apoptosis will be reviewed briefly (Table 23.2). Morphological characteristics of neuronal apoptosis include cell body shrinkage, formation of "blebs" on the cell surface, nuclear condensation and fragmentation, and neurite fragmentation. Biochemical changes that typify neurons undergoing apoptosis include mitochondrial reactive oxygen species production and membrane depolarization (Keller *et al*., 1998a), activation of cysteine proteases of the caspase family (Nicholson and Thornberry, 1997), and loss of plasma membrane phospholipid asymmetry (Kruman *et al*., 1997). Molecular changes associated with apoptosis include induction of the expression of proapoptotic proteins such as prostate apoptosis response-4 (Par-4) (Guo *et al*., 1998a; Chan *et al*., 1999b) and certain members of the Bcl-2 family of proteins such as Bad and Bax (Chan and Mattson, 1999). In addition to such criteria, it is important to establish that the death of neurons in a particular experimental paradigm can be prevented by manipulations that block key steps in the apoptotic cascade. Examples include administration of caspase inhibitors, suppression of Par-4 expression and function using molecular approaches, and use of agents such as cyclosporin A that block mitochondrial membrane permeability transition (Guo *et al*., 1998a; Keller *et al*., 1998a).

Data obtained in studies of postmortem brain tissue from AD patients are consistent with apoptosis playing a role in the neurodegenerative process. Morphological analyses reveal evidence for nuclear DNA fragmentation in degenerating neurons (Smale *et al*., 1995; Su *et al*., 1994) and lack of morphological evidence of classic necrotic cell death (e.g., cell swelling and organelle damage). In addition, immunohistochemical data indicate increased caspase activation (Masliah *et al*., 1998; Chan *et al*., 1999a) and increased expression of apoptosis-related genes such as Bax and GADD45 (Torp *et al*., 1998; Tortosa *et al*., 1998) in neurons in brain tissue from AD patients compared to age-matched control patients. Analyses have also documented increased levels of Par-4 mRNA and protein in vulnerable regions of AD brain (e.g., hippocampus and inferior parietal cortex) compared to the same regions of age-matched control patients and to less vulnerable brain regions of AD patients (Guo *et al*., 1998a). Double-labeled immunohistochemical analyses in the latter study further showed that Par-4 levels are increased in many neurofibrillary tangle-bearing neurons.

Perhaps the strongest evidence supporting a major role for apoptosis in the pathogenesis of AD comes from experimental studies in animal and cell culture models. Exposure of cultured hippocampal and cortical cultures to Aβ induces neuronal apoptosis (Loo *et al*., 1993; Mark *et al*., 1995b; Kruman *et al*., 1997), which is mediated by Par-4 induction and caspase activation (Guo *et al*., 1998a; Chan *et al*., 1999a). Mutations in APP that are linked causally to inherited forms of AD increase production of the apoptosis-inducing Aβ, while decreasing production of the antiapoptotic secreted form of APP (Furukawa *et al*., 1996; Mattson, 1997; Guo *et al*., 1998b). Further support for a role for apoptosis in AD comes from studies of cultured neurons and transgenic mice expressing presenilin-1 mutations linked to early-onset autosomal dominant AD. Overexpression of presenilin-1 mutations in cultured PC12 cells increases their vulnerabilty to apoptosis induced by amyloid β-peptide and trophic factor withdrawal (Guo *et al*., 1996, 1997). The proapoptotic effect of presenilin-1 mutations appears to result primarily from an alteration of calcium regulation in the endoplasmic reticulum, such that levels of calcium release are increased when neurons are exposed to various insults (Guo *et al*., 1997, 1998c, 1999a). The disturbed cellular calcium homeostasis, in turn, endangers neurons by promoting Par-4 production (Chan *et al*., 1999b), mitochondrial dysfunction, and caspase activation (Guo *et al*., 1998a, 1999b; Chan *et al*., 1999a). Moreover, treatment of primary neurons expressing mutant presenilin-1 with neurotrophic factors, including basic fibroblast growth factor and activity-dependent neurotrophic factor, counteracted the proapoptotic action of the presenilin mutation (Guo *et al*., 1999c).

C. Involvement of Apoptotic Cascades in Dysfunction and Degeneration of Synapses

Synapses are believed to be sites where the neurodegenerative process begins in AD (Terry, 1994; DeKosky *et al*., 1996). The reason may be that both proapoptotic (e.g., glutamate receptors) and antiapoptotic (e.g., neurotrophic factor receptors) signaling pathways are highly concentrated in synaptic terminals. Moreover, it appears to be the case that Aβ is preferentially deposited in synaptic regions, most likely because the APP is axonally transported and therefore is present at high levels in presynaptic terminals (Mattson, 1997). Studies of cortical synaptosomes and cultured hippocampal neurons have provided evidence that insults relevant to AD can induce apoptotic biochemical cascades in synaptic compartments (Mattson and Duan, 1999). Exposure of rat cortical synaptosomes to apoptotic insults, including Aβ, results in caspase activation, loss of plasma membrane phospholipid asymmetry, and mitochondrial dysfunction (calcium uptake, membrane depolarization, and oxyradical production) (Mattson *et al*., 1998b). Synaptic degeneration in AD likely involves membrane lipid peroxidation and impairment of ion-motive

ATPases and glucose transporters (Mark *et al*., 1995b; Keller *et al*., 1997a). Par-4 levels are increased rapidly in cortical synaptosomes and in dendrites of hippocampal neurons in culture following exposure to Fe^{2+} and 4-hydroxynonenal, two insults relevant to the pathogenesis of AD (Duan *et al*., 1999). Treatment of synaptosomes with the protein synthesis inhibitor cycloheximide or Par-4 antisense oligonucleotides attenuated insult-induced mitochondrial dysfunction and caspase activation in synaptosomes and prevented death of cultured hippocampal neurons following exposure to excitotoxic and apoptotic insults, indicating a necessary role for Par-4 expression in synaptically driven apoptotic cascades. Additional support for a role for synaptic apoptosis in AD comes from studies in which cortical synaptosomes from transgenic mice expressing AD-linked presenilin-1 mutations exhibit enhanced elevations of cytoplasmic calcium levels following exposure to depolarizing agents, Aβ, and a mitochondrial toxin compared to synaptosomes from nontransgenic mice and mice overexpressing wild-type presenilin-1 (Begley *et al*., 1999). Consistent with apoptosis, it was shown that mitochondrial dysfunction and caspase activation after exposure to amyloid β-peptide were exacerbed in synaptosomes from presenilin-1 mutant mice. Treatment of synaptosomes with agents that buffer cytoplasmic calcium or prevent calcium release from the endoplasmic reticulum protected against the adverse effects of the presenilin-1 mutations.

That evidence that apoptotic cascades can be activated locally in pre- and postsynaptic compartments has important implications for the pathogenesis of AD. As described earlier, overactivation of glutamate receptors is implicated in the neurodegenerative process in AD. Influx of calcium into postsynaptic spines resulting from glutamate receptor activation is likely to be an important initial trigger for local activation of apoptotic cascades involving Par-4 induction, caspase activation, and mitochondrial dysfunction (Fig. 23.7). This would result in degeneration of postsynaptic spines, followed by dendrite degeneration and ultimately cell death. However, deficits in neurotrophic factor signaling might initially result in dysfunction and degeneration of presynaptic terminals, the compartments where receptors for neurotrophic factors are most concentrated. It is therefore likely that many neurons are functionally disconnected from their afferent input cells in the early stages of AD. The latter possibility suggests that the blockade of propogation of apoptotic signals from synapses to the cell body may prevent neuronal death and provide the opportunity for formation of new synapses.

D. Implications of Apoptotic Signaling for Prevention and Treatment of AD

What are the implications of evidence for neuronal apoptosis in AD for prevention and treatment of this disorder? One could inhibit the apoptotic process by preventing initiation of the cascade, by blocking a specific step in the cascade, or by stimulating antiapoptotic signaling pathways. Altered processing of APP appears to be an early event in AD, and drugs that modulate APP processing in a manner that decreases Aβ production are therefore being developed. Oxidative stress also appears to be a relatively early event in the neurodegenerative process in AD. Studies of experimental models of AD have

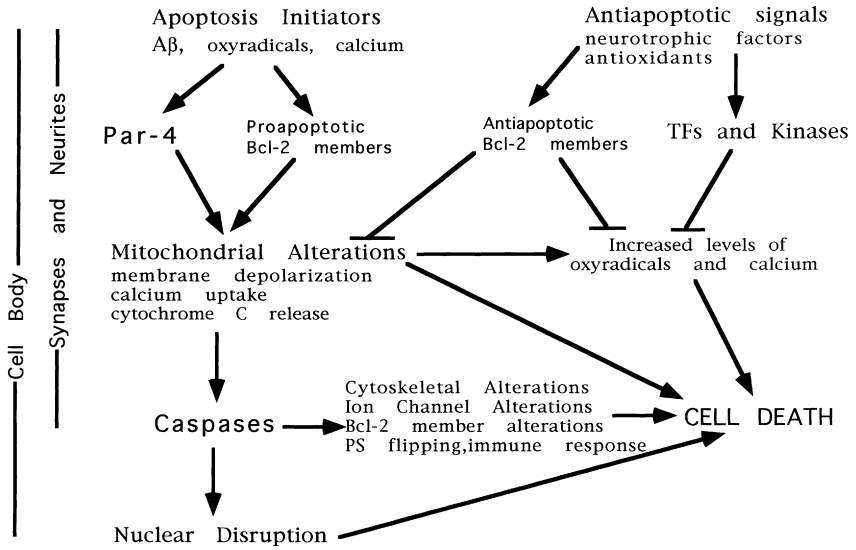

FIG. 23.7. General view of the biochemical pathways involved in neuronal apoptosis and neuroprotection. Apoptotic and antiapoptotic signals can be activated locally in synapses and neurites. Initiating signals, such as amyloid β-peptide, oxyradicals, and calcium, lead to induction of Par-4 and Bcl-2 family members. Par-4 and proapoptotic Bcl-2 family members induce mitochondrial alterations, which, in turn, lead to caspase activation and alterations in cellular calcium homeostasis and free radical metabolism. Caspases cleave substrates that modulate synaptic plasticity. Caspases also mediate proteolysis of substrates that lead to nuclear chromatin condensation and fragmentation. Antiapoptotic pathways can be activated by neurotrophic factors and other signals. Such pathways lead to activation of transcription factors (TF) that induce expression of neuroprotective proteins such as antioxidant enzymes and calcium-regulating proteins. In addition, antiapoptotic signals may modulate cell death pathways by activating kinases that phosphorylate substrates such as ion channels and Bcl-2 family members that influence the cell death process.

shown that the efficacy of several antioxidants is effective in preventing neuronal apoptosis, including vitamin E, uric acid, and estrogens (Goodman and Mattson, 1994; Goodman *et al*., 1996; Mattson *et al*., 1997; Keller *et al*., 1998a). Epidemiological and clinical trial data suggest that vitamin E and estrogens may indeed be effective in reducing risk for, and slowing the course of, AD (Sano *et al*., 1997; Tang *et al*., 1996). Looking further down the apoptotic cascade, one finds that calcium-stabilizing agents, such as dantrolene and nifedipine, are effective in experimental models of AD (Guo *et al*., 1997, 1999a). Caspase inhibitors and agents that stabilize mitochondrial function (cyclosporin A) are additional approaches warranted by experimental data. Another approach is the administration of neurotrophic factors or compounds that enhance the production of neurotrophic factors (Mufson and Kordower, 1997). The potential utility of agents that target specific proteins in the apoptotic cascade, such as caspase inhibitors and Par-4 antagonists, awaits further studies in animal models of AD. Perhaps the most clear information that has arisen from studies of the role of neuronal apoptosis in AD is that the neuronal cell death process involves increased levels of oxidative stress and disruption of calcium homeostasis, processes that appear to be convergence points in both apoptotic and nonapoptotic neuronal death.

Perhaps the approach that, at the present time, is most likely to be effective in preventing age-related neuronal apoptosis and AD is dietary restriction. Epidemiological studies (Mayeux *et al*., 1999) and experimental data (Bruce-Keller *et al*., 1999; Zhu *et al*., 1999) suggest that dietary restriction increases the resistance of neurons to age-related neurodegenerative disorders, including AD. Dietary restriction may exert its beneficial effects by reducing levels of oxidative stress and by enhancing the expression of neuroprotective proteins such as heat-shock proteins and neurotrophic factors (Duan and Mattson, 1999; Lee *et al*., 1999; Yu and Mattson, 1999). Although preventative approaches for AD appear promising, treatment of AD patients is problematic because by the time patients manifest symptoms, considerable neuronal loss has already occurred. Nevertheless, therapies based on antioxidants, calcium-modulating agents, and neurotrophic factors may prove effective in slowing the course of the disease process and should therefore continue to be pursued. Whether therapies that target specific apoptotic proteins such as Par-4 and caspases will prove effective remains to be determined.

V. Metals and the Pathophysiology of AD

Perhaps no area of research on AD has received more coverage in the lay press than investigations of possible roles of heavy metals. Indeed, statements such as ''don't use aluminum pots or antiperspirants containing aluminum'' or ''have the fillings in your teeth replaced—they contain mercury which may cause AD'' have been aired. Unfortunately, available data indicate that aluminum and mercury exposure are not major risk factors for AD. However, a building body of evidence based on sound chemistry and cell biology does suggest important roles for iron, copper, and zinc in the pathogenesis of neuronal degeneration in AD. Levels of iron, copper, and zinc are increased in neurofibrillary tangle-bearing neurons and neuritic plaques. Iron (Fe^{2+}) plays a particularly prominent role in free radical biochemistry as it catalyzes the conversion of hydrogen peroxide (present in all brain cells) to hydroxyl radical, a highly destructive radical that induces membrane lipid peroxidation. Iron, copper, and zinc have been shown to potentiate aggregation and neurotoxicity of Aβ and may thereby render neurons vulnerable to excitotoxicity and apoptosis. Copper and zinc also interact with APP in ways that may alter its metabolism so as to impair its normal functions and increase amyloid production. Zinc (Zn^{2+}) exhibits several actions that may modify the neurodegenerative process in AD, including its ability to modify neurotransmitter release and excitatory amino acid receptor activation. Finally, molecular genetic data suggest that aberrancies in genes that regulate iron and copper metabolism may contribute to some cases of AD (Fig. 23.8).

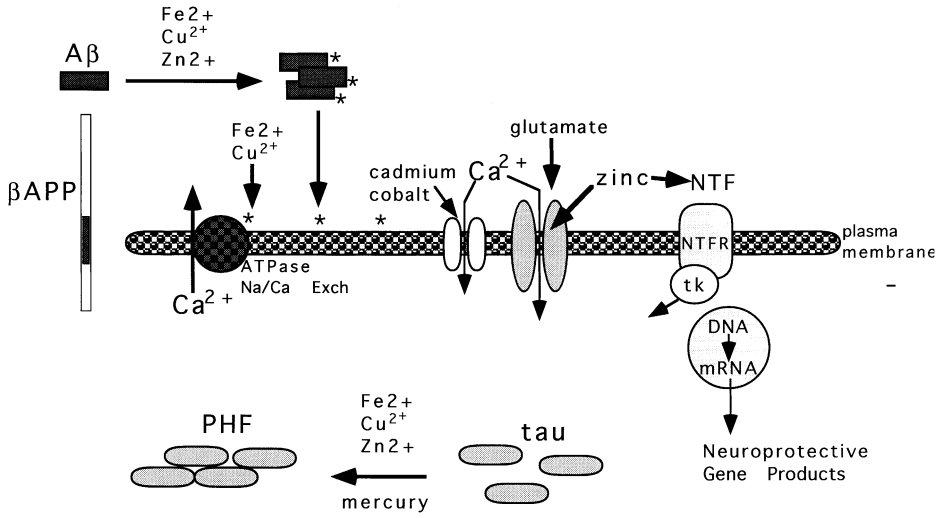

FIG. 23.8. Mechanisms whereby metals may promote neuronal degeneration in AD. Asterisks denote sites of free radical production. Aβ, amyloid β-peptide; βAPP, β-amyloid precursor protein; NTF, neurotrophic factor; NTFR, neurotrophic factor receptor; tk, tyrosine kinase domain.

A. Metal Neurochemistry

The literature on AD is filled with studies that have examined the possible involvement of heavy metals such as aluminum, iron, zinc, and mercury in the disease process. Although considerable controversy has surrounded this particular area of research, even a brief consideration of the chemistry of metals and experimental demonstrations of their abilities to damage cells makes them a reasonable focus of research in the field of neurodegenerative disorders. Metals are obtained in the diet and are generally bound to proteins in the blood and in cells. Metal-binding proteins include the iron-binding proteins ferritin and transferrin, the copper-binding protein ceruloplasmin, and the metallothionein family of metal-binding proteins that are responsible for sequestering iron, copper, and zinc in various tissues, including the brain (Aschner *et al*., 1997). Metals can be moved between cellular compartments via specific membrane transporters, whereas in ionic form some metals can move through ion channels. Metal-binding sites play important roles in a variety of biochemical reactions in brain cells (Prohaska, 1987). For example, iron plays a central role in the electron transport process that ultimately results in ATP production. Activation of soluble guanylate cyclase by nitric oxide requires interaction of nitric oxide with the iron-binding heme domain of the cyclase. The activity of other enzymes, such as copper-zinc superoxide dismutase, requires their binding two different metals. A final example of the diverse functions of iron in the brain is its role in the concentration of amine transmitters, including dopamine and serotonin. Before examining the possible roles of heavy metals in AD, it is important to understand at least the fundamentals of the neurochemistry of these metals.

The chemistry of iron in biological systems has been described in detail in previous review articles (Koeppen, 1995; Boldt, 1999). Iron concentration is quite high in the brain, reaching millimolar concentrations in basal ganglia structures and 200–600 μM in the hippocampus and cerebral cortex. By comparison, plasma iron concentrations are 10- to 50-fold lower. Several iron-binding proteins play important roles in controlling the amount of free iron in the brain. Transferrin is the major iron-binding protein in plasma. Specific receptors for transferrin are located in cells that comprise the blood–brain barrier and are largely responsible for the transport of iron into the brain, and neurons also possess high-affinity transferrin receptors, which may play a major role in uptake of this metal by neurons (Bradbury, 1997). Plasma membranes of endothelial cells and neurons also contain transferrin-independent transporters. In order for iron to be transported across membranes by either type of transporter it must first be reduced from Fe^{3+} to Fe^{2+} via a ferrireductase activity. Iron is stored within cells bound mainly to ferritin, a large multisubunit protein that can bind at least 4000 atoms of iron. In the brain, ferritin is present at highest levels in microglia and oligodendrocytes.

Previous review articles have covered the field of copper biochemistry nicely (Linder and Hazegh-Azam, 1996; Malmstrom and Leckner, 1998). Concentrations of copper are approximately five times higher in the brain than in plasma, and within the brain are higher in gray matter as compared to white matter. Copper is essential for the function of many different enzymes in the brain, including cytochrome c oxidase, dopamine β-monoxygenase, and lysyl oxidase. Within neurons, copper concentrates in nerve terminals and mitochondria. In contrast to the blood, wherein the majority of copper is bound to ceruloplasmin, the majority of exchangeable copper in the brain is in the form of low molecular weight amino acid complexes. The uptake of copper into the brain is mediated by a carrier-mediated facilitated diffusion process similar to that of neutral amino acids. Cellular copper storage and detoxification are mediated largely by metallothioneins and glutathione, the latter being the most abundant nonprotein thiol in brain cells. As with zinc (see later), copper can be released at synapses in a calcium-dependent manner, and synapses contain a low-affinity copper uptake system.

Of particular importance from the perspective of neurodegenerative disorders is the ability of Fe^{2+} and Cu^{2+} to promote membrane lipid peroxidation. This is accomplished via the Fenton reaction, which involves hyroxyl radical production as the result of the interaction of Fe^{2+} and Cu^{2+} with hydogen peroxide. Indeed, the Fenton reaction appears to play a prominent role in the pathogenesis of several different neurodegenerative disorders, including Parkinson's disease (Jellinger, 1999), stroke (Gutteridge, 1994), and AD (Markesbery and Carney, 1999). Whereas Cu^{2+} can also catalyze the Fenton reaction, available data suggest that the concentration of free Cu^{2+} is normally so low in cells (approximately one Cu^{2+}/cell) that it is unlikely to contribute meaningfully to lipid peroxidation during normal aging.

In contrast to iron and copper, zinc is redox inert. However, zinc binds readily to nitrogen and sulfur donors and plays a key role in the function of many different enzymes. In plasma and cerebrospinal fluid the vast majority of zinc is bound to proteins such as albumin. Interestingly, zinc concentrations are several orders of magnitude greater in brain tissue than in plasma or cerebrospinal fluid. The regulation of free zinc levels in tissues is controlled by zinc-binding proteins called metallothioneins and by specific membrane transporters (Ebadi, 1991; McMahon and Cousins, 1998). Three different zinc transporters have been identified: ZnT-1, ZnT-2, and ZnT-3; only ZnT-1 and ZnT-3 are expressed in the brain. ZnT-1 is localized in the plasma membrane and is responsible for the extrusion of zinc from cells, whereas ZnT-3 is localized in secretory vesicles and serves to concentrate zinc therein. Zinc concentrations vary dramatically among neuronal populations. For example, dentate granule neurons concentrate zinc at very high levels in their axon terminals, whereas very little zinc is present in cholinergic neurons of the basal forebrain. Zinc is released from axon terminals along with neurotransmitters (particularly the excitatory amino acid glutamate) and may serve a neuromodulatory function.

Other metals appear to play less widespread roles in brain neurochemistry. Selenium is central to the function of several enzymes involved in free radical metabolism, including glutathione peroxidase (Allan *et al*., 1999). Manganese is an essential trace element required for the proper function of several different enzymes, and imbalances in manganese regulation can result in brain damage (Newland, 1999). However, metals such as aluminum, cadmium, mercury, and cobalt serve few or no important functions in cells, and their presence in tissues is generally considered deleterious to cell function.

The divalent cations of several of these metals, particularly Cd^{2+} and Co^{2+}, can block voltage-dependent Ca^{2+} channels in neurons, thereby compromising cell function.

B. Roles of Iron and Copper in AD

Good and co-workers (1992) reported that levels of iron and aluminum are increased in neurofibrillary tangle-bearing neurons compared to tangle-free neurons in AD brain tissue sections. Levels of copper and iron are also increased in senile plaques in several different brain regions of AD patients (Lovell *et al*., 1998). Histochemical analyses suggest that levels of iron and ferritin are increased in association with senile plaques (Jellinger *et al*., 1990; Connor *et al*., 1992a). Levels of the iron-binding protein transferrin are decreased consistently in brain tissue from AD patients, particulary in white matter (Connor *et al*., 1992b). Immunostaining of brain sections from AD and control patients with antibodies against the iron regulatory proteins IRP-1 and IRP-2 revealed that neurofibrillary tangle-bearing neurons exhibit a marked increase in IRP-2 immunoreactivity, but no increase in IRP-1 immunoreactivity (Smith *et al*., 1998b). In addition, the soluble form of the iron-binding protein p97 is increased significantly in serum from AD patients compared to age-matched control patients (Kennard *et al*., 1996). There is considerable evidence for alterations in the iron transport proteins lactotransferrin and melanotransferrin in the brains of patients with Parkinson's disease (Qian and Wang, 1998). Data suggest that levels of transferrin receptors are decreased in hippocampal and cortical cells in AD, but are unchanged in cerebral blood vessels (Kalaria *et al*., 1992). Moreover, genetic links between altered iron homeostasis are suggested by data demonstrating an association between the C2 transferrin allele and late-onset AD (Namekata *et al*., 1997).

Experimental data further support a role for Fe^{2+} in the pathogenesis of neuronal dysfunction and degeneration in AD. Neurons are highly sensitive to cell injury and death following exposure to Fe^{2+}. For example, cultured primary hippocampal neurons undergo apoptosis following exposure of concentrations of Fe^{2+} in the upper nanomolar to low micromolar range (Kruman *et al*., 1997). Studies of cortical synaptosomes have shown that Fe^{2+} can disrupt the function of membrane glucose and glutamate transporters and can cause mitochondrial dysfunction (Keller *et al*., 1997a). Thus, Fe^{2+} may contribute to the dysfunction and degeneration of synapses that occur prior to neuronal cell death in AD (Mattson *et al*., 1998). Infusion of $FeCl_2$ into the basal forebrain of adult rats causes lipid peroxidation, depletion of choline acetyltransferase, and impairment of visuospatial memory (Bruce-Keller *et al*., 1998). The aggregation of Aβ is accelerated dramatically by Fe^{2+} as the result of metal-catalyzed oxidation (Dyrks *et al*., 1992; Mantyh *et al*., 1993). Studies of the neurotoxic actions of Aβ in primary hippocampal cell cultures have shown that Fe^{2+} enhances the neurotoxicity of the peptide (Goodman and Mattson, 1994). These experimental findings suggest a role for Fe^{2+} in amyloid aggregation and amyloid-induced neuronal degeneration in AD. A reproducible finding in studies of AD is that levels of membrane lipid peroxidation are increased in association with the neurodegenerative process (see Section II). Fe^{2+} is a potent inducer of membrane lipid peroxidation, and exposure of cultured neurons to Fe^{2+} can induce several alterations similar to those observed in studies of AD patients, including impairment of glucose and glutamate transport (Mark *et al*., 1997a; Keller *et al*., 1997a), disruption of cellular calcium homeostasis (Mark *et al*., 1995a,b, 1997b), and changes in the cytoskeleton similar to those seen in neurofibrillary tangles (Mattson *et al*., 1997b). In addition, the antioxidants vitamin E and estrogen (which data suggest may reduce risk for, and slow the course of, AD) suppress membrane lipid peroxidation, thereby counteracting the damaging effects of Fe^{2+} and Aβ (Goodman and Mattson, 1994; Mark *et al*., 1995; Goodman *et al*., 1996; Keller *et al*., 1997b). Lipid peroxidation induced by iron is likely to have a wide range of effects on neuronal function and degeneration (Mattson, 1998).

Copper plays roles in several different neurodegenerative disorders. Inherited disorders of copper metabolism such as Wilson and Menkes diseases manifest profound neurodegenerative phenotypes, and mutations in copper/zinc superoxide dismutase are responsible for some cases of familial amyotrophic lateral sclerosis (Waggoner *et al*., 1999). Moreover, it was reported that a frameshift mutation in the ceruloplasmin gene is responsible for a rare form of familial dementia (Harris *et al*., 1996). Thus, there is ample precedence for perturbations in copper metabolism and copper-containing enzymes resulting in neurodegeneration.

Several different actions of copper suggest that it may contribute to the pathogenesis of AD. Copper greatly increases vulnerabilty of cultured neurons to Aβ toxicity (White *et al*., 1999a). The latter study also showed that depletion of cellular glutathione greatly increases the vulnerability of neurons to copper toxicity. Atwood *et al*. (1998) showed that Cu^{2+} can induce aggregation of Aβ, particularly under conditions of acidic pH. More complex interactions of the amyloid precursor protein and copper have been proposed based on evidence that APP interacts with copper to enhance formation of Cu^{+}, thereby promoting oxyradical production (Hesse *et al*., 1994; White *et al*., 1999b). Collective data therefore suggest that further investigations of the possible involvement of copper in AD are warranted.

C. Role of Aluminum in AD

Largely as the result of data suggesting that levels of aluminum are increased in brain tissue from patients with AD, it was proposed that aluminum plays a critical role in the neurodegenerative process (Savory *et al*., 1996). Laser-activated microprobe mass analysis-based measurements demonstrated increased levels of aluminum in neurofibrillary tangle-bearing neurons (Good *et al*., 1992). In contrast, using a similar approach, Lovell and co-workers (1993) found no clear increase in aluminum in tangle-bearing neurons. It should be noted that the association of aluminum with tangles may simply result from a charge-based interaction as the tau proteins that comprises tangles are hyperphosphorylated (negative charge) and ionic aluminum is a cation. Indeed, the concentrations of several other cations (Ca^{2+} and Zn^{2+}) are increased in tangle-bearing neurons (Good *et al*., 1992; Markesbery and Carney, 1999).

Some experimental data are consistent with a role for aluminum in neuronal degeneration in AD. Exposure of neurons to

aluminum *in vivo* and in cell culture can cause cell damage, although the concentrations of aluminum required are greater than concentrations measured in the brains of AD patients. Aluminum administration in rabbits results in decreases in levels of choline acetyltransferase in entorhinal cortex and hippocampus, and reductions in serotonin and norepinephrine levels in the cerebral cortex that are correlated with severity of neurofibrillary degeneration (Beal *et al*., 1989). Aluminum can also potentiate the toxicities of several insults, including exposure to agents that induce Ca^{2+} influx (Mattson *et al*., 1993b) and Fe^{2+} (Xie *et al*., 1996). Al^{3+} can induce aggregation of Aβ, which is reversed by aluminum silicates (Fasman *et al*., 1995). It has also been reported that aluminum can induce the aggregation of PHF-tau (Shin *et al*., 1994), suggesting a role for aluminum in the formation of neurofibrillary tangles. However, in contrast to calcium, aluminum does not induce increased tau phosphorylation (Mattson *et al*., 1993b).

Despite the kinds of indirect evidence just described, the role of aluminum in AD appears negligible. Thus, epidemiological data reveal no obvious relationship between levels of aluminum exposure and risk for AD (Martyn *et al*., 1997). Indeed, there is not even a direct relationship between dietary intake of aluminum and blood levels of this metal because the vast majority of aluminum obtained in the diet never enters the bloodstream. Aluminum was found to have no effect on enzymatic processing or expression of amyloid precursor protein in cultured neural cells (Neill *et al*., 1996). Moreover, cultured neurons can withstand exposure to very high levels of aluminum of up to 1 m*M* (Mattson *et al*., 1993b).

D. Roles of Zinc, Mercury, and Other Metals in AD

Conflicting reports have appeared concerning levels of zinc in blood and brain tissue of AD patients compared to controls. Some data suggest that zinc levels might be decreased in brain tissues of AD patients (Corrigan *et al*., 1993). Measurements of zinc levels using proton-induced X-ray emission spectroscopic methods have shown that zinc levels are increased in hippocampus and amygdala of AD patients (Danscher *et al*., 1997). Lovell *et al*. (1998) reported that levels of zinc are increased in senile plaques. Gonzalez *et al*. (1999) reported a significant association between higher serum zinc, copper, and insulin concentrations and the presence of an epsilon 4 allele of apolipoprotein E, but only greater serum zinc concentration appeared to be an independent risk factor associated with the development of AD. Experimental data are consistent with a possible role for alterations in zinc metabolism in the pathophysiology of AD, although its specific role remains unclear. Several studies have reported that zinc can be directly neurotoxic toward cultured hippocampal and cortical neurons (Choi *et al*., 1988; Freund and Reddig, 1994). Oxidative stress can induce the release of zinc from metallothionein (Fliss and Menard, 1992), suggesting the possibility of increased free zinc resulting from the increased oxidative stress associated with aging and AD.

One action of zinc of clear relevance to AD is its ability to promote aggregation of Aβ (Mantyh *et al*., 1993; Bush *et al*., 1993, 1994a; Huang *et al*., 1997). Bush and co-workers (1994b) reported that zinc promotes aggregation of Aβ and inhibits α-secretase cleavage of APP. Both of these effects of zinc would be expected to promote neuronal degeneration (Mattson, 1997). However, it has been reported that lower concentrations of zinc can protect cultured hippocampal neurons against Aβ toxicity (Lovell *et al*., 1999). Another mechanism whereby increased zinc levels might promote neuronal degeneration in AD is by impairing the biological activity of NGF (Ross *et al*., 1997), as studies have shown that NGF protects neurons against insults relevant to the pathogenesis of AD (Mattson and Lindvall, 1997).

Measurements of heavy metals in the cerebrospinal fluid of AD and control patients have demonstrated increased levels of cadmium and mercury in AD patients (Basun *et al*., 1991). However, a subsequent study revealed no difference in cadmium levels in samples from AD and control patients (Basun *et al*., 1994). Mercury is highly toxic to neurons, as is evident in cases of mercury poisoning and in rodents administered mercury (Atchison and Hare, 1994). Based on data correlating the number of dental carries with mercury levels in the body (Mackert and Berglund, 1997), the known neurotoxicity of mercury, and studies suggesting that mercury levels are increased in blood and brain tissues of AD patients (Ehmann *et al*., 1986; Hock *et al*., 1998), it was suggested that mercury may contribute to the pathogenesis of AD. Even in the absence of any other data, this led to many dentists replacing carries filled with amalgum containing mercury with mercury-free amalgum. Subsequent studies have not supported a relationship between mercury-containing dental amalgam and AD (Saxe *et al*., 1999). Epidemiological studies failed to demonstrate correlations between between mercury or lead exposure and AD (Gun *et al*., 1997). Nevertheless, mercury and lead are certainly neurotoxic and can cause mental retardation in children (Prince, 1998). It is therefore possible that these metals contribute to the neurodegenerative process in some cases of AD.

E. Therapeutic Implications

As heavy metals are obtained almost exclusively in the diet, there are direct applications of research findings on the roles of metals in AD to the prevention and treatment of AD. Reducing the intake of mercury, cadmium, and aluminum makes sense because these metals are neurotoxic and serve no clear biological functions. Based on the evidence that aluminum levels may be increased in AD patients, clinical trials of chelation therapy using deferoxiamine were undertaken, with beneficial effects of the therapy being reported (Kruck *et al*., 1990). However, iron, copper, and zinc serve important roles in the nervous system and chronic chelation of these ions is therefore likely to have severe side effects. Recommendations as to the dietary intake of iron, copper, and zinc from the perspective of prevention of AD cannot yet be made. However, it is becoming clear that the high intake of iron increases the risk for cardiovascular disease (de Valk and Marx, 1999), and because iron may also contribute to the pathogenesis of AD and Parkinson's disease, it would seem prudent not to take iron supplements. Data described previously and in Section II above strongly suggest that the major roles of iron, copper, and zinc in AD are to promote cellular oxidative stress. Antioxidant supplementation (vitamins E and C; Morris *et al*., 1998) and dietary restriction (Bruce-Keller *et al*., 1999; Zhu *et al*., 1999) are therefore the

approaches currently available that are most likely to reduce risk for AD without side effects.

Rodent Models of Age-Related Memory Impairment

I. Introduction

In characterizing the effects of aging on memory processes in humans, any review must deal with the issue of diversity. To be sure, age-related loss in memory function occurs, but the degree of functional decline is highly dependent upon what component of memory processing is being assessed (see reviews in Keefover, 1998; Grady and Craik, 2000). Particular components are generally spared, e.g., sensory memory, while others are greatly impaired, e.g., secondary or working memory. In addition, aged individuals differ greatly in the degree of memory impairment observed in any particular component of memory processing. At advanced ages, groups of individuals may perform equivalent to younger cohorts in a working memory task, while others are markedly impaired. In addition, it has become increasingly apparent that memory impairments observed in Alzheimer's disease differ from those observed in normal aging, a fact that adds to the diversity issue (Albert, 1997).

In reviewing the literature on rodent models of age-related memory impairments, the same issue of diversity emerges quite distinctly. The degree of age-related decline observed in a memory task is greatly dependent upon the task and specific parameters of the task. Marked individual differences in performance can also be observed among aged rodents tested in the same memory task. Moreover, differences in the age-related pattern of performance decline in memory tasks can be observed between different rodent strains.

While this diversity may on first glance appear to complicate the analysis of aging on memory function, on further consideration the diversity offers insight and direction into the most fruitful areas of investigation. What components of memory function are most affected in human aging? Are there appropriate rodent models, strains, and paradigms that can be used? Given evidence in humans and rodents that a particular component of memory processing is impaired in aging, does this evidence offer hypotheses about which neural systems might underlie the impairment?

The literature surveyed herein has been addressed in previous reviews that have attempted synthesis of results along various outlines (Sarter, 1987; Gallagher and Pelleymounter, 1988; Barnes, 1990, 1998; Ingram *et al*., 1994; Gallagher and Rapp, 1997). The current review follows the conventional approach of outlining results among categories of behavioral tasks. This approach is offered to provide the reader a description of the various behavioral paradigms that have been used to assess age-related impairments in rodent models. It is important to understand how rodent studies are conducted in order to consider the relevance of the results to other paradigms as well as their relevance to the human literature. In applying this categorical approach, the attempt is also made to synthesize and summarize the findings which demonstrate what aspects of memory processing are most affected in aging. The review will not cover recent studies attempting to assess whether mouse models of Alzheimer's disease exhibit memory impairments. The focus will be on behavior; thus, no discussion will be offered regarding linkage of the behavioral performance to underlying neurobiological mechanisms.

When reviewing this literature, the reader should be cognizant that memory processes are hypothetical constructs that are deduced from examining the ''performance'' of rodents in a particular paradigm. This is not a trivial matter when considering the assessment of age differences in memory function in rodents (Ingram, 1985). Before concluding that a performance difference in a particular test is due to impaired memory function, there must be awareness that other noncognitive performance factors, such as sensory, motor, and motivational differences, can impact upon the performance of aged subject. Aged rodents can have degenerated retina, which can impact upon their visual abilities in a maze; they can be too slow in their reaction time in an operant task requiring speed of response; they may be less responsive to food restriction in an appetitive task or have a higher threshold for pain in an aversive task. Behavioral paradigms can often permit the investigator to assess the involvement of such noncognitive performance factors, yet unfortunately many investigators do

not construct their paradigms in this manner. In addition, just as in human studies, particular diseases, such as anemia, may impact upon performance in a memory task (Spangler and Ingram, 1996). While some investigators implement health screens in attempting to eliminate possible moribund rats, unfortunately many others do not. The lack of attention to extraneous variation caused by noncognitive performance factors can complicate general conclusions regarding the age-related memory impairment.

Another complication for producing rodent models for examining age-related memory impairments is that the tasks do not translate well into theoretical models of human memory processes. Memory processing can be viewed within the basic structure of sensory memory, short-term memory, and long-term memory (Craik and Jennings, 1992). Sensory memory is the limited capacity, very short-term memory for sensory events. Short-term memory includes primary memory (e.g., digit span) as well as working memory, in which events to be remembered are held longer and require active transformation or must be held while further incoming information is processed. Long-term memory includes episodic memory (e.g., free recall), semantic memory (e.g., vocabulary), and procedural memory (skill learning). No rodent equivalent exists for some of these elements, such as, semantic memory. Fortunately age-related impairments in humans have been recorded primarily in tasks involving working and episodic memory, where some rodent tasks are have been useful for investigating as models.

When one examines the large number of studies in this research area, several different rat and mouse strains have been used, but two are predominant, the Fischer-344 (F344) rat and the C57BL/6J mouse.

II. Classical Conditioning

Classical conditioning, also known as Pavlovian conditioning, is considered reflex learning and represents one of the most evolutionarily primitive forms of associative processes. In a conventional classical conditioning paradigm, an initially neutral stimulus, such as a tone, is paired with a noxious stimulus, such as foot shock. The foot shock elicits a reflexive unconditioned response (UR), for example, a decrease in heart rate. After repeated pairing of the tone (or conditioned stimulus, CS) with the foot shock (or unconditioned stimulus, US) the CS itself will elicit the UR, which is then referred to as the conditioned response (CR). The CS–US pairing can be contiguous in time (simultaneous conditioning) or the US can be delayed after offset of the CS (delayed conditioning) or while the CS is still active (trace conditioning). The delay can be manipulated parametrically from a few milliseconds (e.g., 300 msec) to a few seconds (e.g., 3 sec). The primary dependent variables are the number of trails to a criterion measured typically as conditioned responses.

A. Eyeblink and Heart Rate Conditioning

In human studies, the most widely used paradigm is eyeblink conditioning which involves a tone (CS) paired with a puff of air to the eye (US) to elicit an eyeblink (CR) in a trace conditioning paradigm. Clear age-related deficits in this paradigm have been reported but are dependent on the CS–US interval (Solomon *et al*., 1991; Woodruff-Pak *et al*., 1999). Specifically, at shorter trace intervals (400 msec) older persons showed a slower rate of conditioning; however, the age differences disappear when longer intervals are imposed (1000–1500 msec). Persons diagnosed with early Alzheimer's disease also show slow acquisition compared to normal aged controls in this conditioning paradigm (Woodruff-Pak *et al*., 1990).

The value of the classical conditioning paradigm is the potential for direct comparisons between human studies and studies of animal models. Eyeblink conditioning studies have been used successfully in rabbits (Buchanan and Powell, 1988; Woodruff-Pak *et al*., 1990); however, rats and mice are less tolerant to the restraint procedures required in these protocols. Thus, there have been relatively few aging studies in rats and none in mice that have assessed the effect of aging on classical conditioning using eyblink or heart rate conditioning.

Heart rate deceleration has been studied as the CR in F344 rats with a tone as the CS and shock as the US (Buchanan and Ginn, 1988). An age-related decline in acquisition and magnitude of the CR was reported. Leg flexion as the CR has also been analyzed in F344 rats with deficits in conditioning observed in male but not females with a tone CS and shock as the US (Prescott *et al*., 1989).

To overcome problems with the use of restraint in rat conditioning studies, Weiss and Thompson (1992) assessed eyeblink conditioning in freely moving F344 rats with noise as the CS and a periorbital shock at the US in a trace paradigm. An age-related reduction in the rate of conditioning was noted. In a follow-up study, the same authors assessed both F344 rats and the F344 × Brown Norway hybrid (Weiss and Thompson, 1992). Conditioning was superior in the hybrid strain, but age-related decline in the rate of conditioning was still evident in both strains. This paradigm has been further developed for use in rats by introducing an air puff to the eye as the US (Weiss *et al*., 1999) and demonstrating hippocampal involvement in conditioning (Weiss *et al*., 1999), again in freely moving rats.

Besides the advantages of direct human–rodent comparisons, the classical conditioning paradigm also offers the advantage of providing control over noncognitive factors in assessing the effects of aging on performance. Specifically, age differences in response to the US and the CS and be assessed independently of the rate of conditioning either by using pseudoconditioning groups or by parametric manipulations of the variables. In humans and rats there appear to be conditions, such as simultaneous conditioning or under longer delays or traces where there no significant age effects are emerged. Age differences are observed under specific trace conditions, an observation that indicates that the defect is likely specific to cognitive variables.

B. Conditioned Taste Aversion

Conditioned taste aversion is another form or classical conditioning in which the CR can be learned after as few as one pairing of the CS with the US. Typically the CS is a novel tasting liquid (e.g., a saccharin flavored solution) paired with lithium chloride (the US), which will induce a malaise or gastrointestinal upset (UR). The subsequent CR is evidenced by the avoidance of the saccharin solution when the animal is given the opportunity to consume it during later trials, usually occurring 1–2 days after the conditioning. The dependent vari-

able is typically the absolute or percentage consumption of the CS.

There are several methodological advantages to the conditioned taste adversion paradigm. First, the conditioning is one-trial and robust with evidence of the learning remaining over intervals of several weeks. Second, the methodological control over noncognitive factors described above for other classical conditioning paradigms can be maintained. Third, no specialized equipment is required. The major disadvantage of the conditioned taste adversion paradigm is that direct comparisons to human experiments are virtually impossible.

No significant age differences in acquisition and retention of conditioned taste adversion have been noted in a variety of rodent strains including Wistar rats (Guanowsky *et al*., 1983; Martinez and Rigter, 1983), F344 rats (Ingram and Peacock, 1980), and C57BL/6J mice (Springer and Fraley, 1981). Typically the delay between CS and US is on the order of 10–60 min in these paradigms with the strength of resulting conditioned taste adversion decreasing as the interval is increased. However, when the delay between CS and US was increased to 3 hr, clear age differences emerged in Wistar rats (Hinderliter and Misanin, 1993). This difference is not due to a possibly greater US intensity because of a heavier body weight of older rats (Misanin and Hinderliter, 1994) nor to age differences in contextual cues (Misanin and Hinderliter, 1995).

Age differences emerge in during extinction testing in the conditioned taste adversion paradigm. In the classical conditioning paradigm, extinction is defined as the gradual loss of ability of the UC to elicit the CR when the UC is no longer present. An age-related increase in resistance to extinction of conditioned taste adversion has been reported in male F344 rats (Ingram and Peacock, 1980). However, another study using SD rats and multiple CS–US pairings found more rapid extinction in aged rats (Cooper *et al*., 1980). Differences in strain and methodology probably account for the discrepancies in conditioned taste adversion extinction.

C. Fear Conditioning

Conditioned responses, such as freezing, can be observed in relationship to environmental cues that were previously paired with an aversive stimulus, such as a brief foot shock. Such paradigms are referred to as *fear conditioning*. The main manipulation is the interval between the aversive conditioning and the observation of the CR. Environmental cues can also be manipulated to examine the impact of context on the response. The main dependent variable is the time spent freezing. Several procedural advantages can identified for this paradigm. As in conditioned taste adversion conditioning, typically only one pairing of the CS (the environment) and the US (the shock) is conducted. The behavioral variable (freezing) is easily observable and quantifiable. The equipment needed is minimal. The disadvantage is the relevance to human applications as noted for the conditioned taste adversion paradigm.

Recently this paradigm has come into extensive general use in mouse studies, but its application to gerontological studies is still rather limited. Oler and Markus (1998) and Houston *et al*. (1999) reported an age-related decrease in the retention of fear conditioning as a function of the delay interval between conditioning and test in F344 rats. Typically freezing behavior strengthens with time presumably because of the ''memory incubation.'' This phenomenon was observed in young rats, whereas, after 20 days reduced freezing behavior was reported in the aged rats (Houston *et al*., 1999).

