makes it possible to speculate that the inhibitory effects of stress on granule cell production would be preventable by serotonin 1a agonists (Gould, 1999) which is consistent with the idea that volume reductions in parts of the hippocampus after high GC exposure, could be prevented by serotonin reuptake inhibitors and indeed with a study showing that depletion of serotonin decreased neurogenesis in the DG (Brezun and Daszuta, 1999). Whether inhibition of neurogenesis influences synaptic plasticity, or is a main factor in the many GC effects in aging, remains to be further established.

3. Growth Factors

Many investigators have speculated on the role of growth factors like brain-derived neurotrophic factor (BDNF), nerve growth factor (NGF), and their receptors, in the aging process. Most of this interest was based on the early and age-related cholinergic neuronal soma atrophy, which forms an important source of the cholinergic innervation of the hippocampus and neocortex (Sugaya *et al*., 1998). Perturbation of these systems with age has been related to deficits in attention and memory. Interestingly, these behavioral deficits could be prevented or reversed by the administration of some but not all growth factors (Fischer *et al*., 1994), whereas the tyrosine kinase B receptor has also been strongly implicated in hippocampal mediated learning (Minichiello *et al*., 1999). Also, administration of recombinant human NGF was able to prevent the retrograde degeneration of axotomized basal forebrain cholinergic neurons in the rat (Koliatsos *et al*., 1991). In addition, glucocorticoids are known to downregulate the expression and protein levels of growth factors, like BDNF and its receptor, tyrosine kinase B (Smith and Cizza, 1996; Chao *et al*., 1998; Schaaf *et al*., 1998). As growth factors are highly expressed in the hippocampus and involved in many aspects of neuronal viability, they are potentially important for the age-related changes observed in this brain area. Age-related rises in GC levels, for example, could potentially disrupt the mobilization of neurotrophins, whereas abnormal neurotrophic function has been implicated also in human aging and Alzheimer's disease (Salehi *et al*., 1996; Murer *et al*., 1999).

The literature on effects of aging on the expression of hippocampal BDNF mRNA is rather confusing, which may partly relate to the same differences in animal strain, criteria for aging, and methodology as indicated above for studies on GC levels in rodents (see above). BDNF mRNA levels, for example, were found to be decreased in CA3 and CA1 of 18- to 24-month-old Fisher rats (Smith and Cizza, 1996), increased in 28-month-old Long–Evans rats (Sugaya *et al*., 1998) and in hippocampal homogenates of 18-month-old animals of the same strain (Narisawa-Saito and Nawa, 1996), but remained unchanged in hippocampal fields of Spraque–Dawley and Fisher rats up to 24 months of age (Lapchak *et al*., 1993). Furthermore, the low and high affinity receptors for NGF, were found to be reduced in the basal forebrain and septal area of aged rats, in parallel with spatial learning deficits. While NGF concentrations in the hippocampus were reduced in aged and spatially impaired rats, other reports show no change or even increased levels. Chronic environmental enrichment was shown to increase NGF concentrations in the adult rat hippocampus and also to induce GR, but not MR gene expression in specific hippocampal subfields. In addition, it proved to be protective against focal brain ischemia (Dahlqvist *et al*., 1999; Phan *et al*., 1999; Smith *et al*., 1999). However, in brains from patients with Alzheimer's disease, significant, differential reductions were found in the expression of the tyrosine kinase receptors trkA, trkB, and trkC in the nucleus basalis of Meynert, which implies a decreased neurotrophin responsiveness of the cholinergic system in this condition (Salehi *et al*., 1996).

Taken together, these data suggest that altered hippocampal synaptic plasticity as it may occur in the aged brain, is not consistently reflected by changes in the expression of growth factors, or their receptors. However, the age-associated spatial learning impairments in rats could be reversed by administration of some but not all growth factors (Fischer *et al*., 1994), that proved beneficial also after lesions (Mandel *et al*., 1999). Recently, in rhesus monkeys, learning impairments as well as the associated atrophy of subcortical cholinergic neurons could even be reversed using neurotrophin gene therapy (Smith *et al*.,

1999). Together with its protective role in ischemia, this suggests that growth factors still hold some potential for treating age- or stress-related changes, and possibly in the hippocampus as well.

V. Concluding Remarks

In this chapter we have discussed whether corticosteroids are the cause or consequence of brain aging and age-related brain pathology. Although the lability of the HPA axis is increased during aging, recent data challenge the view that elevated corticosteroid levels are generally, and consistently, associated with aging. However, if corticosteroid levels circulate in chronically aberrant concentrations, either too high, or too low, they increase the vulnerability to cognitive decline and disease, rather than the aging process *per se*. The mechanisms underlying one of the most obvious characteristics of the aging process, the great individual variation within an aged group, is poorly understood, but early life events appear to be important for the quality of cognitive performance at old age.

Glucocorticoids mediate their action through mineralocorticoid and glucocorticoid receptors, which are colocalized in hippocampal neurons, but have different affinities and opposing actions. The MR operates in a proactive mode, whereas GR facilitates in a reactive manner, the recovery of homeostasis following perturbation by stress. Together, these steroid receptors effect changes and adaptive processes in the brain and its behavior, by controlling expression of specific target genes involved in many fundamental brain processes like neuronal excitability, calcium homeostasis, energy metabolism, and cell division. Therefore, both MR and GR are critical in the maintenance of homeostasis during neuronal aging. Depending on additional environmental and genetic factors, an imbalance in their actions can result in altered stress regulation, cognitive decline and impaired behavioral adaptation, which could further result in dysregulation through the same genes that are otherwise essential for maintaining homeostasis and health.

The corticosteroid receptors and genes under their control, are therefore not only critical for successful aging, they form at the same time excellent molecular targets for drugs, based on restoring a disturbed neuronal homeostasis through correction of the MR/GR imbalance, and thus to promote the restorative capacity that is still present within the aging brain.

Acknowledgments

This contribution was supported by Grants 903-54-545, 100-007, and 903-43-132 from the Netherlands Organization for Scientific Research (NWO) and by Grant 96-509 from the Internationale Stichting Alzheimer Onderzoek (ISAO). We thank Drs. R. De Rijk and O. C. Meijer for their help with the preparation of the figures.

Growth Hormone, Insulin-like Growth Factor-1, and the Aging Brain

I. Introduction

It is widely accepted that biological aging is a consequence of functional and morphological changes in tissues that result in an increased susceptibility to disease. Although the etiology of these age-related changes continues to be rigorously debated, recent studies have unequivocally established that a decline in several anabolic hormones occurs in aged animals and that hormone replacement therapy is capable of increasing tissue function and, in some cases, preventing the age-related decline in tissue function. These results have led to the conclusion that at least part of the aging phenotype results from hormone deficiency, especially deficiencies in anabolic hormones that regulate tissue growth, maintenance, and repair. To date, two hormones that are capable of reversing the catabolic processes associated with age include growth hormone and insulin-like growth factor-1 (IGF-1). Although the actions of these hormones on peripheral tissues of aging animals are well-established, new data suggest that these hormones may have a critical role in aging of the brain and the cerebrovasculature. In this chapter, age-related changes in the somatotropin pathway is reviewed and the potential contributions of deficiencies in growth hormone and insulin-like growth factor-1 are discussed in relation to age-related changes in the brain and brain vasculature.

II. Overview

A. History

In the early 1900s, a substance was found in blood that promoted body growth in young animals and was later demonstrated to be a secretory product of the pituitary gland (Evans and Long, 1921). However, it was not until 1944 that bovine growth hormone was isolated (Li and Evans, 1944) and subsequently human growth hormone was isolated in 1956 (Li and Papkoff, 1956). Data established that this hormone stimulated amino acid uptake into tissue, increased DNA, RNA, and protein synthesis, and had an important role in cell division and tissue hypertrophy. An assay for measuring plasma concentrations of growth hormone was developed by Utiger *et al*. (1962) and the amino acid sequence was determined in 1969 (Li *et al*., 1969; Niall, 1971).

As early as 1957, Salmon and Daughaday suggested that the growth promoting actions of growth hormone were mediated by a serum factor initially called sulfation factor. Data demonstrated that this factor was regulated by growth hormone and promoted the incorporation of sulfate into cartilage. These data subsequently led to the identification of the somatomedin family of hormones (Van Wyk *et al*., 1974), which are low-molecular-weight peptides ($\sim$7.5 kDa) that circulate in plasma at high concentrations. Because of their structural similarity to proinsulin, they are also termed the insulin-like growth factors (IGF-1 and IGF-II) (Rinderknecht and Humbel, 1978). IGF-1 binds with high affinity to the type 1 IGF receptor, which is widely distributed in tissues throughout the body and mediates the trophic actions of IGF-1. Until recently, it had been widely accepted that IGF-1 was produced only in the liver (Beach and Kostyo, 1968; Goldspink and Goldberg, 1975) and mediated all of the effects of growth hormone. However, it is now understood that IGF-1 is also produced in virtually every tissue and has important local autocrine and paracrine actions (Daughaday and Rotwein, 1989). These studies have led to the concept that growth hormone increases plasma concentrations of IGF-1 and regulates the secretion of IGF-1 at the tissue level, thereby modulating the paracrine and autocrine activities of IGF-1.

IGF-1 circulates in the blood either free ($t_{½}$ of 15–20 min) or bound to specific binding proteins. At present, six binding proteins have been identified (Binoux *et al*., 1986) and these proteins constitute a complicated transport system for the IGFs that serve to facilitate or inhibit the actions of IGF-1 at the target tissues (Kelley *et al*., 1996). Recent studies have also identified proteases that degrade IGF binding proteins, thereby modifying the availability of IGF-1 for its receptor (Lee *et al*., 1993). Thus, although growth hormone is a primary stimulus for cellular anabolic processes through its actions on IGF-1 secretion, a complex hierarchy of factors exists to

regulate the interaction of IGF-1 with its receptor (see reviews by Jones and Clemmons, 1995; Clemmons, 1997).

B. Neuroendocrine Regulation of Growth Hormone and Insulin-like Growth Factor-1

Studies revealed that secretion of growth hormone from the anterior pituitary occurs in discrete pulses throughout the day with the highest levels occurring approximately 2 hr after onset of sleep (Finkelstein *et al*., 1972). Although the precise function of this ultradian pattern remains unknown, the pulsatile release of growth hormone has been confirmed in every species studied to date and is necessary for full biological activity of the hormone. In humans, growth hormone is released in relatively low-amplitude pulses throughout the day and in a large pulse at night that occurs in close association with slow-wave sleep (Quabbe *et al*., 1966; Takahashi *et al*., 1968; Goldsmith and Glick, 1970). Conversely, the growth hormone pulsatile pattern in rodents occurs every 3.5 hr in males (Tannenbaum and Martin, 1976) and hourly in females (Terry *et al*., 1977). It was later discovered that the pulsatile nature of growth hormone release is regulated by two hypothalamic hormones: (1) growth hormone-releasing hormone (GHRH) which stimulates the release of growth hormone (Rivier *et al*., 1982; Ling *et al*., 1984), and (2) somatostatin, which inhibits release (Brazeau *et al*., 1973). The dynamic interaction of these two hypothalamic hormones is responsible for the high-amplitude, pulsatile release of growth hormone. The results of several studies suggest that both hypothalamic hormones are secreted in a phasic manner with release of GHRH and suppression of somatostatin resulting in an increase in pulse amplitude of growth hormone while suppression of GHRH and release of somatostatin contributes to the reduced growth hormone levels observed during trough periods (Tannenbaum and Ling, 1984). Growth hormone circulates in blood and binds to receptors in hepatic tissue, thereby increasing plasma levels of IGF-1. Growth hormone inhibits further growth hormone release in a typical feedback mechanism at the level of the hypothalamus and pituitary gland (Berelowitz *et al*., 1981). For instance, growth hormone administration inhibits the subsequent release of growth hormone in response to GHRH (Nakamoto *et al*., 1986) and stimulates the release of somatostatin (Wehrenberg *et al*., 1992). Similarly, IGF-1 has also been shown to feed back at both the hypothalamus and the pituitary and inhibits release of growth hormone by attenuating the growth hormone response to GHRH and by stimulating hypothalamic somatostatin release (Berelowitz *et al*., 1981; Ceda *et al*., 1987; Aguila *et al*., 1993; Bermann *et al*., 1994; Korbonits *et al*., 1996).

C. Biological Actions of Growth Hormone and Insulin-like Growth Factor-1

It was established in 1912 that growth hormone promotes longitudinal growth (Aschner, 1912) but the levels of growth hormone after the pubertal growth period suggested that this hormone had important regulatory actions in addition to body growth. It is now well-established that growth hormone has significant effects on protein, carbohydrate, and fat metabolism, and regulates body composition, cardiac function, and renal hemodynamics, both directly and indirectly through IGF-1 in an endocrine and/or paracrine manner. In addition, recent studies have demonstrated that both growth hormone and IGF-1 have significant actions in the central nervous system and may be essential to maintain neuronal function. These actions suggest that adequate levels of growth hormone and IGF-1 are critical in many tissues throughout life to maintain normal homeostasis.

In bone, growth hormone and IGF-1 have been shown to work in concert. In children, growth hormone induces differentiation of precursor cells into chondrocytes at the epiphyseal growth plate (Clark *et al*., 1985). Growth hormone also stimulates local production of and increases tissue responsiveness to IGF-1 (Isgaard *et al*., 1988). In turn, IGF-1 stimulates clonal expression of chondrocytes which are necessary for longitudinal bone growth. Growth hormone promotes retention of minerals, such as sodium, potassium, and phosphorus and produces an increased excretion of calcium as well as increased calcium absorption from the intestine (Burstein *et al*., 1983; Marcus *et al*., 1990; Binnerts *et al*., 1992; Antoniazzi *et al*., 1993; Bengtsson *et al*., 1993). More importantly, both growth hormone and IGF-1 have a direct action on osteoblasts (Langdahl *et al*., 1998). Growth hormone stimulates osteoblast formation and differentiation and IGF-1 supports osteoblast activity by increasing osteocalcin production (Kassem *et al*., 1994; Brixen *et al*., 1995). Together, these actions result in increased bone growth in children and maintenance of bone density in adults.

Growth hormone and IGF-1 are also essential for increasing amino acid uptake and protein synthesis at the cellular level. More specifically, early studies were able to show that growth hormone can stimulate amino acid transfer from the extracellular to the intracellular compartment (Noall *et al*., 1957; Riggs and Walker, 1960; Staehelin, 1962). The diminished total amino acid content of cartilage observed in hypophysectomized rats is replenished with growth hormone administration. Growth hormone also stimulates [^{3}H]leucine incorporation into muscle (Kostyo, 1968; Nutting, 1976; Nutting and Coats, 1977) and there is evidence that this effect of growth hormone may be secondary to an increase in tissue IGF-1. In addition, growth hormone has been reported to increase protein synthesis in the tibia (J. A. Martinez *et al*., 1991; D. A. Martinez *et al*., 1996), collagen content in rat skin (Jorgensen *et al*., 1989), rate of wound healing (Barbul *et al*., 1983; Jorgensen *et al*., 1989), and synthesis of erythropoietin (Merchav *et al*., 1988; Christ *et al*., 1997; Jorgensen *et al*., 1997).

Data also indicate that growth hormone has an important role in the regulation of adipose tissue. Studies indicate that growth hormone reduces adipose mass in several species (Bassett and Wallace, 1966; Lee *et al*., 1975) and similar results have been reported in older men (Rudman *et al*., 1991; Jorgensen *et al*., 1994; Thompson *et al*., 1995). It has also been demonstrated that growth hormone retards lipogenesis by decreasing enzyme activity. For instance, chronic administration of growth hormone to hypophysectomized rats results in inhibition of glyceride synthesis and decreased body fat composition (Goodman, 1963). In addition, acute growth hormone treatment decreases fatty acid synthesis in liver and facilitates mobilization of fatty acids from adipose tissue.

It is becoming increasingly clear that growth hormone and IGF-1 are important in maintaining several systems in the

body. For instance, data demonstrate that growth hormone deficiency results in impairments in immune function (Gelato, 1996; Geffner, 1997), cardiac dysfunction (Lombardi *et al*., 1997a,b), and reproductive dysfunction (Homburg and Farhi, 1995). These studies also demonstrate that administration of growth hormone reverses these deficits and thus suggest that normal somatotropin activity is necessary for adequate function of these systems throughout life.

One of the more recent areas of research on the biological actions of growth hormone and IGF-1 is their action within the CNS. Growth hormone receptors and its mRNA have been identified in the brains of rats (Zhai *et al*., 1994), rabbits (Lobie *et al*., 1993), and humans (Sara *et al*., 1982; Lai *et al*., 1993). Although expression is ubiquitous throughout the brain, the highest levels of expression are found in the frontal lobe of the cortex, cerebellum, hippocampus, amygdala, hypothalamus, choroid plexus, thalamus, and glial cells in the cingulum. As expected, it was also demonstrated that the highest level of binding in the brain is in the pituitary and hypothalamus and is important for the negative feedback regulation of its secretion. Despite the presence of growth hormone receptors, localization of growth hormone in the brain is controversial (Hojvat *et al*., 1982; Gossard *et al*., 1987). Additionally, it has not been determined whether growth hormone has direct actions in the brain. Nonetheless, patients receiving chronic, subcutaneous injections of growth hormone report improvements in mood, alertness, vitality and in the comprehensive psychological rating scale (McGauley 1989; McGauley *et al*., 1990; Bengtsson *et al*., 1993; Nyberg and Burman, 1996). Reports have also demonstrated that growth hormone administered subcutaneously has an effect on the turnover of dopamine in the brain via actions on the N-methyl-D-aspartate receptor system (Burman *et al*., 1993), increases the levels of the excitatory amino acid aspartate (Nyberg and Burman, 1996), increases cerebrospinal fluid concentrations of β-endorphin (Johansson *et al*., 1995), and increases cerebral vasculature density (Sonntag *et al*., 1997). Nevertheless, it is currently unknown if the actions of growth hormone on the brain are mediated by increasing peripheral or vascular-derived IGF-1 or whether growth hormone crosses the blood–brain barrier and has direct actions on neurons and/or glia. In this regard, growth hormone administration has been shown to increase the gene expression of IGF-1 in the brain (Lopez-Fernandez *et al*., 1996) and increases the cerebrospinal fluid concentration of IGF-1 (Johansson *et al*., 1995) suggesting that peripherally administered growth hormone may exert an influence on neuronal function by increasing IGF-1 levels. Since the cerebral vasculature has been shown to be an important source for some neurotrophic factors, including nerve growth factor and IGF-1, and these factors have the potential to have important trophic effects on surrounding neuronal tissues (Delafontaine, 1995; Sonntag *et al*., 1997), one potentially interesting hypothesis is that growth hormone acts by regulating vascular-derived growth factors, including IGF-1.