III. Operant Conditioning

Operant conditioning differs from classical conditioning because the animal must actively operate in the process as opposed to the passive nature of classical conditioning. The animal must make the association between its behavioral response to experimentally controlled presentation of stimuli and reinforcement.

Operant tasks are typically conducted in small, enclosed chambers allowing for maximal control over cue presentation, behavioral responses, and reinforcement delivery. Cues are often lights, tones, or levers, the behavioral response is often lever pressing, and the reinforcement is generally food or water, which can be delivered on different types of schedules (fixed interval, fixed ratio, variable intervals, variable ratio, or combinations thereof). In the case of positive reinforcement, animals are typically placed on a deprivation schedule for food or water, while foot shock is used as negative reinforcement. Although many dependent variables can be examined, some measure of the number or percentage of correct responses represent the dependent variables investigated most frequently.

Studies of the effects of age on operant conditioning in rodents have produced conflicting results (Sarter, 1987). Summarizing many early studies of simple operant paradigms, Arenberg and Robertson-Tchabo (1977) reported both increases and decreases with age in lever pressing behavior. While operant paradigms can permit control of experimental conditions, many reports of age-related differences in bar pressing may reflect differences in general activity levels, motivation, and sensorimotor abilities of the animals rather than deficits in associative learning per se. For example, an initial impairment of aged male Wistar rats to learn to press one of two levers in a reversal task for a water reward was attributed to an age-related decrease in the probability of initiating a novel response (Stephens *et al*., 1985). Other evidence suggests that the reaction time of male Long–Evans rats becomes longer with age (Burwell and Gallagher, 1993). Thus, many variables must be considered to properly interpret an operant analyses of aging.

In male F344 rats no age difference was observed in the acquisition of a fixed interval reinforcement schedule for food (Campbell and Haroutunian, 1981), and only an initial impairment was observed in aged male SD rats trained in a differential reinforcement schedule (Hamm *et al*., 1983). Soffie and Lejeune (1991) noted that aged rats were impaired in a differential reinforcement ''low'' which indicated the animals ability to respond to changes in the reinforcement schedule.

For the clearest interpretation of age differences in operant performance, paradigms in which parametric manipulation is made of the experimental variables are most useful. Such paradigms would include delayed matching to sample (DMS) or delayed nonmatching to sample (DNMS) tasks. These tasks involve the presentation of a sample stimulus (a lever, light, or tone) followed by the presentation of the previous stimulus and a novel stimulus concurrently with a delay between the presentations typically ranging from 0 to 60 sec. In the DMS

task the animal must respond to the previous stimulus to receive the reinforcement, while in the DNMS task, to the novel stimulus. Performance in all age groups declines as a function of the delay between presentation of the first and second stimulus presentations. Dunnett *et al*., (1988) introduced these paradigms to gerontological research. At the 0-delay interval, aged rats were unimpaired in either the DMS or DNMS versions of the task. This observation was important for establishing experimental control over the paradigm. Aged rats were equally capable and motivated for performing the task. As the delay was increased from 0 to 24 sec, a clear age-related decline in performance was observed in both versions of the task. In a later replication of the these findings, Dunnett (1991) demonstrated that the delay-dependent deficits in the performance of aged rats were independent of any increased susceptibility to proactive interference, that is, the ability to remember the stimuli within the context of the demands that multiple similar trials place on memory processing. The observation of a delay-dependent deficit in operant responding with a DMS or DNMS task has been replicated in other rat studies (Roux *et al*., 1994; Soffie *et al*., 1999).

Winocur (1986, 1992) used a related version of the task in which LE rats were required to lever press when the brightness of two lights were the same and withhold a response when they were different. Age-related deficits in correct responses were evident at the longer delays (15 sec) between the two stimuli presentations. Similarly Pontecorvo *et al*. (1988) used a paradigm in which a stimulus pair (two consecutive stimuli, light or tone) was presented. The SD rats were reinforced for responding on one lever to a matching pair of stimuli and on another lever for a nonmatching pair. Again at short delays the performance of young and aged subjects was equivalent but the aged rats' performance at longer delays was impaired. Pontecorvo *et al*. (1996) proposed a distinction between delayed response tasks (those tasks for which all information necessary to determine the correct response is available prior to the retention interval) and delayed comparison tasks (those in which the subject must compare stimuli presented prior to and after the retention interval in order to determine the correct response). Delayed comparison procedures were considered to provide potentially purer assessment of the subject's memory capacities, but are also more difficult for rodents to acquire.

These DMS and DNMS tasks are the most useful for assessing the effects of aging on primary memory performance across short intervals within an high interference context. If aged animals can perform the task at short intervals equivalent to the performance of young animals, then control over noncognitive performance factors can be achieved. Another advantage of these types of operant paradigms is that similar designs can be used in assessment of cognitive aging in nonhuman primates (Buccafusco and Jackson, 1991) as well as in humans (Oscar-Berman and Bonner, 1985). What remains unclear, however, is the influence of attentional variables on operant performance of aged animals. Using operant paradigms that assess vigilance and sustained attention, it is clear that aged rats are impaired in these cognitive abilities (McGaughy and Sarter, 1995a,b), which could impact their performance in tasks requiring memory for highly similar stimuli across various delay intervals.

IV. Instrumental Conditioning

Instrumental conditioning again implies that the animal is actively involved in making the association between stimulus and response. Thus, the response typically precedes the stimulus; whereas, the opposite is the true for classical conditioning tasks. A ''reinforcement'' is also involved similar to operant conditioning. The reinforcement can be positive, such as food or water, or negative, such as foot shock. Instrumental conditioning is conducted in a variety of apparatuses.

A. Active Avoidance

The active avoidance paradigm requires the animal to make a locomotor response to avoid a negative reinforcement (e.g., foot shock). In its most common form the rat must move from one side of a two-sided chamber in response to a light or tone cue in order to escape or avoid the negative reinforcement. This is referred to as one-way avoidance. When the animal must return to the previous side of the chamber, such paradigms are referred to as two-way, or shuttle, avoidance. Failure to avoid the negative reinforcement is interpreted as a failure to associate the cue with the necessary response. Other variations of the one-way avoidance paradigm exist such as the following: (1) step-up to a platform, (2) jump onto a pole, (3) run to a particular side of a T- or Y-maze. The primary dependent variable is the number or percentage successful avoidances of the negative reinforcement.

In early studies examining the effect of age on active avoidance performance, there was a lack of consistent results (see reviews in Arenberg and Robertson-Tchabo, 1977; Goodrick, 1980; Sarter, 1987; Barnes, 1990). However, there have been reports of significant age-related decline in acquisition and retention in these tasks. Rat studies supporting this claim include two-way avoidance paradigms (Nakamura and Ishihara, 1989; Valerio *et al*., 1989; Petkov *et al*., 1990; Ghirardi *et al*., 1992), although one study in F344 rats reported superior performance among the aged group (Vasquez *et al*., 1983). An age-related decline in retention of the avoidance response was reported for F344 rats in a earlier study (Gold *et al*., 1981). Using a one-way active avoidance task requiring light–dark discriminations in SD rats, Thompson and Fitzsimons (1976) noted age-related decline in acquisition and retention of the avoidance response. Arendash *et al*. (1995) used a pole jump active avoidance task to document an age-related impairment in performance in SD rats.

Mouse studies have employed a variety of different paradigms other than shuttle type tasks. Using a step-up one-way active avoidance task, Stavnes and Sprott (1975) noted an age-related decline in the performance of C57BL/6J mice but no age differences in DBA/2J which exhibited generally poor performance at all ages. The findings in C57BL/6J mice were replicated by Forster *et al*. (1988) who also noted an age-related decline in retention of this avoidance response over a 48-hr period. In the same study, strains with various degrees of autoimmunity (NZB/BINJ, MRL/MpJ-1pr, BXSB/MpJ, MRL/Mpj-+, and NZB-WF1/J) also showed the age-related decline in performance that was related to their degree of autoimmunity.

Investigators have many reasons for examining active avoidance performance. The protocols, particularly for two-way paradigms, can be automated and the ability for analyzing acquisition and retention is available. Problems with such paradigms for gerontological research that have not been addressed in the parametric fashion reported for operant tasks include possible age differences in aversive threshold of shock, reaction to shock, sensory detection of the stimuli, exploratory activity and emotionality. Aged animals would appear to be handicapped in the main performance requirements in such tasks, specifically quick response to the sensory stimulus and rapid movement to a safe area. In addition, translation to human studies is impossible, and the memory processes being assessed are difficult to discern. Moreover, because of the stressful reinforcement being used, many of the paradigms, particularly the two-way avoidance tasks, generate approach-avoidance conflicts for the animal. Specifically the animal must return to a place where it had previously been punished. All these factors combine to complicate the application of such paradigms for aging research.

B. Passive Avoidance

Passive avoidance tasks offer many advantages over active avoidance tasks in the control of noncognitive performance factors. In passive avoidance tasks, rodents are trained to inhibit a natural response. In a typical paradigm, the animal is placed in a two-chamber apparatus that is designed to promote movement from one chamber to an adjacent chamber. For example, driven by their general photophobia, rats and mice naturally move from a brightly lighted compartment to a darkened one. Upon entry to this chamber, a foot shock is delivered (eg., 1–3 sec in duration) and the animal is quickly removed. After a delay ranging from a few seconds to several days, the animal is returned to the bright compartment. The dependent variable is the time spent in the lighted chamber during this test trial, typically referred to as ''latency.'' Movement into the dark chamber is interpreted as a failure to recall the previously delivered foot shock. Increasing the delay between the original trial and the second ''memory'' trial parametrically increases the memory load of this task. Other versions of this task can involve a ''step-down'' avoidance in which the animal must inhibit its tendency to move from a narrow shelf onto a more open floor where it had received footshock previously.

A potential major confound in the paradigm would be if aged animals displayed differences in their initial entrance into the darkened compartment or onto the floor where they had previously received foot shock. In addition, if they showed impairments shortly after the conditioning experience, this would confound the interpretation of a memory defect. For example, if aged animals showed reduced latency a few minutes after the conditioning trial, then the impairment would have to be considered as a defect in conditioning, or acquisition, rather than memory, or retention. Importantly, in nearly all studies using the passive avoidance paradigm, it would appear that neither potential confound represents a major problem. In general, aged rats show no differences in their initial entry into the darkened chamber, nor are they impaired relative to young rats at short delays. As examples, latency was equivalent among aged and young F344 rats at short (1- to 2-hr) delays but impaired at longer acquisition–retest intervals of 4 hr up to 6 weeks (Lippa *et al*., 1980; Gold *et al*., 1981; Collier *et al*., 1988; Komiskey *et al*., 1988). Similar results have been reported for a variety of rat strains, males and females, when the delay interval is at least 24 hr (Martinez and Rigter, 1983; Jaenicke *et al*., 1991; Miettinen *et al*., 1993; Riekkinen *et al*., 1996; Silva *et al*., 1996; Vannucchi *et al*., 1997). In reviews of the literature, Bartus *et al*. (1982a,b) and Martinez *et al*. (1988) concluded that old rats forget newly acquired information more rapidly than do young rats.

Similar findings have emerged from mouse studies involving a variety of strains and paradigms (Bartus *et al*., 1980; Dean *et al*., 1981; Kubanis *et al*., 1982; Gower and Lamberty, 1993; Scheuer *et al*., 1995; Carrie *et al*., 1999; Reddy and Kulkarni, 1999). However, results are not always consistent. For example, Puglisi-Allegra *et al*. (1986) reported an age-related decline in passive avoidance retention in BALB/c mice but not in C57BL/6J mice. Several previous studies had documented that the latter strain is deficient in this performance (e.g., Dean *et al*., 1981; Kubanis *et al*., 1982). One strain that has shown consistent age-related decline in passive avoidance retention in numerous studies is the P8 line of senescence accelerated mice (SAM/P8) (see review in Flood and Morley, 1998).

One of the strengths of the task is also its weakness. Although one-trial paradigms, such as passive avoidance, are quickly learned, they lack a performance curve. This makes it difficult to separate age-related increases in forgetting from age-related decreases in acquisition. In fact, when the procedures are altered so that it takes the rat more than one trial to learn the task (multiple-trial passive avoidance), aged F344 rats did not show accelerated forgetting compared to young rats (Bartus *et al*., 1982a,b). There are also problems with possible motivational factors to consider. The passive avoidance task is touted as a measure of forgetting, but it is forgetting within an ''approach-avoidance'' conflict. The animal must choose between one naturally aversive spot (light chamber) and another that is preferred (dark chamber) but has been associated one time previously with negative consequences. Another problem is that parallels between the passive avoidance task and human memory tasks are difficult to draw.

C. Maze Learning

Various maze learning tasks have provided the most used instrumental conditioning paradigms in gerontological research in rodents. Maze learning requires locomotion beginning from a specified start area and proceeding through an artificial environment in which the animal must acquire and integrate position discriminations (go left: go right) or spatial locations aided by specific visual cues provided in the environment. Rodents are quite adept in such behavior. In positive reinforcement paradigms, the animals are either food- or water-deprived and provided with the respective reinforcement in a ''goal'' area. In negative reinforcement paradigms, escape or avoidance of footshock, water, or bright light can be used. Simple mazes offer a limited number of discriminations (one

to four choices), whereas the memory demands can be manipulated by introducing delays after informational trials or by introducing other learning events as interference events. Complex mazes usually have a great number of choices to be made or require the use of a myriad of stimuli in order to locate the goal.

1. Simple Maze Learning

Spontaneous alternation refers to the observation that when given repeated exploratory trials in a simple T-maze or Y-maze, rats and mice tend to naturally alternate between choosing the right or the left arm of the maze in the absence of any specifically supplied reinforcement. It is hypothesized that these rodents prefer to explore the more novel part of the maze as part of an evolutionary adapted foraging behavior. Failure to alternate is generally interpreted as failure of the animal to recall the arm entered on the previous trial. Performance is measured as the percentage alternation across several trials, typically more than 10. The intertrial interval can be increased from a few seconds to hours to increase the demand on memory.

Results have been generally mixed with regard to age differences observed in spontaneous alternation. With short intertrial intervals (<3 min), no age differences were observed in rats from several different strains including F344, Brown Norway, and SD (Barnes, 1979, 1990; Zornetzer *et al*., 1982; Bhatnagar *et al*., 1997; Stemmelin *et al*., 1999). However, with the introduction of longer delays, aged rats exhibit less alternation than young rats (Winocur and Hasher, 1999; Willig *et al*., 1987; Zornetzer *et al*., 1982); however, the results are not always consistent and may depend on strain and delay interval (Barnes, 1990). Age-related decline in spontaneous alternation has been observed in mouse studies as well (Lamberty and Gower, 1992; Miller *et al*., 1999), including the SAMP/8 strain (Maurice *et al*., 1996).

The appeal of this task is the simplicity of apparatus and procedure. Age-related decline in memory performance is most convincing when the delay interval is manipulated parametrically (e.g., Zornetzer *et al*., 1982) to demonstrate that the age difference in performance is not present at short intervals but emerges at longer intervals. The weakness of the task is that the behavior is not contingent upon overt reinforcement. It is presumably ''spontaneous''; thus, there is no penalty to the animal for a mistake. This situation should stimulate consideration of motivational factors; maybe aged animals perform worse at longer intervals for factors other than memory.

When the same type of simple apparatus used in spontaneous alternation is used with a reinforcement, the task becomes a learning task requiring a two-choice discrimination. The discrimination can be for position (left-right) or between visual stimuli. The reinforcement can be a positive one to obtain food or water provided in the maze or to escape or avoid a negative reinforcement such as foot shock or water.

Thus, in this simple two-choice positively reinforced situation when the intertrial interval is generally short (<60 sec), rats and mice show no age-related learning impairment (Barnes *et al*., 1980; Dean *et al*., 1981; Sarter and Markowitsch, 1983; Wincour, 1984; Lowy *et al*., 1985; Stephens *et al*., 1985). Spangler and Ingram (1986) noted no significant age differences in the performance of C57BL/6J mice in simple visual discrimination task requiring escape from water. Thus, analysis of discrimination learning requiring few choices and short intertrial intervals reveals little evidence of age differences. Age differences in performance do emerge when a reversal of a simple discrimination is imposed; that is, the correct response must be made to the previously negative stimulus. Such findings have been reported for mice (Dean *et al*., 1981) and rats (Stephens *et al*., 1985) and are interpreted to represent an age-related increase in perseverative behavior (Arenberg and Robertson-Tchabo, 1977). Similarly, if some event designed to interfere with learning, such as training with similar stimuli, is imposed during the intertrial intervals, then age differences are observed (Winocur, 1984, 1988).

The difficulty of the two-choice discrimination task can be increased in several additional ways. For example, if the discrimination task is modified so that the rat must alternate left and right choices on successive trials with a 5-sec delay, aged F344 rats were impaired relative to young rats (Greene and Naranjo, 1987). Similarly, Ritzmann *et al*. (1993) noted age-related decline in the performance of Swiss–Webster mice with a delay in alternation of 30 sec but not 10 sec.

As another example, in a forced-choice, delayed nonmatch-to-sample (DNMS) task, one arm of the T-maze is blocked in the *sample* trial, forcing the rat to enter the arm containing the reward (i.e., food or water). Memory for the arm just visited is assessed in the choice trial where the rat is free to enter either arm. The reward is located in the arm not visited in the sample trial. Thus, entry into the arm visited in the sample trial is considered a memory error. Including a delay between the sample and the choice trial can parametrically increase the memory demand of the task. Aged rats are only mildly impaired in this task when short (< 5 sec) delays are imposed, but show increasing impairments at longer delays (Ordy *et al*., 1988; Aggleton *et al*., 1989). A water escape paradigm can also be used to in a similar fashion to show age-related decline in the performance of rats (Means and Kennard, 1991; Markowska *et al*., 1996). Willig *et al*. (1987) suggested that such impairments can be reduced or eliminated by habituating old rats to the test apparatus.

Another version of this task is a split-stem T-maze that can permit simultaneous examination of two different types of discriminations. The stem of the T-maze is divided; one side allows access to the arms, and the other side is a dead end. The correct path is constant for every trial; thus, entries into the incorrect side are interpreted as errors in reference memory. Reference memory refers to maintenance of information that remains invariant across trials, e.g., always go to the left here. In the arms of the maze, an alternation response is rewarded. Thus, entries into the arm most recently visited are interpreted as errors in working memory. Working memory requires use of temporary and changing information, (e.g., go left now because I went right a few minutes ago). While Ordy *et al*. (1988) observed an age-related impairment only in the working memory component of this task with Long–Evans rats, Lowy *et al*. (1985) noted age-related impairments in both components of American Cancer Institute rats.

Age differences in the performance of simple discriminations in a T-maze can be expanded to examine retention perfor-

mance as well. Flood and Roberts (1988) and Flood and Morley (1990) employed a one-way active avoidance task for mice that measured acquisition and retention of a position discrimination (left–right) in a T-maze. A weak criterion to acquisition was used (one avoidance response within the first 25 trials). Aged C57BL/6 mice exhibited impaired acquisition measured as the number of trials to criterion, and they also exhibited impaired retention which was evaluated by trials to criterion 1 week later. This paradigm has also been used extensively to assess the age-related impairment observed in the SAM/P8. Performance deficits were noted to occur much earlier in this line than in the R1 line as well as C57BL/6J mice (see review in Flood and Morley, 1998).

2. Complex Maze Learning

Complex mazes require multiple position discriminations for learning the correct pathway from a start area to a goal area. Two of the oldest types of complex mazes used in behavioral research are the Hebb–Williams maze series and the Stone 14-unit T-maze.

The Hebb–Williams maze consists of 12 different configurations of barriers within an enclosed arena. The animal is usually given repeated trials in each of several or all versions, and they have access to intra- and extramaze visual cues. Errors are counted as turns made that do not represent the most direct pathway to the goal. This scoring is typically conducted by the experimenter. Although this maze has had extensive use to examine the effects of specific brain lesions on learning, it has had little use in gerontological studies. Using two of mazes in the Hebb–Williams series, Winocur and Moscovitch (1990) reported that aged rats exhibited impaired learning for food rewards.

Compared to the Hebb–Williams maze, the Stone 14-unit T-maze has had much more extensive use in gerontological studies. This maze is enclosed and requires the rodent to make a series of left–right position discriminations to correctly locate the reward at the end of the labyrinth. Salient visual cues are not provided, so it is deduced that the rat must rely on an internally driven response algorithm to solve the task (Ingram, 1988). It learns a route rather than a spatial location. Errors are counted as movement in the wrong direction, whether into cul-de-sacs or retracing a pathway previously negotiated during the trial. Using a food motivated version of the maze in Wistar rats, Goodrick (1968, 1972, 1973, 1975) demonstrated the significant age-related decline in learning performance in this maze. Other laboratories employing different training schedules, motivational conditions, and rat strains have also observed the age-related learning impairment (Jordan and Sokoloff, 1959; Berman *et al*., 1988; Bratt *et al*., 1994a,b). In a series of studies involving a variety of rats and mice, Ingram (1988, 1996), has also demonstrated the robust age effects observed in learning this complex maze task (Ingram *et al*., 1994). In these studies footshock avoidance is used as the aversive motivation. In this version scoring of errors is done automatically by a microprocessor.

Another form of a complex enclosed maze is the *tunnel maze*, which utilizes no specific reinforcement but rather relies on the natural tendency of rats to explore their environment in an efficient manner, similar to that seen in spontaneous alternation tasks. The apparatus consists of six arms radiating from a center area, and each arm contains a small blind alley that branches off from a fixed location. No external visual cues are available to the rat. Entries into arms previously visited on that trial are considered less efficient exploration interpreted as errors of working memory. Entries into blind alleys are considered reference memory errors. In Wistar and SD rats age-related increases in working but not reference memory errors were observed (Jucker *et al*., 1988; Welzl *et al*., 1988).

Several issues should be addressed regarding interpretation of the age effects observed in the mazes described above. First, in those tasks in which food motivation is used, the question can arise whether the age differences in performance are due to age differences in the motivation for food. Typically rats are food deprived for a few weeks to arrive at a target body weight, e.g., 80% of baseline, prior to maze training. Since younger rats are generally lighter and leaner, this level of deprivation could be greater for them compared to aged rats and thus produce a greater level of deprivation. Goodrick (1972) addressed this possible confound regarding age differences in Stone maze performance by reducing the body weight of age rats to 70% compared to 80% for young rats. Even with this procedural control, there was no attempt to demonstrate equivalent motivation for food. In the shock motivated version of this maze, Ingram (1988) employed a pretraining procedure in which the rats are required to show a high level of competence in shock avoidance in a runway to offset arguments about decreased motor and motivational factors contributing the age-related impairment in maze learning.

3. Complex Spatial Maze Learning

The most widely used maze learning paradigms in gerontological research are those that assess the rodent's ability to locate a goal using spatial cues. These tasks require integration of information from various sensory sources—vision, proprioceptive, vestibular—and thus heavily tax memory processes. Abilities demonstrated in these tasks are considered highly ecologically relevant to rodents because they must remember the spatial distribution of multiple goals in an environment (i.e., food and water sources in relation to a home burrow) to promote survival in their niche. Investigators have capitalized on the natural ability of rodents to remember spatial locations in the design of several spatial memory tasks.

The most widely used paradigm to assess spatial memory in rodents in the Morris water maze. This is somewhat of a misnomer because the apparatus is not a maze in the strictest sense. In its most basic form, a large circular tank is filled with opaque water and equipped with an escape platform (the goal) located slightly below the surface of the water, which is maintained at room temperature. On each trial the animal is placed in the tank at different start points and allowed to explore until finding the goal or until a predetermined time has elapsed. During the first few trials, the animal swims randomly in the tank until it finds the hidden platform by chance. After repeated trials, rodents learn to swim quickly and more directly to the goal. Because the platform is hidden below the water, the animal must rely on the distal visual cues in the room to learn the location of the platform within the tank.

As a separate measure of spatial memory, a ''probe'' trial in which the goal is removed is often run at the end of training (typically at least 16–20 trials) or interspersed with the learning trials, for example, every 4–6 trials. The tendency of the animal to search for the goal in its previous location is interpreted as a demonstration of a spatial map of the environment. Again, because the animal must use the spatial configuration of the distal cues to locate the goal, this task is presumed to assess spatial memory.

During acquisition, the typical dependent variables measured include swim time or distance to the platform on each trial. For the probe trial, dependent measures can include the percentage time or distance spent in the region near the location previously occupied by the platform. A more exact measure tallies the number of times the animal crosses over the exact platform position. In its simplest application, data are collected in the water maze task by recording time of the parameters of interest. However, most laboratories are now equipped with automated video tracking systems that record distances as well as time.

An age-related decline in acquisition in this task, measured as time or distance to the hidden platform, has been demonstrated in rats of various strains in numerous studies (Gage *et al*., 1984; Biegon *et al*., 1986; Rapp *et al*., 1987; Markowska *et al*., 1989; Barnes *et al*., 1992; Frick *et al*., 1995) and in C57BL/6J mice (Fordyce and Wehner, 1993; Forster *et al*., 1996; Magnusson, 1997; Frick *et al*., 2000). Probe trial performance also exhibited an age-related decline.

Although the overall age effect appears robust in this task, many investigators report their results as a bimodal distribution (Baxter and Gallagher, 1996). Among groups of aged rats tested, many exhibit performance that is equivalent to that of young rats, either during acquisition or during the probe trial, and are those referred to as ''age unimpaired,'' whereas those aged rats that show clear differences from the young group are referred to as ''age impaired.'' This dichotomous performance groupings can then be used for correlative analyses focusing on various neurobiological parameters as well as identifying appropriate groups for interventive studies. While this approach has been useful for many investigators, others have not observed this type of dichotomous performance in certain rat strains (Lindner, 1997).

The basic features of the task can also manipulated to create other versions of this maze. For example, the location of the platform can be moved on every other trial. The first trial is treated as an information trial, and then the interval between the first and second trials can be manipulated from a few seconds to several minutes to produce a delayed response task. Using such paradigms, age-related declines in performance have been noted in different rat strains (Lindner *et al*., 1992; Shukitt-Hale *et al*., 1998).

While the numerous results from studies of swim maze performance indicate a very robust phenomenon, several caveats must be considered. Many of the studies assessing the ability of aged rodents in the water maze used swim time only as the dependent measure. This procedure is problematic because assessment of cognitive performance might be confounded by age differences in motor performance and motivation. For example, if aged animals swim directly to the goal, but slower than young animals, the dependent measure of swim time would incorrectly lead to conclusion that aged animals had impaired memory for the goal location. Obviously including swim distance as a dependent measure as well avoids this issue. Nonetheless, other possible performance confounds can affect the interpretation of age differences in this task. For example, Rick *et al*. (1996) have suggested that performance impairments observed in aged F344 rats in the swim maze could be due in part to increased fatigue and thermal stress relative to that experienced by young rats.

Another procedural problem can be observed during the first few trials when the animal has not yet had the necessary experience to form a memory for the platform location. Because the animals are randomly searching for the platform at the start of testing, the early performance of animals that will be identified as poor performers at the end of testing should be the same as those animals that will be identified as good performers. Statistically significant differences between young and aged animals in the first few trials suggest that noncognitive factors are responsible, such as impaired swimming ability. Furthermore, if a statistically significant difference in the first few trials is followed by an identical rate of learning between young and aged animals, then again noncognitive factors are suspected.

As with all memory paradigms, the investigator can interpret only performance differences. It should be clear that the water maze is heavily dependent upon the use of visual cues. So not only can there be confounding due to motor impairment in aged rats, sensory confounding is also possible if the aged rat has impaired vision and cannot use the visual cues. For example, Spencer and Raz (1995) identified retinal degeneration in aged SD, the degree of which was correlated with swim maze performance.

Thus, in a visually guided task such as this, it is critically important to show that observed age-related impairments in performance are not due to deficits in sensory, motor, or motivational factors. The standard control procedure for this task requires the subject to swim to a visible platform, thus making the task one of visual discrimination. Although this procedure might be a suitable control to conclude that the age groups examined were equivalent in the motivation and motor requirements, it is not completely appropriate for a similar conclusion regarding visual abilities. After all, demonstrating that a rat can see a platform in the water tank is not equivalent to demonstrating that they can see the distal cues. Gallagher and Pelleymounter (1988), have shown age-related impairment in the water maze even when the cues are made so salient that aged rats could easily discriminate them.

Other studies have underscored the need for correlation between performance in acquisition and probe trials. For example, in a study of male 129SvJ mice, Hengemihle *et al*. (1999) documented a marked age-related decline in performance (distance to platform) during acquisition, but not during the probe trials. This mouse strain had unique performance disabilities, particularly a visual pathology that affected the older mice. Such results argue against the use of this strain as a model of age-related memory impairment.

Another example of such problems in mice is presented in the results of Markowska *et al*. (1998). Marked age-related differences in the performance of SAM/P8 mice during acquisition were recorded for swim time but not distance measures. In

addition, when probe trial performance was recorded as percentage time in the quadrant, no significant age differences were observed; however, when probe performance was measured at the number of platform crossings, there was an age-related decline in performance. This discordance in results in addition to other characteristics of this mouse strain, such as the tendency to float among the older mice, would also render this strain less useful as a model in this behavioral paradigm. Other investigators have noted the difficulties that have been observed in assessing swim maze performance of mice in general compared to the relative ease with which many rat strains can be trained in this task (Whishaw, 1995, Whishaw and Tomie, 1996).

The radial arm maze, or the Olton maze, is another paradigm used to assess spatial memory in rodents that has been applied in aging studies. For this task either a food or water reward is placed at the end of several arms (4–17) radiating from a central platform. The optimal strategy is to visit each of the baited arms without repeating entries into previously entered arms. Although several versions of spatial memory can be assessed with this apparatus, most studies examining the effect of age consistently bait all or a subset of the arms on repeated trials and record arm entries. Entries into never baited arm are interpreted as memory errors for the invariant aspect of the task, or reference memory, while errors into arms previously visited on that trial are interpreted as memory errors for the flexible, working memory store, or memories that need to be reset at the start of each trial.

Age-related impairments in reward retrieval efficiency have been found consistently in many rat strains (Wallace *et al*., 1980; Ingram *et al*., 1981; De Toledo-Morrell and Morrell, 1985; Willig *et al*., 1987; Kobayashi *et al*., 1988; Barnes, 1990; Caprioli *et al*., 1990; Stewart and Reid, 1994; Noda *et al*., 1997; McLay *et al*., 1999; Ward *et al*., 1999). Variations of the radial maze paradigm that attempt to dissect working and reference memory components of the performance show age-related impairment in both components, although some reports indicate greater deficits in the reference memory component (Arendash *et al*., 1995).

Other variations of the paradigm are also possible. Winter (1997) described age differences in the performance of F344 rats in a continuous learning paradigm in which different arms are baited with food, and the rats are not allowed to move to the next version until a criterion is met. Intervals can be imposed between choices. Chrobak *et al*. (1995) described an age-related increase in errors made by SD rats as the delay between choices is lengthened. Environmental cues can be changed to determine how flexible responding differs with age. Tanila *et al*. (1997) noted that aged rats apparently encode only part of the available information to them, but do so in a highly rigid fashion.

When rats were tested in nonspatial versions of the radial arm maze task, no age-related impairments in F344 rats was observed (Barnes *et al*., 1987). This observation is important in interpreting that age deficits observed in spatial versions actually represent defects in spatial memory processing. Moreover, with overtraining, old rats can reach a given level of performance and achieve the same level as young rats (Barnes *et al*., 1980; Gallagher *et al*., 1985), suggesting that the sensory/motor abilities of the aged rats are sufficient to solve the task. When these overtrained rats must learn new environmental cues, the age-related impairments reappear (Gallagher *et al*., 1985). There is also evidence to suggest that aged rats use a more rigid response algorithm to solve the radial arm maze task, perhaps as compensation for impaired spatial memory (Kobayashi *et al*., 1988).

The radial maze paradigm has not seen heavy utilization in mouse studies. Similar to the problems with translation of the Morris maze paradigm for use with mice, similar difficulties have affected the application of the radial maze paradigm to mouse studies. Indeed, a couple of studies of C57BL/6J mice have noted no age differences in performance (Bernstein *et al*., 1985; Ammassari-Teule *et al*., 1994). Even in the SAMP/8 mouse, no age effects in working or reference memory components have been reported (Ikegami *et al*., 1992). However, in the BDF1 hybrid strain, Ikegami (1994) noted significant age-related decline in both working and reference memory components.

The radial arm maze is a highly useful paradigm for aging research because of several features. First, rodents are generally well adapted to such tasks. Second, working memory and reference components of performance can be analyzed separately. Third, task demand on memory can be manipulated by imposing delays between choices. Fourth, the task can be used for long-term within-subject analysis, unlike many other mazes. Despite these strengths, there are also weaknesses in this paradigm for gerontological applications. Similar to other tasks using food motivation, questions arise as how to equate motivational levels across age groups. Second, like the water maze task, efficient performance in the radial arm maze requires use of visual cues, usually located in the extramaze environment. Researchers rarely attend to these possible confounds. In addition, some researchers often neglect to hold the rat in the center arena for a few seconds between choice-trials. Ignoring this procedure will likely result in the rat (young and aged) exhibiting a response strategy, such as visiting arms directly across from the last one entered or visiting only adjacent arms. Design of a good experiment using the radial arm requires attention to all these possible factors.

The circular platform, or Barnes maze, is a spatial memory task that does not require the use of food deprivation or water escape for motivation, but relies on photophobia, or the natural tendency of rats and mice to avoid wide-open, brightly lit environments, favoring instead small dark enclosures. This motivation is arguably less stressful on the aged subject than water escape, shock, or food deprivation.

The animal is placed on an open circular platform that has 18 equally spaced holes distributed around the perimeter. The animal must locate the single hole (in a fixed position) that leads to the darkened goal box by remembering the position of the rewarded location in relation to the distal environmental cues surrounding the platform.

Aged mice (Bach *et al*., 1999) and rats of several strains (Barnes, 1979; Barnes *et al*., 1980; Barnes and McNaughton, 1985; Markowska *et al*., 1989; McLay *et al*., 1999) are impaired at learning and remembering the location of the goal location compared to young cohorts. This finding provides convergent evidence (by use of a different task) supporting the overall conclusion that aged rodents are impaired in spatial memory compared to young cohorts.

One of the same procedural concerns as discussed for the swim maze applies to the use of circular maze. Specifically, the ability of the animal to locate the goal is highly dependent upon its use of extramaze visual cues.

4. Relevance of Mazes

The major problem with virtually all rodent models of learning and memory paradigms is their relevance to tasks used to assess human performance. While many of the aversive tasks will likely never have human counterparts because of ethical considerations, there is increased use of mazes for analysis of human memory. Using computer-generated graphics, virtual Morris mazes (Astur *et al*., 1998) and radial arm mazes (O'Connor and Glassman, 1993; Glassman *et al*., 1994) have been developed as well as other types (Kahana *et al*., 1999). With increased use of these paradigms in human studies, their application in rodent models increases in value. If parallels can be drawn regarding the effects of aging as well as specific brain lesions and pharmacological manipulations on performance of rodents and humans in similar mazes, then greater predictive validity will accrue to use of maze learning as models of age-related memory impairment.

V. Conclusions and Caveats

A variety of tasks have been used to assess age differences in learning and memory processes in rodent models. Similar to the literature on age-related changes in learning and memory in humans, rodents have defects in short-term memory processing in which demands are placed by increasing the number of items to be learned or the interval in which they must be held in memory. Thus, aged rodents exhibit no difficulty in learning simple mazes or operant tasks. However, if the number of decisions is increased (e.g., beyond six choices in a maze) or the interval between stimulus and response is increased, significant age differences emerge. Such performance deficits indicate defects in working memory, in both capacity and duration. Working memory also appears to be highly susceptible to interference effects among aged subjects. Age-related impairment is also observed in reference memory tasks when the situation requires integration of a complex variety of cues, such as in complex mazes, particularly those involving spatial navigation. Despite this emphasis on complexity as a major factor for observing age differences in performance, the results of studies of classical conditioning reveal age differences in simple reflex learning. Again, increasing the interval between stimuli generally increases the age differences observed.

Several caveats can be considered regarding this area of research. One is relevance of the rodent models to human memory performance and the tasks used to assess this. Many of the tasks used in rodents, particularly aversive tasks, have little chance of meaningful generalization to humans. However, several tasks offer this potential. Classical conditioning is a leading candidate in this regard. DNMS tasks can also provide generalization across a number of species, including rodents to human and nonhuman primates. The analysis of maze learning is offering new opportunities for species generalization as virtual mazes are being used increasingly in human studies.

Another caveat is whether investigators exercise sufficient control over noncognitive factors when using various tasks to analyze age differences in learning and memory performance. Control over sensory, motor, and motivational factors is not always apparent. Tasks which conduct parametric analysis in which responses of the aged animal are shown to be equivalent under one condition, e.g., a short retention interval, but impaired under another in which the performance requirements are the same, e.g., a long delay interval, offer the potential for control over noncognitive factors (Olton and Markowska, 1988). Another caveat in interpreting age differences in cognitive performance is the role of attentional factors. Some attempts have been made to assess age differences in attentional factors using an operant paradigm (Moore *et al*., 1992), but more effort is needed in this area, and such assessments should be considered when designing tasks. Also, time of testing has not been given adequate consideration in design of studies. Winocur and Hasher (1999) demonstrated that aged rats were highly affected by the time of day when testing occurred, whereas younger rats were not. A final caveat is the issue of environmental factors. In virtually all applications, rodent models of aging are reared in environments offering minimal stimulation. Several studies have demonstrated that environmental enrichment, such as adding objects to the home cages over a period of many weeks, can improve the performance of aged rats (van Gool *et al*., 1985; Berman *et al*., 1988; Van Wass and Soffie, 1996; Winocur, 1998). Although it should be noted that many of the age differences in performance still exist in these studies even after environmental enrichment, additional consideration of environmental design for rodent studies could be given in future efforts for developing rodent models of age-related memory impairment.

The area of research covered in this review has shown increasing interest generated by the search for rodent models of aging and Alzheimer's disease to investigate neurobiological mechanisms as well as assess possible therapeutic interventions. The area will likely generate even more progress through greater consideration for standardization of procedures to assure more valid assessment of learning and memory processes and generalization to the human condition.

Genetically Engineered Models of Human Age-Related Neurodegenerative Diseases

Aging-related human diseases such as amyotrophic lateral sclerosis and Alzheimer's disease are both progressive and degenerative conditions for which no ''natural'' nonhuman animal models exist. Specific genes have been implicated in the etiology of both conditions, which has led to the development of transgenic rodent models that may mimic important aspects of the human disease. For Alzheimer's disease, mutations in the amyloid precursor protein and presenilin genes have been linked with familial forms of the disease, and apolipoprotein E gene allelic variations have been identified as risk factors. Transgenic studies have helped clarify the role of these genes in the development of Alzheimer's disease-related pathology, particularly with respect to Aβ amyloid plaque formation. Particular transgenic lines that express high levels of the mutated amyloid precursor protein gene and demonstrate aging-related Aβ deposition into plaques may mimic the earliest stages of Alzheimer's disease, representing an important tool for determining novel therapeutic strategies before substantial neurodegeneration has occurred. In amyotrophic lateral sclerosis, mutations in genes for Cu/Zn superoxide dismutase-1 and neurofilament proteins have been associated with a subset of cases, and transgenic models involving these genes have been shown to replicate important features of the human disease, particularly following aging. Thus, transgenic technology is advancing our understanding of the cause of pathology in human neurodegenerative diseases associated with aging and, perhaps more importantly, will provide an important resource for discovering and evaluating new methods to prevent these diseases.

I. Introduction

One of the major goals of biomedical research is to produce animal models that are relevant to human disease. These animal models may serve a multitude of purposes, from understanding the role of particular proteins or cellular processes in a disease mechanism to replicating important aspects of human pathology so that new therapeutic strategies can be developed. With respect to human age-related neurodegenerative diseases, very few ''natural'' animal models exist where nonhuman species develop pathological changes akin to human diseases. This may be partly due to the unmatched evolutionary complexity of the human nervous system as well as our relative longevity.

Advances in molecular biology and genetic engineering are providing new opportunities to alter the genome of animal species so that they may more closely replicate important aspects of human brain pathology. In this respect, the ability to introduce or delete specific genes, or even crossbreed to combine these genetic backgrounds, may lead to a clarification of the role of particular gene products in specific cellular processes and neurodegenerative conditions. This approach may unravel, for example, the role of a gene mutation in neuronal degeneration or how the absence of a particular protein may affect a degenerative process. Obviously, the ultimate objective of the application of this evolving technology is to recreate a human disease in an easily studied animal, such as a mouse. There has been varying degrees of success in achieving this goal, but data derived are useful for clarifying the role of certain genes and proteins in various human age-related neurodegenerative conditions. Certainly there is the danger that genetic engineering may produce pathology in animals of dubious relevance to human disease, that we are ''inventing'' new brain diseases in rodents that are false leads with respect to understanding pathology in aging human brains. It may also be that providing the necessary genetic background is just one factor in the cascade of brain changes that lead to specific diseases. Further experimental manipulation could be required for these new genetically altered animals to demonstrate their worthiness as human disease ''models.''

This chapter examines various genetically engineered animals that are of relevance to human age-related neurodegenerative diseases. These models will be appraised for their ability to either replicate human brain pathology and/or tell us something interesting about the disease process and the role of a particular genetic background or protein. The focus will be particularly on Alzheimer's disease (AD) and amyotrophic lateral sclerosis (ALS) where the insertion or deletion

of particular genes, implicated previously in familial forms of the disease, into rodent genomes has resulted in a spectrum of interesting and useful animal models.

II. Alzheimer's Disease

AD is a major cause of age-related dementia and is associated with specific pathological changes within the brain. These histopathological features correspond principally to extracellular ''plaques'' and intraneuronal ''neurofibrillary'' changes. Plaques are extracellular spherical masses of fine amyloid fibrils composed of a 4 kDa protein known as β/A4, Aβ, or β-amyloid (Glenner and Wong, 1984; Masters *et al*., 1985). Aβ is normally a soluble protein found within the nervous system (e.g., Seubert *et al*., 1992) but appears to undergo age-related conformational alterations to form amyloid fibrils in particular brain regions in humans and some nonhuman species. The other major histopathological feature of AD is an abnormal transformation of the neuronal cytoskeleton, resulting in paired helical filaments (PHFs). These cytoskeletal changes are associated with abnormal or ''dystrophic'' neurites associated with plaques, the development of filamentous ''tangles'' within nerve cells, and the formation of ''neuropil threads'' within the dendrites of tangle-affected neurons. Neurofibrillary pathology involves major modifications in cytoskeletal proteins such as microtubules and neurofilaments (NFs) as well as associated proteins (Vickers *et al*., 2000). In this respect, an abnormal and highly insoluble form of the microtubule-associated protein tau has been demonstrated to be an integral constituent of neurofibrillary tangles (Wischik *et al*., 1988; Lee *et al*., 1991) and is likely to represent the principal protein of the PHFs, which replace the normal cytoskeleton in degenerating neurons (Vickers *et al*., 1992).

Compared to other major human diseases, there are relatively few risk factors associated with AD. The major risk factor for this condition is age, with the incidence of AD rising exponentially with age from the seventh decade onward (Katzman and Kawas, 1994). However, it should be noted that extreme old age (90+ years of age) may be associated with a relatively reduced risk of AD-related dementia, perhaps due to protective genetic factors that are linked with longevity. Neuropsychological and pathological studies indicate that AD may have a relatively long disease course, characterized by a ''preclinical'' phase, where Aβ plaques are gradually formed in the brain, followed by a more aggressive clinical phase associated with neurofibrillary pathology, neuronal degeneration, and overt clinical symptomatology (Vickers, 1997; Vickers *et al*., 2000).

The other major risk factor for AD is a family history of the condition. Approximately 10% of AD cases have a strong familial association and are linked to mutations in specific genes that are inherited in an autosomal dominant fashion. A further 90% of AD cases are considered ''sporadic'' in nature, but a relative risk of the disease may be affected by the inheritance of particular gene variants.

While symptomatic treatments based on supplementing particular neurotransmitters are available, lack of an effective therapeutic agent for preventing, halting, or even slowing AD can be attributed to the absence of appropriate disease models. Other species do not develop the full spectrum of AD pathology. Particular aged primates, dogs, and bears develop Aβ plaques, and some species such as polar bears, goats, and sheep have been reported to develop intraneuronal structures resembling neurofibrillary tangles (Wisniewski *et al*., 1973; Selkoe *et al*., 1987; Walker *et al*., 1987; Braak *et al*., 1994; Tekirian *et al*., 1996; Giannakopoulos *et al*., 1997). Hence, there has been great interest in developing new animal models of AD and related disorders by genetic engineering, with the view that manipulation of the genome of these animals may reproduce crucial aspects of the AD degenerative process. In addition, the development of a rodent model may be advantageous with respect to aging studies due to the relatively short life span of rats and mice relative to other species.

The genetic engineering approach has resulted in variable degrees of success to date, but the pace and intensity of research in this area, coupled with other approaches to understanding and modeling AD, have provided valuable disease models and important new insights into the sequence of pathological events that may lead to dementia.

A. Amyloid Precursor Protein Transgenics

The Aβ peptide that comprises the amyloid fibrils of plaques in AD is derived from the amyloid precursor protein (APP). APP is encoded by a 19 exon single gene on chromosome 21, which can be alternatively spliced to produce three isoforms of 695, 751, and 770 amino acids, corresponding to a 100 to 140 kDa molecular mass (Octave, 1995). Both of the larger isoforms contain an amino acid sequence derived from exon 7, which is homologous to the Kunitz family of serine protease inhibitors. APP770 also contains an exon 8-derived, 19 amino acid sequence homologous to the OX-2 antigen.

APP is likely to be a single membrane-spanning glycoprotein, which can be processed variably to smaller fragments by the action of unidentified enzymes. A putative ''α-secretase'' cleaves through residues 16 and 17 of the Aβ sequence to release a large, soluble N-terminal fragment of APP (Esch *et al*., 1990; Sisodia *et al*., 1990). A soluble form of the Aβ sequence is also produced by the action of a β-secretase and γ-secretase at the N- and C-terminal sides of the peptide, respectively (Haass *et al*., 1992; Seubert *et al*., 1992; Shoji *et al*., 1992).

While APP is expressed by the brain and other tissues, the precise function of the protein has not been determined. In the nervous system, APP may have a role in neuronal development (Masliah *et al*., 1992), cell surface adhesion (Breen *et al*., 1991), and/or neuronal interactions with the extracellular matrix (Narindrasorasak *et al*., 1992). APP has been shown to undergo fast axonal transport to the synaptic terminals (Koo *et al*., 1990) where it may have a functional role (Schubert *et al*., 1991; Ikin *et al*., 1996). APP is also subject to a range of posttranslational modifications such as phosphorylation, sulfation, and glycosylation (Robakis, 1994), which are likely to affect its function and the secretion of various derivatives.

Two regions of the APP gene demonstrate mutations that are clearly linked with early-onset familial AD (FAD). At codon 717 (APP 770 transcript numbering), amino acid substitutions of Val for Ile, Phe, or Gly have been described in different

families (Chartier-Harlin *et al*., 1991; Goate *et al*., 1991; Murrell *et al*., 1991). A double mutation at codons 670 (Lys to Asn) and 671 (Met to Leu) is also present in two families (probably related) in Sweden (Mullan *et al*., 1992). Both of these mutations are likely to affect the processing of APP, with the codon 717 and 670/71 mutations lying close to the N- and C-terminal ends of the Aβ sequence, respectively. Indeed, individuals who inherit the Swedish APP mutation (APP_{SWE}) show an elevation of secreted levels of Aβ from cultured fibroblasts (Citron *et al*., 1994). Another APP mutation at codon 693 (Glu-Gln), at the 22nd residue of the Aβ sequence, is linked with susceptibility to Dutch-type cerebral hemorrhage with amyloidosis, a condition associated with amyloid deposits along cerebral blood vessels (amyloid angiopathy), strokes, and typically, death in the fifth or sixth decade of life (Levy *et al*., 1990; Van Broeckhoven *et al*., 1990).

The linkage of specific gene mutations in APP with FAD indicates that abnormal processing of APP has a pivotal role in the pathogenesis of AD (Selkoe, 1991). In addition, Down syndrome involving trisomy of chromosome 21 and thus, an extra copy of the APP gene is associated with the development of Aβ plaques relatively early in life (third to fourth decade of life) followed, in subsequent years, by neurofibrillary pathology (Wisniewski *et al*., 1985; Mann and Esiri, 1989). Similarly, data indicate that there is a preclinical phase of AD where Aβ plaques accumulate within the brain prior to the neurodegenerative changes that are linked with the emergence of dementia (Morris *et al*., 1996; Vickers *et al*., 2000). Thus, this type of data lends credence to the ''amyloid cascade hypothesis,'' which proposes that abnormal processing of APP and the development of Aβ deposits in the brain precede, and perhaps in some way cause, the pathological changes in neurons (Selkoe, 1991; Hardy and Higgins, 1992).

From the identification of APP gene mutations linked to FAD, and possible overexpression of APP related to Down syndrome and AD, there have been extensive efforts to introduce particular APP gene constructs into rodents in an attempt to recreate important pathological features of AD in these species. One of the first such reported transgenic mice lines was designed to express the human 751 amino acid isoform of APP (e.g., hAPP751) under regulation by the neuron-specific enolase promoter (Quon *et al*., 1991). The chromosomes of these mice incorporated from one to eight copies of the gene and showed a modest increase in total levels of the APP protein, with Aβ immunolabeling deposits of extracellular material in the brain, particularly in animals greater than 4 months of age. These deposits were stained with silver impregnation methods, sometimes labeled with thioflavine S, and not stained at all by Congo red. No overt neuronal pathology was present, and the authors proposed that the Aβ-immunoreactive deposits may represent a precursor to amyloid fibrils. Further analysis of this line indicated that elderly transgenic animals (22 months old) demonstrate larger Aβ deposits in the brain associated with gliosis and abnormal neurites were labeled with an antibody to the abnormal tau characteristic of AD (Higgins *et al*. 1994, 1995). In addition, abnormal tau was also localized immunohistochemically to increasing numbers of neuronal cell bodies in aging homozygous transgenic mice (Higgins *et al*., 1995). This transgenic line showed deficits in spatial memory acquisition (Morris Water Maze) and alternation (Y-maze choice) at 12 months of age (Moran *et al*., 1995), which is particularly interesting as it would be predicted from previous studies that very few of the older animals would contain significant Aβ deposits.

A second early transgenic model, developed by Wirak *et al*. (1991), utilized the APP promoter itself to drive the transcription of a sequence encoding Aβ1-42. This transgene was expressed at lower levels than the mouse APP (mAPP), and clustered punctate deposits in the brain, particularly the hippocampus, were labeled with antibodies to Aβ in 1-year-old transgenic mice. However, Jucker *et al*. (1992) noted that the C57Bl6 mouse strain used for the genetic background of the transgenic mice of Wirak *et al*. (1991) were particularly susceptible to the development of age-related clusters of granules, originating in the processes of astrocytes. These granular deposits could be labeled with a variety of immunohistochemical markers, including antibodies to Aβ. Wirak *et al*. (1992) accepted the possibility that the abnormal structures observed in their animals were more likely due to the genetic background of their mice rather than the presence of the transgene.

Kammesheidt *et al*. (1992) reported on a transgenic mouse line (C57/Bl6 $\times$ SJL) expressing the 104 amino acids of hAPP695 under the regulation of the dystrophin neural promoter. Expression of the transgene was principally localized to the brain, and abnormal punctate deposits of Aβ immunoreactivity were present within neurons or neuronal processes in different lines (Kammesheidt *et al*., 1992). Furthermore, thioflavine S-stained blood vessels were reported in a subset of transgenic mice. A further study demonstrated that these transgenic mice developed significant brain pathology by 18–22 months of age, including degenerating axons and dendrites, necrotic cell bodies, accumulations of secondary lysosomes, and activation of microglia to a higher degree than age-matched, nontransgenic littermates as well as C57/Bl6 or SJL mice (Oster-Granite *et al*., 1996). Another transgenic mouse line that expresses the just-described construct, including the Flag epitope sequence, appeared to show a similar pattern of pathological changes at 12 months of age, although animals of earlier ages were not examined (Oster-Granite *et al*., 1996). Aging homozygote transgenic mice bearing this latter transcript showed more severe neuronal degeneration in the hippocampus and performed worse on learning and memory tests (Morris water maze) than similarly aged heterozygote animals or nontransgenic control mice (Berger-Sweeney *et al*., 1999).

A similar transgenic mouse line [C-terminal 104 amino acids of hAPP regulated by the low molecular weight NF (NF-L) promoter] showed a modest increase (30–50%) in levels of the C-terminal APP fragment, aging-related deposits of Aβ immunoreactivity in the cortex and hippocampus, astrogliosis, and microglial activation as well as neurodegeneration (20% loss of neurons) in the hippocampus (Nalbantoglu *et al*., 1997). In addition, these mice showed deficits in the maintenance of long-term potentiation (LTP) and decreased performance on Morris water maze tasks.

These studies have been interpreted to support the proposal that an approximately 100 amino acid C-terminal fragment of hAPP may be a significant agent of neurotoxicity in AD rather than the Aβ peptide itself and/or plaque formation (Kammesheidt *et al*., 1992; Oster-Granite *et al*., 1996; Berger-Sweeney *et al*., 1999). In contrast, overexpression of the mouse Aβ

TABLE 25.1 Some Transgenic Lines Demonstrating AD-like Histopathology[a]

$hAPP_{SWE}$ or $hAPP717_{Val\text{-}Ile}$	+	−	ND	+	+	+	−	Moechars *et al*. (1999)

[a] Aβ plaques are defined as masses of amyloid fibrils immunoreactive for Aβ; NFT, neurofibrillary tangles; PHF, paired helical filaments; NF, neurofilament; APP, amyloid precursor protein; ND, not determined.

sequence (regulated by the NF-L promoter) in FVB/N mice was related to neurodegeneration, apoptosis, and reactive gliosis in the brain, but not plaques or neurofibrillary pathology, indicating a possible *in vivo* toxicity of the Aβ peptide (LaFerla *et al*., 1995). In addition, these animals displayed heightened seizure activity and premature death.

However, while these constructs lead to age-related neurodegeneration, it has yet to be shown whether the abnormal neuronal changes match authentic AD-specific nerve cell pathology. In addition, there is no direct evidence of APP C-terminal fragment or Aβ toxicity from studies of the AD brain. Another important issue is the genetic background of these various transgenic mice, which may have a major role in determining the pathological and behavioral phenotype of the animals. Hsiao *et al*. (1995) also demonstrated that aging transgenic mice overexpressing mouse or human APP695 on a FVB/N background demonstrate neophobia, increased seizures, impaired spatial alternation in a Y maze, diminished glucose utilization, and astrogliosis in the brain, but that these features can also occur in non-transgenic FVB/N mice with aging. Thus, the presence of APP transgenes appears to lead to a potentiation of normal age-related pathology. The wide range of APP transgenics that do not show AD-like histological hallmarks can also do poorly on such tests, suggesting that a disruption of normal brain function may be linked to the novel gene and/or the overexpression of APP or derivatives.

An alternate approach for introducing larger forms of the APP gene involved germline transmission by injecting mouse blastocysts with embryonic stem cells containing the yeast artificial chromosome (YAC) incorporating the entire hAPP gene (Pearson and Choi, 1993; Lamb *et al*., 1993). Abundant expression of hAPP 695 and 751 isoforms was obtained, at levels similar to endogenous APP species (Lamb *et al*., 1993). Mice containing the YAC–APP gene construct with the Swedish FAD double mutation demonstrate high levels of Aβ in the brain and a decrease in α-secretase-derived fragments (Lamb *et al*., 1997). In addition, transgenic mice bearing YAC–APP gene constructs with the FAD-related, Val-Ile substitution at codon 717 showed particularly high levels of Aβ42/43 (Lamb *et al*., 1997). Thus, while authentic AD-like histopathology has not been reported in these YAC transgenics, they confirm the proposal that FAD-related mutations result in higher levels of Aβ, particularly Aβ species that are likely to be more highly amyloidogenic.

A breakthrough in replicating AD-specific pathology in transgenic mice was heralded by Kawabata *et al*. (1991), who reported on the presence of aging-related amyloid plaques and neurofibrillary tangles in mice expressing a transgene containing the Thy-1 promoter and a sequence corresponding to a C-terminal region of APP, including the Aβ sequence. However, serious concerns emerged regarding the remarkable AD-like pathology in these transgenic mice, and upon failure to replicate the results in further transgenic animals, the original paper was withdrawn (Kawabata *et al*., 1992).

Subsequently, there have been four groups that have developed transgenic mouse models that faithfully replicate the congophilic, amyloid fibril plaques of AD (Games *et al*., 1995; Hsiao *et al*., 1996; Sturchler-Pierrat *et al*., 1997; Moechars *et al*., 1999) (Table 25.1). In the first of such models, the construct utilized was a hAPP minigene, containing introns 6 to 8 for alternative splicing of exons 7 and 8, and also bearing the Val to Phe FAD mutation at codon 717 ($APP717_{Val\text{-}Phe}$) (Games *et al*., 1995). Transgene expression was driven by a platelet-derived growth factor (PDGF)-β promoter and the genetic background was a Swiss Webster × (C57BL/6 × DBA/2) hybrid. Approximately 40 copies of the gene were inserted into the transgenic line 109 genome and greater than 10-fold expression of hAPP relative to mAPP (or AD) was detected in the brain. At approximately 6 to 9 months of age, heterozygote transgenic animals of line 109 developed Aβ deposits in the hippocampus, cerebral cortex, and the corpus callosum, and the density of these plaque-like structures increased with further aging (Games *et al*., 1995; Irizarry *et al*., 1997a). Aβ deposition also showed remarkable specificity in its distribution within the cerebral cortex, closely resembling the pattern of distribution of plaques in AD (Irizarry *et al*., 1997a). Biochemical analysis has demonstrated that Aβ levels, particularly Aβ1-42, were increased massively during aging in transgenic mice (up to 500-fold rise in 18-month compared to 4-month-old animals) (Johnson-Wood *et al*., 1997).

Aging-related plaques in line 109 animals were labeled by Congo red and stained with silver impregnation methods, with a substantial proportion also stained by thioflavine S. The initial report noted that neurofibrillary tangles and/or labeling for tau was absent in these animals (Games *et al*., 1995). However, abnormal neurites labeled with antibodies to hAPP, NF, and synaptophysin were associated with Aβ plaques, as indeed were astrocytes (Games *et al*., 1995; Masliah *et al*., 1996). In addition, there was evidence of microglial acti-

vation within the brains of animals demonstrating plaques. No overt neuronal degeneration was detectable, although a loss of synaptophysin and microtubule-associated protein 2 (MAP2) was noted in particular hippocampal regions.

Further investigation of line 109 using electron microscopy techniques confirmed that these transgenic mice do develop intraparenchymal masses of amyloid-like fibrils with aging (Masliah *et al*., 1996). Furthermore, the plaque-associated dystrophic neurites contained accumulations of NFs as well as abnormal features such as numerous multilamellated bodies and dense-core vesicles. Further neurodegenerative changes in some cortical and hippocampal neurons included apoptotic changes, but it was not clear whether these were spatially related to the Aβ deposits. However, despite the progressive increase of β-amyloid deposition in these mice with aging, stereological analysis revealed no overt nerve cell loss in the hippocampus or in the entorhinal and cingulate cortices up to 18 months of age (Irizarry *et al*., 1997a). An identical PDGF APP717$_{\text{Val-Phe}}$ mutation construct was used to generate another line of mice (H6) that develops aging-related Aβ plaques (Hsia *et al*., 1999). Interestingly, these animals demonstrate a decrease in markers such as MAP2 and synaptophysin in the hippocampus in the months prior to the formation of Aβ deposits. In contrast, animals from line 109 show no such early neuronal changes. Electrophysiological examination of the hippocampus of H6 mice at younger ages (1–4 months) prior to β-amyloid deposition demonstrated no impairment in LTP but deficits in transmission between CA3 and CA1 neurons and increased NMDA receptor activity relative to non-NMDA receptors in postsynaptic potentials. Hsia *et al*. (1999) noted that there may be an insidious deleterious activity of APP transgene products prior to the emergence of plaques, which may be relevant to AD or a consequence of overexpression of APP as observed in numerous other transgenic lines.

Transgenic mice with this construct are also useful for determining the role of other factors in AD. For example, crossing such mice with animals expressing the transforming growth factor (TGF)-β1 results in accelerated Aβ deposition in the brain, suggesting a role of increased levels of this factor in AD (Wyss-Coray *et al*., 1997). In addition, mice bearing the APP717$_{\text{Val-Phe}}$ mutation also show increased cell death in the hippocampus, relative to nontransgenic animals, following experimental brain trauma, indicating that a hAPP$_{\text{mutant}}$ product may augment cellular degeneration following such insults (Smith *et al*., 1998). However, these animals do not show augmented β-amyloid deposition in the form of plaques. In contrast, transgenic animals that overexpress the entire APP gene (via a YAC) do not show elevated neuronal degeneration following brain trauma (Murai *et al*., 1998).

In 1996, Hsiao *et al*. reported on a different transgenic mouse line (Tg2756) that contained a construct comprising the hamster prion protein promoter and the APP695 sequence with the Swedish FAD double mutation at codons 670 (Lys to Asn) and 671 (Met to Leu) (APP$_{\text{SWE}}$ mice). Mice were bred on to a C57Bl6 $\times$ SJL background, and heterozygous transgenic mice were found to have brain levels of total APP from 5- to 6-fold higher than mAPP. Furthermore, there was a 5- and 14-fold increase in Aβ1-40 and Aβ1-42/43 levels, respectively, in old (11–13 months of age) relative to younger (2–8 months of age) transgenic mice. Plaque-like deposits, labeled with antibodies to Aβ and stained with Congo red and thioflavine S, were also present in the 11- to 13-month-old transgenic animals. In addition, astrocytes and silver-stained dystrophic neurites were associated with the plaques in older transgenic mice, but there was no evidence of neurofibrillary tangle formation or nerve cell degeneration reported. Synaptophysin and NF immunoreactive enlarged axonal processes have been localized to plaques in this line (Irizarry *et al*., 1997b), and markers of oxidative stress may also be present within these plaque-related dystrophic neurites (Papolla *et al*., 1998). Furthermore, activated microglia show a close association to Aβ deposits in these animals (Frautschy *et al*., 1998). Despite the presence of Aβ plaques in the hippocampus of APP$_{\text{SWE}}$ mice, stereological analysis demonstrated that there was no associated nerve cell or volume loss in the CA1 subregion, nor loss of synaptophysin labeling in the dentate gyrus (Irizarry *et al*., 1997b).

Hsiao *et al*. (1996) also determined that APP$_{\text{SWE}}$ transgenic mice showed deficits in spatial memory (Morris water maze) and alternation (choice in a Y-maze) tasks at older ages (9 to 10 months), whereas younger transgenic mice performed at equal levels to nontransgenic animals. In addition, further studies confirmed aging-related deficits in spatial memory in APP$_{\text{SWE}}$ mice as well as impaired LTP in the CA1 and dentate gyrus of the hippocampus, indicating an important functional impairment in these animals despite limited neuronal pathology (Chapman *et al*., 1999). In another study, younger transgenic mice that express both APP$_{\text{SWE}}$ and APP717$_{\text{Val-Phe}}$ mutations showed higher levels of Aβ protein in the hippocampus than mice with the APP717$_{\text{Val-Phe}}$ mutation alone (Hsia *et al*., 1999). Furthermore, doubly transgenic mice also demonstrated more severe impairment in synaptic transmission in this brain region than APP717$_{\text{Val-Phe}}$ mice prior to the emergence of plaques, supporting the proposal that elevated nonamyloidogenic Aβ may have deleterious effects on nerve cells (Hsia *et al*., 1999).

The third successful effort at producing AD-like pathology in transgenic mice has come from the laboratories of Novartis Pharma (Sturchler-Pierrat *et al*., 1997). Two lines, expressing either the hAPP751 isoform bearing the APP$_{\text{SWE}}$ mutation and APP717$_{\text{Val-Ile}}$ mutations with the human Thy-1 promoter (line 22) or the hAPP751 isoform bearing the Swedish mutation only driven by the murine Thy-1 promoter (line 23), were shown to develop age-related Aβ plaques. A further ''line 14'' containing the hAPP751 construct with the Swedish mutation and the human Thy-1 promoter did not show Aβ plaque formation with aging. Interestingly, both lines 14 and 22 demonstrated a twofold overexpression of hAPP relative to mAPP, and line 23 showed a sevenfold increase in transgene expression. Mice of line 22 were of a very advanced age (18 months) when they began to show Aβ deposits, whereas line 23 mice demonstrated Aβ deposits by 6 months of age. In addition, plaques in line 22 mice showed reduced levels of Congo red staining and glial reaction as compared with similar structures in line 23 mice. Abnormal neurites stained for acetylcholinesterase or labeled with antibodies to NFs, APP, and synaptophysin were associated with plaques in these animals. Interestingly, congophilic plaques in these two lines were also associated with abnormal neurites labeled with various antibodies to tau, the first such report indicating a link between APP transgenic-associated plaques with AD-like modification in

tau. However, while neurofibrillary tangles were not present in these mice, nerve cell loss of the order of 14 to 25% occurs in the CA1 region of the hippocampus and is correlated with Aβ plaque load, with no appreciable neuronal degeneration in the neocortex (Calhoun *et al*., 1998).

The most recent research group to report on AD-like neuropathology described two different transgenic constructs, FVB/N mice bearing hAPP minigenes with either APP_{SWE} or $APP717_{Val\text{-}Ile}$ mutations under regulation by the mouse Thy-1 promoter (Moechars *et al*., 1999). Heterozygote animals with either of these constructs developed Aβ immunoreactive plaques in various regions of the brain at greater than 12 months of age, whereas transgenic animals overexpressing nonmutated mouse and human APP695 did not. Animals bearing the APP_{SWE} mutation produced higher amounts of β-secretase-derived APP derivatives, indicating the possible consequence of the site of the mutation, whereas mice with the APP mutation at codon 717 demonstrated particularly high levels of Aβ1-42/43. The plaque-like structures were stained with thioflavine S and by silver impregnation. Plaques were surrounded by astrocytes and microglia, as well as by dystrophic neurites labeled with antibodies to NFs, APP, ubiquitin, synaptophysin, MAP1, and tau.

All APP transgenics generated by Moechars *et al*. (1999) showed a heightened risk for early death, which may be related to previous studies of the influence of APP transgenes in the FVB/N mouse strain (Hsiao *et al*., 1995). In addition, these transgenic lines demonstrated abnormal behavior such as heightened aggressiveness, neophobia, and agitation, which occurred at ages long before plaque formation. Furthermore, mice derived from these various APP constructs demonstrated impairments in memory tasks. Further analysis of mice with the codon 717 mutation indicated normal synaptic transmission within the hippocampus, but abnormal decay of LTP (Moechars *et al*., 1999).

Thus, multiple studies involving transgenic mice demonstrate that overexpression of the APP gene (or regions thereof) may have deleterious effects on brain function irrespective of plaque pathology, leading to impairment in synaptic phenomena such as LTP as well as cognitive functioning and behavior. In some mice, overt neuronal degeneration and gliosis also occur. Whether the functional and pathological changes are related to developmental abnormalities in transgenic animals or the toxicity of specific APP fragments remains to be firmly established. Until this is determined, and if evidence of APP/soluble Aβ toxicity in the human brain is established, the value of these animals for replicating important aspects of AD remains to proven.

It is also clear that aging, in addition to the overexpression of APP bearing known FAD mutations, is essential for the emergence of a specific feature of AD-like pathology, the Aβ plaque (Games *et al*., 1995; Hsiao *et al*., 1996; Sturchler-Pierrat *et al*., 1997; Moechars *et al*., 1999). Thus, overexpression of these APP forms is likely to lead to increased levels of Aβ peptide being produced and, in particular, abundant amounts of the more fibrillogenic Aβ1-42/43 may be crucial. The Aβ plaques in these mice are not pathologically inert structures as they are associated with abnormal neurites variably labeled for APP, synaptophysin, NFs, and, in two studies (Sturchler-Pierrat *et al*., 1997; Moechars *et al*., 1999), abnormal tau characteristic of the AD brain. However, there is no evidence of AD-specific intraneuronal abnormal filamentous structures (PHFs) within these affected neurites or in cell bodies. In addition, overt neuron loss around plaques is not obvious in most of these animals, nor are neurofibrillary tangles or neurodegeneration in nerve cells known to be selectively vulnerable in AD (Hof *et al*., 1999). A number of interpretations can thus be made from the current information available. It is possible that Aβ deposits are not particularly vital in the sequence of pathological events leading to neurodegeneration in AD. As indicated by numerous other transgenic models and other studies, a more soluble form of Aβ, or perhaps a different fragment of APP, could be the toxic species in AD. Alternatively, as suggested by Terry *et al*. (1996), APP misprocessing may not be the central early event in AD pathology—abnormal changes in the neuronal cytoskeleton might lead to neuronal degeneration and plaque formation.

However, the correct interpretation of these transgenic models may rely on a closer analysis of the local degenerative changes that are associated with plaque formation. As noted earlier, dystrophic neurites localized to plaques in transgenic mice have a common profile in their labeling with antibodies to APP, synaptophysin, and NFs. In AD, dystrophic neurites can be classified into several subtypes based on their immunolabeling for specific markers. Thus, three main subtypes of dystrophic neurites have been shown to be labeled principally for NFs, tau, or APP/synaptophysin (Dickson *et al*., 1999). As noted in ultrastructural studies by Masliah *et al*. (1996), the plaque-related axonal changes in APP transgenic mice, including an accumulation of NFs and abnormal multilamellated and vesicular structures, bear a striking resemblance to the subset of NF-containing dystrophic neurites in AD. This may be particularly crucial with respect to studies on the preclinical stage of AD, which is characterized by the presence of Aβ plaques but not extensive neurofibrillary pathology or neuronal degeneration (Morris *et al*., 1996; Price and Morris, 1999; Vickers *et al*., 2000). However, neuritic plaques do occur in this early stage of the disease, and these dystrophic neurites are characterized by the presence of APP, synaptic markers, or NF proteins, but not abnormal tau species (summarized in Dickson *et al*., 1999).

Thus, the pathology in transgenic mice demonstrating Aβ plaques most closely resembles the preclinical phase of AD. In a similar fashion to humans, these transgenic animals may require several more years before more profound neurofibrillary pathology could "mature," far beyond the normal longevity of mice. Thus, while these current transgenic models may not ever develop the full spectrum of pathology in AD, their replication of the early stages of the disease will make them extremely valuable for ascertaining new therapeutic strategies to either prevent plaque formation or delay the neuronal reaction to plaque formation, which eventually leads to neuronal degeneration and dementia. In this respect, a study has indicated that early immunization with human Aβ peptides in $hAPP717_{Val\text{-}Phe}$ transgenic mice (Games *et al*., 1995) results in protection against Aβ plaque formation with aging (Schenk *et al*., 1999). Furthermore, immunization at later ages may even reduce Aβ plaque load in animals in which the pathology would already have been established (Schenk *et al*., 1999). The precise mode of effect of the immunization strategy is

unknown, although it is possible that the binding of antibodies to the human Aβ sequence may trigger the immune system to eliminate pathological Aβ species before and after deposition into plaques. If supported by other studies, this report may represent an important step in preventing a key pathological hallmark of AD. However, the vaccination strategy in humans should be approached with caution due to the ubiquitous expression of APP throughout the body (unlike the localized expression of hAPP in transgenic mice) and the possibility of stimulating an ultimately harmful autoimmune/inflammatory response.

The issue of how these plaques cause local changes in axons, and how plaques lead to neurofibrillary pathology in nerve cell bodies in AD, also remains to be firmly established. Plaque-localized oxidative stress may be one mechanism (Papolla *et al*., 1998). Alternatively, we have proposed that the development of masses of amyloid fibrils in the brain leads to compression and deformation of axonal processes (King *et al*., 1997; Vickers, 1997; Dickson *et al*., 1999). The reactive changes in axons would explain the morphological, neurochemical, and ultrastructural features of early forms of dystrophic neurites. In this respect, the neuronal pathology associated with plaques in transgenic mice and early stages of AD can be replicated in experimental models of acute physical injury to the central nervous system (King *et al*., 1997). The chronic stimulation of this response may lead to a localized inflammatory reaction, abnormal processing of tau in dystrophic neurites and the cell body of origin of the damaged axon, and, ultimately, degeneration of the entire neuron (Vickers, 1997; Vickers *et al*., 2000). It is notable that studies of transgenic mice have also described a compression of the neuropil associated with Aβ deposits (Games *et al*., 1995), and plaque-related compression of cell bodies may occur in one transgenic cell line (Calhoun *et al*., 1998).

B. Amyloid Precursor Protein Knockouts

Homologous recombinant techniques can be used to modify endogenous gene structure in embryonic stem cells. This genetic background can then be transferred to embryos and, with appropriate cross-breeding of heterozygous animals, lines in which expression of the gene is disrupted (''knocked-out'') and prevented can be created. Mice in which mAPP has been inactivated with such transgenic techniques are both viable and fertile, but demonstrate reduced weight (Zheng *et al*., 1995). Such animals also develop gliosis in the brain as well as neurological signs such as reduced limb strength and locomotion (Zheng *et al*., 1995). APP knockout animals were impaired in learning tasks associated with the Morris water maze (Phinney *et al*., 1999), but did not show neuron or synapse loss in the hippocampus (Phinney *et al*., 1999). Reduction in MAP2 and synaptophysin labeling, as well as dendrite length, in the hippocampus has been noted in APP knockout mice, in addition to impaired LTP and paired-pulse depression of GABA-mediated postsynaptic activity (Seabrook *et al*., 1999). Cultured neurons lacking the APP were reported to display reduced viability and neurite growth (Perez *et al*., 1997). In contrast, other studies have indicated that cultured neurons from APP-null mice demonstrate normal neuritic growth, as well as reactions to toxic Aβ and oxidative stress that are similar to nontransgenic-cultured neurons (Harper *et al*., 1998; White *et al*., 1998).

Transgenic mice engineered to express only an isoform of APP lacking exon 2 at 5% of normal APP expression levels (a possible ''functional'' knockout of mAPP) are also viable and fertile but showed reduced body weight, impaired learning ability on the Morris water maze, reduced exploratory behavior, and frequent corpus callosum agenesis (Tremml *et al*., 1998; Magara *et al*., 1999). Further analysis of this low-expressing APP_{mutant}, as well as APP knockouts, indicated that these transgenic modifications result in reduced brain weight and decreased size of forebrain commissures (Magara *et al*., 1999). However, the precise genetic background of particular mouse strains appears to regulate the frequency of callosal agenesis in APP_{mutant} and APP knockout mice (Magara *et al*., 1999).

These data indicate that the absence of APP expression may affect neuronal structure and activity in particular brain regions. While a precise indication of the cellular role of APP has not emerged from these studies, some results point toward a role for APP in neuronal development, axonal guidance, and cell–cell interactions. It is also important to note that interpretation of the phenotype associated with knockout of the APP gene may be difficult due to a possible compensatory action of amyloid precursor-like proteins (White *et al*., 1998; Seabrook and Rosahl, 1999).

However, it is interesting that disruption of mAPP expression can result in a phenotype that is similar to many of the structural, pathological, and behavioral changes noted in numerous transgenic animals designed to overexpress various APP constructs. It may be that the alterations in these latter animals are closely associated with a disruption of the normal function of mAPP, rather than overexpression of particular novel forms of the protein.

C. Presenilin Transgenics, Knockouts, and Crosses

APP mutation carriers account for only a minor subset of all FAD pedigrees. A much larger proportion of FAD cases have been linked to mutations (or exon deletion) on genes located on chromosome 14 and 1, which encode structurally similar proteins (67% sequence homology), presenilin (PS) 1 and 2, respectively (Hardy, 1997). PS gene mutations result in an autosomal dominant pattern of inheritance of AD with a relatively early onset of disease symptoms. PS are membrane-bound proteins with multiple (probably eight) transmembrane domains with the amino- and carboxyl-terminal ends likely to be internal (cytosolic) to the membranous structure. FAD-linked mutations occur throughout the protein, particularly in regions conserved between PS-1 and PS-2, with mutations more abundant on PS-1 than on PS-2 (Mattson and Guo, 1997; Hardy, 1997).

The precise cellular function of PS in the brain, as well as their role in AD pathogenesis, remains to be firmly established. PS-1 and PS-2 are similar to *C. elegans* proteins, sel-12 and Spe-4, which are involved in cell fate determination through the lin-12/Notch signaling pathway and protein trafficking in the Golgi during spermatogenesis, respectively (Mattson and Guo, 1997).

PS-1 also appears to have an important role in Notch processing in mammalian cells. A PS-1 gene knockout in mice is

lethal prior to birth, with embryos demonstrating abnormal somite segmentation and differentiation, as well as decreased expression of Notch 1 and associated ligands (Wong *et al*., 1997). Interestingly, APP γ-secretase inhibitors also interfere with the processing of Notch (De Strooper *et al*., 1998). In addition, neuronal cultures derived from PS-1 knockout embryos demonstrate normal α- and β-secretase activity in APP processing, but impairment in APP cleavage at the γ-secretase site, resulting in reduced Aβ and increased C-terminal APP fragments, suggesting the possibility that PS may act as a γ-secretase for APP (DeStrooper *et al*., 1998, 1999). Indeed, studies of cell lines transfected with specific PS-1 mutations have provided evidence that this PS may correspond to the elusive γ-secretase that is important for processing APP into the Aβ peptide (Wolfe *et al*., 1999). Alternatively, PS may act to ''traffic'' proteins such as APP and Notch to the appropriate cellular site where the γ-secretase acts (Hardy and Israel, 1999). These studies therefore indicate that PS mutations may have an important role in the abnormal processing of APP that leads to the generation of amyloidogenic species of Aβ, indicating a toxic ''gain of function'' of the abnormal protein. Loss of function of mutated PS is also contraindicated by the ability to ''rescue'' PS-1-null mice by transgenic introduction of PS-1 genes carrying mutations linked with FAD (Davis *et al*., 1998; Qian *et al*., 1998).

Thus, these data may explain why human PS_{mutant} carriers show elevated A1-42/43 in plasma in a similar fashion to APP_{mutant} carriers (Scheuner *et al*., 1996). In addition, cultured fibroblasts from individuals with PS-1 and PS-2 mutations also show increased release of Aβ1-42/43 (Scheuner *et al*., 1996).

Transgenic mice that overexpress FAD-linked mutations in human PS-1 or PS-2 demonstrate increased levels of the Aβ1-42/43 peptide in the brain relative to transgenic mice expressing wild-type hPS-1 and nontransgenic animals (Duff *et al*., 1996; Oyama *et al*., 1998). Furthermore, an aging-related further increase in Aβ1-42/43 in hPS-2 mice has been reported (Oyama *et al*., 1998). Borchelt *et al*. (1996) demonstrated an increase in brain Aβ1-42/43 levels in crossed transgenic mice expressing a FAD-linked hPS-1 mutation and $hAPP_{SWE}$ as compared to APP_{SWE} alone or transgenic mice expressing wild-type hPS-1 and the Swedish mutation. However, Citron *et al*. (1997) have noted a specific increase in the ratio of Aβ1-42/43 to Aβ1-40 in $PS\text{-}1_{mutant}$ transgenics crossed with mice expressing wild-type hAPP695 at higher levels than mAPP.

PS_{mutant} transgenics do not result in amyloid plaque development, although crossing such animals with transgenic mice with the APP_{SWE} mutation leads to earlier Aβ deposition in the brain (Borchelt *et al*., 1997; Holcomb *et al*., 1998). Cumulatively, studies using the double-transgenic animal models support the contention that PS mutants lead to increased levels of Aβ1-42/43 relative to Aβ1-40, which can accelerate Aβ deposition in the brain. However, it may be possible that PS mutations impart harmful effects independent of Aβ deposition as aged (>13 months) transgenic mice expressing a FAD-linked PS-1 mutation demonstrate apoptotic and degenerative neurons in the hippocampus, cortex, and cerebellum (Chui *et al*., 1999). Furthermore, cultured neurons from transgenic rats expressing high levels of hPS-1 show enhanced susceptibility to apoptosis (Czech *et al*., 1998).

D. Apolipoprotein E

The apolipoprotein E (ApoE) gene is located on chromosome 19 and comes in three allelic variations, ϵ2, ϵ3, and ϵ4, encoding proteins known as ApoE2, ApoE3, and ApoE4, respectively. Inheritance of the ϵ4 allele is associated with a gene-dose related, increased risk of AD, whereas ϵ2 may be associated with decreased risk (Corder *et al*., 1993, 1994). Notably, some ethnic groups may show reduced effects of ApoE gene-related susceptibility to AD (Osuntokun *et al*., 1995; Tang *et al*., 1998). In addition, it is important to note that ϵ4 carriers generally display an increased risk to cardiovascular disease, as well as decreased longevity. It is well known that ApoE has a role in the transport of cholesterol and lipids throughout the body (Mahley, 1988), but the mechanism by which ApoE isoforms may influence relative risk to AD remains undetermined. It has been proposed that ApoE may act as a ''pathological chaperone,'' enhancing the fibrillogenesis of Aβ (Wisniewski and Frangione, 1992; Ma *et al*., 1994). In this respect, ϵ4 carriers show higher levels of Aβ plaque load in AD (Rebeck *et al*., 1993; Schmechel *et al*., 1993; Corder *et al*., 1994; Olichney *et al*., 1996). Alternatively, it has been suggested that ApoE has an important role in regulating the neuronal response to injury by the mobilization and/or redistribution of cholesterol and lipids (Poirier, 1994). Thus, inheritance of particular isoforms of the ApoE gene may influence the neurodegenerative changes in the AD brain. Similarly, it is notable that head injury and ApoE genotype may act synergestically to increase risk for AD (Mayeux *et al*., 1995) and that a poor clinical outcome from head trauma is associated with the inheritance of ϵ4 alleles (Teasdale *et al*., 1997; Jordan *et al*., 1997; Friedman *et al*., 1999).

In the preclinical and end stages of AD, ApoE is immunohistochemically localized to a subset of Aβ deposits and, in particular, the neuritic plaque (Dickson *et al*., 1997). ApoE immunolabeling can also be present in neurofibrillary tangles, but only in the end stage, extracellular forms of this hallmark, indicating a secondary association (Dickson *et al*., 1997). Localization of ApoE to neuritic plaques indicates that these may be the most fibrillogenic plaques or that ApoE becomes secondarily bound to the plaque due to its role in regulating the local neuritic response to injury. Examination of ApoE transgenic animals could, thus, provide important clues to the specific involvement of ApoE in AD pathology.

ApoE knockout mice demonstrate high plasma triglyceride and cholesterol levels and, ultimately, develop artherosclerotic lesions (Higgins *et al*., 1997). These mice are viable and have been shown to develop an age-related decrease in immunolabeling for neuronal markers such as synaptophysin, tubulin, and MAP2, but increased expression of glial markers (Masliah *et al*., 1995). Morphological and ultrastructural studies indicated abnormal dendrites and a loss of synapses in these animals. In addition, ApoE knockout mice show increased brain levels of 3-nitrotyrosine, a possible marker of oxidative stress (Matthews and Beal, 1996). ApoE-deficient animals display impaired ability on Morris water maze tasks, decreased acetylcholinesterase activity in the cortex and hippocampus, and the presence of abnormally hyperphosphorylated tau (Gordon *et al*., 1996). However, Mercken and Brion (1995) have not observed ApoE knockout-related changes in tau expression or

modification. Furthermore, Fagan *et al*. (1998) presented data that indicates no loss of acetylcholinesterase activity with aging in ApoE knockout mice, nor loss of other cholinergic markers with aging or following injury of pertinent cholinergic pathways. In addition, other studies on ApoE knockouts have found minimal age-related brain changes, cognitive impairment, or influence on the neuronal response to injury (Anderson *et al*., 1998). In contrast, other investigations have replicated initial reports, demonstrating that aging in ApoE-null mice is associated with an immunodetectable decrease in synaptophysin and MAP2 labeling, as well as a disruption of NF-immunoreactive axons (Buttini *et al*., 1999) and deficits in cognitive functioning (Raber *et al*., 1998). Interestingly, while noting no effects of the lack of ApoE on the cholinergic system following injury, Fagan *et al*. (1998) demonstrated that damage to other axonal pathways (entorhinal-hippocampus connections) leads to an abnormal prolonged degenerative response in ApoE knockouts. ApoE-null mice also show a greater degree of nerve cell degeneration, associated with motor and cognitive deficits, than wild-type mice following experimental closed head injury (Chen *et al*., 1997).

The underlying cause for the discrepancies in these results with ApoE knockouts remains to be determined: they may be due to genetic background of different strains or, if strains are identical, it has been suggested that animal management-related factors throughout the animal's life may contribute (Buttini *et al*., 1999). Perhaps of greater significance, using transgenic technology to express either $\epsilon 3$ or $\epsilon 4$ genes on the ApoE knockout background has revealed isotype-specific effects on the brain response to various insults. For example, expression of human $\epsilon 3$, but not $\epsilon 4$, minigenes in the brain under regulation of the neuron-specific enolase promoter protects the brain from loss of synaptophysin, MAP2, and NF markers in mice following systemic kainic acid toxicity (Buttini *et al*., 1999). Of particular interest is that $\epsilon 4$-expressing mice do not show a greater extent of neurodegeneration than ApoE knockouts (i.e., the ApoE isoform does not appear to be further deleterious) (Buttini *et al*., 1999), but the same line of $\epsilon 4$ carriers, particularly females, show aging-related impairment in acquisition of the Morris water maze task (Raber *et al*., 1998). These data indicate that more subtle brain changes are linked with specific ApoE isoforms, and the possibility of influences of gender-related effects. Expression of the $\epsilon 3$ gene on the ApoE null background appears to ameliorate the synaptic and dendritic alterations usually associated with aging of the knockout, and expression of the $\epsilon 4$ gene selectively prevents loss of synaptic markers in these animals (Veinvergs *et al*., 1999).

Crossing ApoE knockout mice with $\text{hAPP717}_{\text{Val-Phe}}$ mice resulted in reduced numbers of age-related Aβ deposits, relative to $\text{hAPP717}_{\text{Val-Phe}}$ mice crossed to ApoE-bearing mice, but no changes in either APP expression or Aβ peptide levels in brain (Bales *et al*., 1997). These data strongly support the proposal that ApoE serves to facilitate Aβ plaque formation, rather than having a secondary role in the neuritic response to plaque-induced injury. Likewise, ApoE is localized to amyloid deposits found in peripheral tissues in some APP transgenic animals (Igeta *et al*., 1997). However, a possible role for ApoE isoforms in the neural response to trauma cannot be ruled out, as demonstrated by studies on the response of isoform-specific transgenics following focal brain ischemia (Sheng *et al*., 1998) and excitotoxicity (Buttini *et al*., 1999).

E. Cytoskeletal Proteins

Abnormal changes in cytoskeletal proteins such as microtubules, tau, and NFs are key pathological features of AD (Vickers *et al*., 1999). However, mutations in the genes for these cytoskeletal proteins have not been detected in any FAD cases. Mutations in the tau gene have been linked with a different form of brain degeneration known as frontotemporal dementia with parkinsonism linked to chromosome 17 (FTDP-17) (Hardy *et al*., 1998). This disease can be accompanied by AD-like alterations in the tau protein, leading to a classification of FTDP-17 as a form of ''tauopathy.'' It will thus be very interesting to determine how the tau mutations lead to neuronal degeneration in transgenic animals once they become available. Expression of various forms of human tau in transgenic mice has resulted in neuron-specific expression of the transgene and biochemical modifications in tau that resemble those observed in the neurofibrillary pathology of AD (Gotz *et al*., 1995; Brion *et al*., 1999). These animals do not develop tangles per se, or abnormal filaments characteristic of advanced neurofibrillary pathology, leading to the interpretation that tau alterations in these transgenic mice represent the ''pretangle'' stage of AD pathology.

Further interesting data pertinent to AD and other neurodegenerative disease have been derived from studies of transgenic mice expressing human NF proteins. A transgenic mouse line has been developed that expresses the human NF-M protein at levels substantially lower than mNF-M (Lee *et al*., 1992). In young animals, the human NF protein incorporates into filaments containing endogenous NF subunits and no obvious brain pathology is evident (Lee *et al*., 1992). With aging, tangle-like structures were observed in the neocortex, but these inclusions were composed of NFs and not PHFs (Vickers *et al*., 1994). The pathology in these mice may be illustrative of how the human NF-M protein may be susceptible to age-related pathological alterations. In addition, the tangle-like structures showed a remarkable predilection for certain neocortical layers and cell types that correspond to the neurons showing selective vulnerability to neurofibrillary pathology in AD (Hof *et al*., 1990; Vickers *et al*., 1992). Similarly, aging and the emergence of neurofilamentous pathology in these mice were associated with learning deficits on Morris water maze tasks (Haroutunian *et al*., 1996). Other forms of pathology were evident in these mice, including Lewy body-like structures in the cerebral cortex and axonal ''torpedos'' in the cerebellum, with the latter resembling the cerebellar degeneration characteristic of numerous human diseases (Vickers *et al*., 1994). Finally, these mice also demonstrated retinal changes in NFs in select neuronal subpopulations of retinal ganglion cells (Vickers *et al*., 1995a) that were very similar to the neuronal alterations in primate models of glaucoma (Vickers *et al*., 1995b).

Similar forms of neurofilamentous and cellular pathology, often leading to cell death, have been reported in transgenic mice expressing other neuronal intermediate filament gene constructs (Ma *et al*., 1995, 1999; Tu *et al*., 1997; Ching *et al*., 1999). These results emphasize how alterations invol-

ving individual filament proteins can lead to a general disruption in the cytoskeleton and that cell-type-specific collapse or disruption of proteins such as NFs can result in a panorama of pathological inclusions, resembling numerous human neurodegenerative diseases.