Both IGF-1 mRNA and protein are expressed in the developing and mature brain (Carlsson-Skwirut *et al*., 1986; Rotwein *et al*., 1988) and the type 1 IGF receptor is widely distributed throughout the brain (Sara *et al*., 1982). It is well known that IGF-1 is involved in several aspects of brain function including neuronal growth and differentiation during development and adulthood and brain metabolism. Data strongly suggest that IGF-1 also has an important role as a neurotrophic factor and/or neuromodulator in the CNS. For example, IGF-1 has been shown to support the differentiation of cortical neurons, proliferation of oligodendrocytes (McMorris and Dubois-Dalcq, 1988; Saneto *et al*., 1988; van der Pal *et al*., 1988), synaptogenesis (Ishii, 1989), and neuronal repair (Hansson *et al*., 1986; Sjöberg and Kanje, 1989; Nachemson *et al*., 1990). Electrophysiological and biochemical studies have shown that IGF-1 influences acetylcholine synthesis and release (Sara and Hall, 1990), glutamate activity (Castro-Alamancos and Torres-Aleman, 1993), dopamine release (Beck *et al*., 1993; Beck, 1994), dopamine D_2 receptor activity (Thornton *et al*., 1998), and NMDA receptors by regulating the subunit composition of NMDA receptors (Sonntag *et al*., 2000). Recent data have also demonstrated that the actions of neurotrophic agents (such as nerve growth factor, epidermal growth factor, and brain-derived neurotrophic factor) may be mediated, at least in part, by IGF-1 (Torres-Aleman *et al*., 1990; Han *et al*., 1992; Beck *et al*., 1993). These studies demonstrate that IGF-1 has an important role as a neurotrophic agent and may be essential in maintaining neuronal function throughout life.

III. Growth Hormone, Insulin-like Growth Factor-1, and Aging

A. Age-Related Impairments in the Somatotropin Pathway

1. Growth Hormone Pulse Amplitude

Many researchers have studied the effect of aging on growth hormone secretory dynamics. Initial studies in elderly humans found a decline in the release of growth hormone in response to several stimuli, including insulin-induced hypoglycemia and arginine administration (Laron *et al*., 1970). Subsequent studies suggested that the nocturnal surges of growth hormone are diminished in aged humans (Carlson *et al*., 1972; Finkelstein *et al*., 1972). Although several researchers initially found no change in plasma growth hormone levels in aged humans (Dudl *et al*., 1973; Elahi *et al*., 1982), further investigation revealed that serial sampling of blood is essential to assessing growth hormone secretory dynamics. Subsequent analysis of plasma growth hormone levels by obtaining plasma samples at brief intervals indicated that the pulsatile release of growth hormone is at its zenith during late puberty and gradually declines with age (Martha and Reiter, 1991; Martha *et al*., 1992; Rudman, 1985; Vermeulen, 1987). Iranmanesh *et al*. (1991) revealed through analysis of healthy, nonobese men between the ages of 21 and 71 that the synthesis rate of growth hormone declines by 14% and the half-life of growth hormone declines by 6% with each successive decade of life after 20 years of age. Furthermore, both the amplitude and number of growth hormone secretory bursts have been demonstrated to decrease in adults over 50 years of age (Carlson *et al*., 1972). Data from animal studies are consistent with the human data. For example, a significant decline in the pulse amplitude of growth hormone is found in aged male rats (Sonntag *et al*.,

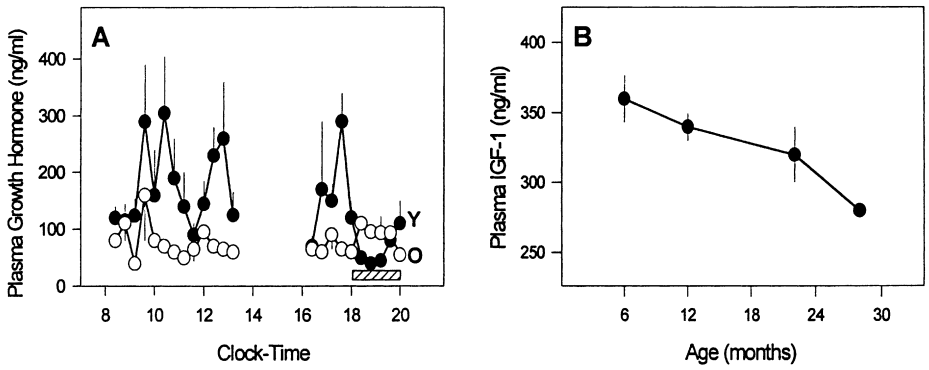

FIG. 63.1. (A) Mean plasma growth hormone concentration in young (Y) and old (O) male rats. Each point represents the mean for 2–15 animals per time point and data are presented as mean ± SEM. The dark phase of the light:dark cycle begins at 18:00 hr and is indicated by the horizontal bar. Adapted from Sonntag *et al.*, 1980, with permission. (B) Age-related decrease in plasma IGF-1.

1980) (Fig. 63.1A) and a similar reduction is observed in aged female rats (Takahashi and Meites, 1987). This age-related phenomenon has been observed in every species studied to date with a decline of approximately 50% in growth hormone amplitude release occurring in aged animals when compared to levels observed in young animals.

The mechanism responsible for the age-related decline in growth hormone secretion potentially results from structural and/or functional alterations within the hypothalamic–hypophyseal axis. Since it is not technically feasible to measure the phasic release of GHRH or somatostatin in humans, the majority of studies investigating the decline in growth hormone release were completed in animal models. Studies had previously demonstrated that passive immunization with GHRH antiserum results in a complete inhibition of the pulsatile secretion of growth hormone (Wehrenberg *et al.*, 1982), whereas passive immunization with somatostatin antiserum results in an increase in the pulse amplitude of growth hormone in young animals (Arimura *et al.*, 1976), demonstrating the necessity of both hypothalamic hormones for normal growth hormone pulses. Furthermore, infusion of somatostatin antisera to old animals increased growth hormone to levels observed in young animals (Sonntag *et al.*, 1981). To date, numerous studies have supported the hypothesis that somatostatin secretion increases with age and contributes to the age-related decline in growth hormone pulse amplitude. For instance, a decline in the number of somatostatin receptors in pituitaries of aged animals has been reported and is consistent with an increased release of somatostatin (Spik and Sonntag, 1989). Researchers have also determined that an increase in total somatostatin content in the pituitary is found with age and an increased ratio of somatostatin-28 to somatostatin-14 is found in aged animals (Sonntag *et al.*, 1986). As somatostatin-28 has been shown to be more biologically potent than somatostatin-14, it was concluded that there may be age-related alterations in posttranslational processing of somatostatin that result in an increased somatostatinergic tone in the aged animal and contribute to the age-related decline in growth hormone pulse amplitude. Although many studies have identified age-related increases in somatostatin levels and activity with age, other studies also suggest that a deficiency in GHRH secretion may be equally important (Morimoto *et al.*, 1988). Studies indicated that the acute response to GHRH was reduced in aged rats (Sonntag *et al.*, 1983), dogs (Cella *et al.*, 1993) and humans (Shibasaki *et al.*, 1984), but more recent studies suggest that chronic GHRH administration restores this response (Corpas *et al.*, 1992b). Further studies revealed that a modest decline in sensitivity to GHRH occurs with age due to a decline in GHRH secretion (DeGennaro *et al.*, 1989; Abribat *et al.*, 1991; Deslauriers *et al.*, 1991). Thus, these data suggest that impairments in the regulation of and response to GHRH secretion as well as an increased level of somatostatin appear to contribute to the age-related decline in growth hormone secretory dynamics.

Several other factors regulate the release of growth hormone and many are also known to decline with age. It has been established that plasma testosterone and estradiol modulate the release of growth hormone (Martha and Reiter, 1991). Plasma estradiol levels are highly correlated with growth hormone and IGF-1 levels (Dawson-Hughes *et al.*, 1986; Ho *et al.*, 1987) and growth hormone secretion declines more rapidly in females after ovariectomy or menopause (Ho and Weissberger, 1990; De Leo *et al.*, 1993). Furthermore, administration of estradiol in postmenopausal or ovariectomized women results in an increased response to GHRH and an elevated growth hormone secretion (Friend *et al.*, 1996; Ho *et al.*, 1996). Similarly, androgen treatment increases the secretion of growth hormone in men with hypogonadrotropic hypogonadism (Martin *et al.*, 1968) and in boys with delayed puberty (Illig and Prader, 1970). Another factor that influences the release of growth hormone is obesity. While it has long been known that growth hormone decreases adiposity, only recently has an increased adiposity been demonstrated to reduce the pulsatile release of growth hormone and shorten the half-life of growth hormone (Iranmanesh *et al.*, 1991; Veldhuis *et al.*, 1991). In addition, the growth hormone secretory response to a GHRH stimulus is diminished in both men and women that exhibit increased adiposity (Kelijman and Frohman, 1988). Since aging is associated with a decline in estradiol and testosterone and an increase in adiposity, it is possible that these factors augment the decline in growth hormone secretion and contribute to the overall deficits in the somatotropin pathway with age.

2. Tissue Resistance to Growth Hormone

In addition to the age-related decline in growth hormone pulse amplitude, recent data also suggest that the response of tissues to growth hormone is diminished in the aged animals. Although a twofold increase in growth hormone receptor density has been reported in hepatic tissue with age (Takahashi and Meites, 1987), further investigation demonstrated that the activity of the growth hormone receptor, as measured by IGF-1 gene expression, declined by 40–50% with age (Xu *et al*., 1995) but no age-related changes in the affinity of the receptor were noted. Subsequent studies in our laboratory demonstrated that the decline in growth hormone receptor activity results from deficits in the signal transduction pathway of the receptor. Xu *et al*. (1995) reported that both growth hormone-induced JAK2 and growth hormone receptor phosphorylation were reduced in aged rodents in response to stimulation with growth hormone and that these impairments contribute to the suppression of MAP kinase activity and IGF-1 gene transcription and release. More recent data demonstrated that the growth hormone-induced phosphorylation and nuclear translocation of STAT3 were diminished in the aged animal (Xu and Sonntag, 1996). These impairments in the signal transduction of growth hormone are believed to result in a diminished tissue responsiveness to the hormone and contribute to the overall somatotropin deficiency.

3. Plasma and Brain Insulin-like Growth Factor-1

Previous studies indicate that plasma IGF-1 declines with age in humans and animals (Florini and Roberts, 1980; Florini *et al*., 1981; Rudman *et al*., 1981, 1990; Sonntag *et al*., 1992) (Fig. 63.1B). The primary source of plasma IGF-1 is the liver and the age-related decline in plasma IGF-1 is the direct result of a decline in hepatic IGF-1 gene expression (Breese *et al*., 1991). Since growth hormone is the major regulator of IGF-1 gene expression and secretion in the liver, the decline in growth hormone secretion and impairments in its signal transduction pathway are considered to be important, if not primary, factors contributing to the decline in hepatic IGF-1 gene expression and subsequently the reduction in plasma IGF-1 (Johanson and Blizzard, 1981; Rudman *et al*., 1990). This latter conclusion is supported by recent studies demonstrating that IGF-1 secretion in response to a growth hormone stimulus is diminished in elderly humans and animals (Lieberman *et al*., 1994; Xu *et al*., 1995). In addition to the age-related decline in plasma IGF-1, analysis of IGF binding proteins have also revealed age-related alterations. IGF binding protein-3, the major carrier of IGF-1 in plasma, has been shown to decline between 18 and 65 years of age (Baxter and Martin, 1986; Donahue *et al*., 1990; Corpas *et al*., 1992a). Frost *et al*. (1996) reported that IGF binding protein-1 increased in older individuals. Moreover, these investigators also found that IGF binding protein-1 was hyperphosphorylated, an event that significantly increases the binding affinity for IGF-1, thereby diminishing the bioavailability of IGF-1 in the elderly. Although the direct significance for tissue IGF-1 activity is unclear, serum IGF binding protein-4 was shown to increase, whereas serum IGF binding protein-5 declines with age (Mohan *et al*., 1995). These data suggest that not only does a deficit in plasma IGF-1 occur with age, but the alterations in levels of IGF binding ptoteins may reduce the bioavailability and/or $t_{1/2}$ of IGF-1.

TABLE 63.1 Insulin-like Growth Factor-1 Protein Expression in Cortex from Young (11 Months), Middle-Age (24 Months), and Old (32 Months) Male Fisher 344 × Brown Norway Rats

Age (months)	ng IGF/g tissue	% Change from young
11	37.8 ± 4.0	—
24	36.5 ± 4.9	3.4
32	$24.0 \pm 3.6^{*}$	36.5

$^{*}P < 0.05$ compared to 11- and 24-month-old animals.

Although deficiencies in the peripheral IGF-1 axis are well-known, only recently have the deficiencies in IGF-1 been studied in the brain, despite the fact that many events associated with brain aging appear to be consistent with deficits in IGF-1. Initial studies demonstrated that IGF-1 gene expression either decreases or remains unchanged in the aged animal (Lopez-Fernandez *et al*., 1996; Niblock *et al*., 1996). Nevertheless, recent studies report that IGF-1 protein expression in the cerebral cortex declines by 36.5% in the aged (32-month) rat compared to a young, adult (11-month) rat (Sonntag *et al*., 1999) (Table 63.1). Furthermore, the mRNA for the type 1 IGF receptor remains unchanged with age while the density of type 1 IGF receptors in cortical layers II/III and V/VI of rats, analyzed by [^{125}I]IGF-1 binding, increased 19.8 and 16%, respectively, between 10 and 19 months but declined by 20.7 and 27.3%, respectively, between 19 and 29 months of age. A similar age-related decrease was observed in the hippocampus (Fig. 63.2, see color insert). To date, analysis of IGF binding proteins in the brain has not been undertaken. Since age-related alterations in plasma IGF binding proteins have been found, it is likely that changes in brain expression of IGF binding proteins also occur and may have a critical role in regulating the activity of IGF-1 in the aging brain. However, it is clear that deficits in the IGF-1 axis occur in the aged brain suggesting that these deficits have the potential to contribute to brain aging.

B. Replacement of Growth Hormone and Insulin-like Growth Factor-1

Because aging has similar clinical and biochemical features to growth hormone-deficient humans and animals, it has been hypothesized that the age-related decline in growth hormone pulse amplitude and plasma IGF-1 contribute to the phenotype of aging (Marcus *et al*., 1990; Christiansen and Jorgensen, 1991; Jorgensen, 1991). The initial studies on growth hormone replacement in the aged were done in rodents and revealed that growth hormone restores tissue protein synthesis in old animals to levels observed in young animals (Sonntag *et al*., 1985) and increases plasma IGF-1 levels (Johanson and Blizzard, 1981). Replacement of growth hormone in elderly humans indicated important alterations in body composition (Rudman, 1985), including improved nitrogen balance (Marcus *et al*., 1990), increased lean body mass, increased skin thickness, increased density of lumbar vertebrae, decreased fat mass, and restored IGF-1 levels (Rudman *et al*., 1990).

Other reports demonstrated that growth hormone or IGF-1 replacement increases the expression of aortic elastin (Foster *et al*., 1990), partially restores the decline in immune function (Kelley *et al*., 1986), and increases the life span of rodents (Khansari and Gustad, 1991). In aged rodents, growth hormone and/or IGF-1 administration has been shown to reverse the age-related decline in thymic function and improve immune responses of both B and T lymphocytes (Kelley *et al*., 1988; Kelley, 1990), thereby improving immune function. To date, there are no reports of the effect of growth hormone administration on immune function in older men and women. However, there are some reports that growth hormone administration results in elevations in osteocalcin, urinary hydroxyproline, and nitrogen balance, suggesting that growth hormone may delay or reverse osteoporosis (Marcus *et al*., 1990; Kaiser *et al*., 1991).

Administration of GHRH has been shown to be an alternative method of increasing endogenous growth hormone secretion. In growth hormone-deficient children, administration of GHRH results in accelerated growth (Gelato *et al*., 1985a,b; Martha *et al*., 1988) and the diurnal profile of growth hormone secretion remains normal during long-term GHRH therapy (Martha *et al*., 1988; Vance *et al*., 1989). Furthermore, treatment with GHRH for 8–14 days in older humans was found to reverse the age-related reductions in plasma levels of growth hormone and IGF-1 and maintain normal diurnal pulsatile release of growth hormone (Corpas *et al*., 1992b). More recent studies of GHRH administration to adults suggest that nightly GHRH injections activate the growth hormone axis and improve deficits in lean body mass, insulin sensitivity, skin thickness, and psychological well-being (McGauley *et al*., 1990; Khorram *et al*., 1997).

Studies on replacement of growth hormone and/or IGF-1, correlated with the actions of these hormones, provide important indications that the decline in growth hormone secretory dynamics and plasma IGF-1 in aged animals and man has clinical significance. The deficiencies in the somatotropin pathway may be responsible, at least in part, for the generalized catabolic state that accompanies normal aging. However, only recently have growth hormone and IGF-1 been studied in the aging brain despite data that suggest that these hormones have important actions in the brain and that deficiencies associated with brain aging are consistent with a deficiency in growth hormone and/or IGF-1 (Fig. 63.3, see color insert).

IV. Memory and Age

A. Age-Related Impairments

A decline in cognitive function has been well-documented in aged animals and man. For example, nonhuman primates exhibit impairments in tasks that measure memory including delayed response and delayed non-match-to-sample tasks (Bartus *et al*., 1978; Arnsten and Goldman-Rakic, 1985; Presty *et al*., 1987; Moss *et al*., 1988; Rapp and Amaral, 1989). Age-related deficits in rodent are also observed in tasks sensitive to spatial reference memory such as the Morris water maze and the Barnes maze (Barnes 1979; Ingram *et al*., 1981; Gage *et al*., 1984; Rapp *et al*., 1987; Gallagher and Burwell, 1989) as well as tasks that emphasize spatial working memory such as the radial arm maze and alternation tasks (Barnes *et al*., 1980; Zornetzer *et al*., 1982). Furthermore, many studies indicate that elderly humans also exhibit memory deficits (Light, 1991). For instance, compared to 20-year-old adults, elderly humans exhibit impairments in free recall, cued recall, and recognition memory (Craik, 1977; Burke and Light, 1981; Poon, 1985; Guttentag and Madden, 1987; Guttentag and Hunt, 1988; Howe, 1988; Hultsch *et al*., 1990). Older adults also show deficits in other memory tasks that represent activities of daily living (West and Crook, 1990; West *et al*., 1992), including recall of information from medicine labels (Morrell *et al*., 1989), recall of topographic information near their homes (Rabbitt, 1989), appearance of common objects (Foos, 1989), activities of daily living (Kausler and Lichty, 1988), and names and faces of acquaintances (Bahrick, 1984; Maylor, 1990). While much research has been undertaken to understand the mechanisms of learning and memory and the etiology of the cognitive decline with age, the specific mechanisms for these impairments remain unknown.