III. Amyotrophic Lateral Sclerosis

ALS is the major cause of human motor neuron disease. In a similar fashion to AD, ALS is generally an aging-related condition that involves progressive neurodegenerative changes, with specific subsets of neurons showing particularly high susceptibility to damage. Selectively vulnerable neurons include motor neurons in the spinal cord as well as subsets of, mostly motor, neurons in the brain stem and cortex (Vickers *et al*., 1995c). In addition, alterations in the cytoskeleton also appear to play a role in the degeneration of neurons in ALS. In the spinal cord, extensively phosphorylated NFs are abnormally localized to the perikarya of ventral horn neurons, Lewy body-like (or hyaline) inclusions occur within the cell body, and accumulations of NFs in the proximal axon lead to the development of ''spheroids'' (Leigh and Swash, 1991). Cytoskeletal changes can also occur in the motor cortex, including aberrant NF phosphorylation in perikarya and the accumulation of NF in the terminal boutons of basket cells (Troost *et al*., 1992). In addition, many of the pathological changes in degenerating neurons are ubiquitinated (Leigh and Swash, 1991).

As with AD, the cause of the neurodegenerative process in ALS remains unknown. It may be that the disease mechanisms are related as, in rare conditions, a motor neuron disease syndrome occurs in conjunction with AD-like changes and dementia (e.g., in the native population of Guam; see Chapter 15). An extensive range of causative factors for ALS has been proposed, including viral infection, autoimmunity, metal toxicity, excitotoxicity, oxidative stress, and genetic factors (de Belleroche *et al*., 1996; Ince *et al*., 1998). Perhaps the best insight into ALS pathogenesis lies in determining the role of specific genes in disease etiology, and, thus, significant progress has resulted by the replication of important features of the human disease in transgenic models.

A. Cu/Zn Superoxide Dismutase-1

Most ALS cases appear to be sporadic in origin, although approximately 5 to 10% appear to inherit the disease in an autosomal dominant fashion. Onset of familial ALS (FALS) is approximately 50 years of age (an appreciably younger onset than sporadic cases), and the disease shows a relatively rapid degenerative course (de Belleroche *et al*., 1996). A major advance for ALS research was the identification of mutations in the Cu/Zn superoxide dismutase-1 (SOD-1) gene, with numerous different mutations in the gene accounting for approximately 20% of FALS cases (Rosen *et al*., 1993). SOD-1 is an enzyme that helps protect cells from oxygen radicals, being specifically involved in the catalysis of superoxide radicals to hydrogen peroxide and oxygen. While it has been proposed that SOD-1 gene mutations may lead to free radical toxicity due to ineffective SOD-1 activity or that overactivity of this enzyme may lead to a harmful increase in hydrogen peroxidase and damage to membranes, data examining peripheral effects of these FALS mutations have been conflicting (Ince *et al*., 1998). The ability to express these gene mutations in mice has represented an important and evolving tool for understanding the role of FALS mutations and SOD-1 in disease pathogenesis (Table 25.2).

The first of such transgenic mice generated expressed either the most common human SOD-1 mutation of alanine to valine at codon 4 (A4V mice) or the glycine to alanine mutation at codon 93 (G93A) (Gurney *et al*., 1994). Whereas A4V mice developed normally, one line of G93A mice that expressed the highest amount of hSOD-1_{G93A} developed tremors and signs of hind limb weakness by 3 to 4 months of age. These neurological changes were progressive, with animals practically paralyzed by 5 months of age and unable to feed. Pathological changes occurred in the spinal cord, including a loss of cholinergic ventral horn motor neurons, neurofilamentous accumulation in cell bodies, degeneration of ventral motor roots (but sparing of dorsal roots), loss of axons, and compensatory sprouting in muscles. Further analysis of this and other lines with the G93A mutation revealed that nerve cell damage was restricted to the brain stem and spinal cord and included vacuolar degeneration localized to the rough endoplasmic reticulum and possibly also mitochondria (Dal Canto and Gurney, 1994, 1995; Tu *et al*., 1996). Other pathological changes included NF-containing spheroids, Lewy body-like inclusions in nerve cell bodies and axons, astrogliosis, ubiquitination of cell bodies and neurofilamentous inclusions, and Wallerian-like degeneration of peripheral nerves. Time course studies demonstrated that the development of NF-containing inclusions and astrogliosis was closely correlated with the onset of neurological symptoms at 2 months of age. Vacuolarization

TABLE 25.2 Some Transgenic Lines Demonstrating Motor Neuron Pathology[a]

Construct	Age of onset (weeks)	Limb weakness	ALS-like cytoskeletal pathology	Vacuolarization	References
hSOD-1_{G93A}	12–16	+	+	+	Gurney *et al*. (1994)

[a]Overt motor neuron degeneration has not been demonstrated.

(particularly in mitochondria) appears to precede frank neuronal degeneration of motor neurons (Kong and Xu, 1998).

These data show that transgenic mice bearing a known FALS mutation can replicate many of the neurological and pathological features of human ALS. However, it is important to note that some pathological features in G93A mice, such as extensive vacuolarization, may occur in some FALS cases (Sasaki *et al*., 1998) but are not a common feature of the human disease. Interestingly, pathological consequences of the transgene appeared to rely on high expression of hSOD-1_{G93A}. In contrast, high expression of hSOD-1 without mutation did not result in such neurodegeneration (Gurney *et al*., 1994), indicating that ALS-like pathology may be due to a toxic gain of function, thus resembling results from many of the APP_{mutant} transgenic mice. In this fashion, elevated indices of lipid peroxidation occur in the spinal cord prior to the onset of ALS-like symptoms in G93A mice, with further increased peroxidation during the active phase of the condition (Hall *et al*., 1998). Increased free radical production selective for the spinal cord has also been reported (Liu *et al*., 1998). Thus, the G93A mutation may lead to altered SOD-1 activity, resulting in increased levels of free radical species and/or increased generation of hydrogen peroxide with consequent peroxidative damage to cell membranes. G93A mice are being used to develop possible new therapeutic strategies for ALS (Klivenyi *et al*., 1999).

A similar spectrum of neurological and pathological features has been described in transgenic mice bearing a FALS-linked glycine to arginine mutation at codon 37 (G37R) (Wong *et al*., 1995). These mice showed a particularly high expression of the transgene in spinal cord relative to peripheral cell types. At approximately 4 to 6 months of age, hSOD-1_{G37R} mice develop tremors and limb weakness as well as appreciable muscle wasting. In a similar fashion to G93A mice, motor function deteriorates, leading to paralysis. Disease onset was associated with vacuolar degeneration in the spinal cord, but unlike G93A mice, the vacuoles in G37R mice were localized to dendrites and the proximal regions of axons and had a particular association with abnormal mitochondria (Wong *et al*., 1995). Focal accumulations of dephosphorylated NF and SOD-1 immunoreactivity surrounded small vacuoles in axons at this stage (Borchelt *et al*., 1998). In addition, a decrease in ventral horn motor neurons, the abnormal localization of phosphorylated NF epitopes to cell bodies, and NF-containing swollen axons were noted in the earlier phase of neurological impairment (Wong *et al*., 1995).

In advanced stages of neurological impairment in G37R mice, there was clear degeneration of large myelinated axons and ventral motor nerve roots (Wong *et al*., 1995). However, it is notable that appreciable degeneration was present in the dorsal nerve roots, the ascending axons of dorsal columns. In addition, brain stem motor nuclei demonstrated degeneration, but so did the olfactory bulb, piriform cortex, pons, and deep nuclei of the cerebellum. Furthermore, vacuolar changes were present in kidney as well as epithelial cells of the choroid plexus. Vacuolar and cellular degeneration may not be spinal cord specific, but is likely to be the key factor associated with motor deterioration in these transgenic animals. In a similar fashion to Gurney *et al*. (1994), overexpression of wild-type hSOD-1 in different transgenic mice did not lead to an overt degenerative phenotype (Wong *et al*., 1995). In addition, 3-nitrotyrosine levels are increased by two- to three-fold in the spinal cord of G37R mice from the earliest pathological changes onward, but no increase in protein-bound nitrotyrosine was detected, nor evidence of increased hydroxyl radicals or lipid peroxidation (Bruijn *et al*., 1997a).

Ripps *et al*. (1995) examined the effects of a FALS-linked mutation in a mouse SOD-1 transgene [glycine to arginine at codon 86 (G86R), equivalent to codon 85 in hSOD-1]. SOD activity in these animals was equivalent to control (mSOD without mutation) animals. Mice showing relatively high expression of the transgene developed hind limb paralysis by 3 to 4 months of age, which progressed rapidly over the following days to a general loss of motor activity. Neuropathology at this end stage included loss of neurons in the ventral horn, with some neurodegeneration in brain stem motor nuclei, superior colliculus, cerebellar nuclei, basal ganglia, thalamus, and motor cortex (Ripps *et al*., 1995; Nimchinsky *et al*., 2000). In the ventral horn, silver staining demonstrated dystrophic neurites, argyophilic perikarya, and swollen processes (Ripps *et al*., 1995). However, the extensive vacuolar degeneration demonstrated in other SOD-1 transgenic animals was not detected in G86R mice (Morrison *et al*., 1998). At disease onset in G86R mice, phosphorylated NF epitopes were localized to cell bodies in the ventral horn, and ultrastructural examination demonstrated misshapen neuronal nuclei, chromatin aggregation, swollen mitochondria, and microvacuoles bordering the nucleus (Morrison *et al*., 1998). Disease onset was also associated with astrogliosis and the rapid loss of nerve cells, including motor neurons and interneurons. Close examination of the phenotype of vulnerable neurons in these mice determined that those interneurons and motor neurons that degenerate are characterized by their selective content of NF triplet immunoreactivity (Morrison *et al*., 1996), which may thus contribute toward their susceptibility to neurofilamentous pathology and neurodegeneration.

Interestingly, transgenic animals that express relatively low levels of hSOD-1 bearing the G85R mutation develop a relatively late-onset (8 to 10 months of age) but fast-progressing (approximately 2 weeks) ALS-like disease with limb weakness and muscle atrophy leading to extensive paralysis (Bruijn *et al*., 1997b). However, pathological examination revealed the presence of Lewy body-like inclusions in astrocytes and not neurons prior to disease onset (at approximately 6 months of age). From the development of neurological signs, there was a rapid loss of motor neurons and other spinal cord nerve cells as well as prominent astrogliosis with associated Lewy body-like inclusions. Unlike transgenic animals that expressed relatively high levels of mutated hSOD-1 (Gurney *et al*., 1994; Wong *et al*., 1995), there was no evidence of vacuole development or abnormal mitochondria in the G85R mice (Bruijn *et al*., 1997b), indicating that overexpression of mutated SOD-1 is responsible for this unusual form of neuronal pathology. Notably, Bruijn *et al*. (1997b) demonstrated a loss of the glial glutamate transported in the G85R mice, which may be similar to that which occurs in ALS (Rothstein *et al*., 1992), contributing toward a putative excitotoxic mechanism of neuronal degeneration (Rothstein *et al*., 1992; Vickers *et al*., 1995c).

Crossing G85R mice with either SOD-1 knockout mice or mice overexpressing hSOD-1 does not exacerbate or protect against the neurological and degenerative changes associated with aging in the G85R animals (Bruijn *et al*., 1998), strongly

indicating that heightened or decreased enzymatic activity may not be responsible for the pathological phenotype.

B. Neurofilaments

Alterations in NFs have a clear role in the pathological changes within upper and lower motor neurons that lead to neurodegeneration in ALS (Vickers *et al*., 1995c). A characteristic phenotype of most SOD-$1_{mutation}$ transgenic mice is the abnormal processing (phosphorylation) of NFs in the cell body as well as accumulations of NFs in the perikarya and axons. Similar changes have been reported in human FALS SOD-$1_{mutation}$ carriers (Rouleau *et al*., 1996). In addition, NF and SOD-1 are colocalized to the same slow phase of axonal transport as well as particular inclusions in G37R transgenic mice (Borchelt *et al*., 1998). Examination of a large number of sporadic ALS cases indicated that specific deletions in the NF-H gene were associated with the disease (Figlewicz *et al*., 1994), although no such polymorphism was detected in a large number of FALS pedigrees (Vechio *et al*., 1996). A further study has confirmed the presence of specific NF-H carboxy-terminal deletions in three sporadic cases as well as a FALS case (Al-Chalabi *et al*., 1999). While these NF-H tail polymorphisms are not common, they further implicate the NF proteins as having a pivotal role in ALS pathology. In this respect, specific transgenic models expressing particular NF gene constructs can also result in an ALS-like phenotype.

Overexpression (4-fold greater than endogenous gene) of the mouse NF-L gene results in a phenotype similar to ALS (Xu *et al*., 1993). Following birth, these animals develop swollen perikarya, NF accumulations in perikarya and proximal axons, distal axon degeneration, and skeletal muscle atrophy. Most animals die within a few weeks of birth. Transgenic animals that express the entire human NF-H gene ($>$2-fold mNF-H) develop fine tremors, abnormal reflexes, and muscle weakness by 3 to 4 months of age, associated with accumulation of NFs in perikarya and axons in the ventral horn (Côté *et al*., 1993). There was also a generalized loss of NFs in more distal segments of axons leading to atrophy of axons in the ventral spinal roots and sciatic nerve. Neurological degeneration appears to be relatively slow, although animals can experience respiratory difficulties at later ages. Notably, motor deterioration is more severe in homozygous transgenics compared to heterozygotes, indicating a gene-dosage effect (Côté *et al*., 1993). Skeletal muscle atrophy is also present in these animals. However, it is important to note that frank motor neuron degeneration has yet to be demonstrated in hNF-H or mNF-L overexpressing animals (Xu *et al*., 1993; Côté *et al*., 1993). Collard *et al*. (1995) demonstrated that these hNF-H transgenic animals show impaired axonal transport. Thus NF accumulation in the cell body and proximal axons may account for the lack of NFs in more distal axonal segments as well as reduced axonal transport and atrophy. Impaired fast and slow axonal transport has also been demonstrated in a transgenic line bearing the G93A hSOD-1 mutation, in parallel with the emergence of NF-containing inclusions (Zhang *et al*., 1997). Indeed, impairment in certain kinds of axonal transport may precede frank neuronal pathology in SOD-1_{mutant}-bearing mice (Warita *et al*., 1999; Williamson and Cleveland, 1999).

Perhaps the best model of ALS pathology has been produced in transgenic mice expressing a mutated (Leu to Pro at codon 394) mouse NF-L (mNF-L_{L394P}) transgene to approximately 50% of endogenous NF-L proteins (Lee *et al*., 1994). Within a few weeks after birth, mNF-L_{L394P} animals develop weakness in upper and lower limbs and abnormal reflexes, with progressive degeneration continuing until death. The pathological correlate of these neurological signs included stereotypical ALS features, such as loss of ventral motor neurons, perikaryal NF phosphorylation, proximal axonal swellings, degeneration of large axons in the ventral root, astrogliosis, and microgliosis, and atrophy of skeletal muscles with an associated denervation. Ultrastructural examination determined that the assembly of NFs was normal but that these filaments were segregated from microtubules and other membranous organelles.

This latter transgenic model confirms that a specific pattern of NF pathology is sufficient to result in an ALS phenotype. Regardless of different environmental and genetic factors, changes in NFs may be a key pathological alteration leading to neurodegeneration in ALS. Ultimately, neuronal degeneration itself may have more to do with the associated deficit in normal axonal transport. However, studies involving cross-breeding of transgenic mice have resulted in data that demonstrate that the pathogenic pathway in ALS may not be that simple. For example, transgenic mice bearing a NF-H construct ligated to the LacZ gene at the tail sequence of the NF gene develop perikaryal accumulations of NF and decreased NFs in axons associated with decreased calibre (Eyer and Peterson, 1994). Crossing NF-HLacZ mice with the G37R mouse (Wong *et al*., 1995) did not affect motor neuron degeneration characteristic of the G37R line (Eyer *et al*., 1998). Thus, NF disruption appeared to have no effect on SOD-1_{mutant}-related degeneration in this study. However, it should be noted that NF-HLacZ mice already result in motor neuron degeneration and axonal damage, indicating that the threshold for producing an ALS-like phenotype may be less in a G37R mouse crossed into this background (i.e., a protective effect may be masked).

A further curious result involved crossing G37R (Wong *et al*., 1995) mice with hNF-H (Côté *et al*., 1993) mice, which resulted in a phenotype where animals showed a markedly increased life span with less motor and sensory axon degeneration (Couillard-Després *et al*., 1998). Couillard-Després *et al*. proposed that the perikaryal accumulation of NF characteristic of the NF-H line (and also NF-HLacZ mice) may act to protect neurons against calcium-mediated toxicity due to the calcium-binding properties of NFs (Lefebvre and Mushynski, 1988).

Finally, crossing G85R mice onto a NF-L knockout background (where the remaining NF triplet proteins do not form filaments) also results in a delayed onset of the ALS phenotype, an increased life span, and a shift in vulnerable cell types to include sensory axons (Williamson *et al*., 1998). Thus, in this example, the absence of NFs ameliorates the G85R phenotype. In addition, increased expression of NF-M and NF-H is present in NF-L knockout mice, and Williamson *et al*. (1998), in a similar fashion to Couillard-Després *et al*. (1998), have suggested that elevated levels of these NF subunits may possibly serve to chelate excess calcium.

Thus, the precise role of SOD-1 and NF gene mutations and protein alterations in ALS remains to be elucidated. It is not perfectly clear whether the expression of hSOD-1 mutations simply leads to problems relating to oxidative stress, or whether NF accumulations are absolutely necessary for the neuronal pathology that leads to functional impairment. As with transgenic models of AD, delineation of the important cellular alterations leading to neuronal degeneration may become apparent through experiments involving the crossing of various transgenic lines. There may be heterogeneous causes of ALS, originating from genetic and/or environmental factors. Certainly, the identification of gene abnormalities in FALS cases lacking SOD-1 or NF gene mutations, or the determination of gene polymorphisms that may be risk factors, may provide important clues to disease causation and targets for transgenic models. There also needs to be a closer examination of how other leading theories of ALS etiology (e.g., excitotoxic mechanisms) relate to data derived from transgenic studies. It could be that the progressive neuronal degeneration that is central to ALS ultimately relates to impairment in the cellular machinery underlying fundamental cellular processes such as axonal transport, an essential feature of neurons with long-projecting axons.

Furthermore, given conflicting results as to whether the presence of SOD-1 mutations leads to heightened oxidative stress in either humans or transgenic mice, perhaps other cellular roles of SOD-1 may need to be explored. Notably, mice in which Cu/Zn SOD-1 expression has been knocked out develop normally and do not demonstrate motor neuron degeneration spontaneously but do show relatively greater vulnerability to motor neuron degeneration following axonal injury (Reaume *et al*., 1996). The axonal pathways of long projecting neurons may be subject to various extraneous physical forces (e.g., stretching and compression), and possession of a mutated SOD-1 protein may thus precipitate an abnormal neuronal response, ultimately leading to degeneration. Studies of the response of SOD-1 mutant transgenic animals to peripheral nerve injury may be instructive with respect to elucidating novel roles of the SOD-1 protein.

IV. Conclusion

Genetic engineering has provided new avenues for developing animal models that replicate key pathological changes in human neurodegenerative diseases. For research in AD, a number of studies have shown that overexpression of APP genes bearing known FAD-linked mutations in mice results in the development of Aβ amyloid plaques, typically in an age-related fashion. Crossing these animals with other transgenic lines carrying genes implicated in the disease process, such as PS and ApoE, has provided new light on the interaction of these factors in AD pathogenesis. Results to date indicate that all of these genes have crucial roles in contributing toward Aβ plaque formation, further implicating plaque pathology as a central event in AD. However, no transgenic animal models have been successful in producing authentic, PHF-related, neurofibrillary pathology such as tangles. Neuronal changes in plaque-bearing mice are indicative of the earliest stages of AD, thus indicating that a longer time frame may be required for substantial neurofibrillary pathology to develop. Irrespective, the current models represent vital new tools for developing methods to prevent or eliminate plaque pathology or the earliest forms of plaque-related neuronal pathology. It will also be important to determine the cause of neuronal pathology and functional synaptic impairment in APP/PS/ApoE transgenic animals that occurs in the absence of overt AD-like histopathology to establish whether these are changes central to understanding AD or a secondary phenomena related to the transgene or perhaps interactions with the genetic background of individual mice strains.

Similar success in replicating human neuropathology has been obtained with transgenic mice bearing FALS-related genes. However, the precise role of SOD-1 in disease etiology remains mysterious and, particularly, how SOD-1 abnormalities may relate to key neuronal alterations in the cytoskeleton that lead to impaired axonal transport. In this respect, crossbreeding of mice with various transgenic backgrounds may help unravel important pathological pathways leading to ALS. It is clear that the currently existing transgenic SOD-1 and NF transgenic lines will be extremely useful for developing new therapeutic strategies.

V. Addendum

As discussed in this chapter, numerous studies have described transgenic mice expressing mutated human genes involved in familial AD, such as APP or presenilins genes. These animals exhibit an increased amyloid peptide level, and amyloid deposits similar to those observed in AD occur, but ball of these models have failed in developing tau intraneuronal aggregates. The first reports of tau transgenic mouse lines focused on models expressing either the longest or the shortest human tau isoform (Götz *et al*., 1995; Brion *et al*., 1999; Ishihara *et al*., 1999; Spittaels *et al*., 1999; Duff *et al*., 2000). A somatodendritic localization of transgenic tau in brain and spinal cord is a constant feature in these models, as well as phosphorylation at sites that are hyperphosphorylated in PHF-tau proteins in AD (Götz *et al*., 1995; Brion *et al*., Ishihara *et al*., 1999; Spittaels *et al*., 1999; Duff *et al*., 2000). The presence of phosphorylated transgenic tau has also been described in glial cells in mice expressing the shortest transgenic human tau isoform (Brion *et al*., 1999). The somatodendritic transgenic tau exhibits a conformational modification revealed by antibody Alz50 that has been considered as a pretangle stage process. Nevertheless, these transgenic models do not exhibit fibrillar structures exactly similar to AD neurofibrillary lesions. In mice with a high level of expression of the shortest human tau isoform (5- to 15-fold the level of endogenous mouse tau), spheroidal intraneuronal inclusions have been observed early in the spinal cord and appear later in the brain where they are smaller (Ishihara *et al*., 1999). These lesions contain hyperphosphorylated tau proteins and NF, and their size and number are transgene dose dependent, as well as age dependent. A fraction of these transgenic proteins are insoluble, and their amount increases with age and worsening of the pathology. Ultrastructural analysis of these lesions has revealed the formation of straight filaments, rather than the characteristic PHF of AD.

Functionally, the overexpression of transgenic human tau isoform in mice induces axonopathy in the brain and spinal cord, as well as motor impairments. These severity of the pathological features is correlated with the level of expression of the transgene and with age (Götz *et al*., 1995; Spittaels *et al*., 1999; Probst *et al*., 2000). More recently, transgenic mice that overexpress a human tau genomic transgene have been described (Duff *et al*., 2000). The six human tau isoforms were generated in their brain, although the normal 1:1 ratio of three to four repeat isoforms seen in human brain was shifted in favor of an increase in three-repeat tau isoforms. A conformational change of transgenic tau similar to those described in the other mouse models was revealed with antibody MC1, but the characteristic somatodendritic showing that the proportion of the different tau isoforms and their compartmentalization are crucial events in the onset of several neurological disorders.

Cognitive Aging in Nonhuman Primates

The study of cognitive aging in nonhuman primates provides a model system for understanding normal cognitive aging in humans, as well as the ability to examine specific potential neurobiological substrates of age-related cognitive impairment. This chapter reviews the evidence for age-related changes in five cognitive domains in nonhuman primates: visual recognition memory, spatial memory, stimulus–reward associative learning, relational memory, and attention/executive function. The effects of damage to specific neural systems on the performance of the particular behavioral tasks used to assess each of these domains are compared to the effects of aging on these tasks. The behavioral profile of aged monkeys is consistent with dysfunction of an inferior temporal-ventromedial prefrontal system for recognition memory and stimulus–reward associative learning, as well as deficits in dorsolateral prefrontal and/or hippocampal function contributing to spatial memory impairment, hippocampal system function contributing to relational memory impairment, and frontal lobe function contributing to executive system dysfunction. The declines in these systems seem to be at least partially independent of each other with increasing age. A focus on individual differences in the profiles of cognitive impairment in aged monkeys, and examination of relationships between behavioral and neurobiological parameters independently of main effects of age on these measures, might provide further insight into the biological basis of cognitive aging.

I. Introduction

Aged monkeys provide an extremely useful model system for understanding both the nature of normal cognitive aging in humans and the neurobiological basis of these cognitive impairments, due to their well-characterized behavioral repertoires, similarity in brain structure to humans, and lack of age-related neuropathological conditions such as Alzheimer's disease (Peters *et al*., 1996). There is a striking similarity between the profile of cognitive impairment in aged nonhuman primates and that of aged humans that are not affected by age-related neuropathological conditions such as Alzheimer's disease (Voytko, 1997).

Five general domains of cognitive function can be identified that have been examined in aged nonhuman primates: visual recognition memory, spatial memory, stimulus–reward associative learning, relational memory, and attentional processing/executive function. The general approach to be taken with each domain of cognitive function is to consider the evidence for impairments in a particular domain in aged nonhuman primates and then review the neuropsychological evidence from young animals linking each domain to the function of particular neural circuits. Much research in this area has been guided by the thesis that a particular behavioral task, known to be sensitive to damage to a particular neural system in young monkeys, should provide a functional index of the integrity of that neural system in aging. Accordingly, the approach taken in this chapter is task oriented, within the broad category of each particular domain of cognitive function. The vast majority of studies of cognitive aging in nonhuman primates have examined rhesus monkeys (*Macaca mulatta*). This is advantageous for the current discussion because most neuropsychological studies in nonhuman primates have also been done in macaques, providing a ready comparison to the effects of aging on cognition. (Although some experimenters have examined the performance of other species of aged nonhuman primates on various cognitive tasks, these experiments are generally consistent with the results in macaques and will not be discussed in this chapter unless they provide data unavailable from studies with rhesus monkeys.)

When data are available, the relationship of performance on different tasks by the same monkeys will be discussed. Identifying dissociations between impairments in cognitive function has been the most productive strategy in understanding the organization of cognitive systems (Olton, 1991). If impairments in two different tasks tend to be correlated across a group of monkeys, a common neural substrate for that impairment might be hypothesized. In contrast, if a group of aged monkeys is impaired on one task but performs normally on another, or if impairment on two different tasks is unrelated, it might be supposed that different neural systems might underlie the different impairments. Also, when data are available, the apparent time course of age-related cognitive decline will be discussed, although these observations are usually based on

cross-sectional comparisons of different groups of aged monkeys (but see Moss, 1993). Possible neural substrates for impairments in particular cognitive domains are noted when neurobiological and behavioral markers are determined in the same subjects; the reader is referred to other chapters in this text for a more comprehensive discussion of these age-related neurobiological changes.

II. Visual Recognition Memory

Behavioral tasks to measure stimulus recognition, literally ''knowing the stimulus again'' (Mishkin and Murray, 1994), were developed as part of an effort to develop an animal model of human amnesia (Correll and Scoville, 1965; Mishkin, 1978). In terms of the overall neuropsychological profile of the aged monkey, deficits in spatial working memory are associated much more consistently with advanced age (see Section III), but because of the intense focus on stimulus recognition memory in neuropsychological studies of nonhuman primates, and the converging interest in examining dysfunction of medial temporal lobe structures as a neural substrate for age-related cognitive decline, we will begin the discussion of cognitive aging in nonhuman primates with this domain of cognitive function.

The most common test of stimulus recognition memory, visual delayed nonmatching-to-sample (DNMS), was developed in its standard form, using trial-unique objects and a performance test that increases memory demand by lengthening the delay between sample and choice, and presenting lists of sample items, by two different research groups in the mid-1970s (Gaffan, 1974; Mishkin and Delacour, 1975). This test capitalizes on the monkey's natural propensity to explore novel objects. In the first phase of each DNMS trial, the monkey is allowed to view a sample object that covers the central well of a three-well test tray. The monkey displaces the object and obtains a food reward hidden underneath the object. An opaque screen is then lowered that occludes the monkey's view of the test tray. In the second phase of each trial, which takes place after a delay ranging from seconds to minutes, the opaque screen is raised and the monkey is allowed to choose between the sample object and a novel object, one covering each of the lateral wells of the test tray. The monkey can obtain another food reward by displacing the novel object. Ordinarily, a very large pool of objects (hundreds to thousands) are available for use as stimuli so the objects the monkey encounters are functionally ''trial unique'' and repeated only rarely throughout testing.

Because of the large number of studies exploring the effects of selective ablations of different brain areas on DNMS performance, this task provides a potentially rich source of information about the nature of functional impairment in aged monkeys; different brain areas may be involved in acquisition of the DNMS rule and in maintaining memory of the objects across delays (see Section II,B). In detecting a memory deficit in such tasks, particular emphasis is placed on the presence of a statistical interaction between condition (age or lesion) and delay: if the effect of condition increases with extended delays, the impairment is interpreted as one of memory because forgetting is occurring more rapidly in the impaired group. [This analysis is not universally accepted; see Murray (1990) and Ringo (1991)]. If there is no such interaction, the impairment could be one of sensory processing, attention, motivation, or some other nonmnemonic factor.

A. Effects of Aging

Aged monkeys (22–29 years old across the different studies) as a group show impairments in acquisition of the DNMS rule as well as impaired performance when the delay interval between sample and choice is increased (Presty *et al*., 1987; Moss *et al*., 1988; Rapp and Amaral, 1989). These initial studies noted some individual differences in the performance of aged monkeys: certain aged monkeys acquired the DNMS rule as efficiently as young monkeys and performed as well across delays as young monkeys. Notably, however, there was no interaction between age and delay in the scores on the DNMS performance test, casting doubt on the interpretation of the DNMS impairment as one of memory.

Although various explanations for this were suggested at the time, Rapp and Amaral (1991), after testing additional aged monkeys, offered an analysis based on classifying the mean performance of aged (22–27 years old) monkeys across all delays as ''impaired'' or ''unimpaired,'' depending on whether the score of each individual aged monkey fell within the range of young performance or not. (A 33-year-old monkey also tested as part of this study could not acquire the DNMS rule at all, and testing of this subject was discontinued after 3000 trials.) The two subgroups of aged monkeys in their sample were of similar chronological age. The subpopulation of aged monkeys who were ''impaired'' (2/3 of their sample) indeed demonstrated differentially impaired performance across longer delays (i.e., an age by delay interaction) that was not observed when the entire sample of aged monkeys was compared as a single group with the young monkeys. Interestingly, there was not a consistent relationship in this study population between impairment in delay performance and impairment in acquisition of the DNMS rule—both subgroups of aged monkeys demonstrated impairments in acquisition of the DNMS rule relative to the comparison group of young monkeys. More recent studies using larger samples of aged monkeys indicate that the incidence of impairment in DNMS acquisition seems to increase with advancing age, although there is no apparent relationship between chronological age and delay performance when aged monkeys are considered as a whole (Herndon *et al*., 1997; Moss *et al*., 1999; Killiany *et al*., 2000).

Rapp and Amaral (1989) also discovered that an alteration in the task demands of the DNMS task could reveal an impairment in performance—testing DNMS performance using only a single pair of objects, rather than trial-unique objects, revealed a dramatic impairment in the aged monkeys. They suggested that while object recognition memory was relatively unimpaired in aged monkeys, memory for temporal order (which of two familiar objects was presented most recently) was affected profoundly by aging. These two cognitive processes have distinct neural substrates (see Sections II,B and III,B).

The level of DNMS impairment seems to increase with advancing age; e.g., monkeys 25–29 years old were numerically more impaired on DNMS than monkeys 20–24 years

old (Presty *et al*., 1987). Inspection of data presented by Herndon *et al*. (1997) suggests that DNMS acquisition impairments are not reliably observed in monkeys younger than 25 years of age, but that impaired delay performance is present in monkeys 19 years of age and older (although, again, there are substantial individual differences, with even very old monkeys demonstrating delay performance in the range of the young monkeys).

Another procedure for assessing stimulus recognition memory, similar to DNMS, is the delayed recognition span task (DRST) developed by Moss and colleagues (1997). In the object and color conditions of this task, either objects or colored disks are placed one by one on a test tray. Each object or colored disk covers a food well. When a new object or colored disk is placed on the test tray, it covers a food reward; the old stimuli are moved to new locations on the test tray but are not rebaited. Hence, the monkey must remember on each trial which stimuli it has seen previously in order to choose the new object or colored disk and obtain a food reward. New objects or colored disks are added until the monkey makes a mistake. Monkeys older than 19 years of age appear to be impaired on the DRST–object condition, whereas impairment on the DRST–color condition does not appear to emerge until 25 years of age (Herndon *et al*., 1997; Moss *et al*., 1997, 1999; Killiany *et al*., 2000).

B. Neural Basis

Since the initial demonstration of an impairment in DNMS produced by combined aspiration lesions of the amygdala and hippocampus in monkeys (Mishkin, 1978), approximating the severe anterograde amnesia produced by a similar neurosurgical operation in human patient H.M. (Corkin, 1984; Corkin *et al*., 1997), considerable effort has been devoted to fractionating the contributions of different neural structures to the performance of this task, particularly within the medial temporal lobe. Of the tasks used to investigate the neuropsychology of memory function in nonhuman primates, DNMS is probably the most widely investigated in terms of the particular neural systems responsible for good performance. Hence, a fairly rich data base exists for the purpose of comparing the effects of aging on DNMS performance with the effects of selective damage to particular brain regions.

DNMS performance seems to involve the interaction of a network of three basic neural structures: the inferior temporal cortex, the mediodorsal thalamus, and the ventromedial prefrontal cortex, with a possible modulatory effect of the basal forebrain cholinergic system (Mishkin and Appenzeller, 1987; Mishkin and Murray, 1994). Within the inferior temporal cortex, the perirhinal cortex seems to be the single most important component for supporting good recognition memory performance, with combined damage to the entorhinal and perirhinal cortex producing an even more severe deficit (Meunier *et al*., 1993; Murray, 1996). Lesions of the entorhinal cortex alone produce only a mild deficit that appears to be transient (Meunier *et al*., 1993; Leonard *et al*., 1995). These deficits are characterized by an impairment in reacquiring the DNMS rule as well as more rapid forgetting across increased delays between sample and choice. Damage limited to the hippocampus produces little or no deficit in performance of this task (Alvarez *et al*., 1995; Murray and Mishkin, 1998; but see Beason-Held *et al*., 1999); similarly, the amygdala appears to make no contribution to performance of this task in its standard form (Zola-Morgan *et al*., 1989b; Murray and Mishkin, 1998; for review, see Baxter and Murray, 2000).

Less information is available about the contribution of specific thalamic and prefrontal structures to this task. Lesions of the mediodorsal thalamus also produce a severe impairment in DNMS performance, with an approximately equal contribution of anterior and posterior groups of thalamic nuclei (Aggleton and Mishkin, 1983a,b; Zola-Morgan and Squire, 1985a). Lesions of the ventromedial prefrontal cortex produce a profound impairment in DNMS performance as well (Bachevalier and Mishkin, 1986). Interestingly, lesions restricted to the inferior prefrontal convexity (ventral prefrontal cortex) appear to produce a selective deficit in reacquisition of the DNMS rule, without an impairment in memory across increasing delays (Kowalska *et al*., 1991), whereas damage to the orbital frontal cortex produces an impairment in memory across increasing delays with less of an impairment in reacquisition of the DNMS rule (Meunier *et al*., 1997). Direct interaction between the frontal cortex and the perirhinal cortex, and between the mediodorsal thalamus and the perirhinal cortex, is critical for visual recognition memory (Parker and Gaffan, 1998). Lesions of basal forebrain cholinergic neurons have little effect on performance of this task, although peripheral administration of a muscarinic receptor antagonist produces DNMS impairments (Aigner and Mishkin, 1986; Aigner *et al*., 1991; Voytko *et al*., 1994).

The overlap between deficits produced by different lesions makes it difficult to draw conclusions about defects in particular neural systems in aging based solely on the pattern of DNMS performance. Decreased performance across delays, as well as impaired acquisition of the DNMS rule, is associated with damage to a number of different neural structures [although the relative magnitude of such deficits can sometimes be dissociated; see, for example, Meunier *et al*. (1997)]. There is a lack of consensus on the relationship between DNMS acqusition and delay performance deficits in aged monkeys; some studies with relatively small numbers of subjects see little association between acquisition of the task and delay performance (Rapp and Amaral, 1991), which would suggest that these two deficits must have their origins in different neural systems. However, a study with a larger sample size reported that acquisition and delay performance loaded onto the same factor in a principal components analysis, suggesting that age-related declines in these two processes are linked (Herndon *et al*., 1997). Finally, an analysis of published data from the first two studies of DNMS performance in aged monkeys (Presty *et al*., 1987; Moss *et al*., 1988), which used similar testing protocols, reveals an association between acquisition of the DNMS rule and delay performance, although again individual differences may exist in this association (see Fig. 26.1). A similar observation has been made with respect to the performance of monkeys with medial temporal lobe lesions (Murray and Mishkin, 1984).

This correlated impairment in DNMS rule acquisition and delay performance is consistent with a dysfunction in the inferior temporal-prefrontal system that subserves visual recognition memory in aging, affecting both DNMS learning and

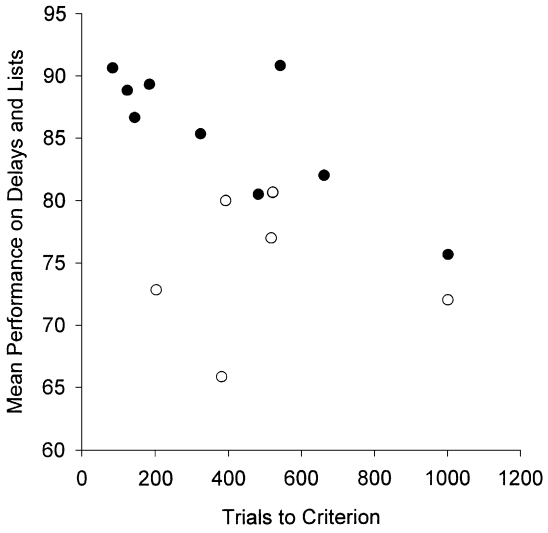

FIG. 26.1. Relationship between trials to criterion in DNMS acquisition and performance across delays (ranging from 30 to 120 sec) and lists of objects (3, 5, and 10 objects) from two studies of aged monkeys that used very similar testing protocols (Moss *et al*., 1988; Presty *et al*., 1987). The filled symbols are subjects from the study by Presty *et al*. (1987) that were older than 20 years (excluding the two aged monkeys with a history of behavioral testing), and the open symbols are subjects from the study by Moss *et al*. (1988). Overall, there appears to be a relationship between DNMS acquisition and delay performance, although the correlation between these variables does not reach statistical significance ($r = -0.48$, $p = 0.07$). However, 2 subjects in the study by Moss *et al*. (1988) show extremely impaired delay performance despite relatively intact acquisition of the DNMS rule, suggestive of individual differences in the relationship between these variables. If these 2 subjects are removed from the analysis, the correlation between these variables from the remaining 13 subjects reaches statistical significance ($r = -0.81$, $p = 0.0008$). Interestingly, this correlation remains even if age is partialled out ($pr = -0.76$, $p = 0.004$), indicating that this relationship is not due to a common main effect of age on DNMS acquisition and delay performance (see Section VII).

delay performance, a hypothesis that would also account for age-related deficits in stimulus–reward associative learning (see Section IV). However, impairments in learning the DNMS rule, without impairments in performance across increasing delays [as was reported for some of the subjects in Rapp and Amaral (1991)] might be suggestive of a selective impairment in prefrontal function, specifically the ventral prefrontal cortex (Kowalska *et al*., 1991).

Performance on DNMS with a single pair of objects appears to be more sensitive to aspects of prefrontal cortex function, likely tapping into similar cognitive processes that underlie performance on the delayed response task (see Section III,B). Monkeys with lesions of the hippocampus are not impaired on performance of DNMS with a small set of objects (Murray and Mishkin, 1984) and indeed monkeys with these lesions are facilitated in learning DNMS with a single pair of objects (M. Mishkin and J. L. Oubre, unpublished observations, as cited in Murray and Mishkin, 1984). Damage to the anterior rhinal cortex produces an impairment in relearning DNMS with a single pair of objects (Murray *et al*., 1996), but monkeys with lesions of the rhinal cortex can perform DMS with a single pair of objects well, even across extended delays, once the rule is relearned (Eacott *et al*., 1994). However, monkeys with damage to the ventral prefrontal cortex are impaired at relearning DMS with a single pair of objects or color stimuli (Passingham, 1975; Mishkin and Manning, 1978), although this impairment may be related to rule learning and not stimulus memory per se (Rushworth *et al*., 1997).

There is little positive evidence linking age-related impairments in DNMS performance to dysfunction of specific neural systems. Hypertrophy of cholinergic neurons in the rostral medial septal nucleus appears to distinguish aged monkeys with DNMS impairment from those with intact performance (Stroessner-Johnson *et al*., 1992), although no such association is seen at more caudal levels of the medial septal nucleus (Stroessner-Johnson *et al*., 1992) or at anterior or intermediate levels of the nucleus basalis (Voytko *et al*., 1995). Amyloid plaque burden in cortical areas is uncorrelated with a global index of cognitive performance that includes DNMS performance (Sloane *et al*., 1997). Similarly, no cell loss has been observed in the hippocampus or in layer II of the entorhinal cortex of monkeys behaviorally characterized on this task (Amaral, 1993); although it might be expected that cell loss in the perirhinal cortex would be linked more closely to DNMS impairment, this has not yet been evaluated. No studies have focused specifically on thalamic or prefrontal regions implicated in DNMS performance. Two studies have noted relationships between abnormalities in area 46 of the dorsolateral prefrontal cortex and impairments in DNMS performance based on white matter pathology in this cortical area (Peters *et al*., 1994) and thickness of layer I of area 46 (Peters *et al*., 1998; but see O'Donnell *et al*., 1999). The significance of these observations is unclear given the lack of effect of lesions of this area on DNMS performance in young monkeys (Bachevalier and Mishkin, 1986); it is also possible that some of these findings are related to common age effects on behavioral performance and neurobiological markers (see Section VII).

III. Spatial Memory

A. Effects of Aging

Medin (1969) first reported an impairment in short-term memory in a group of aged rhesus monkeys (17–18 years old) compared to a group of middle-aged rhesus monkeys (mean age 10 years) as part of a study on pattern reproduction by monkeys. All of these monkeys were experimentally sophisticated, and the magnitude of the difference between the groups was not large. This suggestive initial observation was replicated by Bartus and colleagues (1978), who reported a dramatic impairment of short-term memory for spatial locations in aged rhesus monkeys tested in a similar task. Monkeys were tested in an automated apparatus and were required to remember the location of an illuminated panel (chosen randomly from a matrix of nine locations) across a delay of 0 to 30 sec. Although both young (3–5 years old) and aged (18–23 years old) monkeys performed well at a 0 sec retention interval (demonstrating motivation and mastery of the task principle), aged monkeys were severely impaired at 15 and 30 sec retention intervals. Indeed, there was no overlap between the scores of young and aged monkeys at these two retention intervals, suggesting that aged monkeys were uni-

formly impaired on this task. Further control procedures suggested that these deficits were not due to an impairment in sensory processing in the aged monkeys.

In a more commonly used procedure to assess spatial working memory, the spatial delayed response (DR) task, the monkey is allowed to watch while one of two food wells is baited with a reward. Then an opaque screen is lowered between the monkey and the food wells, and the wells are covered with identical gray plaques. The screen is then raised after some retention interval and the monkey is allowed to displace one of the plaques in an attempt to gain the food reward. The food is not moved in the retention interval, so the monkey must simply remember which well it saw baited and displace the plaque covering that well to obtain the food reward.

Aged monkeys also demonstrate impairments on this more classical short-term spatial memory task (Arnsten and Goldman-Rakic, 1985a; Arnsten *et al*., 1988; Rapp and Amaral, 1989; Bachevalier *et al*., 1991; Voytko, 1993; Roberts *et al*., 1997; O'Donnell *et al*., 1999). It is interesting that aged monkeys appear to demonstrate more individual differences in performance in the DR task than in the more complex automated spatial working memory task originally employed by Bartus. As mentioned, all of the monkeys in Bartus's study (six female rhesus monkeys estimated to be 18–23 years old) were markedly impaired in short-term memory for spatial location (no overlap between scores of young and aged monkeys). In contrast, older monkeys in studies using the DR task occasionally show intact performance; e.g., a 30-year-old male rhesus monkey in the study by Bachevalier *et al*. (1991) performed as well on DR as any of the young monkeys tested in that study, and a wide range of performance is seen in the large sample of aged female rhesus monkeys studied by Roberts *et al*. (1997), from nearly perfect performance across retention intervals ranging from 5 to 60 sec to near-chance performance. Although it is difficult to make definitive conclusions because of the relatively small sample sizes involved in these studies, it is tempting to speculate that the DR task may be less sensitive to age-related memory impairments than the version employed by Bartus; perhaps the increased number of possible locations for responding increases the difficulty of the test. In contrast, however, interference will be higher in the DR task compared to Bartus's task because there are only two possible responses. Indeed, interference, rather than memory, may be a critical factor for age-related impairments in performance on these types of tasks (Rapp and Amaral, 1989), although an increased impairment in performance of aged monkeys with increasing delays in the DR task does reflect an impairment of memory (e.g., O'Donnell *et al*., 1999). It would be of interest to parametrically manipulate both of these factors (number of spatial locations for responding, and interference levels) within a single experiment.

Another related task is the spatial condition of the DRST developed by Moss and colleagues (1997). In this task the monkey is faced with a 3×6 array of wells on a test board. To begin a trial sequence, a brown disk covers a food reward placed in one well of the test board. The monkey displaces the disk and is allowed to obtain the food reward. An opaque screen is lowered between the monkey and the test board; the first disk is returned to its original position, now covering an unbaited well, and a new disk (visually identical to the first) is added, covering a food reward. The screen is then raised and the monkey is allowed to respond. The trial continues in this fashion, with one disk covering a new location and a food reward being added after each response, until the monkey makes a mistake. Thus the monkey must maintain in memory the locations that have already been chosen in order to correctly identify the new location on the test tray and obtain the food reward.

Rhesus monkeys demonstrate impairment on this task as early as 19 years of age (Killiany *et al*., 2000); monkeys 19–24 years of age are impaired on this task as a group, with a mean recognition span of 2.07 compared to a mean span of 2.57 for young monkeys 6–14 years of age (Killiany *et al*., 1999). Although this level of impairment is similar to a group of monkeys 25–27 years of age (mean spatial recognition span of 2.05) (Moss *et al*., 1997) as well as monkeys 30–35 years of age (mean recognition span of 1.83) (Moss *et al*., 1999), there appears to be a robust linear relationship between chronological age and DRST–spatial performance (see Herndon *et al*., 1997). Thus, the pattern of performance in this task is quite similar to that from the classic DR task—an impairment in spatial working memory that increases with advanced age. Notably, within the relatively large sample studied by these authors, few monkeys of advanced age perform as well as young monkeys. Compared with the findings of Bachevalier *et al*. (1991) and Roberts *et al*. (1997) of greater individual differences in DR performance of aged monkeys, this might suggest that the DRST is more sensitive to an aspect of cognitive function that is impaired more consistently in advanced age (possibly, as mentioned before, the ability to monitor many spatial locations instead of just two), but investigation of this possibility awaits a direct test.

The foregoing tests measure memory for locations on a test board, which is placed in a fixed position in front of the monkey. These tests are unable to distinguish between memory for allocentric (environment-centered) and egocentric (subject-centered) space—the monkey may be remembering the absolute position of the response locations within the testing environment or may be remembering its own movements relative to the test board (reaching left or right). Aged monkeys have also been tested in a task that tests allocentric spatial memory, very similar to tests used classically to test spatial memory in the rat. In this task, the monkey is allowed to move around on a large octagonal platform. At the center of each edge of the platform is a small well containing a food reward. The monkey is allowed to retrieve the rewards in any order, provided it returns to the center of the platform between choices (to prevent it from simply running around the edge to collect all the food rewards). This remarkable procedure (Rapp *et al*., 1997) is quite like the radial arm maze task used to test spatial memory in rats (Olton and Samuelson, 1976; Olton *et al*., 1982). Like rats, young monkeys employ the position of distal cues placed within the test room to locate the rewards (Rapp *et al*., 1997). Aged monkeys (23–33 years old) were impaired in acquiring this task and performed very poorly when a delay was interposed between the first four choices and the last four choices. Interestingly, the same monkeys that showed impaired allocentric spatial memory were unimpaired on standard DNMS testing, suggesting a distinct neural substrate for the spatial memory impairment.

B. Neural Basis

Impairments in spatial working memory (and working memory function more generally) are associated with damage to the dorsolateral prefrontal cortex (area 46) (Goldman and Rosvold, 1970; Bachevalier and Mishkin, 1986). Monkeys with lesions of the dorsolateral prefrontal cortex are unable to acquire the DR task. The integrity of catecholaminergic projections to the prefrontal cortex appears critical for normal spatial working memory (Brozoski *et al*., 1979), and dysfunction of these projections has been suggested as a neural substrate for the age-related impairment in DR performance (Arnsten and Goldman-Rakic, 1985a,b; Arnsten *et al*., 1988, 1995; Arnsten, 1993). Bartus noted the similarity between the short-term memory impairment in aged monkeys (Bartus *et al*., 1978) and the impairment in short-term memory in young monkeys induced by the administration of scopolamine, an antagonist of muscarinic cholinergic receptors (Bartus and Johnson, 1976). Alterations in the function of brain cholinergic systems are unlikely to be the neural substrate of age-related spatial memory decline; lesions of basal forebrain cholinergic input to neocortex in the rhesus monkey are without effect on DR performance (Voytko *et al*., 1994). Frank neuronal or volumetric loss in area 46 does not appear to occur in aging (Peters *et al*., 1994), nor is the volume of this cortical area related to impairments in DR performance in aged monkeys (O'Donnell *et al*., 1999).

Hippocampal damage produces no effect on acquisition of the DR task (Murray and Mishkin, 1986; Zola-Morgan *et al*., 1989a) but does induce a deficit when longer retention intervals are interposed (Zola-Morgan *et al*., 1989a), as does combined ablation of the amygdala and hippocampus, including the subjacent rhinal cortex (Zola-Morgan and Squire, 1985b). Thus, a contribution of impaired hippocampal and/or medial temporal lobe function to impaired performance at longer delays in the DR task is possible. Indeed, an *in vivo* measure of hippocampal glucose metabolism correlated highly with aged monkeys' performance of the DR task (Eberling *et al*., 1997). However, lesions restricted to the hippocampus, made with stereotaxically placed injections of the neurotoxin ibotenic acid, do not impair performance on a closely related task, spatial delayed nonmatching-to-sample (Murray and Mishkin, 1998), which calls into question the specific involvement of the hippocampus in memory for spatial location. Lesions restricted to the hippocampus (produced by injections of ibotenic acid) have also been reported to produce an impairment in the DRST–spatial task (Beason-Held *et al*., 1999). However, the monkeys in that study were also impaired in DNMS performance, a finding that has not been replicated by other investigators (Murray and Mishkin, 1998), so the impairment in DRST–spatial performance by these monkeys must be interpreted with caution. No lesion data are currently available for the allocentric spatial memory task of Rapp and colleagues (1997), but the intact DNMS performance in these monkeys suggests that the locus of this deficit must lie outside of the inferior temporal-medial thalamic-ventromedial prefrontal system (see Section II,B). Certainly, based on ample evidence in rats for hippocampal involvement in allocentric spatial memory (Olton *et al*., 1982), this task would be expected to depend on intact hippocampal function.

IV. Stimulus–Reward Associative Learning

A. Effects of Aging

Stimulus–reward associative learning tasks include classic object and spatial discrimination tasks, in which one of two (or more) stimuli is consistently associated with a reinforcer. Tasks of this nature can be varied to examine a number of different aspects of cognitive function by varying the rate of presentation of individual discrimination problems or by reversing the response–reinforcement contingencies once they are learned. These reversal problems test behavioral flexibility, a component of ''executive'' function, as well as the strength of stimulus–reinforcer bonds.

Monkeys trained on single object discrimination problems appear to show no impairment in the acquisition of individual problems or impairment in retention of these problems (Bartus *et al*., 1979; Rapp, 1990; Bachevalier *et al*., 1991; Lai *et al*., 1995), although aged monkeys tend to demonstrate impairments in pattern discrimination learning problems where the stimuli are black-and-white two-dimensional patterns that are less easy to discriminate (Rapp, 1990). In behaviorally sophisticated aged monkeys, Medin reported that aged monkeys appeared to show a reduced retention of object discrimination problems between the first and second day of testing on a list of 20 problems, each presented once per day (Medin *et al*., 1973), suggesting a selective age-related impairment in long-term memory for stimulus–reward associations. Bachevalier and colleagues reported a similar finding, although retention between the first and the second days of testing was not examined explicitly; their oldest group of monkeys (aged 28–31 years) took almost three times as many sessions to reach a criterion of 90% correct on a set of 20 object discrimination problems, each presented once per day (the ''24-hr intertrial interval (ITI)'' task; Bachevalier *et al*., 1991). This may reflect a selective impairment in a slow-learning, ''habit''-like system for forming stimulus-reward associations (see Section IV,B). Aged monkeys are not impaired on spatial discrimination learning (Lai *et al*., 1995; Voytko, 1999), an interesting contrast to their impairment in spatial working memory (see Section III).

Reversal of stimulus–reward associations is impaired markedly in aged monkeys, although the precise nature of this impairment is somewhat unclear. Impairments in object reversal learning (Bartus *et al*., 1979; Peters *et al*., 1996; Moss *et al*., 1999; Voytko, 1999) and spatial reversal learning (Lai *et al*., 1995; Peters *et al*., 1996; Moss *et al*., 1999) have been reported, as have intact spatial reversal learning (Voytko, 1999) and object reversal learning (Rapp, 1990; Lai *et al*., 1995). All of these studies used similar two-choice discrimination procedures. The discrepancies between these studies may be more apparent than real, however. It is interesting to note that in two of the studies that tested both spatial and object reversal learning, it was the first reversal task administered (whether spatial or object) that was impaired [spatial in the case of Lai *et al*. (1995), and object in the case of Voytko (1999)]. Additionally, Lai *et al*. (1995) noted a statistically significant increase in perseverative errors in both spatial and object reversals in their aged monkeys, although the overall number of errors in object reversal was not different between young and

aged groups. Additional studies suggest impairments on reversal learning after experimental ablation of particular cortical areas may be particularly apparent only the first time a reversal is encountered (see Section IV,B). Rapp (1990) observed no impairment in reversal of pattern discriminations (which were the first reversal problems administered in that study), but the difficulty experienced by the aged monkeys in learning to discriminate those stimuli initally could have confounded this result.

Relatively few experiments have focused on individual differences in aged monkeys performing discrimination and reversal tasks. Lai *et al*. (1995) noted that some of their aged monkeys performed within the range of young monkeys by the second reversal of the spatial discrimination. Voytko (1997, 1999) has noted that some aged monkeys perform object reversals as well as young monkeys, whereas other individuals are impaired dramatically in object reversal learning.

B. Neural Basis

The different forms of discrimination learning and reversal tasks seem to have distinct neural bases. Rapid acquisition of object discrimination problems seems to involve the inferotemporal cortex and ventral prefrontal cortex, as well as the mediodorsal thalamus (Gaffan and Murray, 1990; Gaffan *et al*., 1993; Baxter and Murray, 2000). The entorhinal and perirhinal cortices seem to be required for rapid learning of visual discrimination problems only to the extent that these cortical areas are involved in identification of the stimuli to be discriminated (see discussion in Baxter *et al*., 1999). Other medial temporal lobe structures may be involved in retention of these rapidly learned discrimination problems (Zola-Morgan *et al*., 1994; Alvarez *et al*., 1995). In contrast, slow learning of object discrimination problems (e.g., in the ''24-hr ITI'' task) is independent of limbic structures (amygdala and hippocampus) but does require inferior temporal cortical area TE (Phillips *et al*., 1988) and again the entorhinal and perirhinal cortices only to the extent that object identification is taxed (Buckley and Gaffan, 1997; Thornton *et al*., 1998); as well as the ventral and orbital frontal cortices (Murray and Wise, 1997) and the tail of the caudate nucleus (Wang *et al*., 1990). The commonality between cortical systems required for learning of visual discrimination problems and visual recognition memory is notable (see Section II,B). Interestingly, individual monkeys who are impaired on DNMS performance also appear to demonstrate an impairment in object discrimination learning (Rapp, 1993), suggesting a common neural substrate for these deficits, likely inferior temporal-prefrontal connections (see Section II,B).

Spatial discrimination learning appears to involve hippocampal formation and dorsolateral prefrontal cortex. Monkeys with dorsolateral prefrontal cortex lesions are markedly impaired on acquisition of a spatial discrimination problem (Pohl, 1973), as are monkeys with aspiration lesions of the hippocampus that include the overlying parahippocampal cortex (Jones and Mishkin, 1972). The contribution of the hippocampus proper to spatial discrimination learning is unclear, as monkeys with neurotoxic hippocampal lesions (sparing the parahippocampal cortex) are not impaired on this particular spatial discrimination learning task (Murray *et al*., 1998).

Reversal learning appears to recruit additional neural systems. Lesions that impair the initial discrimination also produce impairment in subsequent reversals of that discrimination. However, lesions of the orbitofrontal cortex, which produce no impairment in initial acquisition of a spatial discrimination, produce a marked impairment in reversal of that discrimination (Jones and Mishkin, 1972). Similarly, rhinal cortex lesions, which have little effect on object discriminations, produce an impairment in subsequent reversals of that discrimination (Murray *et al*., 1998). Lesions restricted to the hippocampus also appear to produce an impairment in object reversals, milder than that produced by rhinal cortex lesions (Mahut, 1971; Murray *et al*., 1998). Of note is the pattern of errors made during reversal learning: Jones and Mishkin (1972) analyzed errors in reversal learning based on whether the monkey was performing below chance (stage 1), at chance (stage 2), or above chance but not yet at criterion (stage 3). Damage to the orbitofrontal cortex is characterized by a marked increase in stage 1 errors, suggestive of perseverative behavior (Jones and Mishkin, 1972). Rhinal cortex lesions produce similar perseverative behavior (Murray *et al*., 1998). Hence, perseverative behavior on reversals may suggest damage to the prefrontal cortex, rhinal cortex, or both. It is also worth noting that impairments in reversal learning may be limited to the first time a particular type of reversal problem is encountered (Dias *et al*., 1997); this may explain why a lack of impairment on reversal learning is observed when the monkeys have previously performed reversals in a different stimulus domain (e.g., testing on spatial reversals after having performed object reversals).

V. Relational Memory

A. Effects of Aging

In an attempt to probe an aspect of memory function that might be related more specifically to the functional integrity of the hippocampus and its associated cortical regions (see Section V,B), some investigations have looked specifically at relational memory processing in aged monkeys.

One task of interest tests transitive inference ability. The task takes the form of a set of ordered object discriminations, such that the stimulus that is rewarded on a particular trial depends on what other stimulus is present on that trial. First the monkey is taught a discrimination between two objects, A and B, where A is rewarded and B is not (A+ B−). On the next discrimination problem, B is rewarded and a new object (C) is not (B+ C−). Additional problems are learned (C+ D− and D+ E−) and then the problems are presented in a randomly intermixed fashion within a test session. The ordering of the discriminations sets up a hierarchy among the different objects: A > B > C > D > E, so that the object highest in position in the hierarchy is chosen on any particular individual trial. It is worth noting that each of the objects in the middle of the list (B, C, D) are each paired with reward 50% of the time, making it difficult to use the associative history of a particular object to guide choices.

Once these problems (referred to as ''premise problems'') are learned, relational probe trials are introduced. On these trials, two objects that have not been paired during training

are presented simultaneously. One such pair (AE) can be solved purely on the basis of reward histories of the individual objects; A is always reinforced during training and E is never reinforced, so no inference is required, but if objects B and D are paired, each has been paired with reward 50% of the time, so this cannot guide the monkey's choice. Understanding of the relationship between the objects in the hierarchy—that B occupies a higher position than D—would produce a choice of B more often than D on such trials.

Aged monkeys trained on this task acquire the premise problems comparably to young monkeys and demonstrate an equivalent level of inferential responding on BD trials, i.e., they choose B over D about 80% of the time (Rapp *et al*., 1996). Extension of the series of discriminations to include an additional two objects (so the objects are ordered such that A > B > C > D > E > F > G) permits testing of "symbolic distance" effects: items farther apart in the list should elicit greater degrees of inferential responding. For example, inferential responding on BF trials (separated by three objects in the list) should be greater than inferential responding on CE or DF trials (separated by one object in the list). Such effects were observed with both young and aged rhesus monkeys, and there was no age effect on the magnitude of the symbolic distance effect (Fig. 26.2A; Rapp *et al*., 1996).

However, despite the preserved choice behavior in inferential probe trials, measures of response time on these trials suggested that the aged monkeys were using an alternative strategy to make these choices. Young monkeys took longer to make responses on inferential probe trials (by about 15% on average); indeed, this effect varied with symbolic distance, with longer response times being elicited on probe trials with shorter symbolic distances. These response time phenomena are predicted by theories of performance in this task, which emphasize cognitive representations of the ordering among the objects (McGonigle and Chalmers, 1992). Aged monkeys, despite levels of choice behavior on inferential probe trials equivalent to young monkeys, did not show these response time signatures of transitive inference (Fig. 26.2B; Rapp *et al*., 1996). Such behavior would be consistent with guiding of choice behavior by reinforcement histories of the individual objects, without recourse to a cognitive representation of the ordering of the objects (von Fersen *et al*., 1991). Hence, aged monkeys may have impairments in forming a cognitive representation of the ordered relationship between these objects or in accessing this representation to guide choice behavior. Nevertheless, other behavioral mechanisms that do not involve formation of an ordered representation presumably remain intact to support accurate inferential choice behavior.

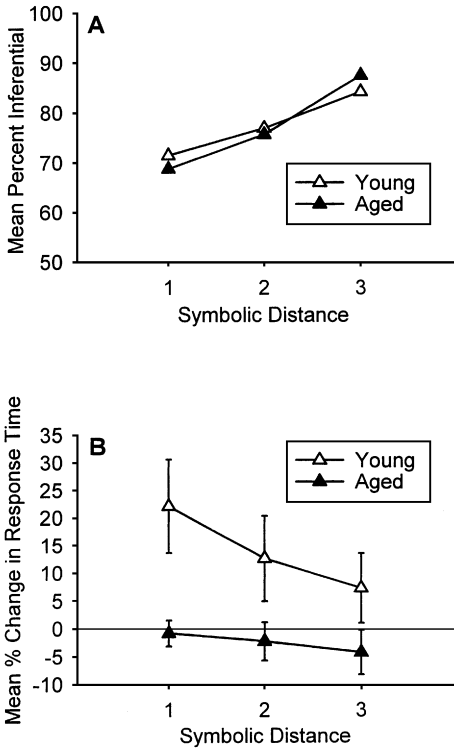

FIG. 26.2. Performance of young and aged monkeys on a relational memory task (Rapp *et al*., 1996). (A) Aged and young monkeys exhibit identical levels of inferential responding on probe trials with novel pairings of elements from the premise problems. Elements farther apart in the series (larger symbolic distance) result in higher levels of inferential responding. (B) Reaction times of young and aged monkeys on the inferential probe trials. Young monkeys exhibit a reaction time signative of inferential processing, longer reaction times on trials where the symbolic distance is lower. Aged monkeys do not display this change in reaction time, suggesting that they are solving the inferential probe trials by a nonrelational strategy. Figures reproduced from Rapp *et al*. (1996) © the American Psychological Association, by permission.

B. Neural Basis

There is currently little information available about the effects of selective brain lesions in monkeys on relational memory tasks. In particular, no lesion data exist for the transitive inference task described earlier. However, rats with damage to the perirhinal/entorhinal cortex, or the fornix, fail to demonstrate inferential choice behavior on a closely related task that used olfactory stimuli (Dusek and Eichenbaum, 1997). Notably, lesions of the orbital frontal cortex do not impair inferential choice behavior in this task (Dusek *et al*., 1997), suggesting that inferential choice behavior in this task may be a particularly sensitive probe of the integrity of the hippocampal system. Hence, the impairment of the aged monkeys is difficult to interpret: they displayed normal inferential choice behavior, but did not demonstrate the response time signatures of inferential processing, whereas rats with damage to the hippocampal system did not display correct inferential choice behavior. Lesion studies in young monkeys will be required to determine whether monkeys with hippocampal system damage show the same kind of deficit as aged monkeys, or a qualitatively different one. Monkeys with entorhinal cortex lesions are unable to make transitive inferences in a similar task (Buckmaster *et al*., 1998), modeled after one used in rats that is impaired by neurotoxic hippocampal lesions (Bunsey and Eichenbaum, 1996), providing support for the notion that the hippocampal formation in monkeys, like in rats, is involved in relational memory processing. Certainly, the sensitivity of the transitive inference task to age-related impairments suggests that this may be a productive line of investigation for testing the cognitive function of aged nonhuman primates.

VI. Attention/Executive Function

A. Effects of Aging

Tasks that examine attention and executive function have not been widely studied in aged nonhuman primates. Reversal learning is sometimes considered to be an indicator of executive function (Lai *et al*., 1995), primarily because of the extent to which it requires flexibility in behavioral performance and the ability to rapidly change responses based on reinforcement contingencies (see Section IV). However, a variety of other tasks have been devised to assess these domains in nonhuman primates, but few have been examined in aging.

The first explicit investigation of attentional processing in aged monkeys examined the performance of adult and aged monkeys on a test of spatial orienting of attention (Baxter and Voytko, 1996). In this task, the monkey must depress and hold the center panel in an array of three panels. A brief peripheral cue illuminates over one of the side panels; during this time the monkey continues to depress the center panel. One of the side panels then illuminates, and the monkey releases the center panel and depresses the illuminated side panel in order to obtain a reward. On most trials, the illuminated side panel (the ''target'') appears on the same side where the cue light appeared; these trials are referred to as ''valid'' trials. On a small fraction of the trials, the target appears on the opposite side from the cue light; these trials are referred to as ''invalid'' trials. The detection of the target is facilitated on valid trials and is delayed slightly on invalid trials, as reflected in the response time of the monkey to release the center panel in order to depress the side panel. The difference in reaction time between valid and invalid trials is an index of shifting or orienting of attention.

Aged monkeys performed identically to adult monkeys when tested in this task, showing no indication of impaired orienting of spatial attention. Furthermore, when ''neutral'' trials were included that permitted separate analysis of costs and benefits of cueing (on neutral trials, both cue lights are illuminated, so no information about the target location is provided), aged monkeys showed similar costs and benefits of cueing compared to adult monkeys (Baxter and Voytko, 1996). These observations are consistent with studies showing preserved spatial orienting of attention in normal aged humans (Greenwood *et al*., 1993), but not in aged humans with Alzheimer's disease (Parasuraman *et al*., 1992). They also suggest that impairments in spatial attention are unlikely to contribute to age-related impairments in the performance of spatial memory tasks such as delayed response (see Section III).

Three other studies have examined attentional function in aged monkeys. One tested aged bonnet macaques (*Macaca radiata*) on a divided attention task that required tracking of multiple moving visual targets on a display. Aged monkeys performed well on the divided attention task and were not impaired relative to the young monkeys in this study, although the small sample size limits the generality of these findings (O'Neill *et al*., 1999). A pair of preliminary reports examined the performance of aged monkeys on visual search and attentional set-shifting tasks (Killiany *et al*., 1998; Moore *et al*., 1998). Aged rhesus monkeys showed increased reaction times in the visual search task, but not an increased number of errors, nor an impairment in orienting of attention or vigilance. In the set-shifting task, monkeys were confronted with an array of stimuli that differed across two dimensions (color and shape). For a block of consecutive trials, one stimulus type was correct (e.g., the red stimulus); then after 10 consecutive correct trials the correct response was switched (e.g., now a response to a triangle was correct, regardless of color). Aged monkeys were characterized by an increased number of perseverative errors and a greater tendency to break set (making six to nine consecutive correct responses and then an error).

B. Neural Basis

The cued reaction time task that tests spatial orienting of attention is sensitive to damage to the basal forebrain in monkeys (Voytko *et al*., 1994) and to parietal cortex damage in humans (Posner *et al*., 1984). Basal forebrain lesions and damage to the parietal cortex increase the ''cost'' of invalid trials, an effect interpreted as an inability to shift attention from the invalidly cued location. The lack of impairment of aged monkeys in this task (Baxter and Voytko, 1996) suggests that the neural systems that underlie this form of attentional processing are functionally intact in aging, although the small sample size in that study precluded an analysis of individual differences in performance.

Little or no data are available for the effects of selective brain lesions on divided attention, visual search, or attentional set-shifting in rhesus monkeys. Compounds that enhanced cholinergic function appeared to produce some improvement in divided attention function in young and aged bonnet macaques (O'Neill *et al*., 1999), suggesting involvement of the cholinergic system in this aspect of attentional processing as well. Damage to the lateral prefrontal cortex of marmosets impairs shifting of attention to different stimulus dimensions (Dias *et al*., 1997) in a similar type of task to that used by Killiany *et al*. (1998), but rhesus monkeys with prefrontal cortex lesions have not been tested on these tasks.

VII. Integration and Conclusions about Neuropsychological Profile of Aged Nonhuman Primates

Aged monkeys generally appear to have a profile of impairments indicative of temporal lobe and frontal lobe function, evidenced by difficulties in recognition memory, spatial memory, stimulus–reward associative learning, and attentional set-shifting, with some attentional capacities intact. To the extent that individual differences in performance have been examined, most of these tasks demonstrate individual differences to some degree—advanced chronological age does not necessarily imply that a particular aged monkey will be impaired on a particular task, although the incidence of age-related impairment on some tasks appears to be relatively high.

Beyond this global assessment, conclusions about altered function in specific cortical areas remain uncertain. Particularly, the wealth of data available from standard behavioral assessments has provided relatively little information about the possible locus of neurobiological alterations that may be responsible for age-related cognitive impairment. Tests of rela-

tional memory and allocentric spatial memory may be particularly useful in detecting age-related impairments in hippocampal function, although the absence of lesion data in monkeys on these tasks limits their usefulness as neuropsychological probes. Despite impairments in a wide array of tasks sensitive to prefrontal cortex function, many of these tasks—learning of the DNMS rule, delayed response, and reversal learning—are also impaired by damage to temporal cortical structures, and the pattern of impairments is difficult to distinguish from those produced by prefrontal cortex damage. Tests of attentional set-shifting might be useful to pursue as a selective index of prefrontal cortex function, although monkeys with temporal cortex damage have not been tested on these tasks, so a potential contribution of these structures to attentional set-shifting remains to be evaluated, and performance of DNMS with a single pair of objects appears to be independent of medial temporal lobe structures. It may be particularly challenging to find behavioral tasks that are affected by rhinal cortex damage but not prefrontal damage, although investigations of object perception and identification following damage to the rhinal cortex are promising candidates (Buckley and Gaffan, 1998; Bussey *et al*., 1999).

Relatively little data are available on the extent to which impairments in different functional domains may coassort with one another. Experiments that have examined this explicitly tend to find that impairments in different domains do not associate with one another, with a few exceptions. In one study population, monkeys that were impaired on DNMS were also impaired in acquiring object discrimination problems (Rapp, 1993), suggesting disruption of a temporal-prefrontal cortical network, although no such relationship was observed in another study (Bachevalier *et al*., 1991). In neither study were these impairments related to impaired delayed response performance, suggesting that these impairments are related to damage to different neural systems. Monkeys impaired on a test of allocentric spatial memory (presumably sensitive to hippocampal function) were not impaired on DNMS (Rapp *et al*., 1997), suggesting that impaired spatial memory in aged monkeys has a neurobiological substrate distinct from that mediating DNMS performance. Of course, an alternative interpretation of this latter finding is that allocentric spatial memory is simply a more sensitive indicator of medial temporal lobe dysfunction than DNMS performance; this question could be addressed by future studies that examine the relationship of DNMS performance to spatial maze performance in a population of aged monkeys that do show DNMS impairments and examining the correlation between performance in these behavioral domains.

Other studies place more of an emphasis on global age-related impairments in cognition (Herndon *et al*., 1997). These authors employed a principal components analysis to examine the pattern of variance in performance on a number of different behavioral tasks. Using data from 30 monkeys tested on six different behavioral tasks in their principal components analysis (DNMS acquisition, DNMS 120-sec delay performance, DRST–spatial, DRST–color, spatial reversal, and object reversal), the first component extracted accounted for 48% of the overall variance and was correlated significantly with age ($r = -0.74$). Using a larger set of monkeys (53 monkeys) who had only been tested on a subset of these tasks produced a similar result, from which the authors derived a composite "cognitive performance index" that was correlated substantially with age ($r = -0.78$). These types of analyses emphasize that overall levels of cognitive performance tend to decline with age, but they neglect the potential dissociations between performance in different domains. When aged monkeys are considered as a group, they frequently will be impaired relative to young monkeys on most cognitive tasks, which will be the component of variance extracted by this type of analysis. However, the most impaired individual aged monkey on one particular task will not necessarily be the most impaired monkey on another task. It is these patterns of dissociation (suggested by experiments that have focused on individual differences in performance) that may provide greater insight into the neurobiological substrates of cognitive aging. The observation that the prevalence of impairment in different cognitive tasks varies across age groups (Herndon *et al*., 1997) provides further support for the hypothesis that aging may differentially affect different neural systems and, by extension, different cognitive abilities.

Caution also needs to be taken when changes in neurobiological variables are related to changes in behavior, when there are common main effects of age on both (Breckler, 1993; Baxter and Gallagher, 1996). There are many instances in which behavioral and neurobiological changes are both correlated with age, creating the possibility for a common age effect and no unique relationship of biological marker to behavior. In these instances, the neurobiological marker serves as a proxy for age when the common relationship with age is not considered in the analysis. As one example, consider the relationship of thickness of layer I of cortical area 46 to cognitive ability in aged monkeys (Peters *et al*., 1998). This study reports a significant relationship between cognitive impairment and thickness of layer I, as well as the density of synapses in the different divisions of layer I. However, all of these morphological variables are correlated significantly with age (r ranging from -0.78 to -0.93) as are the cognitive measures under consideration (r ranging from 0.64 to 0.74). The authors reported a statistically significant correlation of 0.60 between thickness of layer I and performance of monkeys on DNMS at a 120-sec delay. However, when the common relationship of DNMS performance and layer I thickness is partialled out, no significant correlation remains ($pr = -0.11$, $p = 0.73$). (Correlations between other morphological parameters and behavioral performance similarly lose statistical significance when the effect of age is partialled out.) Hence, there appears to be no unique relationship of layer I thickness to behavioral performance, independent of a common effect of age on both. This type of analysis has been useful in identifying neurobiological parameters that are uniquely related with behavioral decline, independently of common main effects of age, in nonhuman primates (Gorman, 1993; Wagster, 1993; Voytko *et al*., 1995) and may provide more informative results.

The complex pattern of age-related deficits in nonhuman primates will likely preclude the identification of a single neurobiological substrate, or even a relatively limited number of substrates, for cognitive impairment in aging. In particular, the behavioral impairments of aged monkeys resemble no lesion of a single cortical region. This is consistent with neurobiological investigations in both rodents and monkeys, which

have found little support for the idea that frank neuronal loss is responsible for age-related cognitive impairment (for review, see Gallagher and Rapp, 1997). Instead, these observations seem to be consistent with alterations in cortical connectivity and more subtle alterations in neural systems with aging that may impair information-processing capacity in less obvious ways (e.g., Gazzaley *et al*., 1996, 1997; O'Donnell *et al*., 1999; Rapp *et al*., 1999).

Despite the complexity of the neuropsychological profile of aged nonhuman primates, these behavioral studies have provided a strong foundation for efforts to define the particular neurobiological substrates of particular aspects of age-related cognitive decline. The development of neuropsychologically characterized behavioral tasks for further probing the functional status of different brain systems in aged monkeys, combined with a focus on individual differences and relationships between performance in different cognitive domains, promises further advances in understanding the biological factors underlying cognitive impairments in aging.

Acknowledgments

I am grateful to Drs. Elisabeth Murray and Peter Rapp for their helpful comments on an earlier version of this chapter.

Brain Aging in Strepsirhine Primates

Among primates, the small nocturnal mouse lemur appears to be a promising species for aging research. With a body size of 60 to 130 g, the mouse lemur lives up to about 13 years in captivity. This primate offers a good model system for aging chronobiology because its life span can be changed by manipulating photoperiodic cycles. Age-related behavioral alterations as well as amyloid deposits, neurofibrillary degeneration, and iron and lipofuscin deposits, the hallmarks of normal and pathological human aging, have been observed in the mouse lemur brain. Cerebral atrophy also occurred in some aged animals. Magnetic resonance imaging allowed the evaluation of the iron content-based indice of aging and the detection, *in vivo*, of iron levels in basal forebrain. Comparative studies of aging should help dissect species-specific factors contributing to aging and to the etiology of dementing illnesses in humans. © 2001 Academic Press.

I. Introduction

A small, rapidly maturing, and short-lived primate model would provide significant advantages for the study of cerebral aging. The small nocturnal primate *Microcebus murinus* (mouse lemur) appears to be a promising species for aging research. This strepsirhine primate belongs to the family Cheirogaleidae, which includes the genera *Microcebus* (mouse lemurs), *Cheirogaleus* (dwarf lemurs), *Allocebus*, and *Phaner*. Strepsirhine primates and tarsiers are usually called prosimian primates, but taxonomy distinguishes strepsirhine primates and their sister group, the haplorhine primates, which includes tarsiers, monkeys, apes, and humans.

Age-specific mortality rate data from mouse lemur (Fig. 27.1) indicate that the longevity of this small primate is far longer that what would be expected for a mammal of that body size (60 to 130 g). Despite a life expectancy of about 5 years in the wild, the mouse lemur lives up to about 15 years in captivity (Hakeem *et al*., 1996). In comparison, the body size of *Rattus norvegicus* averages 265.5 g with a maximum longevity record of 37 months in captivity (Eisenberg, 1981). This situation is similar for the other cheirogaleid primates. The life span of the fat-tailed dwarf lemur, *Cheirogaleus medius* (body weight averaging at 179.0 g), in the wild is not known, but specimens up to 19 years old have been observed in captivity (Hakeem *et al*., 1996). Cheirogaleid primates have the body size as well as the energetic and environmental constraints of small mammals, but their longevity is comparable to larger mammals. In this sense, they are both atypical primates (in terms of body size) and atypical small mammals (in terms of longevity). It should be noted that other mammals, as some bats or the naked mole rat (Sherman *et al*., 1991), also combine small body size and a long life span.

In mouse lemur, puberty occurs by 1 year (Perret, 1992), and reproduction continues in females until about 6–8 years. Because of its small size, rapid maturity, fecundity, and relatively short life expectancy compared to other primates, the mouse lemur therefore constitutes a useful model system for the study of normal and pathological cerebral aging. This chapter summarizes studies on age-related changes in mouse lemur and explores some age-related features that could be studied *in vivo* in this primate.

II. Cognitive Function during Aging in Mouse Lemurs

The study of behavioral alterations is an important step for the evaluation of mouse lemurs as models for cerebral aging. This section focuses on age-related modifications of spontaneous social and sexual behavior, anxiety-related behaviors, and memory.

A. Spontaneous Social and Sexual Behavior

Mouse lemurs are tree-dwelling animals. The general strength and motor coordination of aged animals are fairly conserved. The only activities that become restricted are those requiring an extensive strength and/or good stretching capacities, such as jumps from the ground to an elevated platform placed 50 cm above the floor (Dhenain, 1998). Studies of locomotor behavior revealed heterogeneity in old animals. Some aged animals become more lethargic, e.g., walk instead of jumping and spend more time in their nests. This reduced activity is not the result of impaired physical shape. In contrast, some aged animals develop stereotyped hyperactive locomotor behaviors (Picq,

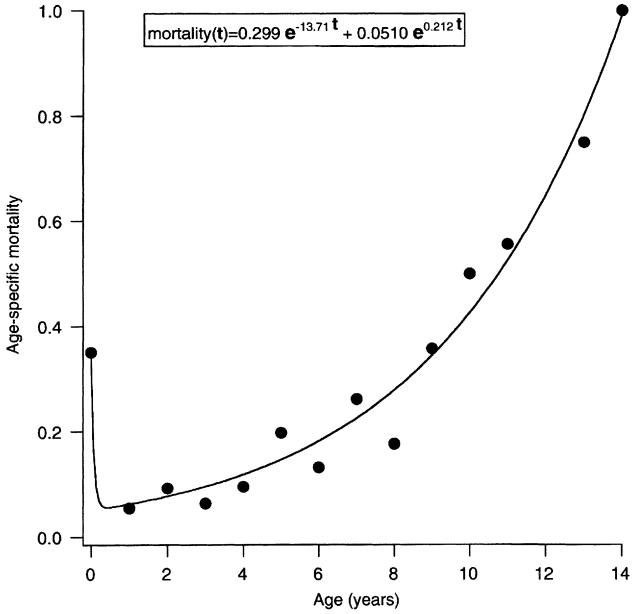

FIG. 27.1. Age-specific mortality data for *Microcebus murinus*. Data are fit by the equation shown in the box. The first term represents infant mortality and the second shows the effects of senescence. For this data set, $n = 140$. Data points represent rates for a population that had survived to a particular age. Unpublished data from Zachary Berger, John Allman, and Atiya Hakeem.

1993a; Dhenain *et al*., 1997c). Curiously, the latter animals are often the ones with the worst physical shape (Picq, 1993a).

In the wild, active animals, which are observed only during the night, are relatively solitary. They move around in well delimited but partly superposed domains. During the day, they gather to sleep in shelters (hollow trees, nests made of leaves, unstuck barks or wood nests in captivity). Mouse lemur meetings, whether they occur by night or by day, are often associated with peaceful tactile contacts called allogrooming, sound emissions, and scent marking. Aggressive behavior is seldom displayed except occasionally during estrus periods (Martin, 1972; Petter *et al*., 1977; Pages-Feuillade, 1988). Studies of social behavior from the observation of single-sex pairs of young and very old (9–12 years) captive animals showed that young animals seek positive social contacts and try to approach their partner to groom it. Older individuals may accept the contacts in a passive manner, but do not seek them. Sometimes, they even threaten or chase their partners in response to attempt of approach (Picq, 1992). This suggests that although they remain socially attractive partners, old mouse lemurs tend to withdraw from social interactions. Moreover, whether they are observed in social groups or alone, old mouse lemurs tend to increase the time spent in self-centered activities such as autogrooming (Picq, 1993a). This increase is at the expense of the time spent observing the environment. These modifications do not seem to be related to alteration of senses such as smell or sight (Picq, 1993a). The withdrawal of old animals from social interactions is similar to observations in other primates, such as macaques (Davis, 1978; Hauser and Tyrrel, 1984).

Mouse lemurs are strict seasonal breeders. During the breeding season, in the wild, males have to compete for the acquisition of large home ranges, which overlap several female home ranges. Laboratory studies suggested that the dominant status of males increases with age until the sixth to seventh breeding season. The dominant status only decreases in very old animals (10–13 breeding seasons) (Aujard and Perret, 1998). Young animals must display a high degree of aggressive behavior to reach a dominant rank and are contested routinely. Aged animals, however, do not need to display as much aggressive behavior to gain a dominant status and this status remains uncontested by other animals. Interestingly, when aged animals are paired with young animals, the aged animals must be more aggressive to obtain dominant status than when they are paired with other aged animals (Aujard and Perret, 1998). Observations of age-matched pairs of males after introduction of a preoestrous female in their cage revealed that old animals display less sexual behavior than young animals, but they are as efficient as young animals in term of reproduction. When old mouse lemurs are paired with young ones, the young animals become less active and display less sexual behavior than when they are paired with age-matched lemurs (Aujard and Perret, 1998). This might reflect the dominant status reached by old animals. This allows their priority access to estrous females and assures reproductive success.

B. Anxiety-Related Behaviors

Mouse lemurs are very sensitive to stress (Perret, 1982). Picq (1993a) described modifications of their behavior as a function of the surrounding stress. A low stress level provokes a rapid exploration of the environment, often characterized by oscillatory movements of the head and of the body. This exploration decreases rapidly in intensity and is replaced by behaviors such as resting, nutrition, or grooming. A moderate stress level brings very active exploratory behaviors. A stronger stress level produces long periods of visual explorations associated with alarm cries or aimless jumps. A very stressful situation gives rise to an absolute freezing where animals are literally petrified. The open-field test is a behavioral test, which consists of direct observation of animals when they are put in a new enclosure. It evaluates the spontaneous response to novelty and allows evaluation of anxiety levels (Halliday, 1966). Overall, there is a decrease of the sensitivity of animals to stress during aging. What slightly worries the young animal does not worry the old at all. What terrifies the young, just worries the old (Picq, 1993a; Dhenain, 1998). However, some aged animals are more stressed than young animals. The inter-individual heterogeneity is a common feature reported in many studies involving old mouse lemurs. It might reflect differences between normal and pathological aging. In a preliminary study, two out of two animals with abnormal sensitivity to stress had diffuse amyloid deposits in the brain (Dhenain, 1998) (Fig. 27.2). This suggests that the open-field test might have a predictive value to detect animals with abnormal aging.

C. Memory

For a long time, prosimian primates were not studied by specialists of animal intelligence because they were said to be timid and not cooperative. However, adaptation of experimental protocols to their sensory-motor capacities revealed very

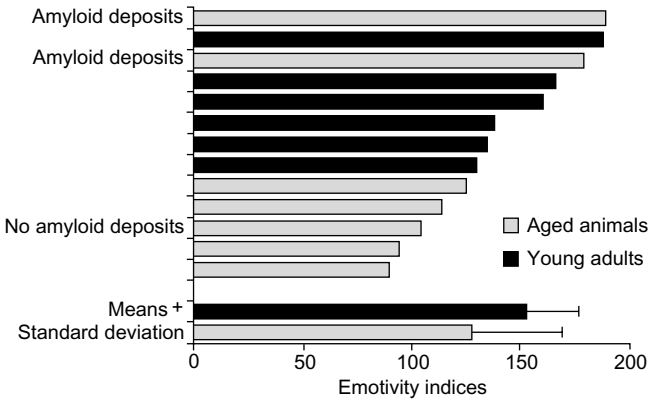

FIG. 27.2. Emotivity indices calculated for different animals. The higher the index, the higher the stress level. In this preliminary study, there was no statistical difference between young and aged animals (Mann–Whitney's $U = 11$, $p > 0.05$). The two aged animals with high stress levels had amyloid deposits in the brain. The brain of only one aged animal with a low stress level has been tested for amyloid deposits and had no amyloid.

good cognitive abilities (Ehrlich *et al*., 1976). In mouse lemurs, it is possible to assess memory in tasks based on spontaneous behaviors where animals do not have to learn any rule to perform the task. As an example, the free object exploration task (Picq and Dhenain, 1998) consists of an enclosure containing various objects placed in permanent positions. First, animals are allowed to visit the enclosure for repeated periods of time to make the environment and its objects familiar and also to suppress anxiety or fear responses. After the habituation period, the object exploration task is done during six tests of 8 min during 6 consecutive days (one test per day). During each test, new objects are added in new locations or familiar objects are displaced to new locations and replaced by new objects. Aged mouse lemurs were more active than young animals in the task (Picq and Dhenain, 1998). This feature is often characteristic of aged animals in behavioral tasks and rules out the possibility that lower performances are related to physical alterations. Aged lemurs tended to spend more time exploring the objects (new or familiar) than young animals, which suggested a higher curiosity or motivation. Young and old animals spent more time exploring new objects than visiting familiar ones. However, only young animals explored new or displaced objects in priority. They explored the new objects for a longer time than old lemurs. In contrast to old animals, young animals' interest for new objects diminished greatly on second contact with the objects (after 1 day). The behavior of young animals indicated that, like other primates (Vauclair, 1987), mouse lemurs are able to mentally ''map out'' the experimental enclosure. They are able to construct internal models of their environment, including the nature and the location of each object. The internal map can be retained for at least 24 hr and be revised after a few minutes of exploration if changes occur in the environment. The behavior of aged animals suggests that they did not detect the new or displaced objects as quickly as young animals. Moreover, the new objects were not perfectly memorized or included in the internal map during the first contact. This suggests an age-related alteration of spatial memory (Picq and Dhenain, 1998).

More subtle memory alterations can be tested by artificial tasks in which animals have to reach a goal to get a reward. In many species the usual rewards are alimentary. In mouse lemurs, most of the studies used the ''right to find refuge'' for approximately 2 min in a nest box as a positive reinforcement. The reason for this choice is that mouse lemurs are very sensitive to stress, and during a test situation, nothing is more attractive than returning to the nest. In rodents, behavioral tasks are often based on spatial paradigms [Olton's radial maze (Olton, 1979), Morris' water maze (Hsiao *et al*., 1996)]. Because of their small size, Olton's radial maze can be adapted readily to mouse lemurs (Picq, 1993b). The maze was made of a central platform from which radiated eight arms ending on a nest box. Each arm was obstructed by an opaque curtain. Four arms (''the blind arms'') were blocked by a door placed just behind the curtain and thus not visible from the entrance. Four arms (''the free arms'') with a free throughway were opened behind the curtain and might freely be explored right through the end where a transparent door blocked the access to the nest box. First, mouse lemurs were habituated to the enclosure. Thereafter, the test phase consisted of eight series of five trials (one series per day) during which the mouse lemur was placed in the central platform and then freely explored the radial maze. Animals had five trials to visit the four free arms. When they visited the fourth free arm, access to the nest box was allowed. Aged mouse lemurs did not visit the blind arms more often than the young. This suggested that their reference memory, which is the memory for data that are stable across trials in tests used in rodents (Olton and Papas, 1979), was not altered. However, during one set of five trials, old animals explored the same free arm several times, whereas young animals were able to visit a new free arm at every new trial. This suggests that old animals' memory for data, which varied from trial to trial (such as which free arms were already visited), was altered. This memory is called ''rodent type'' working memory (Olton and Papas, 1979) (working memory does not have the same meaning for human or other anthropoid primates and rodents).