Many researchers have evaluated the role of the neurotrophin family of growth factors, including nerve growth factor (NGF), brain-derived neurotrophic factor (BDNF), and neurotrophin (NT) 3 and 4/5 in brain aging. Intracerebroventricular infusion of NGF has been reported to improve spatial memory in aged rats (Fischer *et al*., 1987; Fischer, 1994; Markowska *et al*., 1994, 1996; Chen *et al*., 1995). NT-3 and -4/5 infused intracerebroventricular has also been shown to improve spatial memory in rodents, but BDNF was without effect (Fischer *et al*., 1994). While it is apparent that this family of neurotrophins is important in the maintenance and survival of neurons and improves indices of behavioral performance in older animals, the clear demonstration of an age-related decline in these trophic agents is controversial. For instance, some researchers have determined that NGF mRNA levels remain constant (Alberch *et al*., 1991; Crutcher and Weingartner, 1991), increase (Hellweg *et al*., 1990; Katoh-Semba *et al*., 1991; Hasenohrl *et al*., 1997), or decrease (Larkfors *et al*., 1987) with age. Moreover, BDNF mRNA increases with age in the cortex and hippocampus while the protein levels of BDNF, NT-3, and NGF remain constant in the cortex and hippocampus when adult and aged rats are compared (Narisawa-Saito and Nawa, 1996). Together, these studies indicate that members of the neurotrophin family are capable of ameliorating age-related memory impairments but the lack of an age-related decline in these trophic factors suggest that either other aspects of growth factor function (e.g., signal transduction) are impaired with age or that these factors may not have a significant role in normal physiological and functional deficits observed in the aging brain.

B. Effects of [D-Ala^2] Growth Hormone Releasing Hormone

[D-Ala^2]GHRH has been shown to increase growth hormone pulse amplitude and plasma IGF-1 in growth hormone-deficient children and adults (Martha *et al*., 1988; Vance *et al*., 1989; Corpas *et al*., 1992b) and activate the growth hormone axis (Khorram *et al*., 1997; McGauley *et al*., 1990). Since IGF-1 has been shown to exert potent trophic effects in the

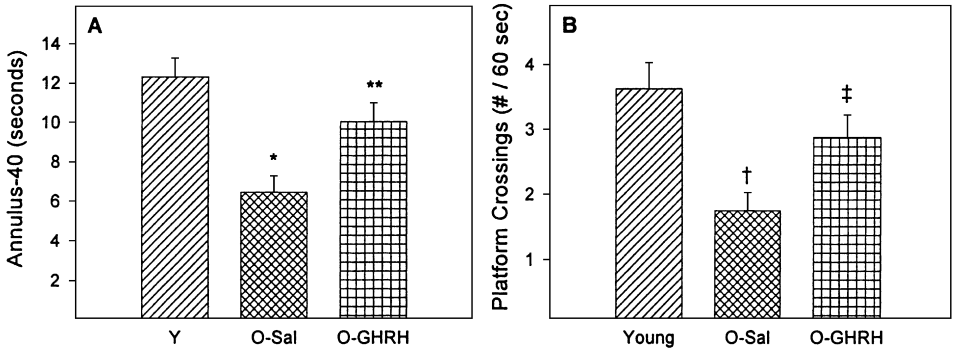

FIG. 63.4. Spatial reference memory as assessed by performance in the Morris water maze. In this task, the Annulus-40 (the time spent in a 40 cm annulus around the platform) and the Platform Crossings (number of times the animal crossed the platform) are sensitive measures of spatial reference memory. (A) An age-related decline in Annulus-40 time was observed between 9-month-old (Y) and 28-month-old (O-Sal) rats ($^{*}P < 0.001$), whereas [D-Ala^2] GHRH treatment from 9 months to 28 months (O-GHRH) prevented this decline ($^{**}P = 0.007$, comparing O-Sal and O-GHRH). (B) Number of times the platform was crossed during the probe trial, considered the most sensitive measure of spatial reference memory, declined with age ($^{\dagger}P = 0.001$ comparing 9-months-old (Y) and 28-month-old control (O-Sal) animals) and [D-Ala^2]GHRH treatment prevented this decline ($^{\ddagger}P = 0.032$ comparing O-Sal and O-GHRH animals). Data are shown as mean $\pm$ SEM.

brain and growth hormone improves cognition in growth hormone-deficient children and adults, we initially proposed that the age-related deficits in the somatotropin pathway may result in memory impairments. Initial studies, however, indicated that acute administration of GHRH did not improve memory (Schneider-Rivas *et al*., 1995). Nevertheless, long-term administration of [D-Ala^2]GHRH in rats from 9 to 28 months of age maintained a daily pulsatile release of growth hormone, partially attenuated the decline in plasma IGF-1 and prevented the age-related impairment in spatial reference memory (Thornton *et al*., 1999a) (Fig. 63.4). In fact, aged animals treated with [D-Ala^2]GHRH had a similar performance in the probe trial of the Morris water maze compared to young animals. Further analysis revealed that long-term GHRH treatment did not influence the decline in locomotion or vision, suggesting that the effects of GHRH were specific to spatial memory. Since acute administration of GHRH did not demonstrate a similar pattern, it was concluded that the effect of GHRH was mediated by an increase in pulsatile release of growth hormone and/or increasing plasma IGF-1 levels.

C. Effects of Growth Hormone

While many studies suggest that growth hormone treatment improves alertness, vitality, mood, and increases a sense of well-being (McGauley, 1989; Bengtsson *et al*., 1993), data suggesting that growth hormone administration improves memory are controversial and, in many cases, anecdotal. For instance, adults with childhood onset growth hormone deficiency are more likely to be unemployed (Ranke, 1987; Bjork *et al*., 1989) and achieve only a junior high school education (Takano *et al*., 1994). Treatment of individuals with childhood-onset growth hormone deficiency has been reported to improve measures of intelligence (Sartorio *et al*., 1995) as well as psychosocial measures (Laron *et al*., 1986). Although there is no direct evidence that growth hormone crosses the blood–brain barrier, it is known that hypophysectomy, which decreases growth hormone and plasma IGF-1, results in a decreases of IGF-1 mRNA in brain. Administration of growth hormone to hypophysectomized or aged animals results in an increase in brain levels of IGF-1 mRNA (Hynes *et al*., 1987; Lopez-Fernandez *et al*., 1996). These data suggest that growth hormone may impact brain function indirectly by increasing plasma IGF-1 or directly by regulating brain IGF-1 levels.

D. Effects of Insulin-Like Growth Factor-1

IGF-1 is well-known to influence neurotransmission and neuronal maintenance and survival which are actions similar to that observed with other neurotrophic agents. Because of its wide range of effects on neurons, it was proposed that IGF-1 contributes to synaptic plasticity and the neural mechanisms necessary for learning and memory. Markowska *et al*. (1998) subsequently demonstrated that replacement of IGF-1 in the lateral ventricle of aged animals ameliorates the age-related impairments in both spatial reference and working memory. Subsequent studies in our laboratory have confirmed this finding in another rat strain and demonstrated that IGF-1 improves learning and spatial reference memory in aged animals compared to age-matched, control animals (Fig. 63.5). In addition, antagonism of IGF-1 binding to its receptor using a specific peptide analog in young animals resulted in impairments in learning and reference memory (Thornton *et al*., 1999b). These data were the first to demonstrate that brain IGF-1 is important for learning and memory in young animals and suggested that the age-related decline in IGF-1 and type 1 IGF receptors (Sonntag *et al*., 1999) and impairments in IGF-1 activity in the brain of aged animals (D'Costa *et al*., 1995) contribute to deficits in memory that are found with increasing age.

V. Cerebrovasculature and Age

A. Age-Related Deficiencies

Despite early studies that suggested that cerebral blood flow was not influenced by age, recent studies using nitrous oxide, xenon, CT, and PET scanning techniques have clearly estab-

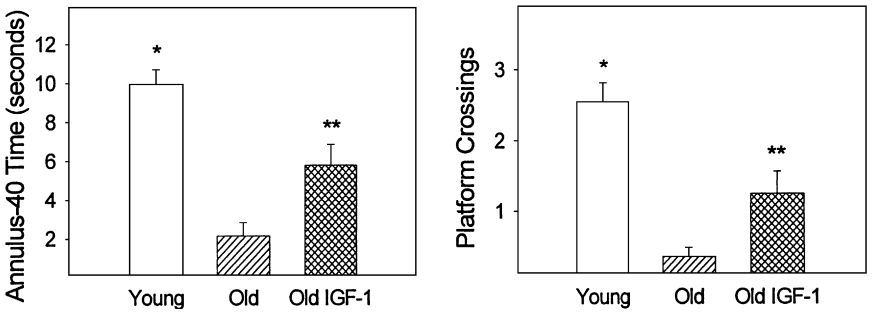

FIG. 63.5. Probe trial in the Morris water maze assessed spatial reference memory. Performance in both Annulus-40 time (left) and platform crossings (right) declined with age ($P < 0.001$ comparing young and old control animals). IGF-1 treatment for 28 days reversed this decline in both measures (left, right; $^{*}P < 0.05$ comparing young to old and old IGF-1; $^{**}P < 0.01$ in both measures comparing old control and old IGF-1 treated animals. Data are shown as mean $\pm$ SEM.

lished that a decrease in cerebral blood flow occurs in aged rodents, nonhuman primates, and man (Kety, 1956; Melamed *et al*., 1980; Amano *et al*., 1982; Shaw *et al*., 1984; Lynch *et al*., 1999). This age-related decline in cerebral blood flow has been hypothesized to result in a loss of metabolic and nutritional support for neurons and may therefore contribute to structural and functional changes that are associated with brain aging (Goldman *et al*., 1987; Bell and Ball, 1990). Although specific mechanisms for the decline in blood flow are unclear, recent studies indicate that perfusion pressure remains constant with age (Elias *et al*., 1995) leading to the conclusion that the decline in blood flow must result from alterations in vascular density. In this regard, several investigators report an age-related reduction in cerebral capillarity and an increase in intercapillary distance in aged humans and rodents (Bell and Ball, 1990; Jucker *et al*., 1990). A decline in total capillary length and capillary surface area per unit volume of tissue was also observed in humans from 26 to 96 years of age (Mann *et al*., 1986). However, other investigators report either an increase or no change in capillaries per unit volume of cerebral tissue (Bar, 1978; Hunziker *et al*., 1979; Meier-Ruge *et al*., 1980; Hughes and Lantos, 1987). The reason for this controversy results from a disproportionate decrease in the volume of cortical or subcortical structures compared to the vasculature in some animal models (Bar, 1978) or from the regulation of cerebral blood flow primarily by arteriolar and arteriole-to-arteriole anastomotic density, rather than capillary density (Zhang *et al*., 1994). More recent data demonstrate that the densities of both arterioles and arteriole-to-arteriole anastomoses on the cortical surface decrease with age (Yamaguchi *et al*., 1988; Sonntag *et al*., 1997) (Fig. 63.6, see color insert). Since vasculature on the cortical surface of the brain has been shown to mimic vascular changes throughout the brain (Rosenblum and Kontos, 1974), the loss in vessels on the cortical surface suggests that a general rarefaction of blood vessels within the brain occurs and contributes to the decrease in blood flow and neuronal function. In effect, not only is there a reduction in blood flow with age, but also a reduction in the ability to maintain homogenous flow to the brain during periods of localized ischemia which may result in an increased risk of neuronal loss in brain regions where vessel rarefaction is prominent.

It is well-known that metabolic support of neuronal tissues requires adequate blood flow. Angiogenesis has been hypothesized to be essential for neurite outgrowth and may precede neuronal growth in some models of neuronal damage (Podhajsky and Myers, 1993). In addition, studies have revealed that an increase in synaptic activity causes an angiogenic response in the cerebellar cortex (Black *et al*., 1990). Data also demonstrate that placing animals in a complex environment induces synaptogenesis and generation of new cerebral microvessels in young rats (Black *et al*., 1989b, 1991), while aged rats have deficits in the generation of new cerebral microvessels to support neuronal plasticity (Black *et al*., 1989a). These data provide important evidence to support the conclusion that an adequate vascular supply to the brain is critical for synaptic plasticity and the acquisition of memory. Thus, the age-related rarefaction of microvessels in the brain may contribute to a decline in synaptic plasticity and age-related impairments in learning and memory.

Recently, several laboratories have reported that the presence of specific growth factors that either regulate growth of the vasculature [i.e., vascular-derived endothelial growth factor (VEGF), transforming growth factor β (TGF-β), platelet-derived growth factor (PDGF), and fibroblast growth factor (FGF)] or are produced in the vasculature (i.e., IGF-1 and NGF) (Engelmann *et al*., 1989; Creedon and Tuttle, 1991; Delafontaine *et al*., 1991; Sonntag *et al*., 1999) (Fig. 63.7, see color insert). The production of IGF-1 and NGF by the vasculature not only has important implications for the paracrine regulation of surrounding tissues but may serve as an essential component in the regulation of neuronal regeneration (Delafontaine, 1995). If such a paracrine relationship between vasculature and neurons is documented by future studies, the rarefaction of the cerebral vasculature that is associated with age may be found to contribute to neuronal dysfunction, not only by diminished oxygenation of tissues and removal of metabolic waste, but also by reducing the expression of trophic agents, thus withdrawing trophic support for surrounding neurons.

B. Effects of Growth Hormone and Insulin-like Growth Factor-1

Both growth hormone and IGF-1 have been shown to be important regulatory factors in the vasculature. Studies indicate that both endothelial and smooth muscle cells have receptors for growth hormone and IGF-1 (Hansson *et al*., 1987;

Delafontaine *et al*., 1991) and IGF-1 immunoreactivity within the vasculature is increased during periods of angiogenesis (Hansson *et al*., 1989). Vascular remodeling in response to hypertension is inhibited by hypophysectomy, which decreases growth hormone and IGF-1, and is restored by growth hormone administration (Folkow *et al*., 1988). Both growth hormone and IGF-1 have been shown to stimulate endothelial cell proliferation, tube formation, and angiogenesis (Foster *et al*., 1990; Grant *et al*., 1993; Sato *et al*., 1993; Gould *et al*., 1995). Additionally, IGF-1 has been shown to increase the synthesis of elastin, thereby enhancing vascular compliance and has been reported to regulate blood flow in some tissues (Badesch *et al*., 1989; Foster *et al*., 1990).

Recent data indicate that vascular density is highly correlated with plasma IGF-1. As previously mentioned, vascular density decreases with age and injections of growth hormone in the aged animal increase cortical vascular density (Sonntag *et al*., 1997), suggesting that deficiencies in growth hormone and IGF-1, rather than aging *per se*, are important components of vascular rarefaction. In addition, it is apparent that growth hormone increases vascular supply to the brain thereby increasing vascular-derived IGF-1 and NGF to potentially act in a paracrine fashion on surrounding tissue. Thus, it appears that the decline in growth hormone that occurs in the aged contributes to the rarefaction of the cerebral vasculature thus diminishing the trophic and metabolic support to the aging brain and may have implications in structural and functional deficits associated with brain aging.

VI. Neuronal Structure, Neurotransmission, and Age

A. Deficits

1. Neuronal Size and Number

Over the past several decades, a number of morphological, functional and biochemical changes have been reported in the brain with age, but the etiology of these diverse changes remains elusive. For example, there is a decline in both glucose and oxygen utilization by the brain, a reduction in synaptic density, and functional changes in both neurons and glia. Many of the aforementioned changes appear to be both regionally and species specific. In humans, it is widely accepted that brain weight decreases with age, predominantly after 55 years of age (Terry *et al*., 1987) but the etiology of this decline has been controversial. Initial studies indicated that a significant and progressive decline in the number of neurons occurs in cortical areas of the aged, human brain (Brody, 1955; Devaney and Johnson, 1980; Henderson *et al*., 1980; Anderson *et al*., 1983), particularly in layers 2 and 4 (Brody, 1980; Hughes and Lantos, 1987). However, more recent studies suggest that neuronal number in cortex remains constant throughout the life span in humans (Terry *et al*., 1987), nonhuman primates (Vincent *et al*., 1989; Tigges *et al*., 1990), and rodents (Peinado *et al*., 1993). A significant decrease in size of neurons, specifically large neurons (>91 μm^2), has also been reported to occur in the aged animal. Furthermore, a significant increase in the number of glia has been observed (Brizzee, 1975; Brizzee *et al*., 1976; Terry *et al*., 1987; Peters *et al*., 1991; Peinado *et al*., 1993). In addition, studies by Landfield *et al*. (1981,1996) indicate a loss of neurons in the CA3 region of hippocampus. More recent analysis using stereological methods suggest that a significant loss of neurons occurs in the subiculum and the dentate gyrus of the hippocampus in elderly humans (West and Crook, 1990). It is now generally accepted that a decline in the size, but not number, of neurons occurs in the cerebral cortex, whereas the decline in hippocampal neurons appears to be regionally specific.

2. Dendritic Architecture and Synaptic Density

In addition to neuronal density, one of the most important morphological features of neurons is related to dendritic architecture and synaptic density. An age-related decline in dendritic arbors has been reported in frontal and temporal lobes of the cortex and in the limbic system (Feldman and Dowd, 1975; Scheibel *et al*., 1976; Geinisman *et al*., 1977; Vaughan, 1977; Geinisman, 1979; Brody, 1980; Cupp and Uemura, 1980; Leuba, 1983; Uemura, 1985; Nunzi *et al*., 1987; Lolova, 1989; Moroi-Fetters *et al*., 1989). The age-related decline begins with a loss of dendritic spines and is followed by alterations in the size and shape of horizontal branches resulting in a loss of basilar dendrites and/or apical branches (Nakamura *et al*., 1985). Concomitantly, an age-related decrease in the number of synapses has been reported (Geinisman *et al*., 1977; Geinisman, 1979; Bondareff, 1980; Gibson, 1983; Haug and Eggers, 1991). Although many of these changes appear to be regionally specific, it is becoming increasingly apparent that these structures have a critical role in integrating neuronal activity and that dendritic architecture, including both extent and pattern of dendrites, and the number of synapses influence neural transmission and neuronal activity (Johnston *et al*., 1996). Therefore, the deterioration of these structures observed in aged animals and man is believed to result in functional deficits including impaired neural transmission, motor function, and memory.

3. Neurotransmission

In addition to structural changes in neurons, dendrites, and synapses that occur with age, functional changes in neurons also occur in aged animals and humans, including a decline in the synthesis, release, and activity of neurotransmitters (Amenta *et al*., 1991; Strong, 1998). Since aging is associated with deficits in memory and motor function, the neurotransmitter systems that are closely associated with these functions have been of intense interest, specifically the cholinergic, glutaminergic, and dopaminergic systems. The deficits in these neuronal systems are believed to result in impairments in the aged brain and result, at least in part, in the loss of motor and cognitive function.

The hypothesis that the cholinergic system mediates learning and memory was first supported by studies demonstrating that anticholinergic agents produce memory impairments in young adults similar to impairments common in the elderly (Drachman and Leavitt, 1974). As a result of this important study which suggested that the cholinergic system mediates learning and memory, this system has been extensively studied

with age and specific declines in levels of acetylcholine noted. Specifically, choline acetyltransferase (ChAT), the rate-limiting enzyme for acetylcholine synthesis, declines by 50–60% in both the hippocampus and the cortex (Court *et al*., 1993). Similarly, acetylcholine release has been reported to decrease by 61% in the hippocampus and 73% in the striatum (Amenta *et al*., 1993). Analysis of muscarinic receptors have produced equivocal results. Muscarinic receptors have been reported to decline by as much as 50–60% in the caudate, putamen, hippocampus, and frontal cortex (Perry, 1980; Dewey *et al*., 1990; Strong *et al*., 1991; DeKosky and Palmer, 1994; Goldman *et al*., 1994), while others report a preservation of receptor density in the neocortex and hippocampus with a trend toward a decline in the striatum (Decker, 1987; Sherman and Friedman, 1990). Analysis of the levels of the specific muscarinic receptor subtypes has also produced controversial results when putative M_1 receptors were analyzed (Norman *et al*., 1986; Sirvio *et al*., 1988a,b; Watson *et al*., 1988; Biegon *et al*., 1989; Araujo *et al*., 1990). Similarly, density of the M_2 receptor has been reported to exhibit no change or increase in cortical areas and in the molecular layer of the dentate gyrus (Norman *et al*., 1986; Biegon *et al*., 1989; Araujo *et al*., 1990; Aubert *et al*., 1995) or decrease (Nordberg *et al*., 1992). In a subsequent study, a 60% decline in slow excitatory, postsynaptic cholinergic transmission in the hippocampus was reported with age using intracellular recording methods but no alterations in either presynaptic or postsynaptic inhibitory afterhyperpolarization were observed (Taylor and Griffith, 1993), suggesting an impairment in receptor function. While the age-related decline in the cholinergic system is well-founded, the consequence of these deficiencies remains unclear. For example, in diseases that result in deficiencies in ChAT expression and activity that are as profound as those observed in Alzheimer's disease (including olivopontocerebellar atrophy), no significant loss of memory occurs (Kish *et al*., 1988). In addition, recent studies suggest that the cholinergic system may have an important role in attention rather than memory in both rodents (Sarter and Bruno, 1997; Turchi and Sarter, 1997) and nonhuman primates (Voytko *et al*., 1994; Voytko, 1996), thereby influencing cognition rather than a direct effect on learning and memory.

More recently, glutaminergic neurotransmission has been shown to be essential for learning and memory. The glutaminergic system is comprised of several types of receptors, such as the NMDA, α-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA), and metabotropic glutamate receptors (Cotman *et al*., 1988, 1995; Monaghan *et al*., 1989). Most studies have focused on the NMDA receptors since: (1) NMDA receptors are expressed throughout the brain but are found in high concentrations in brain regions involved in learning and memory including the hippocampus and cortex (Mayer and Westbrook, 1987; Ishii *et al*., 1993), (2) NMDA agonists increase acquisition of memory whereas NMDA antagonists impair memory (Collingridge and Bliss, 1987; Collingridge and Singer, 1990; Ingram *et al*., 1994), and (3) induction of long-term potentiation (an event necessary for learning and memory) requires Ca^{2+} flux through NMDA receptors concentrated in the hippocampus (Artola and Singer, 1987; Collingridge and Bliss, 1987; Cotman *et al*., 1988; Ito, 1989; Collingridge and Singer, 1990). Despite the importance of glutaminergic neurotransmission for learning and memory, the assessment of age-related changes in this system have been inconsistent. For example, initial studies using MK-801 binding to the NMDA receptors demonstrated no age-related alterations in hippocampus or entorhinal cortex (Shimada *et al*., 1997). Recent studies suggest that [^{3}H]glutamate binding decreases modestly in aged animals whereas the binding of specific NMDA receptor subtype agonists and antagonists exhibit more profound decreases (Magnusson and Cotman, 1993). The efficacy of the NMDA receptor has been found to depend upon the assembly of both NMDA R1 (NR1) and R2 (NR2) subunits. Expression of the NR1 subunit in *Xenopus* oocytes demonstrated that a functional receptor is not formed with expression of NR1 alone (Chazot *et al*., 1992; Grimwood *et al*., 1996). Similarly, the expression of NR2 subunit alone does not result in a functional receptor; however, coexpression of the NR1 and NR2 subunits results in the formation of a functional NMDA receptor in both oocytes and mammalian cells (Meguro *et al*., 1992; Monyer *et al*., 1992; Ishii *et al*., 1993). The importance of this receptor heterogeneity is supported by a recent study demonstrating that transgenic mice lacking the NMDA R2 subunit exhibit impairments in spatial memory (Sakimura *et al*., 1995). In relation to aging, recent data from our own laboratory suggest that no changes in the NMDA R1 subunit occur with age but an age-related decline in both NMDA R2A and NMDA R2B subunits occur in the hippocampus compared to young animals (Sonntag *et al*., 2000). The implication of these studies is that alterations in subunit composition of the NMDA receptor with age may result in changes in physiological and pharmacological properties of the receptor resulting in impaired neuronal function.

It is well-known that deficiencies in the dopaminergic system are involved in several age-related neurological disorders such as Parkinson's disease (Hierholzer *et al*., 1998; Kelly *et al*., 1998) and stroke (Dawson *et al*., 1994) and contribute to the altered regulation of hypothalamic and hypophysiotropic hormones (Meites and Sonntag, 1981; Borowsky and Kuhn, 1992; Durham *et al*., 1997). Investigators have also reported that the dopaminergic system is involved in processes of learning and memory (Smith *et al*., 1973; Shaywitz and Pearson, 1978; Altman and Quartermain, 1983; Dubrovina and Il'iuchenok, 1990). Previous studies suggested that age-related impairments in the dopaminergic system result, at least in part, in deficits in both motor and cognitive function (Marshall and Berrios, 1979; Marshall, 1982; Morgan, 1987; Arnsten *et al*., 1995). Decreases in density of D_1 receptors (Araki *et al*., 1997), levels of striatal dopamine uptake sites (Zelnik *et al*., 1986), dopamine transporters (Bannon *et al*., 1992), dopamine content (Goldman-Rakic and Brown, 1981), and dopamine release in aged animals (Wenk *et al*., 1989) have been reported. Assessment of D_2 receptor density indicate either a decrease (Henry *et al*., 1986; Hess *et al*., 1987) or no change (De Keyser *et al*., 1990; Araki *et al*., 1997) with age. Despite controversial results on age-related changes in D_2 receptor density, recent data from our laboratory suggest that D_2 receptor activation of G-proteins declines, intrinsic efficacy of the agonist (a measure of the coupling efficiency between G-proteins and receptors in response to agonist stimulation) decreases, and receptor reserve for G-protein activation (the receptor level in excess of that required for a maximal response

to an agonist) is reduced with age in both cortex and hippocampus. These changes occurred despite the absence of changes in D_2 receptor density (Thornton *et al*., 1998). These results suggest that many aspects of the dopaminergic neurotransmission are deficient in the aged animal and contribute to deficits in both motor and cognitive function.

Although alterations in neurotransmitter levels and changes in receptor density, composition, and activity are one aspect of the decline in functional capacity of neurons, deficiencies in intracellular signaling in neurons have been reported to contribute to the decrease in neuronal function with age. For example, data demonstrate that protein kinase C (PKC), phospholipase C (PLC), protein kinase A (PKA), and calcium signaling are diminished with age (Friedman and Wang, 1989; Pisano *et al*., 1991; Undie and Friedman, 1992; Wang *et al*., 1992; Undie *et al*., 1995). It is also believed that these deficits, alone or in combination, result in impaired signal transduction in aged animals and humans and contribute to neuronal dysfunction (Roth, 1989; Pisano *et al*., 1991; Sugawa and May, 1993; Battaini *et al*., 1994; Undie *et al*., 1995). While the etiology for these general impairments remains unknown, several potential mechanisms have emerged. For instance, a reduced ability to activate receptor-linked G-proteins and/or phosphorylate critical intracellular proteins in response to receptor activation is a common finding in several neurotransmitter systems of the aged animal (Roth, 1995). It has been hypothesized that these alterations are due to age-associated changes in phospholipid content, resulting in a loss of membrane fluidity (Tacconi *et al*., 1991; Joseph *et al*., 1995). Johnson *et al*. (1995) have demonstrated that responsiveness of G-protein coupled receptors declines with age due to reductions in mRNA and protein levels of Gα subunits. However, general impairments in neuronal function are also observed in response to stimuli that produce a rapid induction of the intracellular protooncogene *c-fos*, resulting in the activation/transcription of a number of targets on the genome. Results comparing young and old animals demonstrated a >50% reduction in the number of neurons capable of activating *c-fos* in aged animals (D'Costa *et al*., 1993). Together, these studies provide convincing evidence that signal transduction is diminished in the brain of aged animals and these decreases contribute to diminished neuronal function.

B. Effects of Insulin-like Growth Factor-1

While growth hormone has been shown to influence brain levels of IGF-1 as well as other neurotrophins and the cerebral vasculature, and empirical data suggest that growth hormone may improve mood and cognition, there is no evidence to date that growth hormone has a direct action in the brain. However, IGF-1 has been demonstrated to cross the blood–brain barrier (Reinhardt and Bondy, 1994) and is produced and secreted from the cerebral vasculature, neurons and glia. In addition, IGF-1 has been shown to exert trophic actions in the brain. Nevertheless, the influence of the decline in plasma and brain levels of IGF-1 on the aging brain has only recently been studied. Data suggest that IGF-1 has a critical role in maintenance, protection, survival, and function of neurons and that the decline in brain IGF-1 may be a causative factor in deficits associated with brain aging.

As previously mentioned, IGF-1 is a potent neurotrophic agent and has been shown to stimulate DNA, RNA, and protein synthesis, cell proliferation, survival, and neurite outgrowth *in vitro* (Lenoir and Honegger, 1983; Recio-Pinto and Ishii, 1984; Recio-Pinto *et al*., 1986; Shemer *et al*., 1987; Han *et al*., 1988; Toran-Allerand *et al*., 1988; Torres-Aleman *et al*., 1989; D'Costa *et al*., 1995) and regulates synaptogenesis, myelin synthesis, and is neuroprotective *in vivo* (McMorris *et al*., 1986; McMorris and Dubois-Dalcq, 1988; Saneto *et al*., 1988; Ishii, 1989; Shinar and McMorris, 1995). In addition, recent studies using an organotypic slice preparation suggest that IGF-1 regulates the density and complexity of apical dendrites (Niblock *et al*., 1997). Deficiencies in protein synthesis, synaptic density, and dendritic architecture occur with age and these changes appear to be temporally correlated with the decline in IGF-1 and type 1 IGF receptors.

While the effect of IGF-1 on the morphological changes associated with aging are still correlative, deficits in IGF-1 have been closely linked to impaired neural transmission. IGF-1 influences acetylcholine neurotransmission by stimulating ChAT activity (Sara and Hall, 1990) and regulates K^+-induced release of acetylcholine from hippocampal neurons and cortical slices (Nilsson *et al*., 1988; Araujo *et al*., 1989), both of which decline in the aged animal. In addition, recent data from our laboratory suggest that administration of IGF-1

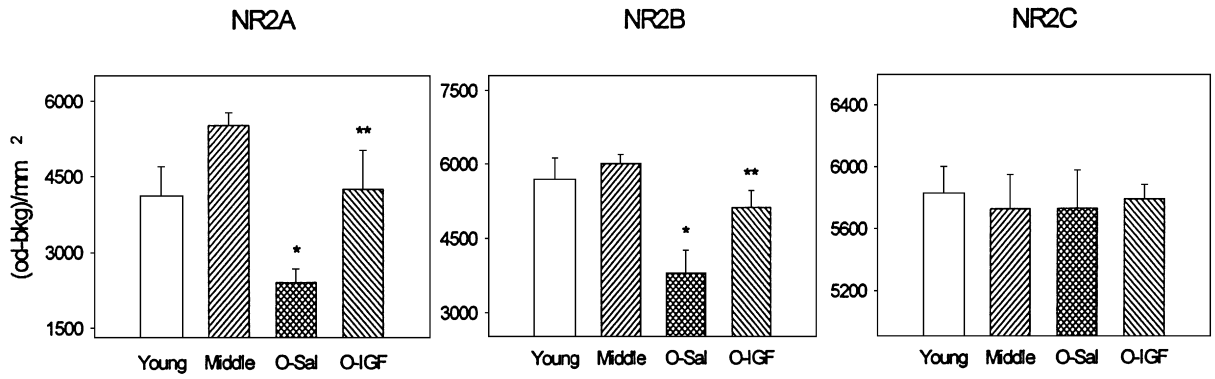

FIG. 63.8. Analysis of changes in NMDA R2 receptor subtype protein expression in hippocampus assessed by Western analysis. NMDA R2A (left) and NMDA R2B (center) indicated a significant decline between 21 and 30 months of age ($P < 0.05$) that was reversed by treatment with IGF-1 for 28 days. No alterations in protein expression of NMDA R2C were observed with age or treatment with IGF-1.

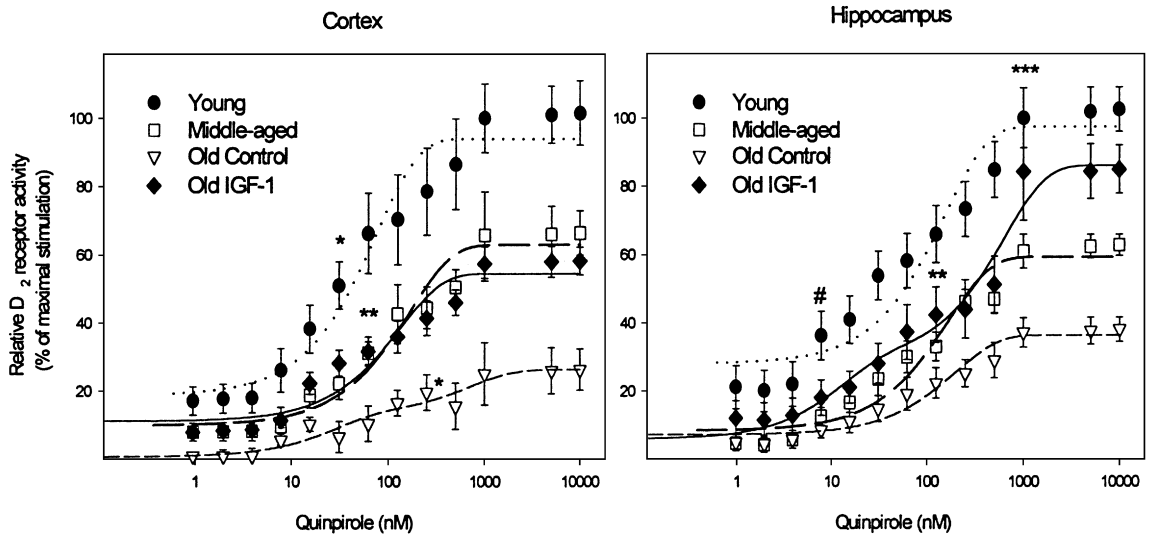

FIG. 63.9. The [^{35}S]GTPγS assay assesses the response of G-protein coupled receptors to an agonist, specifically the displacement of GTP for GDP on the α-subunit of the G-protein thereby measuring activity of the receptor. The dose–response relationship of quinpirole (a specific D_2 receptor agonist) stimulation of [^{35}S]-GTPγS binding in cortex (left) and hippocampus (right) of young (5 months), middle-age (15 months), old control (28 months), and old IGF-1 treated (28 months) Brown Norway rats demonstrates an age-related decline in agonist-stimulated G-protein activation and IGF-1 treatment for 28 days reverses this decline in both cortex and hippocampus ($^{*}P < 0.05$ compared to middle-aged, old control, and old IGF-1 treated; $^{**}P < 0.05$ compared to middle-aged and old control; $^{***}P < 0.05$ compared to old control).

icv reverses the alterations in the subunit composition of the NMDA receptors by upregulating the NMDA R2A and R2B subunits in the hippocampus (Fig. 63.8). Since the heterogeneity of the NMDA receptor is necessary for full receptor activity, it was hypothesized that IGF-1 may increase the efficacy of glutamate at the NMDA receptor, thereby modulating neural transmission of the glutaminergic system, resulting in improvements in learning and memory (Markowska *et al.*, 1998; Thornton, *et al.*, 1999b).

The effect of IGF-1 on dopaminergic neurotransmission has also recently begun to be elucidated. Biochemical studies have shown that IGF-1 is involved in the development and maintenance of dopaminergic neurons (Knusel and Hefti, 1991; Beck, 1994) and influences dopamine release (Beck *et al.*, 1993), all of which decline with age. More recent data demonstrate that icv infusion of IGF-1 in the aged animal reverses the age-related decline in D_2 receptor activated G-proteins (Thornton *et al.*, 1998). These studies demonstrate that IGF-1 improves the maximal stimulation of [^{35}S]GTPγS binding in response to a D_2 receptor agonist (Fig. 63.9), reverses the age-related decline in intrinsic efficacy of the agonist, and increases receptor reserve for G-protein activation without altering the density of D_2 receptors. Thus, IGF-1 modulates the response of dopamine D_2 receptors and the age-related decline in IGF-1 may contribute to impairments in dopaminergic neurotransmission.

IGF-1 binds to the type 1 IGF receptor and results in activation of several intracellular signaling pathways including inositol triphosphate (IP_3), insulin-related substrate-1 (IRS-1), mitogen activated protein kinase (MAPK), PKA, PKC, calcium signaling, and cAMP (Sadler and Maller, 1987; Farese *et al.*, 1989; Renganathan *et al.*, 1997). Furthermore, many of these signaling pathways are impaired with age (Roth, 1997). While studies have demonstrated that replacement of IGF-1 improves calcium flow and intracellular signaling in skeletal muscle of aged animals (Renganathan *et al.*, 1997), no studies have evaluated the actions of IGF-1 on these signaling pathways in the brain. Since IGF-1 has been shown to induce activity of these intracellular signaling proteins, it is probable that IGF-1 may also regulate neuronal function and signaling by increasing the activity of specific intracellular proteins in the brain. Similarly, deficiencies in IGF-1 similar to those observed in aged animals may induce signaling impairments and contribute to neuronal dysfunction and functional deficits.