The neuropsychological models used to assess memory involved in rodent and human tasks are different. This makes it difficult to compare alterations described in rodent tasks with alterations in humans. In anthropoid primates, several tasks, such as discrimination (Buerger *et al*., 1974; Zola-Morgan and Squire, 1984), delayed response (Fletcher, 1965), delayed nonmatching-to-sample (DNMS) (Mishkin and Appenzeller, 1987) or delayed alternation (DA) tasks (Mishkin and Pribram, 1955; Winocur, 1991), have been developed to study animal models of amnesia. They are conceptually very similar to tasks that can be used in humans. These tasks have also been used to study aging primates. Generally, they are based on the visual recognition of objects and on manipulation of the recognized objects. Mouse lemurs have a limited ability to handle objects; for this reason, Picq developed a spatial version of these tasks. His apparatus (Fig. 27.3) is composed of a starting box in which the animal is placed at the beginning of the test. This starting box gives access to a work chamber from which there are six corridors leading to a reinforcement chamber housing the mouse lemur's nest box. The corridors can be shut off at each end by sliding doors. They can be illuminated, and their relevance is based on whether they are lit. An opaque screen

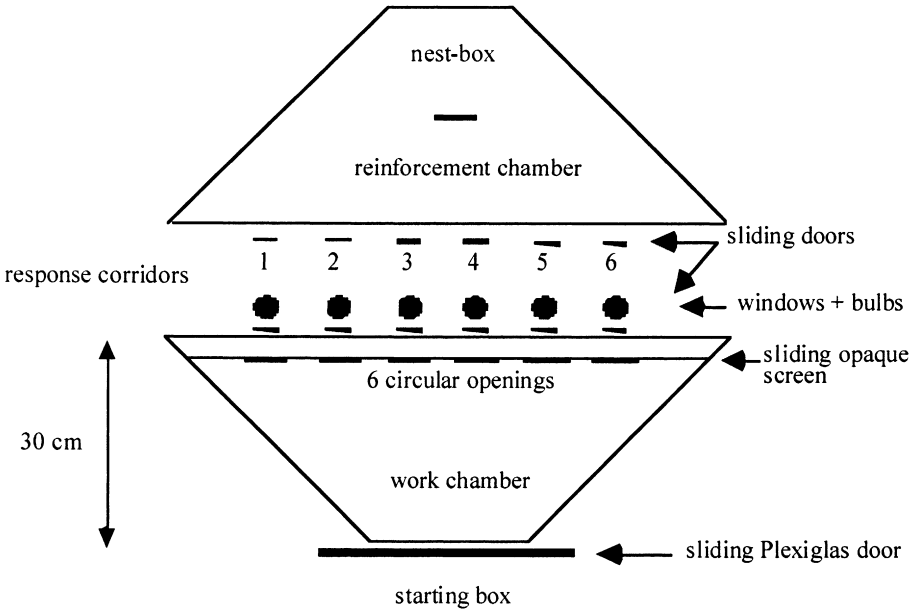

FIG. 27.3. Apparatus used in memory tasks in lemurs. The entire apparatus was made of plywood and was covered with a Plexiglas roof. It was lit by a 15 W red bulb. The mouse lemur's urge to find its nest box was the only motivation. No food reward was necessary.

can be slid between the corridors and the working chamber to impose delays between the visualization of illuminated corridors and the possibility to walk through them. A positively reinforced corridor gives access to the reinforcement chamber where the mouse lemur may rest in its nest box for 2 min. When a mouse lemur enters in a nonreinforced corridor, the exit door remains shut and the sliding entrance door is lowered behind it. The animal is immediately returned to the starting box for another trial.

Discrimination tasks have been performed with this apparatus. Mouse lemurs learned to go through corridors that were illuminated (which is against their natural instinct). This test required that animals associate the stimulus (illuminated corridor) to the response (walk through the corridor), which was associated to the reward (stay 2 min in the nest). This stimulus–response–reward test is a rule-based test (Ridley, 1991). Young and aged lemurs learned the task similarly (Picq, 1995). After 3 months without contact with the apparatus, they were both still able to perform the task (Picq, 1995). The apparatus can also be used to teach other rules to lemurs. For example, to teach a "nonmatching-to-sample" rule, one out of the six corridors was lit. The mouse lemur had to choose this corridor to access the reinforcement chamber. Five seconds later, the animal was put back in the starting box and two corridors were lit: the previous corridor and a new one. The animal had to go through the new corridor to get a reward. The task was performed similarly by young and old animals (Dhenain *et al*., 1998b). In humans, general concepts and rules about the world are stocked in semantic memory. This memory also refers to language and knowledge of facts (Tulving, 1972). In the context of animal experiments, Ridley (1991) regarded the rules as equivalent to knowledge about the "meaning of things," e.g., associations among stimuli, responses, and rewards. They may be regarded as an equivalent of semantic memory (Ridley, 1991), especially if the behavioral response to the "rule-based test" requires flexibility (Eichenbaum *et al*., 1992), as is the case for the DNMS test. In this context, rodent reference memory, which refers to data stable from one trial to another, is also comparable to semantic memory (Ridley, 1991). The performances of mouse lemurs during discrimination learning, nonmatching-to-sample learning, or reference memory tasks suggest that rule acquisition by semantic memory is not altered during aging and that this memory is stable for at least 3 months even in aged animals. In humans, semantic memory is not altered during normal aging (Nebes, 1992) but is altered during Alzheimer's disease (AD) (Nebes, 1989).

Once animals have learned the discrimination or the nonmatching-to-sample rules, delays can be added between the presentation of the stimulus (illuminated corridor) and the response (go in a corridor). Delayed response (DR) tasks have been performed with mouse lemurs by adding delays up to 60 sec between the presentation of one lit corridor out of four and access to go through the corridors. To get a reward, animals had to choose the corridor illuminated during the presentation phase (application of discrimination rule). Performances of young animals were decreasing slightly from zero to 15-sec delays and after remained stable. Old animals displayed severe time-related memory alterations. After 30 sec, they were performing at chance level (Picq, 1995). The time-related deficiency for delays inferior to 30 sec suggested a severe alteration of short-term memory in old mouse lemurs (Wright *et al*., 1985; Baddeley, 1998). Such an alteration is very similar to the short-term memory alteration described in other primates (Bartus, 1979; Rapp and Amaral, 1992) or reported by some authors in humans during normal aging (Craik, 1977) or AD (Nebes, 1989).

Delayed nonmatching-to-sample tasks have been performed with mouse lemurs by imposing 40 sec delays between the presentation and the choice phases of the nonmatching-to-sample task. Tests involving delays from 30 to 60 sec with intervening distracting events are known to assess long-term memory in animals (Ridley, 1991). The distracting event used in lemurs consisted of moving the animal from the reinforcement chamber to the work chamber. Two kinds of DNMS-related tasks exist (Ridley, 1991). If different pairs of objects are used for each trial, then the DNMS is a trial unique task because there is no interference between the current trial and former trials. However, if a very limited number of stimuli is used, the DNMS is a trial-dependent task; earlier trials provide interfering information and the task requires the memory of the event presentation (Rapp, 1993; Pertrides, 1994). The small number of corridors that mouse lemurs had to discriminate during the DNMS (six corridors) would make the task a trial-dependent task (see Dhenain *et al*., 1998b, for discussion). Good performance in the task depends on the integrity of temporomedian and prefrontal areas (Otto and Eichenbaum, 1992). The memory involved is similar to the human episodic memory, which is a memory for precise events, specific of every subject life and occurring in particular temporospatial contexts (Squire *et al*., 1993). Performances of aged mouse lemurs in the DNMS task were significantly poorer than those of young adults (Dhenain *et al*., 1998b). Interestingly, as described previously, aged mouse lemurs' memory is also impaired in the ''rodent'' working memory task of the radial maze, which is also a trial-dependent task. This suggests an alteration of the long-term episodic memory in aged mouse lemurs. This alteration is similar to episodic memory alteration described during human normal aging (Nebes, 1989) and also in AD (Baddeley *et al*., 1991).

Age-related behavioral alterations in mouse lemurs suggest that prefrontal areas are altered during aging. This is supported by the observed DNMS memory impairment and also by poor performances of aged mouse lemurs in other tasks known to involve this area, such as the DR task (Fletcher, 1965; Goldman and Rosvold, 1970). The perseverance tendency of aged animals in several tasks (Picq, 1993b) also favors this hypothesis. Alteration of the prefrontal area in mouse lemurs is similar to the one described in other primates (Rapp, 1993) and also in human during normal aging (Schacter *et al*., 1996; Petit-Taboue *et al*., 1998). The temporal lobe also seems altered during aging in mouse lemurs, as suggested by the poor performances in the DNMS and in spatial memory tasks such as the free object exploration task or the radial maze. The hippocampus in particular is the temporal region involved in spatial tasks (Olton and Papas, 1979). A medial temporal alteration has been described in a subpopulation of primates (although in a task more dependent on entorhinal cortex) (Rapp and Amaral, 1992; Rapp, 1993). Temporal alteration has been shown to be particularly severe in subjects with AD (Desgranges *et al*., 1998).

As a conclusion, mouse lemurs present behavioral alteration during aging. Actual studies described average behavioral changes in populations of aged animals. In these studies, individual heterogeneity has often been reported in aged animals. Future work must characterize the normal pattern of age-related behavioral changes so that pathological aging can be identified accurately by comparison.

III. Age-Related Cerebral Atrophy and Neuronal Alterations in Mouse Lemurs

Neuromorphological studies revealed ventricular enlargement associated to a severe cortical and hippocampal atrophy in a few aged specimens. Other regions, such as the corpus callosum, the fornix, the basal ganglia, the brain stem, and the cerebellum, are atrophied in some aged animals (Bons *et al*., 1991a,b). More recently, Dhenain *et al*. (2000) showed in a longitudinal magnetic resonance imaging (MRI) study that cerebral atrophy only occurs in aged mouse lemurs but that the aged animals are not all atrophied. Atrophy thus appears to be an age-related pathological condition and not an inevitable effect of age. The atrophy process evolves within a few months and starts between 5 and 8 years old. Several subgroups of animals can be distinguished on the base of regional atrophy. For example, some animals showed a severe atrophy of the temporal lobe, whereas others displayed diffuse cortical atrophy in addition to temporal atrophy. Further studies are necessary to determine the relationships between these different types as well as the origin of cerebral atrophy, which might be associated with the presence of neurites and neuronal degeneration (Bons *et al*., 1991b). The detection and follow-up of the atrophic process *in vivo* with MRI offer the possibility to search for the biological correlates of ongoing neurodegeneration.

IV. Amyloid Deposits, Amyloid Angiopathy, and Cytoskeletal Alterations

Senile plaques are extracellular β-amyloid deposits associated to reactive astrocytes, microglial cells, dystrophic neurites, and neurofibrillary tangles (NFT). Amyloid angiopathy is amyloid deposits surrounding blood vessels. NFT are neuronal accumulations of hyperphosphorylated tau proteins, and with senile plaques, and amyloid angiopathy, are the neuropathological hallmarks of AD (Wisniewski *et al*., 1989; Ball *et al*., 1997). They can also be present in nondemented aged subjects, although in lower density and in more restricted areas (Hyman *et al*., 1993).

A. Amyloid Deposits

The Aβ peptide sequence in mouse lemurs is homologous to the human Aβ (Silhol *et al*., 1996). In mouse lemurs older than 7 years old, histological studies (amyloid-specific silver method, histochemistry for Aβ 1–40 and APP, binding of the amyloid-indicating dyes, thioflavin and Congo red, and immunocytochemistry against Aβ) revealed the presence of Aβ protein aggregates in the cerebral cortex, the meninges, and the cerebral vasculature (amyloid angiopathy), of neuritic plaque-like deposits composed of degenerated neurites surrounding an amyloid deposit, and of neurofibrillary changes such as bundles of argyrophilic filaments in pyramidal neurons (Bons *et al*., 1991a,b, 1994, 1995b; Mestre-Francés *et al*., 1996) (Fig. 27.4). The temporal and parietal lobes are especially affected by Aβ deposition. In animals older than 7 years, Aβ protein deposits were observed in four forms, from small cloudy deposits to a dense core of Aβ surrounded by a halo

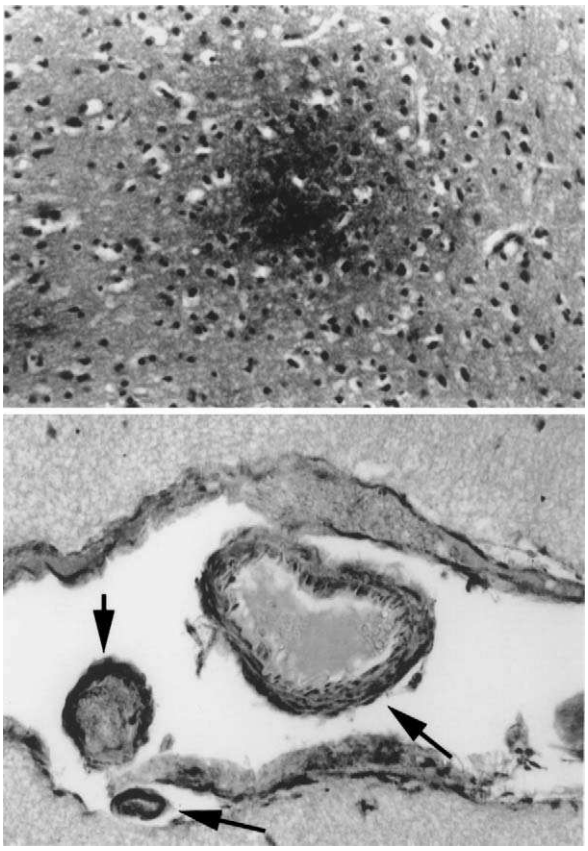

FIG. 27.4. Amyloid deposits in a 11.4 year old female mouse lemur cortex ($\times$20, top) and amyloid angiopathy in leptomeningeal vessels ($\times$20, arrows, bottom). Tissues were stained with antibody E50 against Aβ.

of amyloid fibrils (Mestre-Francés *et al*., 1996). These different forms may characterize different stages of maturation. Only a few animals over 7 years presented very numerous amyloid deposits, which seemed to represent a characterized pathology (Mestre-Francés *et al*., 1996). Diffuse amyloid deposits were also found in very young adults (1 year old).

B. Cytoskeletal Alterations

Tau is a cytoskeletal microtubule-associated protein. In humans, and NFT are neuronal accumulations of pathological hyperphosphorylated tau proteins that form the basic matrix of paired helical filaments (PHF) within degenerating neurons. The biochemical profile of tau proteins during cerebral aging has been characterized in the mouse lemur using immunoblotting and several probes directed against human tau proteins and PHF by Delacourte *et al*. (1995). The molecular weight of tau proteins increased during aging in mouse lemurs, reflecting age-related states of hyperphosphorylation (Bons *et al*., 1995b; Delacourte *et al*., 1995). The localization of abnormally phosphorylated and PHF-immunoreactive tau proteins has been studied in lemurs by immunohistochemistry (Bons *et al*., 1995a,b; Giannakopoulos *et al*., 1997). Antibodies directedagainst ''normal'' human tau proteins (Flament *et al*., 1989) revealed staining in almost all of the tested animals. Antibodies directed against both normal and abnormally phosphorylated tau proteins (961-S28T) (Delacourte *et al*., 1990) revealed tau proteins aggregated in thick granules in almost all of the tested animals (independent of their age). This particular form of tau proteins seems to be specific of lemurs and has not been described in humans (Bons *et al*., 1995b). Numerous aggregated tau proteins were always found in lemurs with numerous amyloid deposits. Lemurs without amyloid deposits either displayed numerous neurons with aggregated tau proteins or few labeled neurons (Bons *et al*., 1995a). Neocortical areas were frequently affected, even in young mouse lemurs, whereas the subiculum and entorhinal cortex were only involved occasionally in animals older than 8 years (Giannakopoulos *et al*., 1997). The fact that the hippocampus was relatively nonlabeled in lemurs, whereas it is one of the first structure to be involved by NFT formation in AD (Braak and Braak, 1991), could be explained by different characteristics of neuroprotection in nonhuman primate and human hippocampus. It could also be related to the nonspecificity of the antibodies used in the lemurs to detect abnormal tau proteins characteristic of AD. Finally, the use of antibodies directed against abnormally phosphorylated tau proteins revealed either no staining (Dhenain *et al*., 2000) or a weak immunolabeling in comparison to the one obtained in AD patients (adsorbed anti-PHF antibody; Bons *et al*., 1995a). Animals that displayed a weak immunolabeling with anti-PHF antibody labeling displayed numerous aggregated tau proteins with 961-S28T antibodies. This suggests that PHF-immunoreactive tau proteins are related to the presence of high number neurons with aggregated tau proteins. However, some animals showing numerous aggregated tau proteins with 961-S28T antibodies did not display labeling with anti-PHF antibodies.

In conclusion, alterations in tau metabolism occur during aging in lemurs and pathological tau metabolism might be related to amyloid deposits. However, the tau immunoreactivity that is displayed by plaque neurites in mouse lemurs can hardly be compared to the tau immunoreactivity seen in AD (it is weaker or absent) and PHF have never been described in lemurs. From these results, it appears that the production of highly specific immunological probes directed against specific tau protein isoforms is needed to evaluate better the tau pathology displayed by lemurs.

C. Genetic Origin of "Alzheimer-like" Lesions in Lemurs

In humans, mutations of different genes, such as the β-amyloid precursor protein (APP) gene (which codes for large glycoproteins, which can be metabolized to form the Aβ peptide) (Kang *et al*., 1987), presenillin 1 (PS1), and presenillin 2 (PS2), have been associated with familial forms of AD. These genes have been sequenced in lemurs. APP and PS1 distributions in mouse lemur brain are similar to that observed in humans and, similar to humans, are localized in the same brain structures (Calenda *et al*., 1996; Silhol *et al*., 1996). In contrast, few neurons can be marqued with combined PS2 protein and APP immunoreactivity (Calenda *et al*., 1998). The presence of genes related to AD in lemurs suggests that they are genetically susceptible to display mutations in genes involved in familial forms of AD. However, so far, neither

the presence of mutations involved in familial cases of AD nor the presence of mutational founder effects has been described in animals with amyloid deposits.

Variations in the age of onset and risk of AD are associated with the apolipoprotein E locus in humans (Strittmatter and Roses, 1996). Three isoforms (E2, E3, and E4) exist and are distinguished by cysteine-to-arginine substitutions at residues 158 and 112 (Mahley, 1988). A strong association has been found between the presence of the E4 isoform and the occurrence of AD (Schmechel *et al*., 1993; Gómez-Isla *et al*., 1996). The human apoE allele system has unique characteristics when compared to other primates (Finch and Sapolsky, 1999), and only the E4 isoform of apolipoprotein E was evidenced in the mouse lemur. ApoE genotyping revealed that nine amino acids differ between human and mouse lemur ApoE isoforms. However, the two amino acids characteristic of the human ApoE4 isoform are conserved, suggesting that the ApoE in mouse lemurs is phenotypically analogous to human ApoE4 (Calenda *et al*., 1995). This result is similar to results in macaque monkey, baboon, cow, pig, mouse, and rat, but not rabbit (Poduri *et al*., 1994).

V. Neurochemical Alterations

Immunocytochemical studies reveal that the structure of the cholinergic basal forebrain, essentially the nucleus basalis of Meynert, is very similar in both strepsirhine and haplorhine primates, including humans. Cholinergic neurons have been observed in the mouse lemur brain with choline acetyltransferase (ChAT) immunocytochemistry in the septum, the diagonal band of Broca, the nucleus accumbens, the nucleus basalis of Meynert, the caudate, the putamen, the globus pallidus, and the olfactory tubercle. In the aged mouse lemur, cytological changes and neuronal loss have been observed in these structures, suggesting an alteration of the cholinergic function during aging (Mestre and Bons, 1993). However, the ChAT activity increases during aging in lemurs (Dournaud *et al*., 1994). The apparent contradiction between immunocytochemical and biochemical studies might be related to different age ranges of the animals included in both studies. Studies of other neurotransmitter systems revealed a loss of serotonergic and catecholaminergic neurons during aging (Jallageas *et al*., 1998). Biochemical studies revealed that cortical somatostatin levels do not change with aging (Dournaud *et al*., 1994).

VI. Iron Accumulation

A. Captive Lemurs and Iron Overload

In various mammals, including human and nonhuman primates, a progressive increase of iron deposits in the brain, especially the basal ganglia, is characteristic of normal aging (see Koeppen, 1995, for a review). Strepsirhine primates are of particular interest in the study of iron absorption and deposition because hemosiderosis has been observed consistently in captive aged animals. Spelman *et al*. (1989) observed that all 49 lemurs necropsied since 1968 at the San Diego Zoo were hemosiderotic. Their high protein chow diet may have contributed to excessive iron absorption. The absorbed iron is first apparent in the macrophages of the intestinal lamina propria, in Kuppfer cells, in splenic cells, and in other nonparenchymal cells. With increasing iron overload, liver parenchymal cells are also affected, and hepatic cell necrosis, as well as periportal fibrosis, is observed. Iron overload in lemurs to some extent resembles human transfusional siderosis (Iancu and Shiloh, 1994). As in humans, the severity of the disorder is correlated to age. Indeed, iron homeostasis is disrupted during the aging process (Gelman, 1995).

Histochemistry of brain iron deposits, using Perl's staining, in old animals (8–15 years old) revealed that iron pigments are localized mainly in the globus pallidus, the substantia nigra, the neocortical and cerebellar white matter, the thalamus, and in anterior forebrain structures, including the nucleus basalis of Meynert (Fig. 27.6, see color insert) (Dhenain *et al*., 1998a; Gilissen *et al*., 1998, 1999b). This distribution agrees with previous findings in monkeys and humans, but among primates, only cheirogaleids and humans show iron deposits in the thalamus. Nonheme iron in the brain is encapsulated by ferritin, the primary tissue iron storage protein.

B. I*n* V*ivo* Detection of Iron with MRI during Brain Aging

MRI can detect *in vivo* naturally occurring brain depositions. Because of iron's paramagnetic characteristic, brain regions with a high iron content have short T2 relaxation times, yielding a hypointense (dark) signal in T2 or T2*-weighted images as compared to regions with a low iron content (Drayer, 1989). This effect is more prominent at a high magnetic field because susceptibility effects, such as iron-related T2 relaxation time decrease, are at least linearly dependent on magnetic field strength (Fisel *et al*., 1991; Lee, 1991; Bartzokis *et al*., 1993; Lee *et al*., 1995; Schenck, 1995; Vymazal *et al*., 1995; Gati *et al*., 1997). In addition, an iron-dependent contrast is enhanced with increasing field strength, whereas the other T2 effects are not changed. The effects of other processes that can affect T2 relaxation times (tissue characteristics) (Bartzokis *et al*., 1993) would therefore be proportionately less important at a high magnetic field.

Brain iron content was examined in young and aged cheirogaleid primates by Dhenain *et al*. (1997a,b, 1998a) with 4.7 T magnetic resonance (Bruker Biospec 47/30 system) and by Gilissen *et al*. (1998, 1999b) with high field magnetic resonance microscopy (Bruker AMX500 11.7 T MRI system) (Narasimhan and Jacobs, 1996). Results obtained from MR images were corroborated to histochemistry studies. The age-dependent MRI signal decrease in dwarf and mouse lemur brains appeared to be related to iron accumulation.

1. Iron Content of the Globus Pallidus: An I*n* V*ivo* Indice of Brain Aging

Dhenain *et al*. (1997a,b) observed very high correlations between the T2-weighted MRI signal decrease (T2ws) and the natural logarithm of mouse lemur age in the globus pallidus ($r = 0.95$), in the substantia nigra ($r = 0.81$), and in the thalamus ($r = 0.80$). The T2ws decreased rapidly until the age of 4 years. After this age, in middle-aged and older animals the signal decrease became less important. A rapid

T2ws decrease in young individuals, less rapid in middle-aged and slower in aged individuals, has also been observed in humans (Pujol *et al*., 1992; Schenker *et al*., 1993; Bartzokis *et al*., 1997). Further studies are necessary to assess if the kinetics of signal intensity decrease during aging is similar in mouse lemurs and humans.

The high correlation coefficient for the pallidum ($p < 0.0001$) suggests that it should be an excellent structure to study the T2 signal decrease as a marker of age. The T2 signal measure might be useful in assessing the efficiency of pharmaceutical agents aimed at reducing iron deposition in the aging process as well as standardizing the brain iron content during pharmaceutical tests.

2. Iron in the Basal Forebrain

The nucleus basalis of Meynert, the largest source of cholinergic fibers in the brain, is affected during pathological aging in humans (Samuel *et al*., 1991; Cullen *et al*., 1997 see Chapter 19). Bartzokis *et al*. (1994, 1997) suggested that future directions of *in vivo* evaluation of tissue iron with MR should focus on structures that are highly relevant for pathological aging, such as the basal forebrain. In particular, the nucleus basalis of Meynert is structurally and functionally closely associated with the ventral extension of the globus pallidus. Iron levels in the ventral globus pallidus are among the highest in the brain and are well visualized in humans with standard clinical magnets (1.5 T). Increased iron levels in the globus pallidus may be a marker of increased iron in the basal forebrain (Bartzokis, 1997). In humans, iron deposition in basal forebrain cholinergic structures is difficult to visualize *in vivo* because of their small size. High resolution and high magnetic field (11.7 T) MRI images of mouse lemurs allowed the detection of iron in the basal forebrain (Gilissen *et al*., 1999b). The areas of iron accumulation largely overlap the distribution of ChAT-immunoreactive neurons. Moreover, the MR contrast resulting from the iron content is comparable in the basal forebrain structures and in the globus pallidus (Figs. 27.5 and 27.6). This suggests that iron deposits affect basal forebrain cholinergic structures because of their close relationship with the ventral globus pallidus. Further longitudinal studies are necessary to assess how correlated are the iron depositions in the basal forebrain and the globus pallidus.

VII. Lipofuscin: Another Marker of Aging Unrelated to Iron Deposits

Accumulation of lipofuscin, an age pigment derived by lipid peroxidation, constitutes another reliable but invasive marker of aging. Iron promotes *in vivo* lipofuscin formation and is

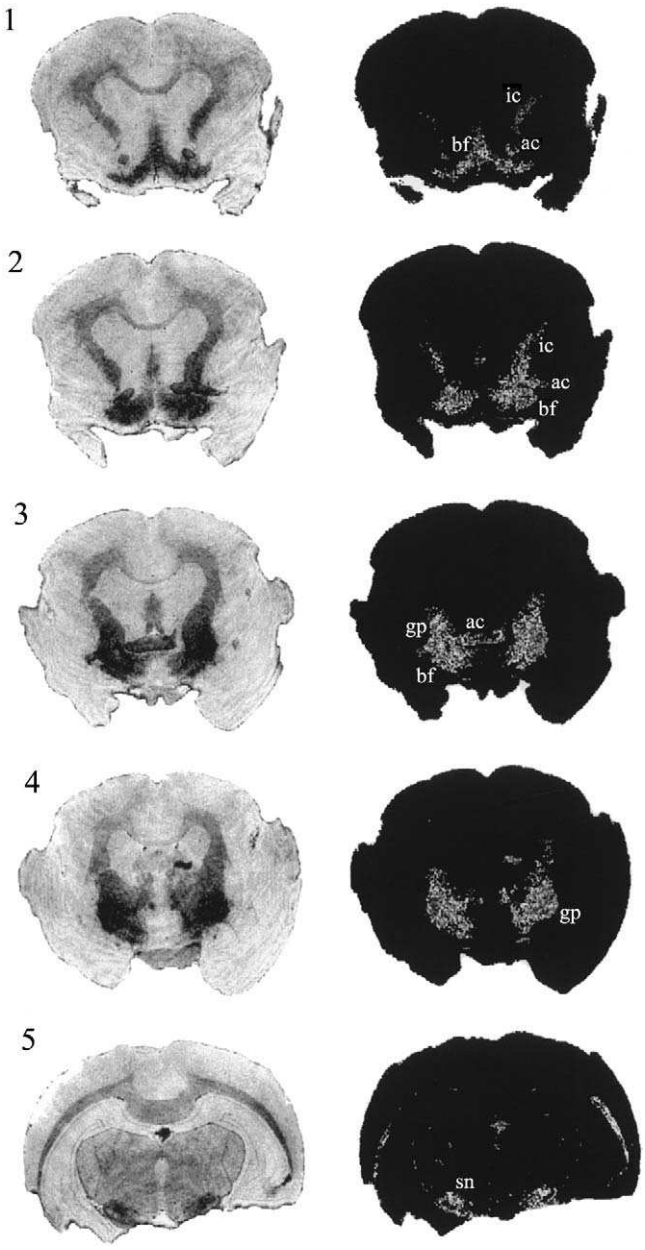

FIG. 27.5. Coronal MR scan T2*-weighted images of a 12-year-old mouse lemur brain. The hypointense (dark) signal on the left images corresponds to iron accumulation in basal forebrain structures (bf) such as the septum, the diagonal band of Broca, and the substantia innominata (1–3), in globus pallidus (gp) (3 and 4), and in substantia nigra (sn) (5). Iron is also present in the anterior commissure (ac) and internal capsule (ic). Signal intensity was measured using a gray scale ranging from 0 (black) to 255 (white). Gilissen *et al*. (1999b) assessed the maximum intensity value of the globus pallidus, substantia nigra, and basal forebrain structures. Upper thresholds were finally applied in order to set defined ranges of voxel values to be displayed. These thresholds correspond to the maximum intensity values of globus pallidus, basal forebrain structures, and substantia nigra. The lower voxel threshold was set at 0. In the right images, the voxel values beyond the upper thresholds are eliminated. In the case of the specimen illustrated here, upper thresholds were set at 35.2 (1–4) and 41.0 (5). To permit the remaining voxels to be visualized, the intensity histogram was adjusted to enhance contrast. In the right images, the resulting views display the basal forebrain structures (1–3), the globus pallidus (3 and 4), and the substantia nigra (5), as well as some adjacent structures with similar maximum intensity values. On a series of four aged animals (8–15 years old), the mean value of the upper threshold is 34.7 for the globus pallidus, 35.1 for the basal forebrain structures, and 40.8 for the substantia nigra (Gilissen *et al*., 1999b). The right images indicate that the contrast resulting from the iron content is similar in the basal forebrain structures and in the globus pallidus. (From Gilissen *et al*., *J. Neurol. Sci.*, vol. 168, 1999. Reprinted with the permission of Elsevier Publishers.)

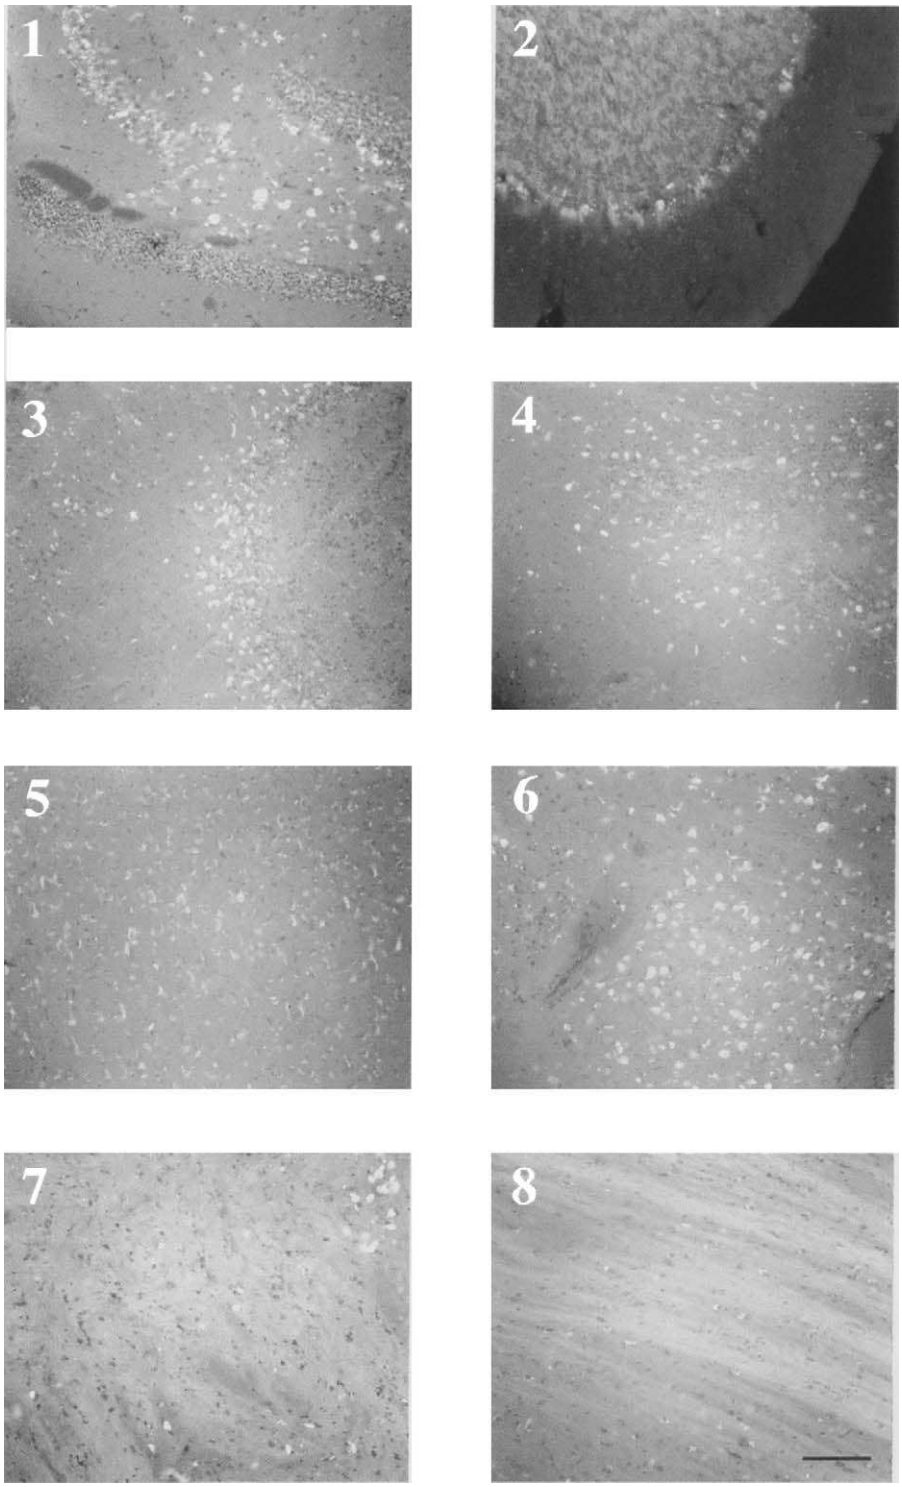

FIG. 27.7. Different fluorescence microscopy views of parasagittal cryostat sections of a 15-year-old dwarf lemur brain. The age pigments appear bright on the gray background. 1, hippocampus; 2, cerebellar folium; the age pigments are localized in the Purkinje cell layer; 3, olfactory bulb; the age pigments are mainly localized in the mitral cell layer; 4, olfactory nucleus; 5, neocortex; 6, basal forebrain; 7, globus pallidus; and 8, substantia nigra. The age pigments are less visible in the globus pallidus and the substantia nigra, where iron deposits are abundant. Scale bar: 0.1 mm. (From Gilissen *et al.*, *Am. J. Primatol.*, vol. 49, 1999. Reprinted with the permission of Wiley-Liss Publishers.)

usually detectable in high concentrations in lipofuscin granules. Nevertheless, even though iron is known to catalyze lipid oxidation (see Gilissen *et al*., 1999a, for a review), Gilissen *et al*., (1999a) observed that iron deposits and lipofuscin accumulation are not always coincident. Brain sections of aged (8–15 years old) and young (2–3 years old) dwarf and mouse lemurs were examined by autofluorescence and processed for iron histochemistry. Similar to iron, lipofuscin accumulation was observed in the aged animals but not in the young ones. Affected regions include the hippocampus (granular and pyramidal cells), where no iron accumulation was observed, the olfactory nucleus and the olfactory bulb (mitral cells), the basal forebrain, the hypothalamus, the cerebellum (Purkinje cells), the neocortex (essentially in the pyramidal cells), and the brain stem. Nevertheless, only a few scattered pigments were present in the thalamus, the globus pallidus, the substantia nigra, the striatal fundus, and the striatum, where dense iron deposits were observed (Fig. 27.7). Different biochemical and morphological cellular compartments might be involved in iron and lipofuscin deposition. Finally, the nonuniform distribution of lipofuscin indicates that brain structures are not equally sensitive to the factors causing their accumulation.

VIII. Manipulation of Aging: Changes in Photoperiodic Cycle

The mouse lemur is a good model system for the study of aging chronobiology. This primate exhibits behavioral and physiological seasonal cycles that are strictly controlled by variations in day length (photoperiodic variation). Perret (1997) revealed that, in the mouse lemur, seasonal rhythms can be accelerated by exposing captive animals to accelerated photoperiodic conditions consisting of 5 months of a long photoperiod followed by 3 months of a short photoperiod instead of 6 months of a long period followed by 6 months of a short period (as is the case in the natural environment). Long-term acceleration of seasonal rhythms obtained with accelerating photoperiodic cycles reduced the mean life span from 63.2 ± 2.5 to 45.5 ± 2.1 months and the maximal life span from 98 ± 3.9 to 79.3 ± 3.3 months. This corresponds to about a 30% reduction of life span and is neither accompanied by a desynchronization of biological rhythms nor related to an increase in reproduction or in duration of time spent in active conditions (Perret, 1997). A striking conclusion emerges from this study. When the number of seasonal cycles experienced by one individual is considered rather than chronological age, the mean life span was 5 seasonal cycles and maximum survival reached 9–10 cycles, independent of sex or of photoperiodic conditions. It is therefore possible that in mouse lemurs, and probably in other seasonal mammals, longevity may depend on the expression of a fixed number of seasonal cycles rather than on a fixed biological age (Perret, 1997).

IX. Summary and Conclusions

When compared to other primates, the life history parameters of the mouse and dwarf lemurs make them an excellent model system for the study of normal and pathological cerebral aging. Age-related behavioral alterations, as well as cerebral atrophy, have been observed in some aged animals. Amyloid deposits and neuritic degeneration associated with the presence of abnormally phosphorylated tau proteins (probably different than those observed in AD) have also been observed in the cerebral cortex of mouse lemurs. Other markers of aging, such as lipofuscin and iron deposits, have also been described in the brain of these primates. Iron distribution constitutes a reliable marker of cerebral aging. Brain regions with a high iron content have short relaxation times, yielding a hypointense (dark) signal in T2- and T2*-weighted MR images. T2 measures in the pallidum might be a useful *in vivo* marker for assessing the efficiency of pharmaceutical agents aimed at reducing iron deposition during the aging process. Because iron homeostasis is disturbed in pathological aging, the estimation of iron content in basal forebrain is of importance because of the implication of this structure in aging or AD. In humans, the basal forebrain is, however, very small when compared to the rest of the brain, and its iron content is difficult to study *in vivo*. Because of their specific brain proportions, mouse and dwarf lemurs appear to be an ideal model system for studying *in vivo* iron changes in the basal forebrain in relation to aging and neurodegeneration. Finally, this primate offers a good model system for aging chronobiology because its life span can be changed by manipulating photoperiodic cycles.

Aspects of age-related neurodegeneration differs between primate species or even between strepsirhine primates and related species (Schmechel *et al*., 1996). Different species-specific mechanisms can induce species-specific hallmarks of normal and pathological aging. If the combination of factors contributing to the onset of AD is specific to the human species, comparative studies are certainly of prime interest for dissecting the relationships between these factors and for elaborating therapeutic strategies.

Acknowledgments

The authors thank P.R. Hof, A. Louie, and G. Bartzokis for helpful comments as well as S. Atsalis and J. Maina for illuminating discussions. The contributions of F. Boller, C. Duyckaerts, K. Glander, P. Ghosh, R. E. Jacobs, J.-L. Michot, M. Perret, J.-L. Picq, N. Privat, and A. Volk are greatly acknowledged. The body weights were extracted from a data file assembled by R. D. Martin and A. MacLarnon under the support of a grant from the Medical Research Council (UK). Funding was provided by the Human Brain Project with contributions from the NIH (NIDA and NIMH), the NSF, and the Fondations Bettencourt-Schueller and France-Alzheimer.

Age-Related Morphologic Alterations in the Brain of Old World and New World Anthropoid Monkeys

Anthropoid monkeys are subdivided into two large groups, the New World platyrrhine monkeys (callithricids and cebids) and the Old World catarrhine monkeys (macaques, baboons, guenons, and leaf-eating monkeys). Most taxa are poorly known from a neurobiological point of view, but many species are used for laboratory studies (in particular, some macaques and baboons [*Macaca* and *Papio*], the Patas monkey [*Erythrocebus*], and the Central and South American marmoset [*Callithrix*], owl [*Aotus*], squirrel [*Saimiri*], and capuchin [*Cebus*] monkeys). Aging is particularly well documented among these taxa from the long-tailed and rhesus macaques and from the squirrel monkey. The neurobiological basis of declining cortical function in primate aging remains to be defined. One possibility is that the structural integrity of the neocortex is compromised by frank neuronal degeneration, synaptic loss, or other morphologic alterations. The consensus emerging from recent studies, however, is that many cortical areas, including subdivisions of the hippocampal, prefrontal, motor, and sensory cortices known to participate critically in sensory integration and memory-related processes, are relatively resistant to cell death during normal aging in monkeys. In contrast, subcortical structures are more consistently affected in a manner that correlates with the severity of cognitive deficits. Importantly, recent ultrastructural and cellular analyses have demonstrated that subtle alterations involving the neuropil as well as restricted domains of the dendritic trees are likely to contribute massively, together with molecular changes in specific neurotransmitter receptor proteins, to the cognitive and memory deficits observed in aged anthropoid monkeys.

I. Introduction

Primates exhibit a considerable number of pathological alterations in the brain as well as a decline in certain cognitive functions during aging. Many anthropoid primate species including taxa commonly used in laboratory research, such as squirrel monkeys (*Saimiri*), macaque monkeys (*Macaca*), and baboons (*Papio*) have a potential life span in captivity of over 25 years, with some individuals surviving beyond 30 years, and a maximal longevity for macaques of about 35 years (Tigges *et al*., 1988). At such an advanced age, these animals present all of the characteristic senescent changes that are typically observed in aging human populations. In New World and Old World monkeys, these changes include amyloid deposition in several brain structures and impairment of delayed nonmatching-to-sample task, delayed recognition span task, and spatial and object reversal learning (Bartus *et al*., 1978; Moss *et al*., 1988, 1997; Rapp and Amaral, 1989, 1992; Heilbronner and Kemper, 1990; Walker, 1991, 1997; Baxter and Voytko, 1996; Peters *et al*., 1996; Rapp *et al*., 1996a,b, 1997; Herndon *et al*., 1997; Sloane *et al*., 1997; Voytko, 1998; see also Chapter 26). Monkeys offer a remarkable opportunity to collect a wide range of data on the process of primate senescence (Rapp *et al*., 1996b; Peters *et al*., 1996, 1998b; Lacreuse *et al*., 1998; Voytko, 1998), because they are the only practical laboratory animal model to be so closely related to humans. In addition, macaques have a large repertoire of behaviors that can be extensively tested using neuropsychological testing batteries derived from tasks developed originally for humans (see Chapter 26). Most importantly, monkeys (as well as great apes; see Chapter 29), do not present during aging with brain pathologies, such as Alzheimer's disease, which occur only in human, and therefore provide a model in which the effects of aging can be studied independently from confounding concomitant aging-related dementing illnesses (Lacreuse *et al*., 1998). Whereas age-related morphological alterations have been well described, the neural substrate of such changes is still poorly understood, and a wide range in behavioral deficits

indicates that a widespread cortical and subcortical dysfunction is likely to occur in aged monkeys (Bachevalier *et al*., 1991; Lai *et al*., 1995). In addition, other factors, such as hormonal status and reproductive senescence, dominance history and social rank, and degree of parenting are likely to influence the severity of cognitive decline and longevity potential in anthropoids (Roberts *et al*., 1997; Veenema *et al*., 1997; Allman *et al*., 1998).

Neurochemical investigations of the brain composition in aged monkeys have shown changes in the levels of certain metabolites such as *myo*-inositol and creatine in old animals, but failed to reveal clear relationships between these alterations and the cognitive status of the animals (Herndon *et al*., 1998a). Increased activation of microglial cells has been shown in the brain of old macaque monkeys using antibodies against HLA-DR, inducible nitric oxide synthase, and the indicator of protein nitration 3-nitrotyrosine (Sloane *et al*., 1999). This study demonstrated the occurrence of widespread microglial activation in the subcortical white matter as well as increased levels of protein nitration. Also, the density of activated microglial cells is correlated with cognitive impairment in old animals, suggesting a role for microglia in the pathologic events associated to normal brain aging (Sloane *et al*., 1999). Concomitantly, the subcortical white matter displays astrocytic hypertrophy and increased content of glial fibrillary acidic protein, indicating the presence of altered protein degradation and turnover in old macaque monkeys (Sloane *et al*., 2000). Magnetic resonance imaging demonstrated that the total volume of brain parenchyma decreases linearly with age at a rate of approximately 0.3% per year and affects mostly the gray matter (Andersen *et al*., 1999). Positron emission tomography studies of regional cerebral metabolic rates for glucose revealed that old macaque monkeys had lower metabolic rates in all cortical regions examined and particularly in the temporal neocortex (Eberling *et al*., 1995). Similarly, age-related changes in delayed response performance are correlated with lower metabolic rates in the hippocampus, and age is a predictor of the metabolic rate in the orbitofrontal cortex, linking deficits in delayed response task in aged monkeys to alterations of limbic and neocortical systems involved in learning and memory (Eberling *et al*., 1997).

However, most anatomopathologic studies of brains of aged monkeys point to the fact that few, if any, changes can be observed in total neuron numbers in the cerebral cortex and in subcortical structures, although a breakdown of myelin integrity and thinning of layer I in the cerebral cortex have been reported (Vincent *et al*., 1989; Tigges *et al*., 1990, 1995, 1996; Peters *et al*., 1994, 1996, 1997, 1998a,b; Peters, 1996, 1999; Gazzaley *et al*., 1997; Kim *et al*., 1997; O'Donnell *et al*., 1999; Hof *et al*., 2000). Moreover, brain weight does not decrease in aged macaque monkeys, unlike the situation in chimpanzee and humans (Herndon *et al*., 1998b, 1999). In this chapter we review anatomic and pathologic alterations that occur during aging in the brain of old monkeys, including amyloid deposition, possible occurrence of Alzheimer's disease-type neurofibrillary degeneration, variability in estimates of volumetric and region- and cell type-specific changes in neuronal numbers and morphology, ultrastructural changes, and subcellular pathology affecting neurotransmitter systems and their receptors in the context of identified neuronal circuits.

II. Age-Associated Deposition of Amyloid in the Monkey Brain

Amyloid deposition in the form of senile plaques and diffuse deposits is thought to play a pivotal role in the development of Alzheimer's disease and occurs consistently in the brain of elderly humans, even in cases displaying only very mild cognitive impairment or presenting with a normal cognitive status (Hof *et al*., 1999; see Chapter 7). The amyloid protein and its precursor are highly conserved in vertebrates (Selkoe *et al*., 1987; Podlisny *et al*., 1991). Amyloid deposits have been shown to occur in the brain of old salmonids and in birds (Nakayama *et al*., 1999; Maldonado *et al*., 2000), and their deposition has been studied in many mammalian species as well as in a variety of transgenic mouse models (see Chapters 25 and 30; Walker, 1991, 1997). In monkeys the amyloid precursor protein occurs in similar cellular localization as in human, as well as in large diffuse deposits and in neurites surrounding senile plaques in aged animals (Martin *et al*., 1991). Furthermore, immunoblots of macaque monkey cerebral cortex using antibodies against various regions of the amyloid precursor protein revealed a high similarity with human, and the predicted sequence of the 695-residue peptide is entirely congruent with that of human, whereas rare substitutions were found in peptides including the Kunitz protease domain (Podlisny *et al*., 1991). The frequent occurrence of amyloid protein in the brain of aged nonhuman primates (including prosimians, monkeys, and great apes; Bons *et al*., 1991, 1994; Walker, 1991, 1997; Gearing *et al*., 1994, 1996, 1997; Silhol *et al*., 1996; Giannakopoulos *et al*., 1997; Mestre-Francés *et al*., 2000; see Chapters 27 and 29) makes them a reliable model of β-amyloidosis in Alzheimer's disease (Podlisny *et al*., 1991) and permits to assess the potential toxicity of the β-amyloid protein (Aβ) in a nonhuman primate (Geula *et al*., 1998; McKee *et al*., 1998). In fact, a recent study has shown that following injections of the Aβ1-40 peptide into the frontal cortex of long-tailed macaques (*Macaca fascicularis*) and rhesus macaques (*Macaca mulatta*), dose-dependent lesions can be elicited, which in old animals include the presence of tau- and ubiquitin-immunoreactive neuronal perikarya as well as thioflavine S fluorescent materials in the vicinity of the Aβ depositions (McKee *et al*., 1998). Furthermore, injections of nonsoluble fibrillar Aβ at concentrations equivalent to those found in senile plaques in several neocortical regions in young and old monkeys have demonstrated an age-dependence of amyloid toxicity (Geula *et al*., 1998). In old animals, injections resulted in severe neuronal loss, gliosis, and formation of hyperphosphorylated tau-containing lesions, whereas no toxicity was observed in young animals. These effects were not observed in rats, and were present to a less severe degree in aged New World marmoset monkeys (*Callithrix*) than in the macaques, demonstrating that toxicity to Aβ may be species-specific (Geula *et al*., 1998).

Electron microscopic analyses of senile plaques in old macaque monkeys have shown that they are nearly identical to those seen in Alzheimer's disease, with a central dense amyloid core (Fig. 28.1), differing only by the absence in monkeys of twisted tubules (Wisniewski *et al*., 1973). In macaques, senile plaques are found predominantly in the prefrontal and primary somatosensory cortices, whereas lower densities of

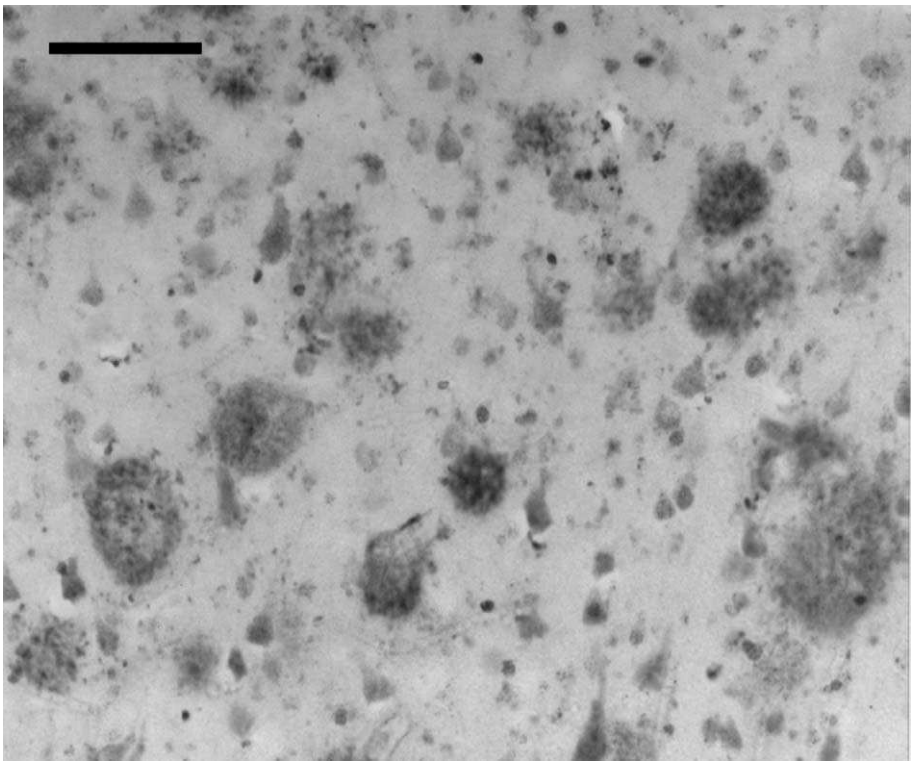

FIG. 28.1. Example of amyloid deposits in the temporal neocortex of a very old rhesus macaque (32 years old). Note the presence of classic senile plaques with well visible amyloid cores, as well as smaller deposits. Materials were stained with an antibody against Aβ1-40. Scale bar, 100 µm.

deposits have been reported in the hippocampus, the insula, and the cingulate, motor, auditory, visual, temporal and parietal cortices, and amygdala (Heilbronner and Kemper, 1990). This distribution differs considerably from that observed in Alzheimer's disease patients in whom these lesions predominate in the temporal limbic and parietal regions (Arnold *et al*., 1991). In the context of cytoarchitecture, it is interesting to note that the distribution of plaques in macaque monkeys does not appear to outline well-defined elements of the cortical circuitry as has been proposed in humans (Pearson *et al*., 1985; Rogers and Morrison, 1985; Hof *et al*., 1999) and that their densities are not correlated to cognitive deficits in old animals (Sloane *et al*., 1997). In fact, a consistent burden of amyloid is present only in some animals older than 25 years, but that number of individuals showing senile plaques increases with age (Sloane *et al*., 1997). It is important to note that in humans no clear correlation exist between the degree of amyloid deposition and the severity of cognitive deficits (Arriagada *et al*., 1992; Hof *et al*., 1999).

Interestingly, in the brain of the squirrel monkey (*Saimiri sciureus*), another species of New World anthropoid, the predominant type of amyloid-containing lesion is a widespread cortical angiopathy. In this species, vascular amyloid has been observed throughout the neocortex, the amygdala and the septal nuclei and is notably sparse or absent from subcortical structures. Moreover, the density of affected vessels is also correlated to the amyloid burden of the surrounding parenchyma (Walker *et al*., 1990; Walker, 1991). This species difference indicates that whereas the macaque represents an interesting model of cerebral amyloidosis, the squirrel monkey may be a more suitable model of vascular amyloid angiopathy. It has also been shown that the vascular Aβ deposits in macaques are stained strongly by antibodies differentiating the carboxy-terminal of the peptide. Thus, the vascular lesions contain preferentially Aβ42(43), whereas both Aβ1-40 and Aβ42(43) are observed in senile plaques, unlike the situation in humans. Furthermore, it appears that in monkeys the ratio of Aβ1-40 to Aβ42(43) is higher than in humans (Nakamura *et al*., 1995; Kanemaru *et al*., 1996), indicating that certain differences exist in amyloid deposition during the aging process between monkeys and humans.

A certain degree of glial response (Sloane *et al*., 1999, 2000) appears to occur prior to the development of senile plaques in macaque monkeys. In a study of the temporospatial relationships between neuronal injury and the deposition of the composants of senile plaques and parenchymal amyloid deposits, the earliest change associated to formation of senile plaques was recognized as the development in presynaptic terminals in dendrites of electron dense bodies and the accumulation of the amyloid precursor protein in astrocytes and microglial cells (Martin *et al*., 1994). In old monkeys, amyloid deposits containing nonfibrillar Aβ were observed in neurites and dendrites as well as glial elements, and the Aβ peptide was found in extracellular fibrils around mature plaques, suggesting that a synaptic pathology precedes the deposition of amyloid precursor protein in neurites and activated glia, and of extracellular fibrillar Aβ within senile plaques. In addition, it appears that the expression of the mRNAs for the 695- and 751-residue isoforms of the amyloid precursor protein is increased in adult macaques prior to reaching senescence, suggesting a role of

the amyloid precursor protein in early molecular events related to brain aging (Sirinathsinghji *et al*., 1995). Finally, in macaque monkeys, both senile plaques and amyloid angiopathy contain several proteins associated with these same lesions in humans. In particular, apolipoprotein E, α1-antichymotrypsin and complement factors C1q and C3c are encountered in these lesions in monkeys (Abraham *et al*., 1989; Podlisny *et al*., 1991; Poduri *et al*., 1994; Härtig *et al*., 1997), demonstrating a close similarity in the processes leading to senile plaque formation between monkeys and human.

III. Neurofibrillary Changes in Old Monkeys

Filamentous neuronal or neuritic changes have been reported in old monkeys albeit in far fewer number than in elderly human brains or in Alzheimer's disease cases. Early reports have described rare neuronal fibrillar materials in the form of 10 nm helical filaments exhibiting a periodicity of 50 nm as well as 13 nm granular, parallel filaments (Wisniewski *et al*., 1973). Other investigators described neurofibrillary tangles in the brains of cognitively impaired monkeys (Cork *et al*., 1989). More recently filamentous tau pathology, morphologically and biochemically comparable to the fibrillary lesions that are characteristics of a variety of human neurodegenerative disorders, have been described in a few aged baboons (*Papio hamadryas cynocephalus*) (Schultz *et al*., 2000), rhesus macaques, and Campbell's guenons (*Cercopithecus mona campbelli*) (Härtig *et al*., 2000). These lesions, that could be labeled by a panel of antibodies to hyperphosphorylated tau proteins, were observed in neurons, astrocytes, and oligodendrocytes of two old baboons, and occurred preferentially in the hippocampal formation. The fact that these lesions were found not only in nerve cells, but in glial cells as well, extend the nonhuman primate spectrum of age-related pathologies to a larger group of degenerative diseases that differ from Alzheimer's disease by their profile of tau proteins and characteristic lesion distributions. Why cellular lesions typical of Alzheimer's disease and other dementias, such as true tau-positive neurofibrillary tangles or glial coiled bodies, develop in only some individuals of a very restricted number of primate species (Cork *et al*., 1989; Härtig *et al*., 2000; Schultz *et al*., 2000; and see Chapter 29) remains to be elucidated. Also, the nature of the lesions observed in these animals differ morphologically and biochemically from the tangle-like lesions found in certain nonprimate species. In this context it is worth noting that fibrillary lesions have been described in the brain of old lesser gray mouse lemur (*Microcebus murinus*) a prosimian primate (Bons *et al*., 1991; Giannakopoulos *et al*., 1997; see Chapter 27). Tau proteins from this species have been shown to undergo age-related modifications in respect to their isoform composition (Delacourte *et al*., 1995), making it another interesting model for the study of biochemical dysfunctions during brain aging and Alzheimer's disease.

IV. Age-Related Ultrastructural Alterations in the Macaque Monkey Cerebral Cortex

There are few, if any, obvious changes to neuron morphology and numbers in the cerebral cortex of aged monkeys. In fact, several studies using traditional as well as stereologic methods have shown that the frequency of profiles displaying a nucleus or the total number of neurons remain unchanged in the neocortex and that the morphology of these nuclei is not altered in old animals (Peters *et al*., 1994, 1998b; Gazzaley *et al*., 1997; Hof *et al*., 2000). The neurons in area 46 of the prefrontal cortex have been shown to accumulate moderate amounts of lipofuscin during aging in macaques (Peters *et al*., 1994). However, there are notable changes in the morphology of the terminal dendrites of these neurons, which show evidence of degeneration particularly in layer I, where large numbers of dendritic branches exhibit changes in their cytoplasm including loss of organelles and accumulation of membranous materials (Peters *et al*., 1994). Peters and colleagues also reported a local thinning of layer I in this region and stereologic counts of the numbers of synapses revealed a consistent reduction in the old monkeys of 30 to 60% of the numerical densities of synapses per unit volume (Fig. 28.2A; Peters *et al*., 1998a; but see below for additional details). Such loss of synapses occurs in parallel to a decrease in the number of postsynaptic dendrites and spines in layer I, implying a considerable degree of involution of the apical tuft of dendrites of neocortical neurons takes place that during aging (Peters *et al*., 1998a). Recent preliminary data from our population of old macaque and Patas monkeys confirm these observations and reveal a significant degree of alterations in the apical dendritic tree of neurons in the prefrontal cortex as well as lower spine densities (see below and Fig. 28.5; Duan *et al*., 1999). Moreover, these dendritic and synaptic changes are accompanied by a degeneration of myelinated axons in the deep layers of the cortex and in the white matter, which correlates in old animals with deficits in visual and spatial recognition tasks (Peters *et al*., 1994). Together, these ultrastructural morphologic changes suggest that age-related cognitive deficits in old monkeys are not due to a loss of neurons, but rather evolve from cellular changes that lead to a disruption of the connectivity between the cerebral cortex and other brain regions.

The axonal pathology in aged monkeys appears to be consistently severe. Myelinated fibers have been shown to undergo several types of alterations. In some fibers there is accumulation of dense oligodendrocytic materials that leads to a splitting of the major dense line of the myelin sheaths (Peters *et al*., 2000). Some sheaths display severe ballooning, due to the opening of the intraperiod lines which becomes filled by fluid. These balloons in the myelin lamellae can be exceptionally large but usually have a diameter of about 10 μm (Feldman and Peters, 1998). Certain fibers display doubling of their myelin sheaths that present as layers of compact myelin surrounding each other, and other sheaths contain too much myelin so that their axons are enclosed by sheaths that are proportionally too large (Peters *et al*., 2000). Such changes of myelin sheaths occur under other conditions independently of aging (Feldman and Peters, 1998). However, their consistent presence in aged macaque monkeys indicate that during aging the oligodendrocytes are losing the capacity to maintain adequate myelin sheaths. It should also be noted that the changes have been observed not only in several regions of the cerebral cortex but in subcortical structures such as the inferior colliculus, cochlear and olivary nuclei, substantia nigra, and the cerebellum (Feldman and Peters, 1998).

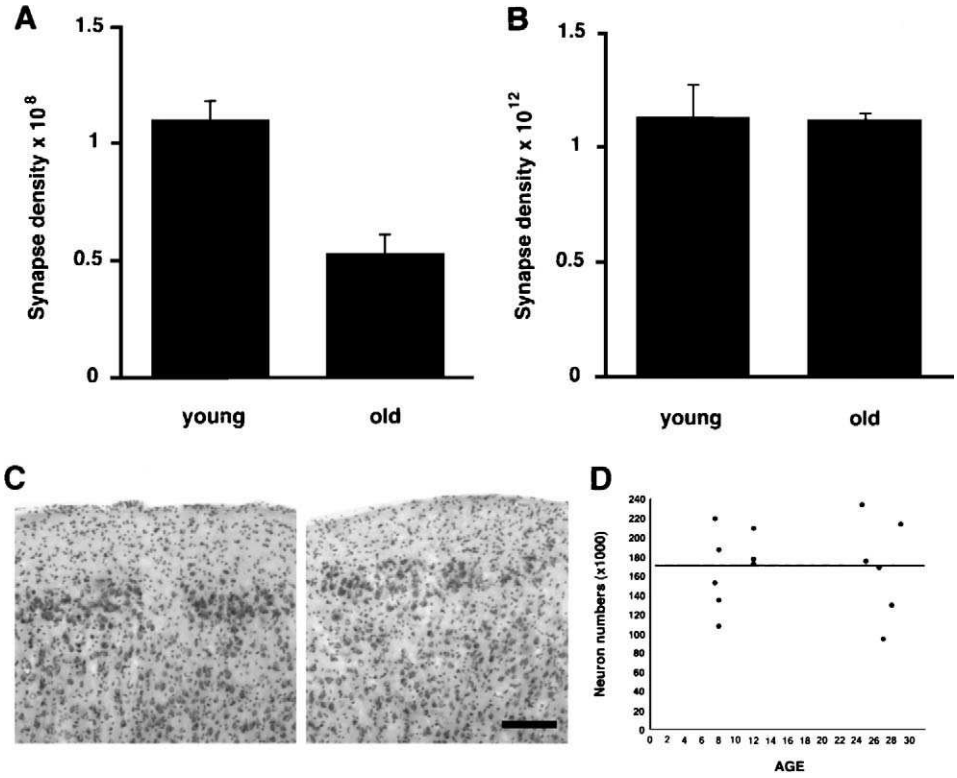

FIG. 28.2. Synapse densities in layer I of prefrontal cortex area 46 (A) and the dentate gyrus outer molecular layer (B) of old macaque monkeys compared to young animals. There is a decrease in the density of synaptic profiles counted under 1 mm^2 of cortical surface in the prefrontal cortex. In contrast, the densities of synapses per cm^3 are unchanged in the dentate gyrus of aged animals (data adapted from Peters *et al*., 1998b, and Tigges *et al*., 1996). (C, left) Layer II of the entorhinal cortex in a young adult rhesus monkey and (right) in an old animal. No cell loss is observed in the neurons of origin of the projection to the dentate gyrus in old monkeys as revealed by stereologic analyses (D; data adapted from Gazzaley *et al*., 1997). Quantitative data are shown as means ± SD. Scale bar on C, 100 μm.

These observations indicate that glial cells may be the principal target of age-related alterations in the brain of aged macaque monkeys, even though their numbers do not seem to change during aging (Peters *et al*., 1994). Further analyses of oligodendrocytes have demonstrated that these cells occur frequently in groups or arranged in rows in old animals, whereas in young adult they are commonly seen singly (Peters, 1996). In aged monkeys they are also observed in the vicinity of brain capillaries, at times with their cell bodies in contact with the basal membrane of the blood vessels, where they disrupt the normal limiting glial membrane formed by the astrocytes. In addition, these clumps of oligodendrocytes may form a network as tight junctions among their cell bodies have been observed (Peters, 1996). Finally, oligodendrocytes and other neuroglial cells accumulate abnormal inclusions or debris in their cytoplasm as do the pericytes (Peters *et al*., 1994).

V. Neuron and Synapse Numbers in the Central Nervous System of Old Macaque Monkeys

A considerable loss of synapses has been estimated in layer I of the prefrontal cortex (Fig. 28.2A; see above), in absence of obvious changes in the morphology of synapses (i.e., symmetric or asymmetric) and the distribution of the various types of synapses (i.e., axodendritic, abutting spines or dendritic shafts, and axosomatic). However, other regions of the cerebral cortex show milder changes. For instance, in the outer portion of the dentate gyrus no changes have been observed in the total counts of axonal terminals synapsing with dendritic spines and shafts, as well as in cross-sectional area of the terminals and length of postsynaptic densities (Fig. 28.2B; Tigges *et al*., 1995, 1996), although a minor decrease in the density of synapses on shafts was recorded when these synapses were considered alone. These data point to the fact that a major hippocampal network involved in memory is likely to be morphologically preserved during aging in these animals. These data agree with the fact that no neuronal loss has been observed in layer II of the entorhinal cortex where the neurons of origin of the projection to the outer molecular layer of the dentate gyrus reside, further supporting the morphological integrity of this pathway during aging (Figs. 28.2C and 28.2D; Gazzaley *et al*., 1997). It must be mentioned, however, that earlier studies of the hippocampal formation in old macaques have shown an approximately 50% decrease in the number of neurons in the CA1 field of the hippocampus proper and lesser differences in the prefrontal cortex, as well as a reduction in the thickness of these regions (Brizzee *et al*., 1980). These data were unfortunately not obtained using rigorous stereologic methods and await further confirmation, as they appear to dif-

fer radically from a host of more recent quantitative analyses (in this context it is worth mentioning that stereologic assessments of the numbers of neurons in the CA1 field and entorhinal cortex of great apes did not reveal any age-related differences; Erwin *et al*., 1999, and see Chapter 29). Similar observations have been made in the primary motor cortex of old macaque monkeys, where no loss in the numbers of the giant Betz cells and of the number of axosomatic appositions on their surface could be detected in spite of a slight age-related shrinkage in the volume of their perikarya (Tigges *et al*., 1990, 1992). It is in fact interesting to note that during adult development in macaque monkeys, the number of neurons in the primary motor cortex decreases significantly in the maturation period, but that the number of Betz cells increases at this time and remains stable for the entire life span of these animals (Tigges *et al*., 1990). It is therefore likely that the age-associated decrease in motility observed in aged macaques is not linked to a central loss of motoneurons and does not involve other components of the primary motor circuits, but is rather directly related to distal causes such as bone involution and joint disorders (DeRousseau, 1985).

The visual system of old monkeys has been extensively studied due to the remarkable similarities that exist between its functional organization and that of humans. Visual abilities decline during normal aging and involve deficits in visual acuity, spatial contrast and temporal-frequency contrast sensitivity and resolution, motion detection, and binocular processing (Spear, 1993; Spear *et al*., 1994). However, the anatomical and physiological study of aged monkeys has revealed very few significant alterations in the retino-geniculo-striate pathways, at least at the level of the retina and lateral geniculate nucleus, suggesting that visual deficits in aging may depend on more central dysfunctions (Spear, 1993; Spear *et al*., 1994). In fact, recent physiological data from old macaques clearly demonstrate the existence of degradation in orientation and direction selectivity in the primary visual cortex, accompanied by increased spontaneous activity and responsiveness, possibly due to an age-related deficit in intracortical inhibition (Schmolesky *et al*., 2000). Previous studies of retinal ganglion neurons and lateral geniculate nucleus neurons have generally failed to reveal any age-related decline in their numbers or size, suggesting that neither the parvocellular nor the magnocellular neurons are affected (Ahmad and Spear, 1993; Kim *et al*., 1996). In addition, aging has no clear effect on the number of neurons in histochemically identified compartments of the primary visual cortex, and the density of these functional domains (i.e., the cytochrome oxidase-rich blobs) remains unaltered in old animals (Kim *et al*., 1997). Furthermore, the area, volume, and thickness of the primary visual cortex is comparable in young and old macaque monkeys (Peters *et al*., 1997; Hof *et al*., 2000; Fig. 28.3A). However, as in other regions of the cerebral cortex, the neuropil in the primary visual cortex demonstrates vacuolar changes and degenerating myelin sheaths, in absence of obvious morphologic alterations to the neuronal perikarya (Vincent *et al*., 1989; Peters, 1996; Feldman and Peters, 1998; Peters *et al*., 2000).

It is therefore likely that the age-related deficits in visual function affect cortical structure at a finer grained level and may involve only certain neuronal subpopulations. One such identifiable cellular class comprises the large layer IVB neurons and the Meynert cells that form direct projections to cortical and subcortical regions involved in motion detection, ocular tracking, smooth pursuit movements, and saccade production (Hof *et al*., 2000). It is reasonable to argue that in view of their particular connectivity patterns these neurons may be affected by aging as the functions they are likely to subserve are not fully intact in old individuals. Used an unbiased stereologic method the optical fractionator estimates of the total numbers of neurofilament protein-containing layer IVB cells and Meynert cells have been obtained in the calcarine cortex and in the opercular cortex, separately (Hof *et al*., 2000). Not surprinsingly, a considerable degree of interindividual variability in neuron numbers and cortical volume was observed among both young and old animals. However, there were no differences in either Meynert cell or layer IVB cell numbers between the aged group and the young group in either parts of the primary visual cortex, confirming earlier data relying on density measurements (Fig. 28.3B; Peters and Sethares, 1993). These investigators had also determined that Meynert cells do not shrink during aging and our study revealed no morphological alterations to these cell populations (Fig. 28.3C). Interestingly, the oldest animal in our sample had the

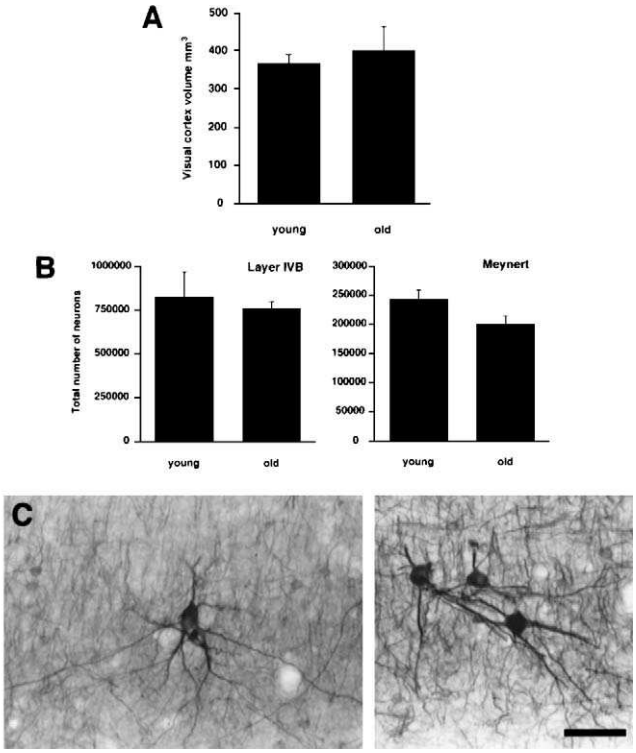

FIG. 28.3. Integrity of the primary visual cortex during aging in macaque monkeys. No changes in the total volume of the primary visual cortex occur in old animals (A). Specific populations of projection neurons, the large layer IVB and the Meynert cells, are not affected by aging as demonstrated by stereologic analyses (B). Furthermore, these particular neurons exhibit no age-related morphologic alterations (C). C shows clusters of Meynert cells in layer VI of young (left) and old (right) macaque monkeys. Note the distinct morphology of these neurons. Materials were stained with an antibody against nonphosphorylated neurofilament protein. Quantitative data are shown as means $\pm$ SD and were adapted from Hof *et al*. (2000). Scale bar on C, 100 μm.

lowest number of Meynert cells, suggesting that some animals have a certain degree of neuronal loss in the primary visual cortex during aging. These data suggest that the deficits occurring during aging of the visual system are not due to the loss of highly specific neocortical neuronal populations such as those analyzed in this particular study. It is, however, probable that more subtle alterations in the neurochemical characteristics or synaptic organization of the functional pathways subserving the different visual modalities are more directly responsible for these deficits. It should be kept in mind that these neuronal populations may undergo dendritic alterations that could not be detected with the methods used in the available studies. In view of the documented changes to the dendritic tree in other cortical regions (Peters *et al*., 1998b; Duan *et al*., 1999), it would be important to investigate the possible involution of dendritic arborizations as well as spine changes in Meynert cells in old monkeys.

VI. Neuronal Alterations and Loss in Subcortical Systems in Aged Macaque Monkeys

Whereas the cerebral cortex appears remarkably resistant to the aging process in old monkeys, significant alterations have been observed in subcortical nuclei that contain the neurons of origin of the cholinergic and aminergic systems. Cholinergic deficits have long been implicated in the memory deficits of aging and Alzheimer's disease. Although no definitive stereologic analyses have been performed in the nucleus basalis of Meynert and associated cholinergic cell groups in old monkeys, a study has documented an approximately 40% loss of cholinergic neurons in the caudalmost part of the nucleus of Meynert (Rapp and Amaral, 1992; Stroessner-Johnson *et al*., 1992). Age-related decreases in packing densities and numbers of neurons in the nucleus raphe centralis superior have been demonstrated in a group of old rhesus monkeys and concern a supopulation of small neurons and a group of serotoninergic neurons, with a cell loss of about 50% (Kemper *et al*., 1997). Finally, a recent study has shown that a substantial loss of dopaminergic neurons in the substantia nigra pars compacta and the ventral tegmental area occur in the macaque monkey during aging (Siddiqi and Peters, 1999; Siddiqi *et al*., 1999). The volume of these nuclei was not reported to change with aging in these studies, and the most severe neuronal loss in the substantia nigra involved the small, presumably GABAergic neurons (Siddiqi *et al*., 1999). Overall, about 25% of the substantia nigra pars compacta and 34% of the ventral tegmental area neurons are lost during aging. Furthermore, only slight changes in the size of individual nigral and tegmental neurons were observed by these investigators, although many of these cells accumulated lipofuscin and Marinesco bodies and underwent severe dendritic alterations during aging (Siddiqi and Peters, 1999). This study also revealed a considerable pathology of the neuropil of the substantia nigra pars compacta in aged animals, with increases in the number of astrocytic processes, and the presence of astrocyte-derived spheroids, oligodendrocytic inclusions, and breakdown of myelin sheaths.

Importantly, changes in all of these subcortical systems furnishing divergent projections to the cerebral cortex are correlated with the severity of cognitive deficits in aged animals (Rapp and Amaral, 1992; Stroessner-Johnson *et al*., 1992; Kemper *et al*., 1997; Siddiqi *et al*., 1999). These cellular alterations may exert a significant influence on the integrity of neurochemically specific afferent projections on neocortical function. In fact, age-related morphologic and pharmacological alterations of catecholaminergic systems are known to play a central role in the development of cognitive and memory impairment in aged monkeys (Arnsten, 1998, 1999). In this context, it is important to note that the cortical dopaminergic appears to be particularly affected (Goldman-Rakic and Brown, 1981; Wenk *et al*., 1989; Arnsten, 1998, 1999), which supports the morphological evidence (Siddiqi and Peters, 1999; Siddiqi *et al*., 1999). Interestingly, a recent study demonstrated that the age-related atrophy and loss of cholinergic neurons can be reversed by delivery of human nerve growth factor in old macaque monkeys (Smith *et al*., 1999). These data suggest that in spite of the fact that subcortical regions may exhibit greater vulnerability than other brain areas in aging macaques, cellular atrophy is an important contributing factor to the cognitive decline observed in these animals that can be potentially improved by gene transfer of neurotrophic molecules.

VII. Age-Related Cognitive Deficits in Monkeys Involve Subtle Morphological and Molecular Changes

The fact that only minor morphologic modifications in neuronal circuits are seen in old monkeys and that major changes appear to be restricted to a small number of specific systems, the cognitive deficits observed in aged animals may be more strongly related to rather minute alterations affecting certain populations of cortical neurons. Such alterations are additionally unlikely to be brought to evidence even by refined morphometric and stereologic methods, or during general neuropathologic evaluation of the brain, but require quantitative investigations at the subcellular level. The major age-related changes in catecholaminergic and cholinergic systems seen in old animlas (Arnsten, 1999) indicate a pathology involving specific receptor molecules and specific sites on the dendritic and somatic compartments of the target neurons. For example, a recent study of cortical volume of prefrontal cortex area 46 revealed no gross change in the volume of layer I and of the total cortex in macaque monkeys cognitively impaired on a delayed-response task (Fig. 28.4; O'Donnell *et al*., 1999). These data, together with those of other studies of neuropil changes in area 46 (Peters *et al*., 1996, 1998b), indicate that subtle subcellular alterations are likely to have substantial repercussions on the functional connectivity of affected cortical circuitry in aging. In addition, specific shifts in the expression of certain glutamate receptor subunit proteins, which may lead to functional decline without neurodegeneration, have been shown to occur in aged monkeys, but not in juvenile and adult monkeys (Gazzaley *et al*., 1996; Rosene and Nicholson, 1999). Recent data have demonstrated that NMDAR1 receptor levels detected by quantitative immunohistochemistry decrease specifically and consistently in the outer molecular layer of the dentate gyrus where part of the perforant path terminates, but there are no such changes in AMPA or kainate

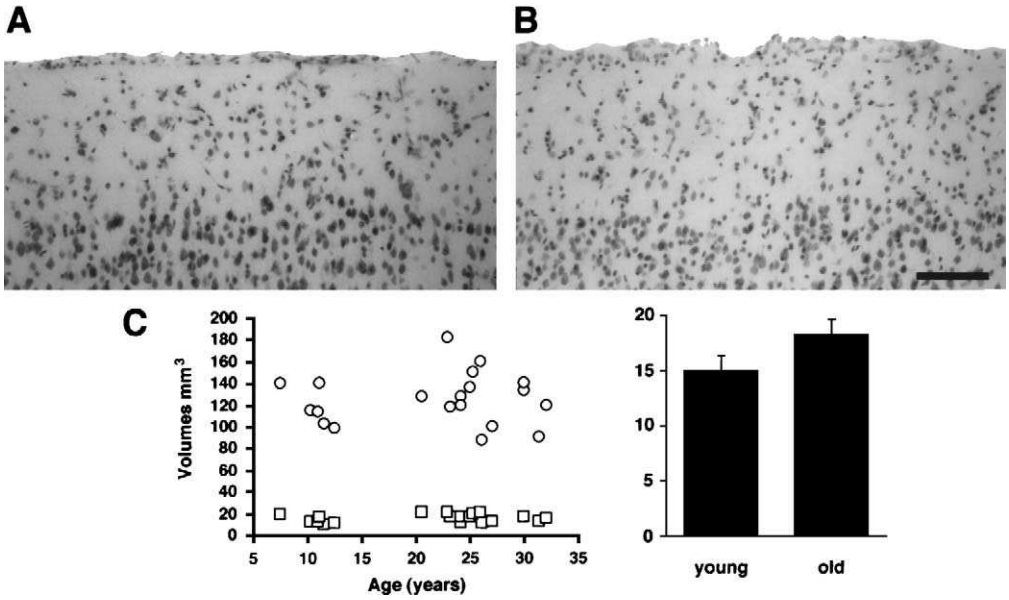

FIG. 28.4. Morphology and stereologic analysis of prefrontal cortex area 46 in macaque monkey aging. No gross alterations can be observed between young (A) and old (B) animals in the thickness and morphology of layer I. Volumetric analyses show no correlation between volumes of layer I or total volume of area 46 and age (C, left; total volumes are shown by open circles, and layer I volumes by open squares) or between the two groups of animals (C, right). Quantitative data are shown as means ± SD and were adapted from O'Donnell *et al*. (1999). Scale bar on B, 100 μm.

receptor subunits, and no morphologic reflection of degeneration of the perforant path (Gazzaley *et al*., 1996). In particular, there is no neuronal loss in layer II of the entorhinal cortex in these aged animals (Gazzaley *et al*., 1997). These data are consistent with the minor changes in synapses in the dentate gyrus of aged monkeys (Tigges *et al*., 1995), and with reports of receptor binding assays in old animals (Wenk *et al*., 1991; Rosene and Nicholson, 1999). Recent analyses of identified

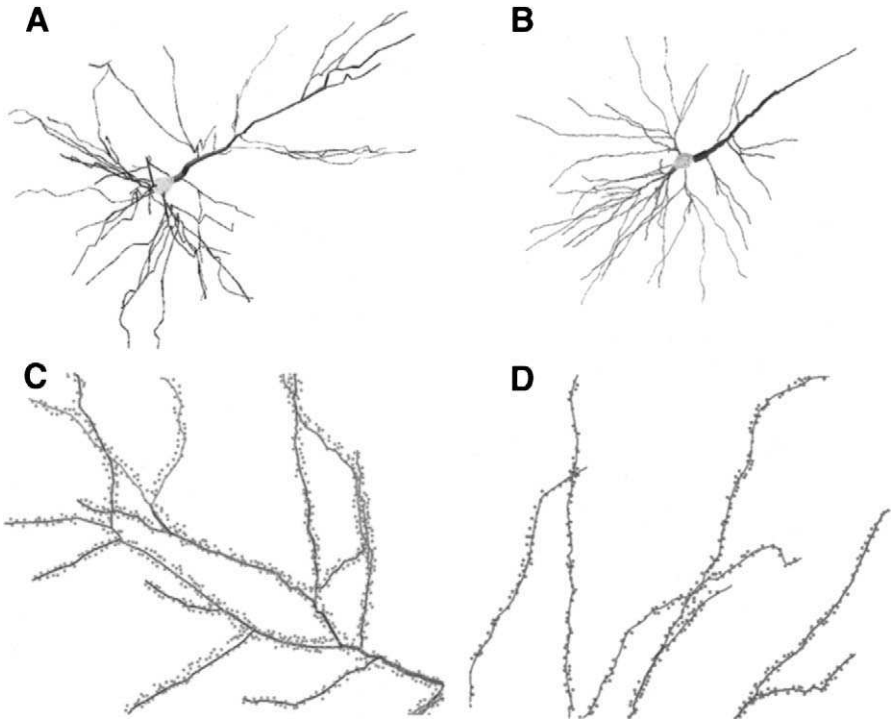

FIG. 28.5. Three-dimensional reconstruction of dye-loaded, retrogradely labeled neurons furnishing identified projections from the superior temporal cortex to prefrontal area 46 in a young (A) and an old (B) macaque monkey. Note the less complex and reduced dendritic arborization patterns in the old animal. Spines densities are also decreased in the old animal (D) compared to that seen in the young one (C). Spines were mapped in three dimensions at the same time that the neurons were reconstructed (Duan *et al*., 1999).

neurons furnishing corticocortical projections have demonstrated that a considerable downregulation in the expression of the glutamate receptor subunits NMDAR1 and G1uR2 occurs in old rhesus and Patas monkeys, so that in aged animals there are 20–40% fewer neurons expressing these subunit proteins depending on the type of corticocortical projections (Duan *et al*., 1999). Furthermore, the three-dimensional reconstruction and modeling of these cortical projection neurons showed that in both species they undergo a consistent impoverishment of the complexity of their distal dendritic arborizations and exhibit a severe decrease (20–30%) in spine densities (Fig. 28.5).

These findings suggest that the intradendritic parcellation of a neurotransmitter receptor is modifiable in an age-related and circuit-specific manner and that this change is anatomically positioned to influence the information-processing capacities of systems critical for normal learning and memory. Defining the functional significance of these alterations, however, will require a multidisciplinary approach, combining morphological and biochemical analysis in relation to the cognitive outcome of normal aging.

Acknowledgments

We thank B. Wicinski, W. G. M. Janssen, K. A. O'Donnell, T. L. Page, M. Einstein, and Dr. Y. He for their participation in our analyses of cortical aging in monkeys and Drs. P. R. Rapp, J. H. Morrison, E. A. Nimchinsky, and J. M. Erwin for stimulating discussions. Supported by NIH Grants AG05138 and AG06647 and the American Federation for Aging Research.

The Study of Brain Aging in Great Apes

The great apes are the closest biological relatives of humans. The resemblence is close from genetics to brain structure and cognitive function. Endocasts from fossil hominoids and hominids reveal that the brains of *Australopithecus* were similar in size and shape to those of modern chimpanzees, and that a dramatic increase in brain size occurred as *Homo* evolved. Studies of extant great apes (bonobos, chimpanzees, gorillas, and orangutans) in the wild and in captivity have provided evidence on patterns of sociality, behavior, communication, cognition, and self-awareness. These data have identified many characteristics that are apparently homologous among apes and humans, suggesting that these were also present in a common ancestor. Cerebral lateral asymmetries recently reported in the great apes suggest that some of the neurological foundations of language have long been present in the ape–human lineage. Neuronal loss with aging is associated with neurodegenerative pathology in humans. Studies of great ape brains using quantitative stereology have not yet found substantial neuronal loss associated with aging in the entorhinal cortex and CA1 field of the hippocampus, regions that are especially vulnerable to age-related cell loss in humans. However, two neuronal types have been recently found in anterior cingulate cortex that are unique to humans and great apes. One of these cell types, a large spindle cell found in a region implicated in self-awareness and regulation of autonomic functions, is diminished by about 60% in human victims of Alzheimer's disease. The application to great apes of improved methods of assessing cognitive decline, genetic risk, and gene expression, along with functional imaging and quantitative stereological research, offers prospects of additional insights into normal and pathological brain aging.

I. The Great Apes

The great apes are more like humans than are any other living creatures. Their genetic, anatomic, physiologic, cognitive, behavioral, and social similarity to humans recommends them highly for inclusion in comparative studies of many kinds, including studies of normal aging and age-related disorders. One of the most important reasons for studying the aging and other processes in the great apes is the greater prospect than with any other taxa of studying homologous structure, function, and malfunction.

Who are these great apes and why are we so much like them? The human species (*Homo sapiens*) is but one of about 200 extant species within the mammalian order, Primates. The Primate order includes the prosimians, the New World monkeys, the Old World monkeys, and the apes and humans. The living prosimians resemble widespread fossils dated beyond 40 million years before the present. The New World monkeys include the callitrichids (marmosets, tamarins, and *Callimico*) and the cebids (e.g., capuchins, squirrel monkeys, night monkeys). The Old World monkeys all fit into a single family, Cercopithecidae, with two branches cercopithecinae and colobinae. The cercopithecines include baboons, macaques, mangabeys, and guenons, while the colobines include leaf monkeys and odd-nosed monkeys. Authorities disagree on some aspects of the classification of apes and humans. Most agree that the lesser apes, Hylobatidae (gibbons and siamangs) form one family, but classification of the great apes and humans is problematic in several ways. This species cluster includes four genera, *Pongo* (orangutan), *Gorilla* (gorilla), *Pan* (''common'' chimpanzee and bonobo), and *Homo* (humans). Some authorities place the African apes (bonobo, chimpanzee, and gorilla) with the Asian orangutan in family Pongidae, while others reserve the name Panidae for the African ape family (Tuttle, 1999). Modern humans and their fossil predecessors (including several species of *Australopithecus* and *Homo*) are reliably assigned to family Hominidae. Several authorities place all the great apes and humans in family Hominidae (Goodman, 1974; Groves, 1986). Orangutans are assigned to subfamily, Ponginae. Gorillas, chimpanzees, and bonobos are assigned to subfamily Paninae (Gantt, 1986) or Homininae (Groves, 1986). Humans are classed in subfamily Homininae (Goodman, 1974; Groves, 1986). The nomenclature can be confusing when references to ''hominids'' (members of family Hominidae) can mean all great apes and ''hominoids'' (members of superfamily Hominoidea) can mean all apes, including gibbons.

Regardless of nomenclature, it is clear that all great apes and humans have shared common ancestry within about the past 12–15 million years, that the common ancestor of African

apes and humans lived less than 10 million years ago, and that the common ancestor of humans and chimpanzees lived 5–8 million years ago (Sarich and Wilson, 1967; Ciochon, 1983; McHenry, 1984; Kelley and Pilbeam, 1986). By contrast, the common ancestor of humans and Old World monkeys (such as rhesus macaques) lived about 30–32 million years ago. Humans are separated from the ancestors they share with all nonprimate mammals by at least 60 million years of evolution. Considering that both divergent lineages were evolving from that common ancestor, the minimum evolutionary distance between extant forms should be twice the postdivergence interval (i.e., more than 120 million years separate humans from any nonprimate mammal and perhaps as little as 10 million years from the chimpanzee). Reference to this time scale can be useful as we discuss the brains of great apes in relation to those of humans and other primates. Clearly the greatest homology must be expected between humans and chimpanzees or bonobos, somewhat less for gorilla, and less yet for orangutan.

II. Brain Evolution

The most obvious difference between the human brain and the brains of chimpanzees and other great apes is size. Whether we consider brain weight, cranial volume, or an encephalization index that considers brain weight relative to body weight, human brains are extraordinarily large relative to those of our nearest relatives (Tobias, 1971; Stephan *et al*., 1981, 1988; Semendeferi *et al*., 1997; Rilling and Insel, 1998, 1999; Semendeferi and Damasio, 2000). Brain weights given by Stephan *et al*. (1981, 1988) are as follows: rhesus (93 g), chimpanzee (405 g), and human (1330 g). When adjusted for body weight to produce an encephalization index, the values were 8.0, 11.4, and 30.1, respectively. Of the 45 species examined, the encephalization index of the chimpanzee was second only to that of humans. It should be noted that the gorilla brain is larger than that of the chimpanzee, but due to the gorilla's huge body mass, its encephalization index is less than that of the chimpanzee. It should be obvious that brain size and function can vary independently of body mass, so modest differences in encephalization index should not be regarded as indicating differences in cognitive functioning or intelligence; however, the difference is enormous between humans and chimpanzees, both in encephalization index and absolute brain size (Fig. 29.1). Interestingly, recent data suggest that although the absolute brain volume varies considerably among hominoids, the relative volume and cellular composition of certain regions, such as the prefrontal cortex, remain quite constant among these taxa (Semendeferi *et al*., 1997; Semendeferi and Damasio, 2000).