VII. Conclusions

The prominent role of IGF-1 on the developing brain and the association between age-related changes in the brain and the actions of IGF-1 have led us to propose that decreases in plasma growth hormone and IGF-1 and/or deficiencies in the endogenous production of IGF-1 by the aging brain are contributing factors in brain aging. Certainly, previous studies support an important neuromodulatory role of IGF-1 on acetylcholine synthesis and release, protein synthesis, neurite outgrowth, synaptogenesis, and myelination, all of which are known to decrease with age. In addition, there are recent, compelling data suggesting that IGF-1 has additional actions that may influence brain aging including the regulation of subunit composition of the NMDA receptors and D_2 receptor activity. Intracerebroventricular infusion of IGF-1 into old animals was recently found to increase working and reference memory, supporting the hypothesis that age-related impairments in learning and memory result, at least in part, from hormone deficiency similar to that found in peripheral tissues. It is currently unknown if deficiencies in growth hormone or IGF-1 in early adulthood result in or facilitate functional deficits similar

to those observed in the brain of aging animals and humans. Furthermore, the etiology of the deficiencies in IGF-1 remains elusive. Furthermore, it is unknown if these hormonal deficits are a pathophysiologic response to attenuate age-related pathologies. These questions must be addressed before one can completely understand the role of growth hormone and IGF-1 in brain aging.

It is clear that we are beginning to evolve from the concept of biological aging that uses unidimensional models where aging is viewed as changes in a single system to multidimensional models where there is an interdependence and interrelationship of age-related changes across a number of systems. As a result of these evolving models, new concepts of brain aging are emerging that are the result of deficiencies in endocrine, vascular, neural, and glial components that closely interact, resulting in the aging phenotype. Although investigation of these interactions pose enormous challenges for scientists, the continued development of conditional transgenic animal models and virus-mediated gene transfer targeted to specific cell types should begin to isolate specific mechanisms contributing to brain aging and offer specific interventions to ameliorate age-related memory deficits.

The Aged Sympathetic Nervous System

I. Basal Sympathetic Activity in Human Aging

Sensitive assays for the quantitation of norepinephrine (NE) and epinephrine (E) in plasma and other body fluids have now been available for nearly three decades. It is generally accepted that circulating NE originates from sympathetic nervous system (SNS) nerve terminals, while E is produced almost exclusively by adrenomedullary secretory activity (Lee *et al*., 1984). As a result, a number of earlier studies utilized these relatively noninvasive measurements when examining the potential role of the sympatho-chromaffin system in the pathophysiology of specific disease states. For example, plasma NE levels were measured in individuals who suffered from either hyperthyroidism or hypertension. SNS dysregulation was thought to play a significant role in both conditions. Nevertheless, in thyrotoxic (Christensen, 1973), as well as hypertensive (Pedersen and Christensen, 1975) individuals, plasma NE levels were similar to those measured in appropriately age-matched controls suffering from neither condition. However, plasma NE levels increased with the age of subject, irrespective of the individuals' thyroid or hypertension status (Christensen, 1973; Pedersen and Christensen, 1975). These findings have now been reproduced in a larger number of studies, with reported basal plasma NE levels as much as 50% higher in older individuals than in younger controls (Ziegler *et al*., 1976; Kuchel and Kuchel, 1993). In contrast, plasma E levels do not appear to be significantly influenced by the subjects' age (Kuchel and Kuchel, 1993). Similarly, urine and cerebrospinal fluid NE, but not E, levels tend be higher in older individuals (Kuchel and Kuchel, 1993). Moreover, recordings of sympathetic nerve activity in skeletal muscle have revealed that this activity correlates with plasma NE levels and increases with age (Wallin *et al*., 1981). Although difficult to detect, recent evidence points to dopamine as another catecholamine with important peripheral effects (Kuchel and Kuchel, 1991, 1993). In addition to being the direct precursor of NE, peripheral dopamine appears to exert significant cardiovascular and renal effects (Kuchel and Kuchel, 1991). Interestingly, in spite of significant increase in basal plasma NE levels with age, urinary dopamine excretion (Fukagawa *et al*., 1995), as well as dopamine fibers (Amenta *et al*., 1990) and receptors appear to decline with aging of the peripheral nervous system. Moreover, since dopamine promotes renal salt excretion, these changes could contribute to the increased prevalence of hypertension and of disorders in salt fluid and salt handling observed in old age (Kuchel and Kuchel, 1991).

However, caution must be exercised when interpreting human studies of basal SNS activity, particularly as related to aging (Rowe and Troen, 1980). Most importantly, a number of criteria should be met in order to be able to assume that plasma NE levels are truly reflective of SNS activity (Lee *et al*., 1984). Since plasma NE can be affected by many factors, it is essential to ensure that in each subject NE release, its diffusion into the circulation and subsequent neuronal reuptake, as well as extraction or clearance by other tissues all be in a ''steady-state'' at the time of blood sampling (Lee *et al*., 1984). Thus, efforts must be made to ensure that the subject's SNS activity is truly at a basal state. These considerations are particularly crucial in aging studies since older subjects have been shown to require a longer period of time to reach basal NE levels (Rowe and Troen, 1980). In addition to higher basal SNS activity, older individuals tend to demonstrate evidence of sympathetic dysregulation in response to a wide variety of physiologic and behavioral stimuli. As a result, following most stimuli older subjects tend to exhibit elevations in plasma NE levels which are both greater and more prolonged that those induced by equivalent stimuli in younger individuals (Rowe and Troen, 1980; Kuchel and Kuchel, 1993).

Another potential confounder in gerontologic research is the presence of disease. A disease process, either overt or subclinical, could potentially influence both SNS activity and NE levels. Thus, details of health screening in the research subjects are important. Nevertheless, age-associated increases in NE plasma levels do not appear to be related to the presence of hypertension (Lake *et al*., 1997), carbohydrate intake (Chen *et al*., 1986), thyroid hormone status (Christensen, 1973), or obesity (Sowers *et al*., 1983). However, even in the absence of identifiable disease, individuals experience a highly variable pattern of changes as they grow older. It has been proposed that it may be useful to further separate aging without disease or ''normal'' aging into two categories, usual and successful (Rowe and Kahn, 1987). Many of the differences between individuals in the two categories could then be attributed to ex-

trinsic factors such as diet, exercise, personal habits, and psychological profiles (Rowe and Kahn, 1987). Since many of these factors are potentially modifiable, addressing them raises the hope that specific lifestyle interventions could be designed with the goal of modifying the aging process and its associated disability. Studies of extremely fit elderly bicycle marathon racers have shown that their basal NE levels are similar to those obtained in older individuals who were less fit, yet healthy (Lehmann and Keul, 1981, 1986). Thus, elevated basal NE levels in old age cannot be attributed to degree of physical fitness or muscle strength (Lehmann and Keul, 1981, 1986). More recently, it has been proposed that elevated SNS activity in old age may be related to a smoking history, rather than age itself (Jensen, 1999). The significance of these preliminary observations is unclear, at least in part, due to the fact that few geriatric patients are current or past smokers. Nevertheless, it is possible that in addition to the aging process, other associated lifestyle factors may contribute to SNS dysfunction in old age.

II. Sympathetic Dysregulation in the Older Subject

Nearly all maneuvers known to induce SNS activity have been shown to result in greater and more prolonged increases in NE plasma levels in older, as compared to younger subjects (Rowel and Troen, 1980; Kuchel and Kuchel, 1993). This type of NE hyperresponsiveness with aging has been seen after standing (Young *et al*., 1980; Sowers *et al*., 1983), various types of exercise (Lehmann *et al*., 1981; Lehmann and Reul, 1981, 1986; Sowers *et al*., 1983; Fleg *et al*., 1985), oral glucose ingestion (Young, *et al*., 1980), and mental stress (Barnes *et al*., 1982). Only following a euglycemic insulin administration was the NE increase diminished in older subjects (Minaker *et al*., 1982). In contrast, similar challenges generally do not result in E hyperresponsiveness in older subjects (Kuchel and Kuchel, 1993). In spite of this type of SNS hyperresponsiveness, older individuals tend to be more likely to experience difficulty in maintaining normal blood pressure (Lipsitz, 1989) or temperature (Kenney, 1997; Young and Lee, 1997). This type of vulnerability is particularly evident in the frail elderly who suffer from significant concomitant morbidity, as well as in healthy older subjects who have been exposed to several concurrent homeostatic challenges (Shannon *et al*., 1986). Since SNS activity contributes to, among other things, the maintenance of normal blood pressure and temperature, one has to reconcile the apparent discordance between elevated SNS activity and enhanced vulnerability to such homeostatic challenges in old age.

A variety of human studies have indicated that although indicators of presynaptic SNS activity are generally elevated even under basal conditions in old age (i.e., sympathetic nerve recordings and plasma NE levels), postsynaptic responses to adrenergic tend to be diminished. Although it was once thought that the postsynaptic changes are as a result of diminished numbers of receptors (Schocken and Roth, 1977), most studies now point to a desensitization of many G-coupled receptors, including both pre- and postsynaptic receptors, while the absolute numbers of adrenergic receptors generally do not change in old age (Lakatta, 1995). These findings, together with a variety of alterations in signaling pathways, particularly involving calcium, have been used to explain well-established pharmacological phenomena such as an age-associated decline in the chronotropic cardiac response to isoproterenol (Scarpace, 1988; Lakatta, 1995).

The above observations can be explained by two different mechanisms. Sympathetic activity could be heightened due to a primary increase in sympathetic drive originating in the central nervous system and adrenergic receptor desensitization would then be the result of adrenergic hyperactivity. In contrast, it is possible that a primary deficit in the ability of receptors and tissues to respond to adrenergic stimulation would result in the activation of compensatory reflexes which would then produce secondary stimulation of SNS activity. Unfortunately, neither hypothesis completely explains all of the research findings to date (Scarpace, 1988). For example, decreased baroreceptor sensitivity which has been demonstrated in old age (Tonkin and Wing, 1994) could result in diminished suppressibility of SNS outflow in the setting of increasing blood pressure (Rowe and Troen, 1980). Nevertheless, studies showing a normal ability of centrally acting α2-agonists to suppress plasma NE and NE appearance in older individuals (Featherstone *et al*., 1987) suggest that at least these central mechanisms for SNS suppression remain intact into old age.

Although studies involving humans are not amenable to a direct assessment of synaptic function, indirect evidence exists to suggest that age-associated changes in the handling of NE at the nerve terminal level may contribute to the pathophysiology of the hyperadrenergic state of aging (Hoeldtke and Cilmi, 1985). Plasma NE concentration is determined by rates of NE release into plasma and its subsequent removal (Lee *et al*., 1984). Thus, higher NE levels in the elderly could result from increased NE entry into the plasma and/or from a reduced clearance of NE. Most studies of arterialized plasma NE kinetics have demonstrated increased appearance of NE in the plasma (Hoeldtke and Cilmi, 1985; Veith *et al*., 1986; Kuchel and Kuchel, 1993) of older subjects. NE clearance results have been less consistent with some studies reporting no change, while others reported small decreases in old age (Kuchel and Kuchel, 1993). However, the reported declines in NE clearance have been relatively modest and have not correlated with increased plasma NE levels as well as did the increased plasma appearance (Veith *et al*., 1986).

As discussed, increased appearance of NE could be due to increased NE synthesis and/or altered NE handling at the level of the nerve terminal. Catecholamine synthesis and release is increased by nerve activity, principally by regulation of tyrosine hydroxylase (TH), the enzyme involved in the rate-limiting step of catecholamine synthesis. Increased nerve activity, as has been demonstrated by sympathetic fiber recordings, could increase NE synthesis through two distinct mechanisms involving TH. Brief neural stimulation can cause TH to be activated through posttranslational (phosphorylation) modification (Zigmond *et al*., 1989), while prolonged stimulation can induce TH activity by increasing TH enzyme quantity (Zigmond, 1980; Schalling *et al*., 1989). In the absence of human data, support for a role for TH upregulation in the hyperadrenergic state of aging comes from several rodent stu-

dies demonstrating evidence of increased TH activity (Reis *et al*., 1977), as well as TH gene expression (Kedzierski and Porter, 1990; Kuchel *et al*., 1997a) in aged sympathetic superior cervical ganglia.

Hoeldtke and Cilmi (1985) have described an increase in the entry of NE into plasma without any apparent change in overall NE production in elderly subjects. They have interpreted these findings as suggesting that human aging is associated with alterations in the local disposition of sympathetic neuronal NE (Hoeldtke and Cilmi, 1985). A diminished capacity for neuronal reuptake of released NE would further increase the entry of NE into plasma (Lee *et al*., 1984). Although a direct evaluation of NE reuptake at the level of the nerve terminal is not possible in humans, animal studies do point to decreased specific NE uptake by aged sympathetic fibers (Kuchel and Zigmond, 1991). Increased synaptic spillover has been shown to result in the depletion of neuronal NE stores, as even increased catecholamine synthesis can fail to keep up with NE stores, since NE is being released, but it is not being efficiently recovered by the neuron through usual reuptake mechanisms (Bhatnager and Moore, 1971). Catecholamine fluorescence appears to be diminished in both aged human sympathetic ganglia (Hervonen *et al*., 1978), as well as in individual sympathetic fibers (Waterson *et al*., 1974) and catecholamine levels decrease in aged arteries (Neubauer and Christensen, 1978).

III. Mechanisms of Cellular Aging in Sympathetic Neurons

A. General Structural Changes

A number of changes in the sympathetic nerve supply have been described in a variety of targets in old age, including the vasculature, heart, thermoregulatory system, gut, bladder, and iris (Waterson *et al*., 1974; Neubauer and Christensen, 1978; Amenta and Mione, 1988; Baker *et al*., 1991; Abdel-Rahman *et al*., 1992; Abdel-Rahman and Cowen 1994; Andrews and Cowen, 1994a; Warburton and Santer 1994; Gavazzi *et al*., 1996). Nevertheless, the commonly held concept that aging involves the widespread degeneration and death of neurons throughout the nervous system is probably generally misleading (Morrison and Hof, 1997) and is almost certainly incorrect in relation to the sympathetic nervous system (Cowen and Gavazzi, 1998). Although human sympathetic ganglia have not been systematically investigated, studies of the rat superior cervical (Santer, 1991) and coeliac–superior mesenteric sympathetic ganglia (Baker and Santer, 1988) have provided no evidence of significant neuron loss. Pathologic studies of human sympathetic ganglia have revealed lipofuscin and neuromelanin accumulation (Hervonen *et al*., 1978), diminished histochemical staining for catecholamines (Hervonen *et al*., 1978), and evidence of neuroaxonal dystrophy (Schmidt, 1991; Schmidt *et al*., 1991). In spite of the preponderance of negative and subtle findings, the possibility that subpopulations of neurons may be selectively affected cannot at present be ruled out (see below) (Kuchel *et al*., 1997a). Furthermore, spinal neurons providing preganglionic input to the peripheral sympathetic neurons in elderly subjects may undergo cell loss, estimated at 5–8% per decade (Low *et al*., 1977).

The likelihood that sympathetic and other neurons do not die in large numbers in the aging nervous system does not mean that there are no changes in neuronal structure which might relate to significant losses of function. Morphometric light and confocal laser scanning microscopy methods have been used to characterize and quantify age-related changes in sympathetic nerve fibers and their associated neurotransmitters (see Figs. 64.1–64.3). These changes are almost invariably local in nature and neighboring neurons from the same gang-

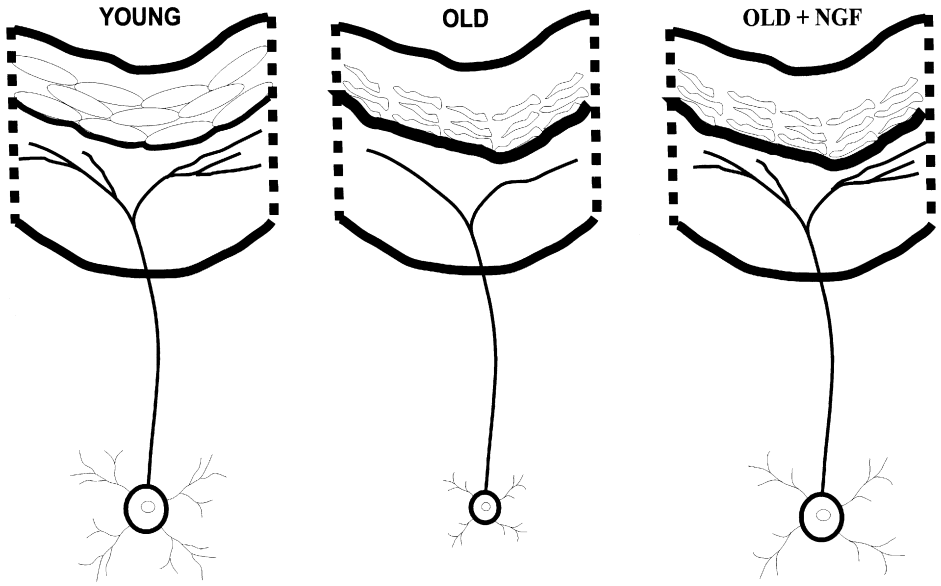

FIG. 64.1. Diagrams illustrating changes in nerve and smooth muscle in the aging blood vessel wall. In aging there is atrophy of autonomic neurons, including loss of axon collaterals and shrinkage of dendrites and the nerve cell body. Shrinkage of muscle cells also occurs, with thickening of basal lamina at the adventitial–medial border. Following NGF treatment there is regrowth of neurons, including axon collaterals, cell body, and dendrites.

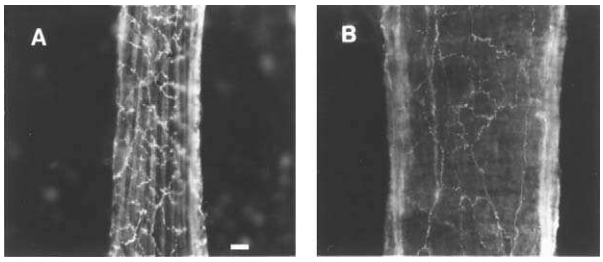

FIG. 64.2. Photomicrographs showing the sympathetic innervation to the rat middle cerebral artery through development and old age using catecholamine histochemistry (Andrews and Cowen, 1994a; Kuchel *et al*., 1997b) Nerve plexuses were investigated at 6 weeks (A) and 24 months (B). Scale bar = 25 μm.

lion but supplying different target tissues are often not affected. Where changes do occur, they may involve increases, for example in nerve fiber density or transmitter expression, as well as decreases. The changes seen are frequently sufficiently subtle to require measurement, although this should not be taken to mean that the functional outcome is insignificant. These types of studies have not been performed with human tissues. Nevertheless, the general concepts have been supported in studies where some preganglionic (Schmidt, 1991) and postganglionic (Jengeleski *et al*., 1989) sympathetic nerve fibers exhibit neuroaxonal dystrophy, while related terminals are unaffected.

B. Effects of Age on the Sympathetic Nerve Supply to Cerebral Blood Vessels

An area which has been relatively extensively studied, because of its possible relevance for the blood supply to the aging brain, is the sympathetic nerve supply to the major cerebral arteries of the circle of Willis. In humans (7th–8th decade) (Collins and Cowen, 1997) and rats (24–36 months old) (Andrews and Cowen, 1994a; Thrasivoulou and Cowen, 1995), these nerves undergo consistent age-related changes. In humans, the loss of nerve fibers affects mainly the anterior choroidal, posterior communicating, and internal carotid arteries, while in rats the changes affect the middle and posterior cerebral and basilar arteries. In rats, where the changes can be studied in more detail, sympathetic, vasoconstrictor nerves decline significantly in density between 18 and 24 months (Andrews and Cowen, 1994a), while vasodilator nerves, including sensory and parasympathetic fibers, may increase. Although sympathetic nerves in the rat cerebral vasculature decline in density with age, it appears that levels of the noradrenaline-synthesizing enzyme, tyrosine hydroxylase, may increase within these nerve fibers (Thrasivoulou and Cowen, 1995). Tracing studies using retrogradely transported dyes (Andrews *et al*., 1994) have shown that soma size and total length of dendrites of neurons projecting to different targets, including cerebral arteries, tend to reduce (or increase) in parallel with the age-changes in their peripheral axons. In addition, dystrophic changes were observed in some of these neurons of the superior cervical ganglion. More general dystrophic changes in neurites have been demonstrated using electron microscopy in sympathetic ganglia of aged human subjects and rodents. (Schmidt, 1991; Schroer *et al*., 1992; Uvelius and Gabella, 1998).

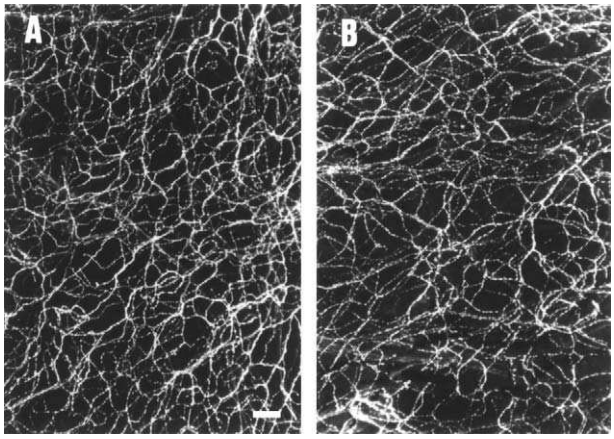

FIG. 64.3. Photomicrographs showing the sympathetic innervation to the iris through development and old age using catecholamine histochemistry (Kuchel *et al*., 1997b). Nerve plexuses were investigated at 6 weeks (A) and 24 months (B). Scale bar = 30 μm.

C. Effects of Age on the Sympathetic Nerve Supply to Sweat Glands

One of the only other systems where the effects of aging have been investigated in parallel in humans and in laboratory animals concerns the sympathetic nerve supply to cutaneous sweat glands (Abdel-Rahman *et al*., 1992; Abdel-Rahman and Cowen, 1994). In support of the evidence for impaired thermoregulation in the elderly, local deficits have been demonstrated in the structure and function of sympathetic (cholinergic) nerves around the sweat glands of elderly subjects (Abdel-Rahman *et al*., 1992). Sweat output, which is known to be a vital part of thermoregulation, declines after the seventh decade, in parallel with reduced size of glandular acini and substantially reduced density of the periacinar sympathetic nerves (Abdel-Rahman *et al*., 1992). Comparable changes were found in the structure and function of the sympathetic innervation of eccrine sweat glands of the rat footpad (Abdel-Rahman and Cowen, 1994).

D. Effects of Age on the Sympathetic Nerve Supply to Other Tissues

Other tissues have been investigated, but only in laboratory animals. Sympathetic nerve fibers from the coeliac–superior mesenteric ganglion complex of aged rats, supplying the enteric nervous system, were much reduced (Baker *et al*., 1991), as was the sympathetic nerve supply to the renal vasculature at the level of the renal artery in rabbits and around intrarenal arterioles in rats (Warburton and Santer, 1994). To emphasize the variable effects of aging on sympathetic nerves, in the iris of the aged rat, sympathetic nerves increased in density while sensory and parasympathetic nerves were reduced in density by 20–30% (Gavazzi *et al*., 1996).

A recent study has demonstrated a loss of sympathetic innervation to the aging rat pineal gland (Kuchel *et al*., 1999). Tyrosine hydroxylase-immunoreactive profiles were quantified in

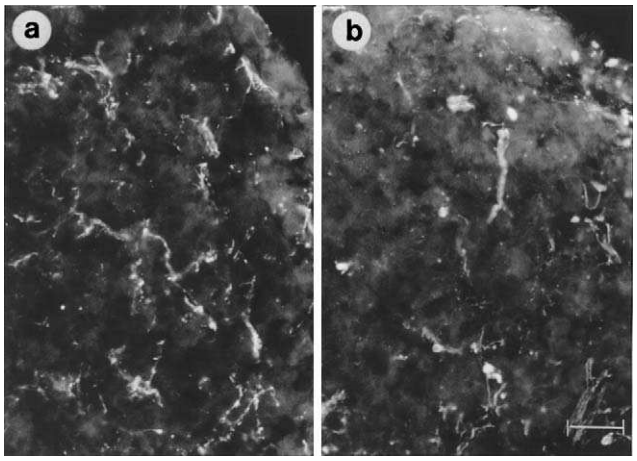

FIG. 64.4. Tyrosine hydroxylase immunoreactivity in sections of pineal glands obtained from young (a) and aged (b) animals (Kuchel *et al*., 1999). Scale bar = 50 μm.

pineal glands of young and aged male Sprague–Dawley rats. The density of TH-immunoreactive fibers was 30% lower in aged pineals, although the remaining fibers contained 20% more TH immunoreactivity, measured densitometrically (Fig. 64.4; Table 64.1) (Kuchel *et al*., 1999). Orthograde tracing of the pineal sympathetic innervation using biotinylated dextran was also performed (Fig. 64.5) (Kuchel *et al*., 1999). Quantitation of confocal images of individual labeled fibers revealed that average axon length, varicosity numbers, branch point numbers, and numbers of terminations were all decreased by approximately 50% in aged tissues (Table 64.2) (Kuchel *et al*., 1999). These findings suggest that whole branches, along with their associated varicosities are lost in old age. Although pineal melatonin production has been shown to decline dramatically in the course of mammalian aging (Kuchel and Zigmond, 1991), the primary role of melatonin in the aging process or in diseases associated with aging remains to be defined (Reppert and Weaver, 1995). Nevertheless, significant losses of sympathetic fibers to the mammalian pineal gland as described above could contribute to diminished function of this target tissue in old age.

Based on morphometric studies it seems likely that various types of growth changes (lengthening, retraction or atrophy) of axons and dendrites, combined with alterations in soma size

TABLE 64.1 Quantitation to Tyrosine Hydroxylase Immunoreactivity

Age	Area percentage	Intercept density (mm)	Gray value
Young (6)	1.65 ± 0.049	12.1 ± 0.35	67.6 ± 2.3
aged (6)	1.2 ± 0.12	8.2 ± 0.87	81.1 ± 2.14
	**	***	***

Note. Tyrosine hydroxylase immunoreactivity signal was quantified in pineal gland sections obtained from young and aged male Sprague–Dawley rats. Statistical differences in different measures of tyrosine hydroxylase immunoreactivity were compared between young and aged were examined using Student's *t* test ($^{*}P<0.05$; $^{**}P<0.01$; $^{***}P<0.005$). All results are presented as the mean ± SEM (Kuchel *et al*., 1999).

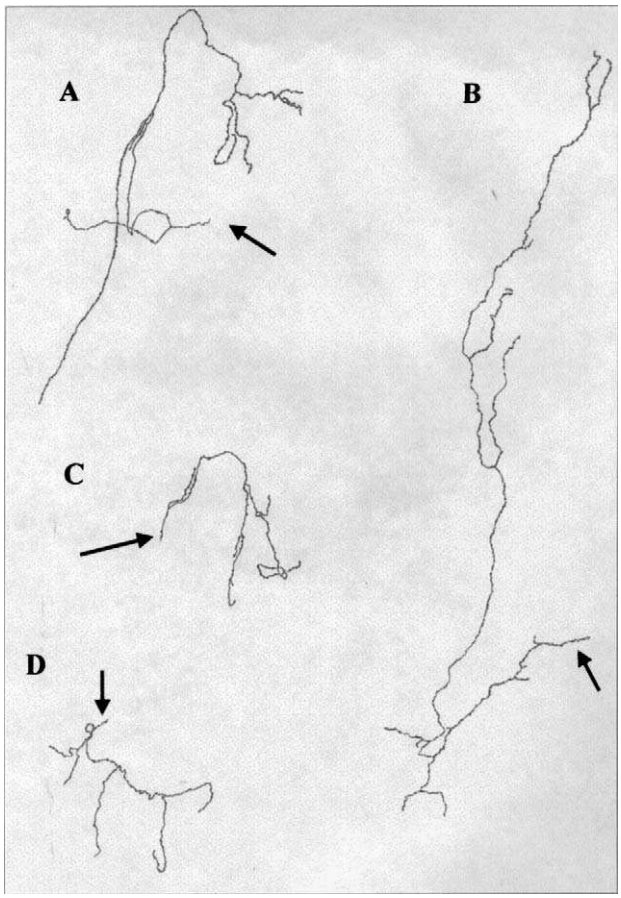

FIG. 64.5. Tracings to typical results of orthograde labeling using biotinylated dextran injections into right superior cervical ganglia demonstrating sympathetic arborizations in young (A,B) and aged (C,D) pineal glands. Note the marked reductions in extent of arborizations and numbers of varicosities in tracings from aged animals (C,D), compared to those from young animals (A,B) (Kuchel *et al*., 1999).

and neurotransmitter expression may occur in different situations. Since neurotransmitter markers are generally used to identify the peripheral fibers of particular nerve groups in tissues with multiple innervation, it is not always possible to know whether a change in staining pattern indicates altered levels of neurotransmitter, altered growth of nerve fibers, or both. The divergent changes in sympathetic neurons with age suggests that compensatory changes occur in neurons and groups of neurons as they attempt to respond to the altered demands of old age. These extra demands could contribute to the dramatic upregulation in TH mRNA expression is a small subpopulation of aged rat superior cervical ganglion neurons (Kuchel *et al*., 1997a). Moreover, additional metabolic and other stresses may contribute to the death of subsets of neurons in aged sympathetic ganglia. Alterations in the autonomic centers of the brain and spinal cord and in the dendrites of postganglionic sympathetic neurons in aging suggest altered patterns of central connectivity. The overall picture is of relatively small, quantitative changes, which, perhaps because of accumulated effects at different hierarchical levels of neural organization, lead to the rather more widespread deficits in autonomic function which have been observed clinically.

TABLE 64.2 Quantitation of Orthograde Labeling

Age	Total axon length (μm)	Total varicosities	Intervaricose distance (μm)	No. of branch points	No. of terminations	Segment length (μm)
Young (6)	1207 ± 199	110 ± 14.5	10.7 ± 1.0	8.3 ± 1.6	9.3 ± 1.6	130 ± 14.6
Aged (4)	575 ± 108	52.0 ± 7.0	10.9 ± 1.3	3.5 ± 0.6	4.8 ± 0.5	121 ± 23.3
	*	**	NS	*	*	NS

Note. Quantitation of orthograde labeling was performed in pineal glands of young and aged male Sprague–Dawley rats. Statistical differences in different measures of orthograde labeling were compared between young and aged animals using Student's *t* test ($^{*}P<0.05$; $^{**}P<0.01$). All results are presented as the mean ± SEM (Kuchel *et al*., 1999).

Two strands of thought may help us understand these diverse phenomena associated not only with the aging mammalian sympathetic nervous system, but with other aging cells and systems. The first strand, the neurotrophic theory (Purves *et al*., 1988; Gavazzi and Cowen, 1996; Cowen and Gavazzi, 1998), was originally developed to explain the rules governing survival in the embryonic sympathetic nervous system. The second strand is the network theory of aging which proposes some simple rules governing the allocation of resources in multicellular organisms (Lithgow and Kirkwood, 1996).

E. Neurotrophic Theory and Its Relation to Neuronal Aging

The neurotrophic theory states that during early development neurons compete with their neighbors for a share of limited quantities of trophic factors which are derived from the target tissues that the neurons will innervate (Purves *et al*., 1988). Success is rewarded by the survival and connectivity of an appropriate number of neurons. The first of these trophic factors, nerve growth factor (NGF), was identified when a mouse sarcoma tumor was discovered to synthesize a peptide capable of inducing extravagant growth of sympathetic nerve fibers (Levi-Montalcini and Hamburger, 1951; Levi-Montalcini *et al*., 1995). Proof of the dependent relationship of sympathetic neurons on target-derived NGF has come from experiments either depriving developing neurons of NGF, leading to extensive cell death (Bjerre *et al*., 1975), or, more recently, overexpressing NGF in target tissues in transgenic mice (Albers *et al*., 1994), which results in survival of a huge excess of sympathetic neurons. It took a further 35 years to discover that NGF was a member of a larger family—the neurotrophins—with trophic effects on many different neurons in the central and peripheral nervous systems. In addition to NGF, the neurotrophins are now known to include brain-derived neurotrophic factor (BDNF), NT3, NT4-5, and NT6, (Thoenen, 1995) of which NGF and NT3 play a crucial part in the survival of developing sympathetic neurons (Davies, 1995).

The effects of NGF on sympathetic neurons are specified by the relatively specific *trkA* receptors, and the nonspecific glycoprotein p75 receptor (Chao and Hempstead, 1995). The latter receptor binds all neurotrophins with varying affinities, but its role remains controversial (Bothwell, 1995). Interestingly, it has recently become clear that NT3 is capable of binding to *trkA*, as well as to p75 receptor with relatively high affinity (Chao and Hempstead, 1995). Although trk receptors can transduce most of the known effects of the neurotrophins, p75 NGF receptors are probably important in modulating some of these effects, particularly in later stages of development (Miller *et al*., 1994). In addition to the neurotrophins, there are a number of cytokines including CNTF (ciliary neuronotrophic factor), the FGFs (fibroblast growth factors), retinoic acid, and, more recently, GDNF which have important trophic effects on developing sympathetic neurons (Stemple *et al*., 1988; Burnham *et al*., 1994; Kobayashi *et al*., 1994; Buj-Buello *et al*., 1995).

The relevance of neurotrophic theory does not end in early development. The theory has been extended to suggest that neuron–target interactions and neurotrophic factors are vital contributors to the regulation of plasticity in the adult and aging nervous system, including in sympathetic neurons (Gavazzi and Cowen, 1996; Cowen and Gavazzi, 1998).

F. Maintenance Programs in Neuronal Plasticity and Aging

Organismal, and perhaps cellular, longevity is regulated by the amount of energy expended by the organism on maintenance of its constituent cells and systems (Lithgow and Kirkwood, 1996). Aging, therefore, may be understood as a failure of ongoing maintenance programs—a concept that is likely to be more relevant to postmitotic cells such as neurons than aging theories based on the accumulation of defects in processes associated with cell division. Over a number of years, one of us (T.C.) has investigated the relevance of neurotrophic theory, as a paradigm of an ongoing cell maintenance program, in relation to aging processes as they affect sympathetic and other neurons.

Dynamic maintenance programs are essential for adult neurons. For example, plasticity in mature sympathetic neurons includes energy-demanding changes associated with growth (or retraction) of axons and dendrites to alter their territory and connectivity, regeneration of nerves after injury, growth or shrinkage of cell soma, and changes in expression of neurotransmitters and other markers of dynamic behavior. While plasticity is generally associated with the developing nervous system, it becomes increasingly clear that plasticity continues to be an important feature of the mature, and even aged, nervous system as it attempts to respond to altered demand.

Plastic changes in adult and aging neurons may use mechanisms "inherited" from earlier stages of development. The peripheral processes of mature autonomic and other neurons innervating target tissues continually grow and retract over

periods of a few days (Purves *et al*., 1986). The mechanism that has been proposed to control this form of plasticity is the synthesis and release by the target tissue of limiting amounts of neurotrophic factors. Adult sympathetic and other neurons appear thus to remain intimately related to their targets, providing them with appropriate signals for their activation, and receiving, in return, trophic messages required for their maintenance and continued plasticity.

Trophic interactions with target tissues are therefore important elements of plasticity at all stages of life. However, the nature of the relationship may change with age. As we have already stated, in early life, neurotrophic factors control survival of sympathetic, as well as the establishment of appropriate patterns of growth, connectivity (Voyvodic, 1987, 1989) and neurotransmitter phenotype (Landis, 1990). In later periods of life, the survival of sympathetic neurons becomes independent of NGF (Orike and Cowen, unpublished data). However, interactions between sympathetic neurons and their targets remain important for the regulation of growth of axons, soma and dendrites (Purves *et al*., 1990), and neurotransmitter expression (Schotzinger *et al*., 1994). Studies of experimentally induced hypertrophy of smooth muscle in gut and bladder have shown that the associated sympathetic and other autonomic neurons undergo a parallel hypertrophy (Gabella *et al*., 1992), providing strong evidence of the ongoing influence that target tissues can have on their innervating neurons during adulthood. Trophic interactions between nerves and end organs are therefore a vital feature of maintenance and plasticity in the mature nervous system and alterations in this relationship are likely to be critical determinants in the aging process.

G. Sympathetic Neuron–Target Interactions in Aging

Transplantation studies have been used to explore the capacity of target tissues to regulate neuronal phenotype during aging. Target tissues with known age-changes in their sympathetic innervation have been removed from old donor rats and transplanted into young host animals, making contact with the axon terminals of host sympathetic neurons (Gavazzi *et al*., 1992; Cowen *et al*., 1996a). The donor tissues are denervated on removal, providing new territory over which host nerves can grow. Transplants of cerebral arteries and sweat glands, two target tissues where the density of sympathetic innervation is reduced by about 50% with age, become reinnervated by strikingly fewer host nerves than transplants of comparable young tissues. Similar studies have attempted to find out whether target tissues can influence age-changes in neurotransmitter expression, in addition to peripheral nerve fiber density. Eccrine seat glands are innervated by sympathetic neurons, which are unusual in using acetylcholine as their peripheral neurotransmitter. Evidence from early development shows that these neurons switch from a catecholaminergic to a cholinergic neurotransmitter phenotype at the time when their peripheral axons first contact their target sweat glands (Schotzinger *et al*., 1994). Whereas sweat glands from aged rats were, like rat cerebral arteries, less attractive to host nerves, they remained competent to invoke cholinergic characteristics in the reinnervating host neurons (Cowen *et al*., 1996a), suggesting that different target-associated factors regulate nerve growth and transmitter expression.

Transplantation has also been used to find out whether neurons retain regenerative capacities in old age. Aged sympathetic neurons from the rat superior cervical ganglion, transplanted into young hosts have generally shown unimpaired plasticity, in terms of survival as well as extent of neurite outgrowth (Gavazzi and Cowen, 1993). However, in the few studies in which transplants have been made into old host rats, both young and old neurons are impaired in their capacity for neurite outgrowth, suggesting that changes in the aging environment as well as changes in neurons themselves in old age, could contribute to altered plasticity (Gavazzi *et al*., 1992). Denervation studies also show that collateral sprouting (the capacity of axons to expand their territory) is impaired in sympathetic neurons of the aged rat (Crutcher, 1990; Kuchel and Zigmond, 1991; Kuchel, 1993). These observations demonstrate that sympathetic neurons remain to some extent dependent on their target tissues for signals which regulate both the pattern and the density of their peripheral arborizations and also their patterns of neurotransmitter expression. This ongoing influence appears to extend throughout mature life and into old age. In addition, there are hints that intrinsic changes in neurons and alterations in their environment contribute to age-related changes in plasticity, presumably allowing more-or-less continuous adjustment of neuronal phenotype to altered functional demands.

H. Molecular Influences on Plasticity of Aging Sympathetic Neurons

As we have tried to show, trophic support from targets continues to be important for the maintenance and plasticity of mature sympathetic neurons. Mature neurons ''inherit'' dependence on particular factors from earlier stages of life but respond in different ways, for reasons which are often unclear. Thus, mature autonomic neurons remain dependent on NGF for growth (Ruit *et al*., 1990), collateral sprouting (Gloster and Diamond, 1992), and neurotransmitter expression (see above). However, unlike developing neurons, they are not dependent on neurotrophic factors for their survival (Orike and T. Cowen, unpublished data). In addition, regeneration of sympathetic (and sensory) nerves in mature animals is probably also not NGF-dependent (Diamond et al., 1992; Gloster and Diamond, 1992).

That adult sympathetic neurons remain dependent for their growth on NGF raises the possibility that NGF treatment could rescue those neurons that exhibit selective vulnerability from age-related neurodegeneration. Local infusion of relatively high doses of NGF with miniosmotic pumps into the third ventricle or subdural space of aged rats induces regrowth of a pattern of innervation around the internal carotid and middle cerebral (Andrews and Cowen, 1994a) arteries that resembles that seen in young rats. Sprouting of fibers mainly involved the sympathetic nerves, whereas sensory nerves also responded to NGF infusion with elevated transmitter levels (Isaacson *et al*., 1990). Dendrites of the sympathetic neurons projecting to cerebral blood vessels were also found to be capable of regrowth following local treatment of their peripheral axons with NGF (Andrews and Cowen, 1994b). Withdrawal of treatment predictably resulted in atrophy, indicat-

ing the need for a continuous supply of NGF for neuronal maintenance.

It is not clear at present whether the effects of treatment with NGF on growth of mature autonomic nerves are evidence of a pharmacological effect or whether NGF treatment supplements target-derived, endogenous NGF in the regulation of neuronal plasticity. In early postnatal life, target levels of either the NGF protein or its messenger RNA tend to correlate with the density of sympathetic innervation (Shelton and Reichardt, 1984; Weskamp and Otten, 1987), as predicted by the neurotrophic theory. However, attempts to extend this concept to the aging nervous system (Cowen, 1993) have not so far been successful. For example, sympathetic nerves are induced to sprout into the adult rat hippocampus following its denervation by lesions of the fimbria-fornix and this response is reduced in aging animals (Crutcher, 1988). However, the same group was unable to demonstrate an age-related loss of hippocampal NGF levels which could have caused the failed response (Crutcher and Weingartner, 1991). Studies of the target tissues supplied by those subpopulations of sympathetic neurons which are selectively vulnerable to aging, such as cerebral arteries (Cowen *et al*., 1996b) and the pineal gland (Kuchel *et al*., 1999) have also failed to demonstrate any alterations in NGF levels which might underpin age-related neuronal atrophy or cell death. Because targets are known to remain important in the maintenance of phenotype of adult and ageing sympathetic neurons, this lack of correlation between NGF levels and local neuronal atrophy implies that the key target-associated regulators of plasticity in adult and aging neurons may be different from those which are required by developing neurons. A further related possibility is that neuronal responsiveness to neurotrophins alters in adulthood and old age.

I. Target-Associated Factors in the Extracellular Matrix

Whilst studies of NGF have yielded important information about plasticity in mature and aged autonomic neurons, it is probable that we are only beginning to identify the different trophic factors that affect aging neurons. The extracellular matrix contains a number of insoluble, bound factors with important neurotrophic activities, to which sympathetic and other neurons respond. Extracellular matrix elements are found in the basal lamina at sites of neuroeffector junctions of somatic and autonomic (including sympathetic) neurons and are therefore ideally positioned to influence dynamic growth processes of the kind described previously through contact with terminal nerve fibers. Although the role of extracellular matrix molecules in aging has not been extensively investigated, recent studies implicate laminin and extracellular matrix in sympathetic nerve fiber atrophy in aged rats. For example, levels of laminin are reduced in the basal lamina associated with nerve terminals in cerebral arteries of aging rats (Gavazzi *et al*., 1995). *In vitro* studies have shown that laminin and NGF act synergistically to promote growth of adult and aging sympathetic neurons and that aging neurons become significantly less responsive to this combination of factors (Cowen *et al*., 1997). These results suggest an interesting scenario of coactivation of two sets of tyrosine kinases by target associated factors: one associated with integrin receptors (for laminin) and the other with *trk* receptors for the neurotrophins. In addition, they suggest that altered neuronal responsiveness to growth- and survival-promoting factors may regulate age-associated loss of plasticity.

J. Neuronal Responsiveness to Trophic Factors

Recent evidence indicates developmental shifts in the responsiveness of sympathetic neurons to NGF, some of which have been described (see above). Later in life, further changes occur that may require a revision of our understanding of the role of NGF in the mature nervous system. Aged sympathetic neurons express lower levels of both *trkA* and p75 (Kuchel *et al*., 1997a), while demonstrating fewer NGF binding sites (Uchida and Tomonaga, 1985). Thus, they may become less able to scavenge and utilize available NGF, making them vulnerable to trophic factor deprivation and providing a possible explanation for the reduced capacity for collateral sprouting previously described (Crutcher, 1990; Kuchel and Zigmond, 1991; Kuchel, 1993). *In vitro* studies also indicate reduced responsiveness of aging sympathetic neurons to NGF (Uchida and Tomonaga, 1985). Whereas NGF binding is reduced in aged sympathetic ganglia, it is not yet known for certain which NGF receptors are involved in these changes. Reduced NGF-responsiveness of aging sympathetic neurons projecting to the iris, in the absence of changes in irideal NGF levels, suggests that NGF receptor expression is no longer as tightly coupled to levels of NGF at the target as it was during early development (Gavazzi *et al*., 1996). The search for alternative influences on the responsiveness of aged autonomic neurons to trophic factors forms an important area for further study.

By virtue of their large size and surface area and high metabolic requirements, neurons become exposed to a number of local and systemic changes during the aging process which may influence plasticity. For example, circulating growth hormone levels decline substantially with age, with undetectable serum levels of growth hormone in 50% of all subjects by their seventh decade (Borst *et al*., 1994). Declining growth hormone levels have been proposed as a major influence on aging, including in the nervous system. A related pathway which may be important in the maintenance of adult sympathetic neurons is that mediated by the insulin-like growth factors (IGF-1 and IGF-2). Circulating IGF levels decline in parallel with, and perhaps in response to, growth hormone during aging and are known to affect growth in developing cultured sympathetic neurons (Recio-Pinto *et al*., 1986). Treatment of growth hormone-deficient patients with the recombinant hormone partially rescues the sweating responses, perhaps as a result of regenerative effects on sudomotor nerves (Hasan *et al*., 2000).

Altered levels of sex hormones may also affect targets of autonomic neurons such as sweat glands (Rees and Shuster, 1981) and thereby influence their autonomic innervation. The high metabolic rate of neurons means that during aging neurons are increasingly likely to encounter the damaging effects of partial ischemia or raised levels of free radicals. These changes are relatively specific to old age and introduce a negative influence, not present at earlier stages of development, on neuronal plasticity. In relation to the role of free radicals in aging, it is interesting to note that neurons which synthesize and use the free radical, nitric oxide, as a neurotransmitter

appear to be relatively protected from the cell death that affects their neighbors (Santer, 1994; Belai *et al*., 1995), although how they achieve this apparent invulnerability is not understood.

Basic Genetic Concepts

I. Chromosomes and Genes

Chromosomes and their functional units, genes, are the basic units of inheritance. They consist of chromatin, long strands of deoxyribonucleic acid (DNA) packed around a scaffold of proteins called histones (Fig. A.1). When a cell is quiescent, the DNA strands are loose in the cell nucleus. When the cell is preparing to divide (mitosis or meiosis), the chromatin packs tightly into chromatids. Sister chromatids attach together at the centromere, and the chromosome appears as a bottom-heavy X-shaped structure (Fig. A.1). The short arm of the chromosome is referred to as the ''p'' segment, and the long arm is the ''q'' segment.

Chromosomes and genes come in pairs. One member of each pair is maternally inherited; the other is paternally inherited. Humans have 46 chromosomes: 22 pairs of autosomes and one pair of sex chromosomes. Although many people assume that more complex organisms must have more chromosomes than simpler organisms, there is actually no correspondence between chromosome number and the complexity of an organism. For example, the crayfish (*Astacus trowbridgei*) has 188 pairs of chromosomes, the dog (*Canis familiaris*) has 39 pairs, and the mouse (*Mus musculus*) has 20 pairs.

Chromosomes vary in size, depending on how many genes they have, and how many bases comprise each gene. There are about 3000–4000 genes on each chromosome. The largest human chromosome, Chromosome 1, consists of 250 million bases. In contrast, the smallest chromosome, the Y chromosome, consists of 50 million bases. Altogether, the human genome consists of approximately 3 billion bases, on about 100,000 genes.

Gene pairs determine different traits. When both genes at a locus are the same, the individual is said to be homozygous at that locus. If the two genes differ, the individual is heterozygous at that locus. A gene is said to be dominant if the phenotype depends on the presence of this gene alone. A gene is recessive if homology is necessary for its phenotype to be expressed.

II. DNA and RNA Are Long Chains of Nucleotides

In gross terms, DNA is a set of instructions for making ribonucleic acid (RNA) and proteins. In molecular terms, DNA and RNA are polymers of nucleotides. As shown in Fig. A.2, nucleotides are units consisting of three components: a nitrogenous base, a sugar molecule, and a phosphate molecule. In DNA, the sugar is deoxyribose, and the nitrogenous base may be adenine (A), guanine (G), thymine (T), or cytosine (C). In RNA, the sugar is ribose. The bases are the same as in DNA, with one exception: in RNA, uracil (U) substitutes for T. A and G are purine bases; T and C and U are pyrimidine bases. The sugar and the phosphate molecules link together in repeating units, forming the backbone of the nucleic acid. The bases are attached to the sugar molecules.

DNA is a two-stranded molecule, whereas RNA consists of a single strand. In the DNA molecule, the two strands are held together by weak hydrogen bonds between pairs of bases (Fig. A.2). The strands are complementary rather than identical, because a long purine base on one strand always links to a shorter pyrimidine base on the other strand. The pairing of bases on the two strands of DNA is very specific. A always pairs with T, and G always pairs with C. When RNA is replicated, or when it attaches to a single strand of DNA during the process of transcription, U always pairs with A. Except during transcription or replication, the double-stranded DNA molecule is coiled into a helix (see Fig. A.1).

A different kind of DNA is found in specialized intracellular organelles called mitochondria. Mitochondrial DNA (mtDNA) is arranged in a double-stranded ring rather than a helix, and its genetic code differs from that of nuclear DNA (nDNA). More will be said about mtDNA later.

III. Each Gene Codes for a Specific Polypeptide

Every cell of the body has the same set of genes and nDNA, yet cells differ in structure and function. This is due to differ-

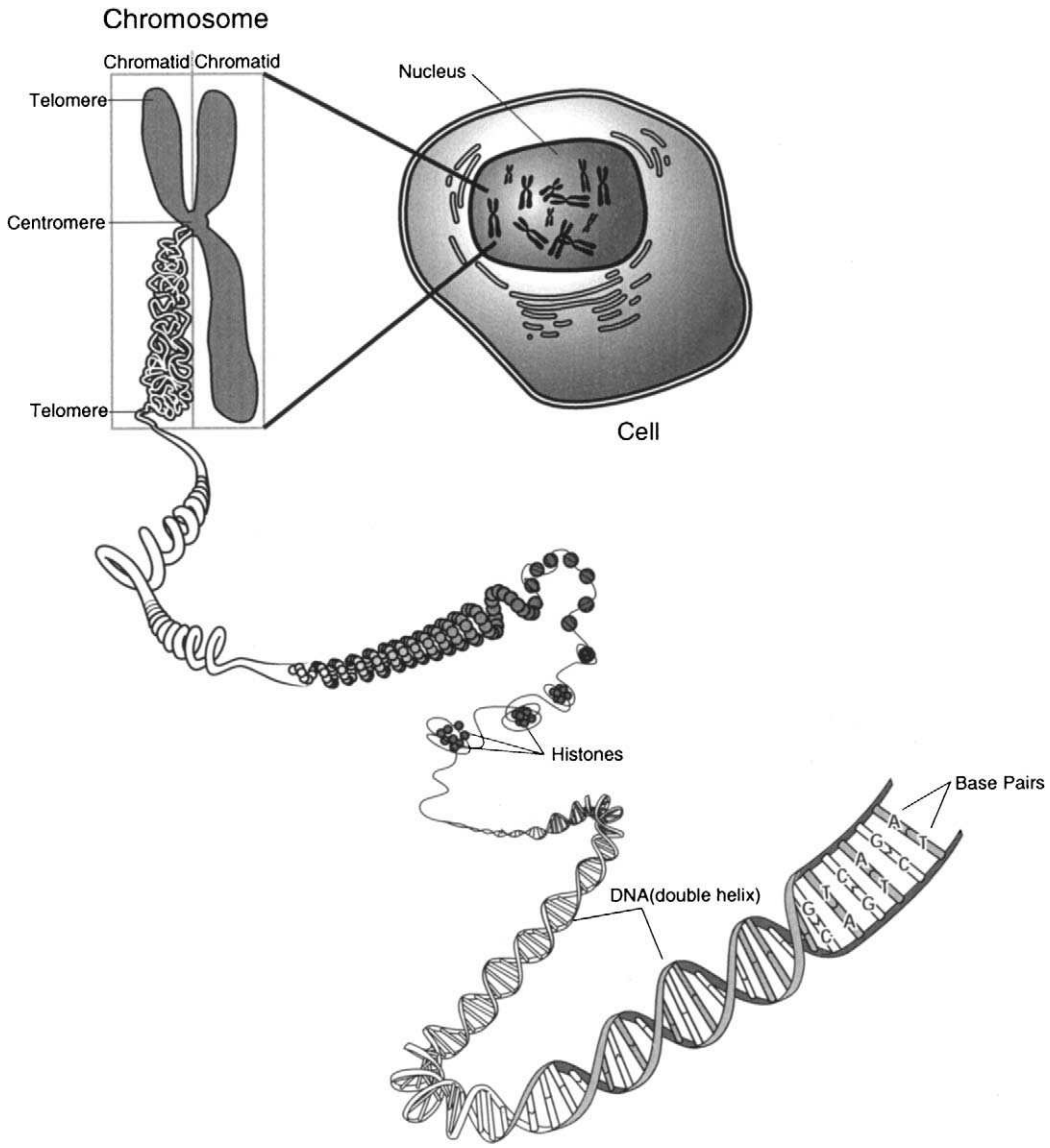

FIG. A.1. Several views of a nuclear chromosome. Sister chromatids are connected at the centromere. Each chromatid consists of tightly coiled strands of DNA and histones. (Illustration created by Darryl Leja, and obtained from the National Human Research Genome Institute, URL: www.nhgri.hih.gov.)

ential expression of proteins, related to the activation of different genes. Once a gene is activated by a cellular or environmental event, the processes of transcription and translation are set into motion. The final product is a protein, which does most of the work of the cell.

Each gene codes for a particular polypeptide, or chain of amino acids (Fig. A.3). The instructions for assembling the amino-acid chain are represented by the sequence of bases comprising a gene. The amino-acids in a chain are linked together with peptide bonds. Two linked amino acids form a unit called a ''dipeptide,'' and three linked amino acids form a ''tripeptide.'' When many (generally hundreds to thousands) amino acids are linked together, the functional unit is a protein. Proteins and their constituent amino acids perform many functions essential to life. Amino acids can act as neurotransmitters and antioxidants; proteins can act as structural elements, antibodies, enzymes, membrane channels, receptors, regulators of gene function, and molecular transporters. Proteins can also combine with nonproteins to form glycoproteins, lipoproteins, and nucleoproteins, all of which are essential to cell integrity and function.

IV. Proteins Are the End Product of Gene Expression

Gene expression involves transcription and translation (Fig. A.4). Transcription refers to the process of making a copy of the genetic code carried by the DNA of the gene. This is the function of messenger RNA (mRNA). Translation refers to the process whereby amino acids are assembled into polypeptide chains, as specified by the genetic code. This pro-

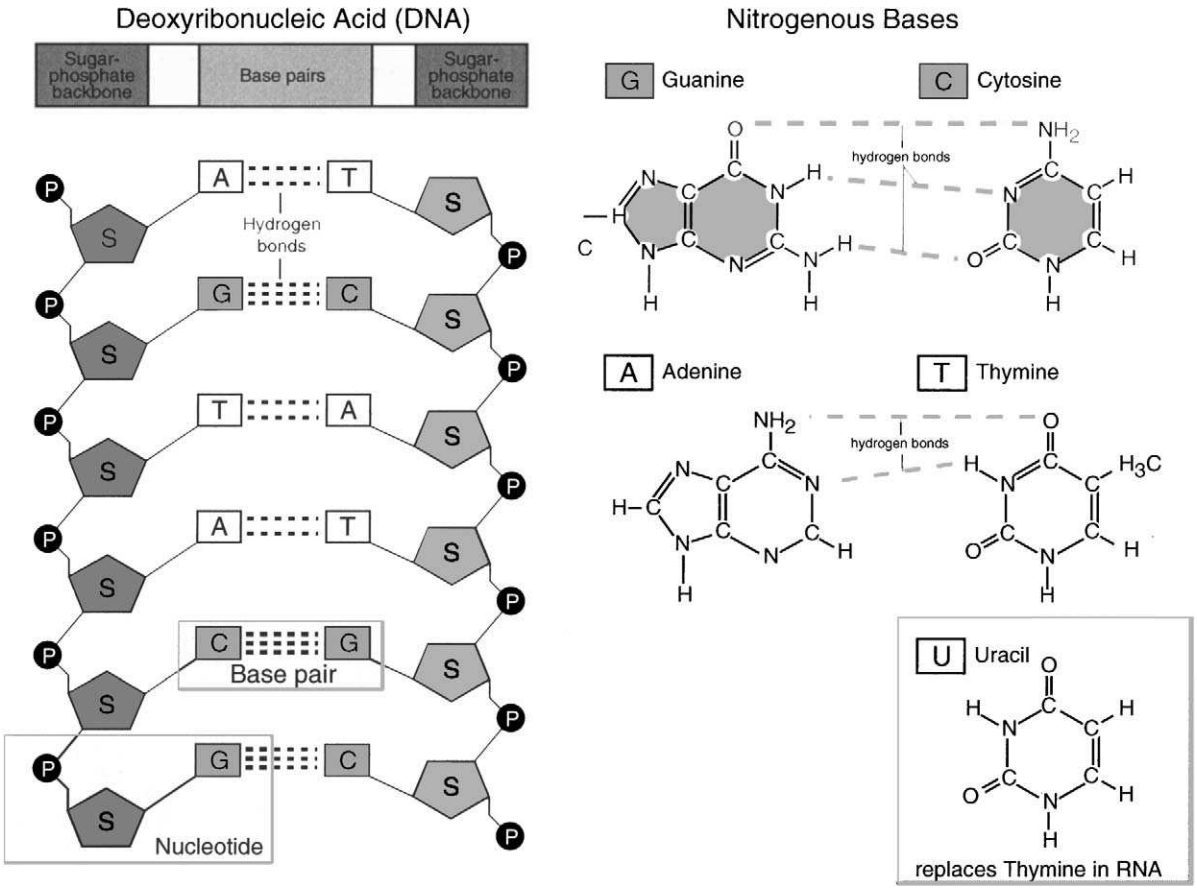

FIG. A.2. The structure of DNA. Four nitrogenous bases (adenine, A; thymine, T; cytosine, C; guanine, G) are linked like rungs of a ladder to a sugar-phosphate backbone. The two strands of DNA are held together by weak hydrogen bonds between pairs of bases. The sequence of bases contains the information necessary for protein synthesis. (Illustration created by Darryl Leja, and obtained from the National Human Research Genome Institute, URL: www.nhgri.hih.gov.)

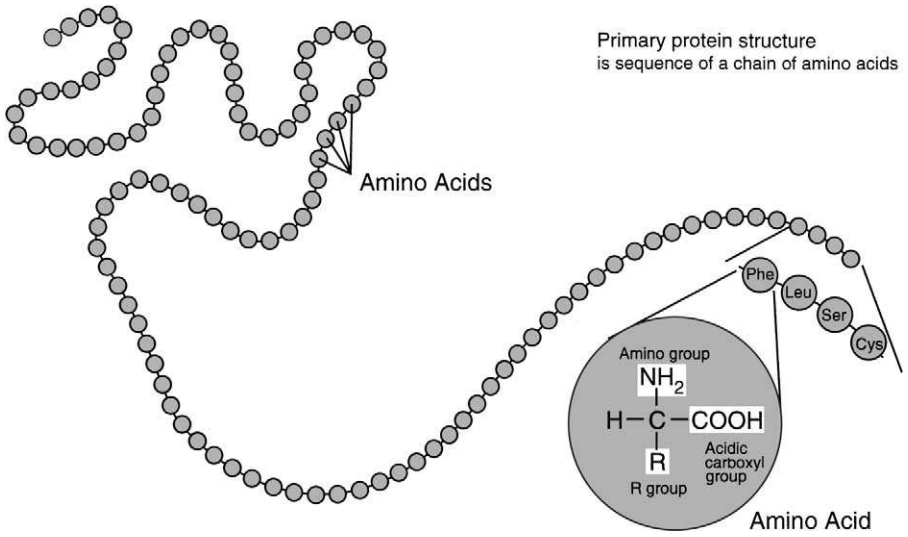

FIG. A.3. Primary structure of a protein. Proteins are long chains of amino acids, linked together with peptide bonds. Every amino acid has an amino group (NH_2) and a carboxyl group (COOH). Differences in the R group define specific amino acids. Functional proteins are characterized by a complex three-dimensional shape that makes them biologically active. (Illustration created by Darryl Leja, and obtained from the National Human Research Genome Institute, URL: www.nhgri.hih.gov.)

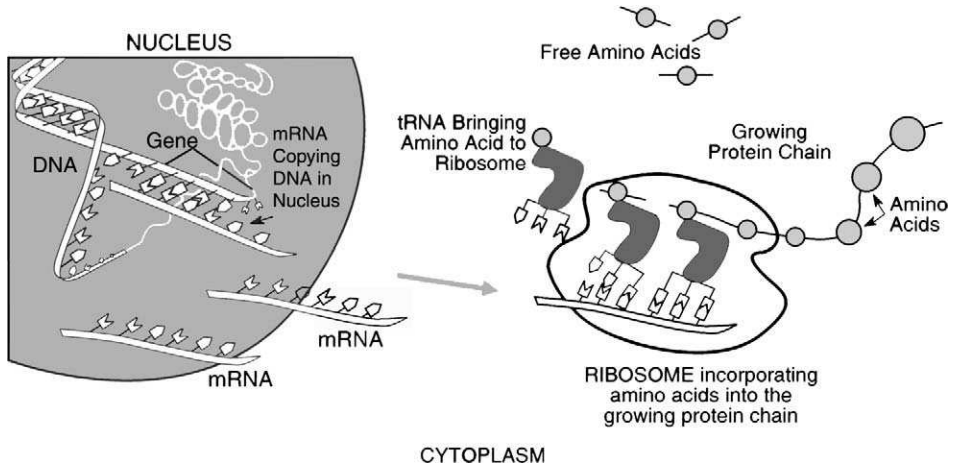

FIG. A.4. A summary of gene expression (transcription and translation). When a gene is activated, the two strands of DNA separate, and the base sequence of a strand is transcribed (copied) to messenger RNA (mRNA). The mRNA molecules are processed to remove introns (see text), then travel from the nucleus to the ribosomes in the cytoplasm of the cell. The ribosomes translate the genetic code, specified by triplets of bases called codons, and construct proteins from amino acids supplied by transfer RNA (tRNA). A protein is the final product of gene expression. (Illustration courtesy of the U.S. Department of Energy Human Genome Program, from the Primer on Molecular Genetics, which may be downloaded from www.ornl.gov/hgmis.)

cess requires ribosomes, ribosomal RNA (rRNA), amino acids, and transfer RNA (tRNA).

The transcription process begins when the gene is activated. As shown in Fig. A.4, the two strands of DNA separate, and a copy of the DNA strand is made by mRNA, a transient intermediary molecule similar to a single strand of DNA. In eukaryotic cells, only about 10% of the bases on the DNA molecule code for proteins; these coding sections are called exons. Noncoding portions are called introns. The mRNA is processed before it leaves the nucleus to remove all introns and to add ''start'' and ''stop'' sequences to the ends of the mRNA molecule. The start sequence is added to one end, called the 5′ end, and a ''poly(A)tail,'' or end sequence, is attached to the opposite (3′) end.

After the mRNA has been processed, it travels to the ribosomes in the cytoplasm of the cell, where translation occurs (Fig. A.4). Amino acids are carried to the ribosomes by tRNA, and the ribosomes incorporate them into a polypeptide chain. The sequence of amino acids is specified by the sequence of bases on the mRNA. Each three bases forms a unit called a codon, as illustrated in Fig. A.5. Three codons are ''stop'' codons that signal the end of gene transcription. Other codons represent particular amino acids, as summarized in Table A.1. For example, the DNA base sequence ATG codes for the amino acid methionine. The corresponding base sequence for RNA is AUG. Since there are 64 possible codons and 20 amino acids, there is considerable redundancy in the genetic code. For example, glycine, the simplest amino acid, is represented by four different codons: GAA, GCC, GGG, and GGT (or GGU for RNA).

V. Gene Mutations Can Take Many Forms

A mutation is a change in the original DNA code for a protein. Mutations can arise through mistakes in DNA replication or DNA damage caused by chemical mutagens or radiation. Mutations of somatic DNA will affect only that individual, whereas mutations in the DNA of a reproductive cell (gamete) will be passed on to the individual's offspring. If this occurs, every cell of the offspring's body will contain that particular mutation. Assuming that the mutation is not lethal, the off-

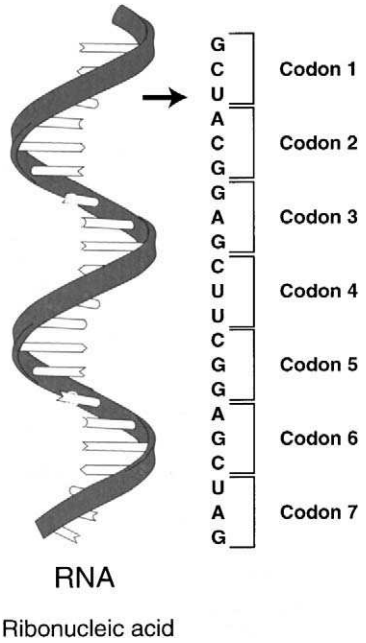

FIG. A.5. Codons on a segment of RNA. Every three bases form a codon, which is the code for a particular amino acid. Codons 1–6 represent the amino acids alanine, threonine, glutamate, leucine, arginine, and serine, respectively. Codon 7 is a ''stop'' codon signal the end of the RNA chain. (Illustration created by Darryl Leja, and obtained from the National Human Research Genome Institute, URL: www.nhgri.hih.gov.)

TABLE A.1 DNA Codons for 20 Amino Acids

Amino acid	Codons
Alanine	GCA, GCC, GCG, GCT
Arginine	AGA, AGG, CGA, CGC, CGG, CGT
Asparagine	AAC, AAT
Aspartic acid	GAC, GAT
Cysteine	TGT, TGC
Glutamic acid	GAA, GAG
Gutamine	CAA, CAG
Glycine	GGA, GGC, GGG, GGT
Histadine	CAT, CAC
Isoleucine	ATT, ATC, ATA
Leucine	CTA, CTC, CTG, CTT, TTA, TTG
Lysine	AAA, AAG
Methionine	ATG
Phenylalanine	TTT, TTC
Proline	CCA, CCC, CCG, CCT
Serine	TCA, TCC, TCG, TCT, AGC, AGT
Threonine	ACT, ACC, ACA, ACG
Tryptophan	TGG
Tyrosine	TAC, TAT
Valine	GTA, GTC, GTG, GTT

spring will in turn pass the mutation on to future generations. Individuals with single recessive mutations are known as carriers.

DNA mutations can take many forms. These include point mutations (alterations in a single base or nucleotide), single and multiple deletions or insertions of small DNA segments, and duplications of entire coding sequences. A change in a codon that results in the wrong amino acid being incorporated into the polypeptide chain is referred to as a missense mutation. A change in a codon that leads to premature termination of translation is referred to as a nonsense mutation. Hundreds of genes control auditory system development and function. Mutations of genes required for the maintenance of cochlear homeostasis through life would be expected to render the cochlea more vulnerable than normal to environmental insults or to cause hearing loss directly.

VI. Mitochondria

Mitochondria are bacteria-sized intracellular organelles (Fig. A.6) that play a pivotal role in cellular energy production through synthesis of adenosine triphosphate (ATP). They are also involved in other important cellular functions, such as synthesis of lipids, heme, and some amino acids. Each mitochondrion consists of an external membrane that is freely permeable to low molecular mass ions and molecules, and an internal membrane that is highly folded and relatively impermeable, especially to ions. The inside of the mitochondrion, the matrix, contains a variety of enzymes and fiber-like structures that are involved in the production of ATP in the oxidative phosphorylation pathway. The matrix is also the location of 2–10 molecules of double-stranded mtDNA. Unlike nDNA, mtDNA is arranged in a closed loop.

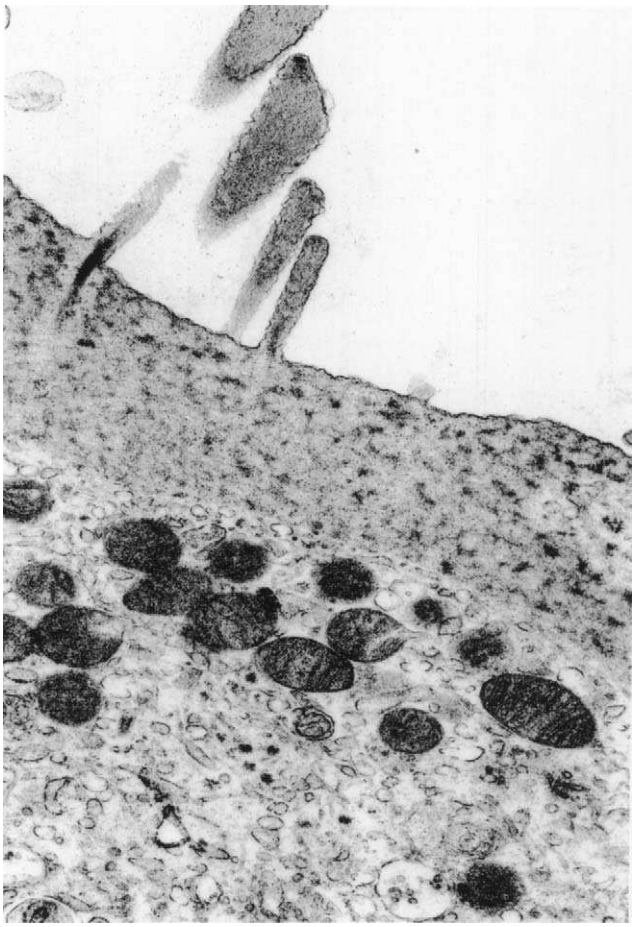

FIG. A.6. Photomicrograph showing mitochondria gathered beneath the cuticular plate of an outer hair cell. Mitochondria vary in shape and size, but each has a highly permeable external membrane, and a highly invaginated, nonpermeable internal membrane. The internal membrane forms the boundary around the internal matrix. The matrix is the location of 2–10 mitochondrial chromosomes, consisting of mitochondrial DNA (mtDNA). The matrix is also the site of oxidative phosphorylation. Toxic reactive oxygen species produced as a by-product of oxidative phosphorylation can cause damage to the mtDNA. (Photo courtesy of Dalian Ding, Center for Hearing and Deafness, SUNY at Buffalo.)

A. Genetics of mtDNA

Mitochondrial DNA has 37 genes, and it is 16,569 base pairs long. The outer strand codes for 12 proteins, 14 tRNAs, and 2 rRNAs, while the inner strand codes for 1 protein and 8 tRNAs. The 13 mRNAs are translated on mitochondrion-specific ribosomes into 13 of the proteins required for making the five enzyme complexes that perform oxidative phosphorylation. The rest of the 60 or so protein subunits required for synthesis of the respiratory chain enzymes are produced by

nuclear DNA and imported into the mitochondrion. It is notable that the genetic code of mtDNA differs from the nDNA code, and there is only one noncoding sequence in the compact mtDNA molecule.

Mitochondrial DNA is transmitted exclusively through mothers. Thus, when a disease has a maternal pattern of inheritance, mtDNA mutations are suspect. The precise mechanisms governing mtDNA replication are poorly understood, but it is clear that mtDNA transcription is not closely restricted by the cell cycle. mtDNA may replicate at any time, independent of the cell cycle, and mitochondria have a relatively rapid turnover rate (weeks). This is one reason why mtDNA is far more susceptible to mutation than is nuclear DNA. There are several other reasons as well. First, mtDNA is not protected by a histone coat, and DNA repair mechanisms are lacking relative to nDNA. Of the five eukaryotic DNA polymerases known, only one is found in mitochondria, and this polymerase is inefficient in protecting DNA from inaccurate replications. (Stable mutations of nuclear DNA are actually rare, because the cell nucleus has many repair mechanisms.) Second, since mtDNA is present in high copy number within a cell, mutations are numerically more likely. Most importantly, mtDNA is located in the matrix of the mitochondrion, where it is exposed to high levels of free radicals and reactive oxygen species produced during oxidative phosphorylation. During normal aerobic respiration, mitochondria consume oxygen, reducing it in a stepwise fashion to water. Energy is harnessed in the high-energy bonds of ATP. Reactive oxygen species, particularly superoxide and hydroxyl radicals, are by-products of the process. These highly reactive molecules can attack proteins and membranes, damage DNA and trigger cell death through apoptosis if they are not ''neutralized'' by free radical scavengers and antioxidants, such as mitochondrial manganese-superoxide dismutase (Mn-SOD).

As with nDNA, mtDNA mutations can arise through mistakes in mtDNA replication or exposure to environmental agents (including certain medications such as AZT). Some autosomal recessive and autosomal dominant inherited genetic disorders can lead to mtDNA pathology. Cells and tissues with high energy demands (e.g., the central nervous system and the inner ear) are the most vulnerable to mitochondrial dysfunction due to reactive oxygen species damage.

When a mtDNA mutation arises within a cell, the cell will have two populations of mtDNA, one wild type (normal) and the other mutant. This situation is termed heteroplasmy. Since mtDNA may segregate unevenly to daughter cells during meiotic or mitotic cell division, heteroplasmy ratios may vary from one daughter cell to another. Over many divisions, the percentage of mutant and normal mtDNA molecules drifts toward homoplasmy, with the mtDNA within the cell being either purely mutant or purely normal. This process is known as replicative segregation. Rapidly dividing cells such as leucocytes often have low levels of heteroplasmy. In contrast, cells that are postmitotic, such as mammalian hair cells and neuronal cells, accumulate mutant mtDNA molecules and have a high ratio of heteroplasmy. As the percentage of mutant molecules increases, the ability of the mitochondria to carry out their normal functions becomes increasingly impaired. When the energetic threshold of the cell is exceeded, the cell will die. When the energetic threshold of an organ is exceeded, clinical manifestations will emerge.

B. Biology of mtDNA

Evidence is accumulating that mitochondrial pathology plays a role in the pathogenesis of many late-onset neurodegenerative disorders, including Parkinson's disease, Alzheimer's disease, Huntington's disease, and amyotrophic lateral sclerosis. Mitochondrial dysfunction has even been implicated in the degenerative processes of aging itself (see reviews by Wallace *et al*., 1995; Simon and Johns, 1999; Wallace, 1999). The ATP-generating capacity of a tissue declines with age, and this decline is correlated with an age-related increase in somatic mtDNA damage in postmitotic tissue (Brown and Wallace, 1994). The decline in energetic capacity with age may exacerbate disease expression, or make disease expression more likely. Some mtDNA mutations might lead to disease only in the presence of a specific nuclear genotype or environmental agent. Other mtDNA pathology may have direct effects on tissue and organ function. For example, the relationship between mtDNA defects and presbycusis is entirely speculative at this time. However, mutations in mitochondrial genes have recently been found to be associated with a variety of hearing defects, and it is plausible that they contribute to presbycusis as well (Fischel-Ghodsian, 1998).