Another indicator of relative brain size can be obtained by measuring endocranial volumes. Holloway (1974, 1996) has used endocranial casts of fossil hominid skulls to measure size constraints and organizational features apparent form shape. Tobias (1971, 1996) reviewed the cranial volumes that had been found in studies of a large number of great ape skulls and related these data to those obtained for fossil *Australopithecus* and *Homo*, as well as modern humans (see also Falk, 1986). The endocranial volumes for the great apes were the following (pooled male and female data sets): orangutans, 404.8 cm^3 (n = 402); gorillas, 504.6 cm^3 (n = 668); bonobo, 343.7 cm^3 (n = 11); and chimpanzee, 383.4 cm^3 (n =363). The corresponding values for *Australopithecus* range from 350 to 530 cm^3, well within the range of extant great ape species. Early *Homo* (*habilis*) endocranial volume ranged from about 450 cm^3 to nearly 900 cm^3, and *H. erectus* averaged more than 900 cm^3, ranging from about 650 cm^3 to nearly 1400 cm^3—within the range of modern humans (mean = 1370 cm^3; range, 1070–1670). Interestingly, classic Neanderthal brain size (mean = 1470 cm^3; range, 1145–1795) was greater than that of modern humans.

Endocasts of *Australopithecus* crania do not usually provide much detail regarding the topical features of the brains they contained (Holloway, 1974; Eccles,1989; but see also Kochetkova, 1978). The features shared by *Australopithecus* specimens from South Africa and East Africa but not by extant apes are sumarized by Tobias (1996). Some controversy exists over the degree to which sulcal patterns are evident from these endocasts. The most important point is that modest differences in the topography of sulci and gyri may or may not indicate functional changes underlying these landmarks. While it seems likely that some reorganization of the brain was already in progress in *Australopithecus*, we may never know what these changes were. The endocasts of early *Homo* (*habilis*), however, reveal a dozen, or so, clear departures from the patterns seen in extant apes (summarized by Tobias, 1996). The changes in size and shape suggest that a dramatic reorganization of the brain was in progress as *H. erectus* emerged and eventually gave rise to *H. sapiens*. The morphological changes evident within the past 2 million years may have increased human vulnerability to age-related changes, but many age-related phenomena encountered by present-day humans seldom, if ever, could have been experienced during the relatively brief life spans of our ancestors. Human life expectancy has increased dramatically in recent times (over 120 years in one documented case) by comparison with that which was typical throughout the evolutionary history of *Homo*. The life expectancy of great apes in the wild is certainly less than 30 years, but in captivity, with the benefits of hygiene, nutrition, and health care, they can live beyond 40, 50, and possibly 60 (Erwin *et al*., 1998) (Fig. 29.2).

III. History

Comparative brain anatomy studies of great apes were underway early in the 20th century, including studies of orangutan and chimpanzee (Campbell, 1905), orangutan (Mauss, 1911), chimpanzee (Brodmann, 1912), and gorilla (Bolk, 1910). These included examination not only of surface topography, but also detailed microscopic examination of underlying tissue and documentation of homologies between ape and human brain areas (Campbell, 1905). Research on the effects of ablations and lesions on learning, memory, and emotionality continued for many years (Blum, 1948; Rosvold *et al*., 1961; see Markowitsch, 1988, for a review). Especially significant was a series of studies by Bailey and colleagues comparing and mapping human and chimpanzee neocortex (Bailey, 1948; Bailey *et al*., 1950). While these studies did not focus

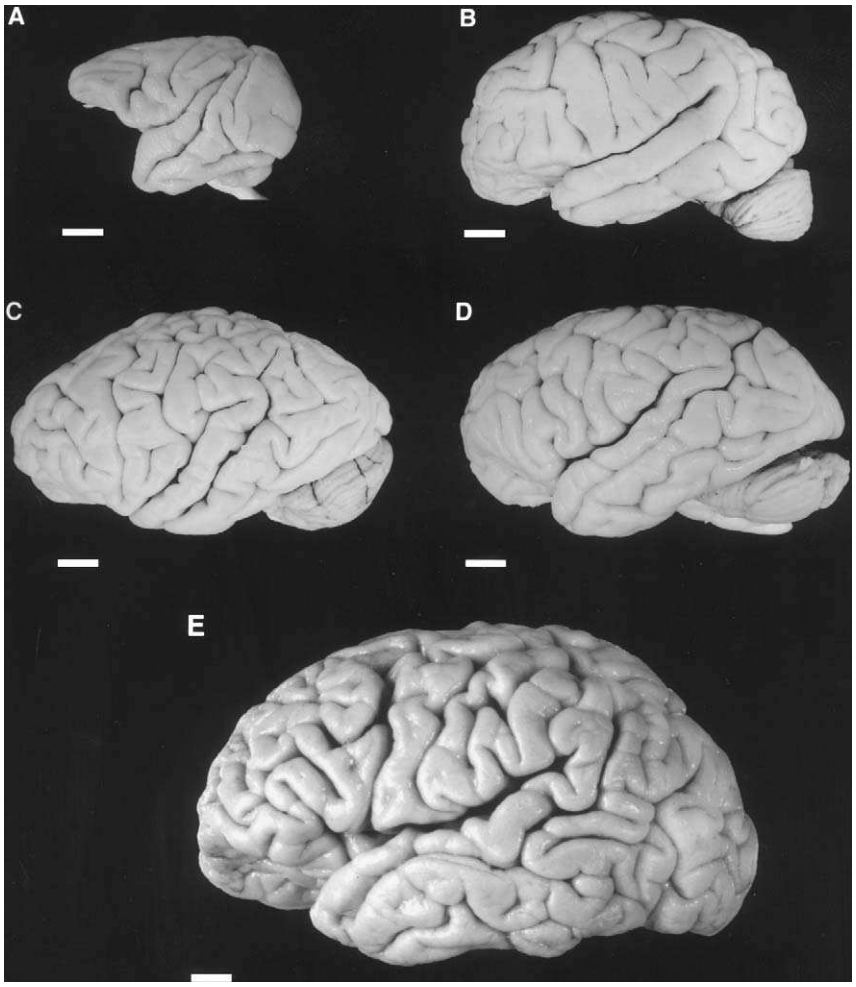

FIG. 29.1. Lateral views of the left hemisphere of the brains of (A) a 19-year-old patas monkey (*Erythrocebus patas*), (B) a 37-year-old Sumatran orangutan (*Pongo pygmaeus abelii*), (C) a 48-year-old Western Lowland gorilla (*Gorilla gorilla gorilla*), (D) a 45-year-old common chimpanzee (*Pan troglodytes*), and (E) a nondemented 82-year-old human. All specimens are shown at the same scale (scale bars, 1 cm). Note the similar size of the gorilla and chimpanzee specimens and the considerable increase in the volume of the frontal and temporal regions in hominids compared to the patas monkey. Although all of these specimens were obtained from relatively old individuals, no gross age-related alterations are visible.

on aging, the results are useful in understanding the functional neurobiology of great ape and human brains. It is unlikely that further ablation or lesion studies will be done on great apes. Most invasive research involving great apes has ceased, partly due to studies such as those cited below that indicate how similar the great apes are to humans.

IV. Communication

Many attempts have been made to establish language communication with great apes. Two notable (unsuccessful) attempts to teach chimpanzees to speak were those of Kellogg and Kellogg (1933) and Hayes and Hayes (1951). Another attempt at sophisticated communication was more successful. Premack used nonverbal symbols on a form board to successfully establish a system of communication with a chimpanzee named ''Sarah'' (Premack, 1971). Even though chimpanzees lack the ability to produce articulated speech (Lenneberg, 1975), they were found to be capable of a remarkable facility to use sign language and other artificial languages, and several successful demonstrations of this have been carried out with chimpanzees (Gardner and Gardner, 1969; Fouts, 1974; Rumbaugh, 1977; Matsuzawa, 1999), orangutans (Miles, 1980), a gorilla named ''Koko'' (Patterson and Cohn 1990), and a most remarkable bonobo named ''Kanzi'' (Savage-Rumbaugh and Lewin, 1994). The extent to which language production and comprehension of symbolic communication have been demonstrated is astonishing. While the communication systems established in these cases do not constitute actual human language, they certainly *approach* human language and challenge alternative explanations. A few groups have recently revisited the issue of functional asymmetry of language areas in the brain (Gannon *et al*., 1998a,b, 1999; Hopkins *et al*., 1998; Kheck *et al*., 1998). They have reported that the anatomic pattern and left hemisphere size predominance of the

FIG. 29.2. Photograph of an elderly female common chimpanzee. This individual is close to her 6th decade of life and is known, according to monitoring by the zoo keepers, to exhibit what may represent age-related cognitive and behavioral disturbances. More than 200 chimpanzees older than 35 years live in various facilities thoughout the world.

planum temporale, a language area of the human brain (Wernicke's posterior receptive language area), are also present in chimpanzees. This discovery suggests that human language functions evolved within an anatomic substrate that was already lateralized to the left hemisphere in the common ancestor of humans and chimpanzees 5–8 million years ago. Functional imaging studies of humans and some of the chimpanzees that have been involved in communication and language studies may reveal whether or not homologous brain regions are used for similar tasks. One such study compared two language-experienced chimpanzees, ''Panzee'' and ''Lana,'' with humans (Rilling *et al*., 1999). Humans, but not chimpanzees, exhibited lateralized activation of Heschl's gyrus, planum temporale, and frontal cortical areas. The two chimpanzees exhibited different patterns of activation from the humans and from each other, suggesting that different neural substrates are used for language-like processing in chimpanzees than are typically used for language in humans.

V. Tool Use and Culture

The invention, manufacture, and use of tools by the great apes exceeds that exhibited by any other nonhuman. The use of tools to solve problems was impressively demonstrated by Koehler (1925) with captive chimpanzees in the Canary Islands. Many other investigators replicated and extended this work (Yerkes, 1943; Beck, 1980). The most impressive reports of tool use have been those from field studies, in which great apes, especially chimpanzees, were reported to manufacture and use tools to crack nuts (Nishida, 1973; Boesch and Boesch, 1983) or retrieve termites from termite mounds (Goodall, 1964; Suzuki, 1966; McGrew, 1974; for a review, see Candland, 1987). Tool use in captivity and the wild have been directly compared (Matsuzawa, 1999). The case has recently been made that the differing tool-using traditions observed in various chimpanzee populations constitute distinct ''cultures'' (Whiten *et al*., 1999).

VI. Self-Awareness

The question of whether or not nonhumans are aware of themselves has been a matter of much speculation. Gallup (1970) devised a clever method of objectively addressing this question by studying responses of animals to their mirror images. Most of the animals tested responded to their mirror image as if the reflection were another animal. Gallup argued that this indicated a lack of self-concept. He observed that chimpanzees responded differently. They at first acted as if their reflection was another animal, but after a period of 2 or 3 days of mirror exposure they began to engage in self-directed behavior while observing the reflection of themselves doing so. Gallup devised a ''mark test'' in which chimpanzees were anesthetized, marked with red dye on an eyebrow ridge and ear, and allowed to regain consciousness. When they were again exposed to the mirror they immediately responded by touching and inspecting the marks while watching the reflection. ''Visual self-recognition'' in chimpanzees and orangutans was replicated by several investigators and shown to be a reliable phenomenon. Numerous other primate species were tested using this technique, but all failed to exhibit self-recognition (Gallup, 1987). Although gorillas that were specifically tested did not demonstrate self-awareness (Suarez and Gallup, 1981; Ledbetter and Basin, 1982), Patterson (1978) reported that ''Koko'' gorilla engaged in purposive self-directed behavior using mirrors. The demonstration that humans and great apes, but not lesser apes or other primates, exhibit visual self-awareness is an intriguing finding that suggests an exceptional cognitive capacity. Some of the great apes involved in language and cognition research are now elderly. It will be interesting to see how their cognition is affected by aging.

VII. Maps, Math, and Models

The evidence for the development of cognitive maps was reviewed by Meador *et al*. (1987). Among the most compelling studies reported were those of Menzel *et al*. (1978). Chimpanzees who were allowed to watch on a small black-and-white television monitor a caretaker hiding food in an outdoor enclosure were more efficient at finding the hidden food than were those who were not allowed to view the monitor. More recently, Boysen and Berntsen (1995) demonstrated that some chimpanzees (but not others) were able to use information from a scale model to solve a similar hidden reward problem. Matsuzawa (1985) and his colleagues (Biro and Matsuzawa, 1999) have been studying the use of numbers by a chimpanzee named ''Ai'' and have recently reported responses to introduction of the numerical concept ''zero.'' In other studies, Boysen demonstrated ordinality and transitivity in chimpanzees and found an interesting paradox in quantitative cognition (Boysen *et al*., 1993; Boysen and Berntson, 1995; see Deacon, 1997, for discussion). Given the choice between two piles of candy, chimpanzees could not inhibit choice of the larger pile, even if that meant that they were rewarded only with the smaller pile. This

response is similar to that observed in human children. When Arabic numerals were substituted for the piles of candy the chimpanzees could solve the problem. Boysen is currently developing noninvasive methods of assessing cognitive decline associated with aging and is currently working with Premack's "Sarah," who is over 40 years of age.

VIII. Nervous System and Aging

What do nervous systems do, and how are their functions vulnerable to the effects of aging? Willott (1999) sets forth seven fundamental functions of nervous systems, including the following: (a) maintain vital functions; (b) obtain information; (c) store information; (d) produce behavior; (e) modulate overall activity; (f) integrate information and behavior; (g) promote reproduction. Aging is likely to affect every aspect of the nervous system from control of vital functions and sensory input to memory and behavior. Few aspects of aging have been addressed in the great apes, partly because so few great apes in the past reached very advanced age in captivity, and partly due to the difficulty of obtaining a sufficient number of brains from great apes of different ages. This problem is currently being addressed by our Great Ape Aging Project, which includes a great ape central nervous system tissue bank component (Erwin *et al*., 1998, 1999, 2000).

One way of prioritizing neurobiology of aging studies of great apes is to focus first on points of vulnerability in humans. The sensory systems responsible for informational input almost inevitably decline with aging, including audition, vision, chemical senses (olfaction and taste), somatosensory modes (touch, pressure, heat, cold, pain, proprioception, etc.), and vestibular sensation, with some of the deficits occurring in peripheral sensory mechanisms and others resulting from central processing mechanisms. The processing of visual information, for example, is extremely complex for primates (Allman and McGuinness, 1988; Kaas and Huerta, 1988; Rodieck, 1988; Yin and Medjbeur, 1988), as are audition (Newman, 1988) and the somatosensory system (Kaas and Pons, 1988). Interestingly, a recent study has demonstrated unique patterns of expression of cytoskeletal proteins in the human primary visual cortex, as well as derived features in this cortical region in humans and great apes compared to that seen in Old and New World monkeys (Preuss *et al*., 1999). There is a need to understand not only how these systems are affected by aging but how they differ among the various primates including humans. Methods of testing for peripheral sensory deficits can include the use of visual evoked potentials (Boysen and Berntson, 1985), auditory evoked potentials (Kraus *et al*., 1985), and other innovative techniques. These clinical assessments can contribute to fundamental advances in knowledge relevant to aging, but they can also be of great value for clinical diagnosis of peripheral sensory deficits for individuals. Fundamental comparative data on motor systems are also important to an understanding of the processes of aging and to the treatment of age-related disorders, but few studies to date have focused on aging of motor systems in the great apes. Relevant reviews are available regarding primate motor cortex (Hepp-Reymond, 1988), neural control of vocalization (Sutton and Jürgens, 1988), and cerebellum (Haines, 1986).

The central processing mechanisms involved in learning and memory functions can change with age. Some of the structures involved are the hippocampus, neocortex, basal forebrain, amygdala, thalamus and hypothalamus, and the basal ganglia. The hippocampus and associated regions, such as entorhinal cortex, are especially implicated in some neurodegenerative processes associated with aging in humans, so comparative studies of cell populations in this area are important.

IX. Entorhinal Cortex

As a part of the Great Ape Aging Project we have initiated neuropathology screening of great ape brains using stereologic methods. We are focusing on regions that are severely affected in Alzheimer's disease (AD) and are involved early by age-related neuropathologic changes in humans. To analyze the cellular characteristics of brain aging in the great apes, we estimated the total number and cell volume of neurons in layer II of the entorhinal cortex using stereologic tools in a series of 18 postmortem brain specimens of common chimpanzees ages 1 to more than 45 years. There was no apparent neuron loss in the oldest case relative to the younger ones, and no significant shrinkage of mean neuronal volume related to age was detected (Erwin *et al*., 1999; Hof *et al*., 1999) (Figs. 29.3, see color insert, and 29.4). These data are similar to those from rhesus macaques (Peters *et al*., 1996, 1998; Gazzaley *et al*., 1997; O'Donnell *et al*., 1999; Hof *et al*., 2000). They also resemble the pattern seen in brains from healthy elderly humans, in which degenerative disorders are not present—but they do not resemble the results of studies of humans exhibiting neurodegenerative pathology. Additional studies are needed, including studies of the brains of older individuals with or without accompanying neuropathology. Perhaps chimpanzees are just not vulnerable to cell loss and loss of cell volume. If they are not, we must learn why, and find ways of using that knowledge to forestall the onset of neurodegenerative pathology in humans.

X. Senile Plaques and Neurofibrillary Tangles

Up to now, β-amyloid plaques have been found in the brains of elderly great apes (Gearing *et al*., 1994, 1997), but the neurofibrillary tangles typical of AD have not been reported for great apes. We know of only two reports of neurofibrillary tangles in nonhuman primates, one for an elderly rhesus macaque (Cork *et al*., 1989) and another, more recently, for elderly hamadryas baboons and guenons (Härtig *et al*., 2000; Schultz *et al*., 2000). These animals ages 26 and 30 years at the time of death, exhibited a combination of neuronal and glial cytoskeletal pathology that preferentially affected limbic areas such as the hippocampus and amygdala. In the hippocampus of the older animal, numerous tau-immunoreactive inclusions were seen in the granule cells of the dentate gyrus. The granule cells even displayed argyrophilic neurofibrillary tangles. The cytoskeletal changes of glial cells, previously unreported in nonhuman primates, affected both astrocytes and oligodendrocytes. The occurrence of neurofibrillary tangles in a nonhuman primate suggests that vulnerability extends beyond humans.

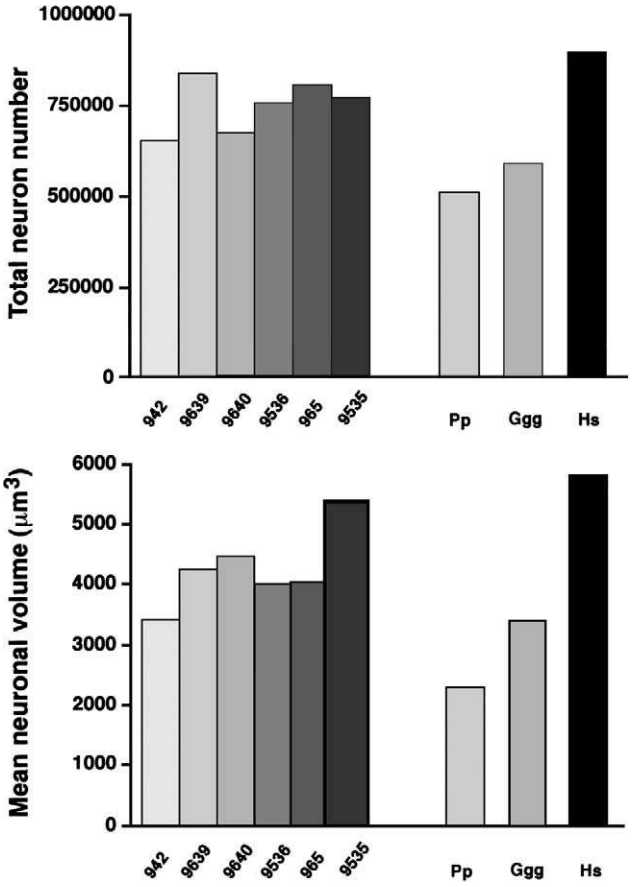

FIG. 29.4. Quantitative analysis of the total number of neurons (top) and mean neuronal volume (bottom) in layer II of the entorhinal cortex in a series of six chimpanzees (13–45 years old, see bars at left on each graph) and, for comparison, in a 13-year-old orangutan (Pp), a 34-year-old gorilla (Ggg), and an 81-year-old normal human (Hs). There are no age-related differences among the chimpanzees for these parameters. Overall, it appears that the orangutan and the gorilla have smaller and fewer layer II neurons than *Pan* and *Homo*.

XI. Unique Neurons in Anterior Cingulate Cortex

The cerebral cortex is reduced in volume in the brain of elderly victims of AD and this is associated with neural cell loss (for reviews, see Morrison and Hof, 1997; Willott, 1999). Large pyramidal cells in the frontal, parietal, and temporal lobes are among the most vulnerable neurons, and the death of these cells certainly disrupts cognitive function. Cells in various cortical layers are differentially affected. For example, layers I and V in the entorhinal cortex have the greatest concentrations of neurofibrillary tangles. The cingulate cortex is also vulnerable to cell loss in AD. Nimchinsky *et al*. (1995) found that the abundance of a large spindle neuron located in layer Vb of the anterior cingulate cortex (subareas 24a and 24b, following the nomenclature of Vogt *et al*., 1995) was reduced by about 60% in the brains of AD victims relative to that seen in normal controls. These neurons are characterized by a very elongate, gradually tapering, large-sized soma that is virtually symmetrical about its vertical and horizontal axes, as well as a light staining pattern with Nissl stain (Fig. 29.5A, see color insert). The first description of this type of neuron was by Betz (1881), and it had been documented a few times prior to the discovery of its vulnerability in AD. Unlike most other cell types in the neocortex, spindle neurons seemed to be uniquely human. They were not present, for example, in the anterior cingulate cortex of rhesus macaques. A literature review revealed a single report of this cell type in a chimpanzee (Rose, 1927). Nimchinsky *et al*. (1999) assembled anterior cingulate cortex specimens from 28 primate species, ranging from mouse lemurs to humans, including specimens from great apes. None of the prosimian, New World monkey, Old World monkey, or gibbon specimens yielded any spindle cells. The spindle cells were sparse, but were clearly present in the orangutan specimens. They were more abundant in gorilla, and even more so in common chimpanzee (Fig. 29.5B, see color insert). In the bonobo, spindle cells were not only abundant, but were clustered in a manner very similar to that seen in humans. Spindle cell volumes were estimated from measures of samples from each individual specimen. Those from humans were more than twice as large as those from chimpanzees and bonobos, while those for orangutans and gorillas were smaller yet. The functions of these spindle cells are not yet known for certain, so we do not know what the functional implications of differential cell volume might be. Spindle neurons are not the only cell type affected in AD, nor is AD neuron loss confined to the anterior cingulate cortex, but this region of the brain clearly is involved in attention, memory, emotionality, vocalization, and other functions, including visual self-recognition. A second neuron type, an intermediate size pyramidal cell that contains the calcium-binding protein calretinin, has now been discovered in the same region. The prospect that the presence of these cell types might be involved in phenomena such as self-recognition is intriguing. The anterior cingulate cortex is connected with the hippocampus and amygdala and the neocortex. Disruption of such circuitry would surely have dramatic consequences, possibly including some of the memory and visual recognition disorders, as well as autonomic and language deficits that accompany AD.

Age-related loss of spindle cells in great apes has not yet been documented—nor has any evidence of AD beyond deposition of β-amyloid been found in great apes. The brains thus far examined, however, have all been from individual great apes who had not been reported to show signs of dementia. The Great Ape Aging Project currently is obtaining behavioral profiles, cognitive assessments, and videographic documentation of motor behavior of elderly great apes in zoos and research institutes. These data in addition to clinical records and caretaker reports will be used to identify individual great apes who may exhibit some impairment. Following natural death, neuropathology assessments are conducted to identify neurodegeneration if it exists.

XII. The Future of Ape Research

The role of zoos is tremendous in caring for great apes and participating in cooperative projects such as the Great Ape Aging Project. All the orangutans and gorillas and most of

the bonobos involved in the project reside in zoological gardens. The vast majority of captive common chimpanzees live in research facilities—more than 1600 of them (Fig. 29.2). Many of these, especially the older ones, have been designated as "surplus to research needs." In the year 2000, there were more than 200 chimpanzees over 35 years of age. A small number of the oldest ones were provided with full or partial support from the Great Ape Aging Project with some funding from the National Institute on Aging. We are hopeful that more of these individuals will be supported in comfortable circumstances for noninvasive studies of aging. The maximum life span of chimpanzees is above 60 years, and other great apes have lived into their 50s. They are susceptible to many of the same age-related diseases and disorders as are humans, including arthritis, osteoporosis, diabetes, benign prostate hypertrophy, and cardiovascular disease. Further study, especially of elderly individuals may also reveal instances of cancer, Parkinson's disease, and AD. Genetic risk factors for humans and the great apes can be compared and basic studies of neurochemistry and neurogenetics may be compared between humans and our nearest biological kin. We should learn what we can from worms, fruit flies, zebrafish, and mice, and we should continue the precise and productive experimental neuroscience research with nonhuman primates such as rhesus macaques; but we also have an obligation and an opportunity to continue learning from the great apes in ways that contribute to their well being and our own.

Acknowledgments

We thank Dr. N. Kheck and P. Lee, C. Sherwood, M. Deftereos, and A. P. Leonard for helpful assistance. This work was supported by NIH Grants AG05138 and AG14308 and by the Mount Sinai School of Medicine.

Neurobiological Models of Aging in the Dog and Other Vertebrate Species

The rodent and nonhuman primate are not the only species to develop neuropathologic lesions similar to those seen in the aged human brain. Dogs and cats develop diffuse senile plaques with age, but do not show neurofibrillary tangle formation. The goat, sheep, bear, and wolverine, by contrast, are reported to develop neurofibrillary-like lesions but, in the first two cases, not senile plaques. The only one of these six species that has been extensively studied, however, is the dog, and the neurobiology of aging in canines is therefore the main focus of this chapter. Dogs exhibit extensive individual variability in the aging process on measures of learning and memory and in extent of β-amyloid (Aβ) deposition in the brain. Dogs, like humans, also show variability in cognitive aging. Some dogs develop severe cognitive impairment; these same dogs develop extensive Aβ deposition. Other dogs remain cognitively intact, and also show little or only moderate Aβ deposition. These findings suggest that dogs can be used to model the earliest phases of cognitive and neuroanatomical changes associated with pathological aging in humans. In addition, the existence of aged dogs that can learn and remember as well as younger dogs may also offer us insight into promoting successful aging in humans.

I. Introduction

Previous chapters in this volume have discussed the behavior and anatomy of the aging rat and the nonhuman primate. The present chapter will discuss the functional neurobiology of aging in other vertebrate species (excluding nonhuman primates, see Chapters 26–29). Our primary emphasis will be on the dog, but we will also include descriptions of the sheep, goat, bear, wolverine, and cat. Both dogs and cats are appropriate models for the study of aging in humans since they share many of the same age-related diseases such as arthritis, cardiovascular disease, cancer, bone loss, hypertension, and atherosclerosis (Committee on Animal Models for Research on Aging, 1981). As this chapter will also discuss, many of these other vertebrate species develop some of the hallmark lesions of both normal and pathological aging in the human brain.

Companion animals, such as the dog and the cat, provide two unique advantages as aging models. First, they inhabit environments similar to those of their owners, which may provide a unique opportunity to evaluate the effects of environmental variables on the aging process. Second, the possibility for analysis of genetic contributions to both brain and cognitive aging can be studied by taking advantage of the presence of different breeds of dogs and cats and studying littermates (Russell *et al*., 1992; Bobik *et al*., 1994).

Our underlying strategy for studying aging in the dog is to use a clinical-neuropathology approach in which we first give dogs a battery of tasks in an effort to test the function of several cognitive domains such as spatial attention or learning. In using this approach we have modeled our evaluation of the cognitive function of dogs after that with humans where both global and then more specific tests such as those for memory, learning, and visuospatial skills are administered. We combine cognitive evaluations of our dogs with extensive analyses of neuropathology in an effort to determine whether it is possible to detect various forms of pathology in the brain on the basis of behavior.

II. Cognitive Function and Aging in the Dog

Cognitive aging in humans is a complex process. Cognitive deterioration does not occur uniformly; some cognitive abilities show age-related decline, whereas others remain relatively intact. Striking individual differences are more likely the rule than the exception; some individuals show little decline (successful agers), some show mild decline (age-associated memory impairment), and yet others of the same age may develop dementia. As we will discuss in more detail later in the chapter, the same pattern of individual differences in aging occurs in dogs, with some showing evidence of successful aging, others showing relatively mild impairments, and still others showing severe impairment corresponding, perhaps, to a global dementia. Also, we have evidence that learning pro-

cesses and memory processes are dissociable in dogs, and we believe that age-associated learning impairments can occur independently of age-related memory impairments and vice versa.

A. Dogs Show Age-Related Learning Impairments That Are Task-Dependent

This section will describe age effects in dogs on tests of simple procedural learning tasks, associative learning problems, and more complex rule-learning problems.

1. Age and Previous Experience Play a Role in Procedural Learning

Procedural learning tasks are those that reflect a form of skill learning such as learning to ride a bike. In dogs, procedural learning is used to describe tasks given to teach the skills necessary to work in the testing apparatus. We have developed standardized procedures for the initial training of dogs in the Toronto General Test Apparatus, which is a modified form of the Wisconsin General Test Apparatus used to test cognitive function in nonhuman primates (Milgram *et al*., 1994). After training dogs to expect a food reward, the dogs are then tested on a procedure called reward approach learning. In this task, animals are rewarded if they respond to the sight of food. After learning this, the dogs are then trained on object approach learning, which is intended to teach dogs the skills to manipulate objects by pushing them away from a food well to reveal the reward. The first task appears trivial, but that does not seem to be the case for many of our dogs. Learning these types of skills appears to depend on both the age of the dog and potentially previous experience. For example, aged random-source dogs that were formerly companion animals learned these skills as quickly as younger random-source dogs (Milgram *et al*., 1994; Head *et al*., 1998). On the other hand, kennel-reared beagle dogs showed evidence of slower learning on these same tasks.

2. Associative Learning: Simple and Complex Discriminations Have Differential Age Sensitivities

Associative learning tasks involve the establishment of a link between two events as a consequence of repeated pairing of those events. Discrimination learning is one example of an associative learning task in which an animal is required to establish an association between a particular stimulus and delivery of a reward, while another stimulus is not associated with a reward. Dogs readily acquire simple discrimination learning problems, such as a visually based object discrimination task where the two stimuli are different objects (Milgram *et al*., 1994).

We have also looked at more complex types of discrimination tasks. These tasks include a size discrimination task (where the objects are identical in all respects except for size), a double discrimination task (two pairs of objects are used in alternating trials), concurrent discrimination learning (10 pairs of objects presented once per day), and olfactory discrimination learning (where the objects are associated with different odors) (Head *et al*., 1996, 1998).

Discrimination learning, in other animal models, is typically insensitive to age, except when the discrimination is difficult (Bartus *et al*., 1979; Arnsten and Goldman-Rakic, 1985; Moss *et al*., 1988; Markowska *et al*., 1989; Rapp, 1990; Baxter and Gallagher, 1996). We have obtained similar findings in dogs. We typically find no difference between old and young dogs on a simple object discrimination task. We do, however, find greater variability among old animals. This is probably because some aged dogs show a global impairment on all tests of cognitive function, and this can also include impairments on simple discrimination problems.

The individual variability in discrimination learning tasks, in general, may be a consequence of existing object preferences. We tested this hypothesis directly by determining object preferences prior to training on a simple object discrimination learning task. Assigning a preferred object as a positive stimulus to aged dogs actually conferred an advantage over that of young dogs, resulting in a trend toward lower error scores. On the other hand, aged dogs assigned a nonpreferred object performed more poorly than young dogs. Thus, existing object preferences lead to higher or lower error scores on a visual discrimination task, which is particularly true for older dogs (Head *et al*., 1998).

One possible explanation for this effect is increased perseverative responding in aged dogs, which is likely dependent upon frontal lobe function (Brush *et al*., 1961; Mishkin *et al*., 1964). In fact, as will be discussed later in the chapter, visual discrimination learning using a nonpreferred object is indeed sensitive to prefrontal cortex neuropathology (Head *et al*., 1998). This may also be the reason for olfactory discrimination impairments in aged dogs; although detection thresholds were similar in young and old dogs, an olfactory task is sensitive to orbitoventral frontal lobe dysfunction (Allen, 1939, 1943).

3. Complex Rule Learning Tasks Reveal Three Groups of Aged Dogs: Successful Agers, Impaired, and Severely Impaired

More complex learning tasks are also age-sensitive in dogs and other animals. These include both complex discrimination learning and tasks such as reversal learning, requiring both the inhibition of an existing response and the acquisition of a new response. In addition, the acquisition of a new association appears to be age-sensitive in dogs and other animals (Bartus *et al*., 1979; Milgram *et al*., 1994; Head *et al*., 1998) but see (Rapp, 1990; Rapp and Amaral, 1991). One hypothesis is that these more complex rule-learning tasks recruit several brain regions or a cortical circuit, leading to a greater chance of detecting brain dysfunction. For example, size discrimination learning requires the intact function of a ventral processing stream thought to underlie object identification (Mishkin, 1972; Felleman and van Essen, 1991; van Essen *et al*., 1992). This ventral processing stream consists of a circuit beginning with visual input from the primary visual cortex that is transfered to the striate cortex and then ventrally into the inferotemporal cortex. Reversal learning of an object discrimination task would also require this ventral processing stream in addition to the orbitoventral prefrontal cortex (Mishkin, 1964; Jones and Mishkin, 1972).

An object-recognition memory task, which is typically used in monkeys and has also been applied to dogs, tests the function of several components of the ventral processing stream

(Mishkin and Delacour, 1975; Milgram *et al*., 1994). The first component of this problem is teaching animals the nonmatching-to-sample rule necessary to perform the task. Dogs are first shown a single object covering a food reward in the center of a presentation tray. Following a brief delay period, dogs are presented with the previous object and a novel object each covering the left and right food wells. The correct response is for dogs to select the novel object. Our first study of object recognition memory acquisition in dogs suggested that old dogs were impaired relative to young dogs, which was consistent with impairments found in aged monkeys (Moss *et al*., 1988; Rapp and Amaral, 1989, 1991; Milgram *et al*., 1994). The most notable observation was that the task was extremely difficult, and only a small proportion of the subjects was able to meet a very weak learning criterion. We have subsequently discovered that dogs are capable of excellent performance on this task if we take into consideration that the dogs' visual near point is between 25 and 30 cm (Callahan *et al*., in press).

Whereas object recognition memory is thought to rely upon the ventral processing stream, another form of complex rule learning problem, spatial learning, is thought to depend on a dorsal processing stream (Mishkin, 1972; Felleman and van Essen, 1991; van Essen *et al*., 1992). The dorsal stream includes the visual cortex, the posterior parietal cortex and the dorsolateral prefrontal cortex. We can test dogs for their ability to learn a spatial nonmatching-to-sample rule using a similar procedure as that described for object recognition memory training. Dogs are first shown an object covering a food reward on either the left or right side of the presentation tray. After a brief delay interval, dogs are offered a choice between selecting two identical objects, one each covering both the left and right food wells. The correct response is to select the object on the side opposite to that seen previously. When testing dogs with a spatial memory task, delayed nonmatching to position, consistent age effects, has been found (Head *et al*., 1995; Adams *et al*., 2000). The results of these studies indicate that aged dogs are impaired when learning the nonmatching-to-position rule. More importantly, it is possible to differentiate three groups of aged dogs on the basis of spatial learning, that some old dogs obtain scores similar or better than young dogs (unimpaired), some obtain scores that are poorer (impaired), and others obtained scores that are impaired relative to other old dogs (severely impaired) (Fig. 30.1)

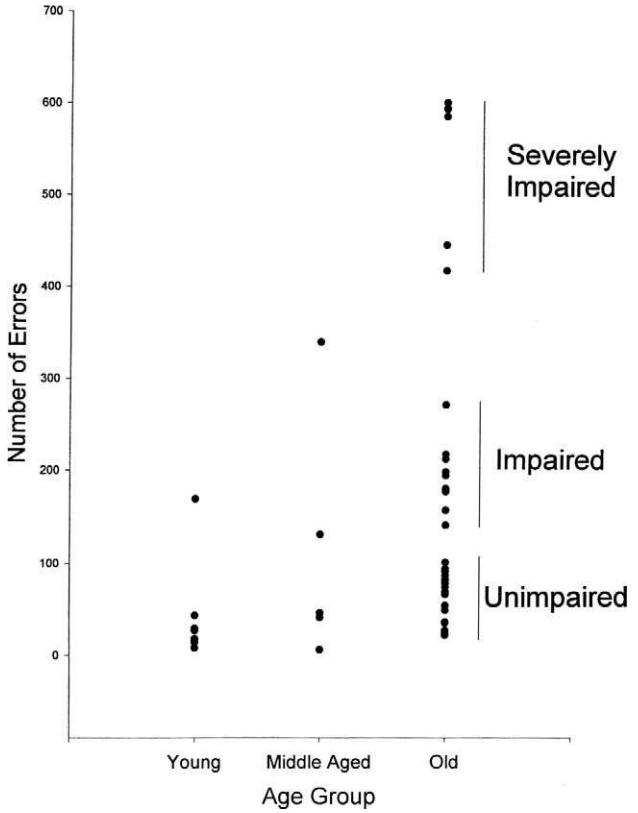

FIG. 30.1. Spatial learning as a function of age in dogs reveals that old dogs can be characterized as belonging to one of three groups: unimpaired (scores fall within the range of young dogs' scores), impaired (scores fall outside of those obtained by young dogs), and severely impaired (at least one standard deviation outside the average of the old dogs).

B. Memory Tasks Reveal Striking Differences in Young and Old Dogs

In humans, memory impairment is one of the most important criteria for diagnosing dementia associated with neurodegenerative disorders such as Alzheimer's disease. We have two protocols for studying memory in the dog. One involves measuring accuracy of responses as a function of increasing memory demands (working memory) and the second involves progressively increasing the memory demand until a dog fails a task (maximal memory). These are dissociable from deficits in learning ability, as will be shown shortly.

As discussed in the previous section, spatial learning ability is compromised in a subset of aged dogs. However, some old dogs can learn the rules of the task as adequately or as rapidly as younger dogs but then go on to have difficulty when the memory demands are increased. We have developed two different protocols for studying the effect of memory demands on spatial abilities. The first uses a variable delay paradigm in which the interval between the initial presentation of an object on the left or right side of the presentation tray and the choice presentation is set at either 20, 70, or 110 sec. Typically, all dogs show a decline in accuracy scores with increasing memory demands, which can be plotted as a "memory curve." We typically see much more variation in old dogs on this task than we do in young dogs. The large majority of young dogs show a very small performance decrement with increasing delays. This is also true of some old dogs. Others, by contrast, show a marked decrement (Head *et al*., 1995). This age-dependent memory impairment is not necessarily associated with an impairment in learning the rules of the task. Thus, dogs can show dissociable age effects in spatial learning and in memory; one old dog may be impaired in learning a task, but once acquired can remember information as long as younger dogs. The opposite can also occur, where an aged dog can learn the task as quickly as a younger dog but cannot attain the same accuracy as the memory demands are increased.

The second protocol involves progressively increasing the delay interval over which dogs must remember information in a stepwise procedure (Adams *et al*., 2000). Prior to advancing to a longer delay interval, and thus higher memory

demand, dogs are required to reach a criterion level of responding. Dogs are tested until they fail to reach criterion in a set number of test sessions. It is this delay interval where dogs can no longer reach a criterion level of accuracy that we call the maximal memory capacity. Young dogs can typically solve the spatial memory task with delays ranging up to 210 sec. Old dogs have a shorter spatial memory capacity and on average can reach delays of only 50 sec.

C. Individual Variability in Learning and Memory Is a Consistent Feature of Aging in Dogs

Aged dogs are not globally deficient across all cognitive tasks and not all old dogs are impaired. Some of the individual variability in aged dogs may be related to factors such as breed differences, previous experience, reproductive status, and selection biases. Our preliminary cognitive studies in dogs included two populations: random source pound dogs and kennel-reared beagle dogs. Although young dogs from both populations learned the cognitive tasks with a similar number of errors and trials, aged dogs showed some very interesting differences, suggesting a possible age by source interaction. In some tasks, aged random source dogs were deficient and in others they performed with fewer errors than both young and old beagle dogs. Some of the variability may be a result of differences in previous experience. For example, aged kennel-reared beagle dogs were poor at learning procedural-type tasks, whereas old random-source dogs learned as well as younger dogs; this may be due to the lack of experience of beagle dogs and thus these tasks are a form of new learning.

D. Clinical Indices of Cognitive Dysfunction in Pet Dogs

As in humans, tests of neuropsychological function can yield results that are quite different from tests of daily function. A similar phenomenon occurs in dogs. Pet dogs are evaluated in a clinic and global indices of behavioral dysfunction in dogs indicate a number of age-related deficits. In a survey of 26 pet dogs owners with dogs greater than or equal to 10 years of age the most common complaints were destructive behavior in the house, inappropriate urination or defecation, and excessive vocalization. In some cases, pet owners noticed an increase in separation anxiety characterized as an increase in vocalization when the owner is absent (Ruehl *et al*., 1995). These behavioral symptoms are observed in dogs that were normal when younger and the existence of other medical conditions to account for abnormal behavior have been eliminated (Chapman and Voith, 1990). In fact, one sign of canine cognitive dysfunction frequently used by veterinarians is the existence of urinary incontinence, which typically results in the pet owner's decision to euthanize their pet (Mosier, 1988).

III. Neuropathology in Aging Dogs

The pattern of intact and impaired learning and memory abilities in aging dogs suggests a selective age-associated vulnerability in specific brain circuits. Whereas the first goal of our work is to characterize cognitive changes as a function of age, the second major goal of our development of the canine model of human aging is to characterize the pattern of underlying brain pathology. This section will describe candidate pathologies including neuronal loss, the deposition of β-amyloid (Aβ) in the form of diffuse senile plaques, and pretangle formation in aged dogs.

A. Aged Dogs Show Evidence of Neuron Loss and Dysfunction

The issue of the occurrence of neuronal loss during normal aging has been controversial (Coleman and Flood, 1987; Flood and Coleman, 1988). Neuron loss in the human brain was thought to be a consistent feature of aging as measured by decreased brain weight at death, cortical atrophy, and increased ventricular volume both at autopsy and during magnetic resonance image (MRI) scans (Katzman and Terry, 1992). One reasonable explanation for the loss of brain tissue is the loss of neurons and recent evidence provided by unbiased stereological cell counting techniques seems to suggest significant cell number losses in the subiculum and hilus of the dentate gyrus of the hippocampus, but not area CA1, with age (West, 1993). In this respect, normal aging contrasts with a dramatic loss of area CA1 neurons in the hippocampus of Alzheimer's disease brain (West *et al*., 1994). Stereological studies to detect cell loss in the aged dog brain have not been conducted; however, there are reports of selective neuron loss in layers III and V of the prefrontal, temporal, and occipital cortex along with the claustrum (Wisniewski *et al*., 1970; Morys *et al*., 1994). More recent evidence of cortical atrophy was found in an MRI experiment examining changes in cortical volume with age in a group of beagle dogs ranging in age from 4.5 to 15.3 years (Su *et al*., 1998). After the age of 10 years, the size of the lateral ventricles increased exponentially until the age of 15 years (Fig. 30.2). These data suggest the need for controlled, unbiased sampling stereological techniques for neuron counts in aged dog brains.

A number of other morphological hallmarks of dysfunction in aging neurons can be seen in the dog brain. Neurons in the prefrontal cortex of aged dogs (13–18 years) show distorted soma, loss of dendritic spines and shrinkage of dendritic branches, tortuous apical dendrites (Mervis, 1978). Similar changes have also been reported in hippocampal neurons of the human brain (Scheibel *et al*., 1975, 1976, 1977; Mervis, 1978). These changes may also be reflected as a loss of synapses as has been demonstrated in the Alzheimer's disease brain (Terry *et al*., 1991), but a similar study has yet to be conducted in aged canine brain tissue. This is an area that requires further research since synaptic loss is more likely to correlate with cognitive dysfunction than gross structural changes *per se*.

Another potential indicator of neuron dysfunction is the presence of DNA damage. As with aging human and Alzheimer's disease brain, aged dogs show an increase in the extent of neurons with damaged DNA (Anderson *et al*., 1996; Cotman and Su, 1996; Kiatipattanasakul *et al*., 1996). The study by Kiatipattanasakul and colleagues (1996) did not find any significant correlation between DNA damage and the extent of Aβ deposition nor were apoptotic bodies observed. Anderson *et al*. (1997), on the other hand, did find a significant correlation between DNA and Aβ deposition. We have observed apoptotic bodies

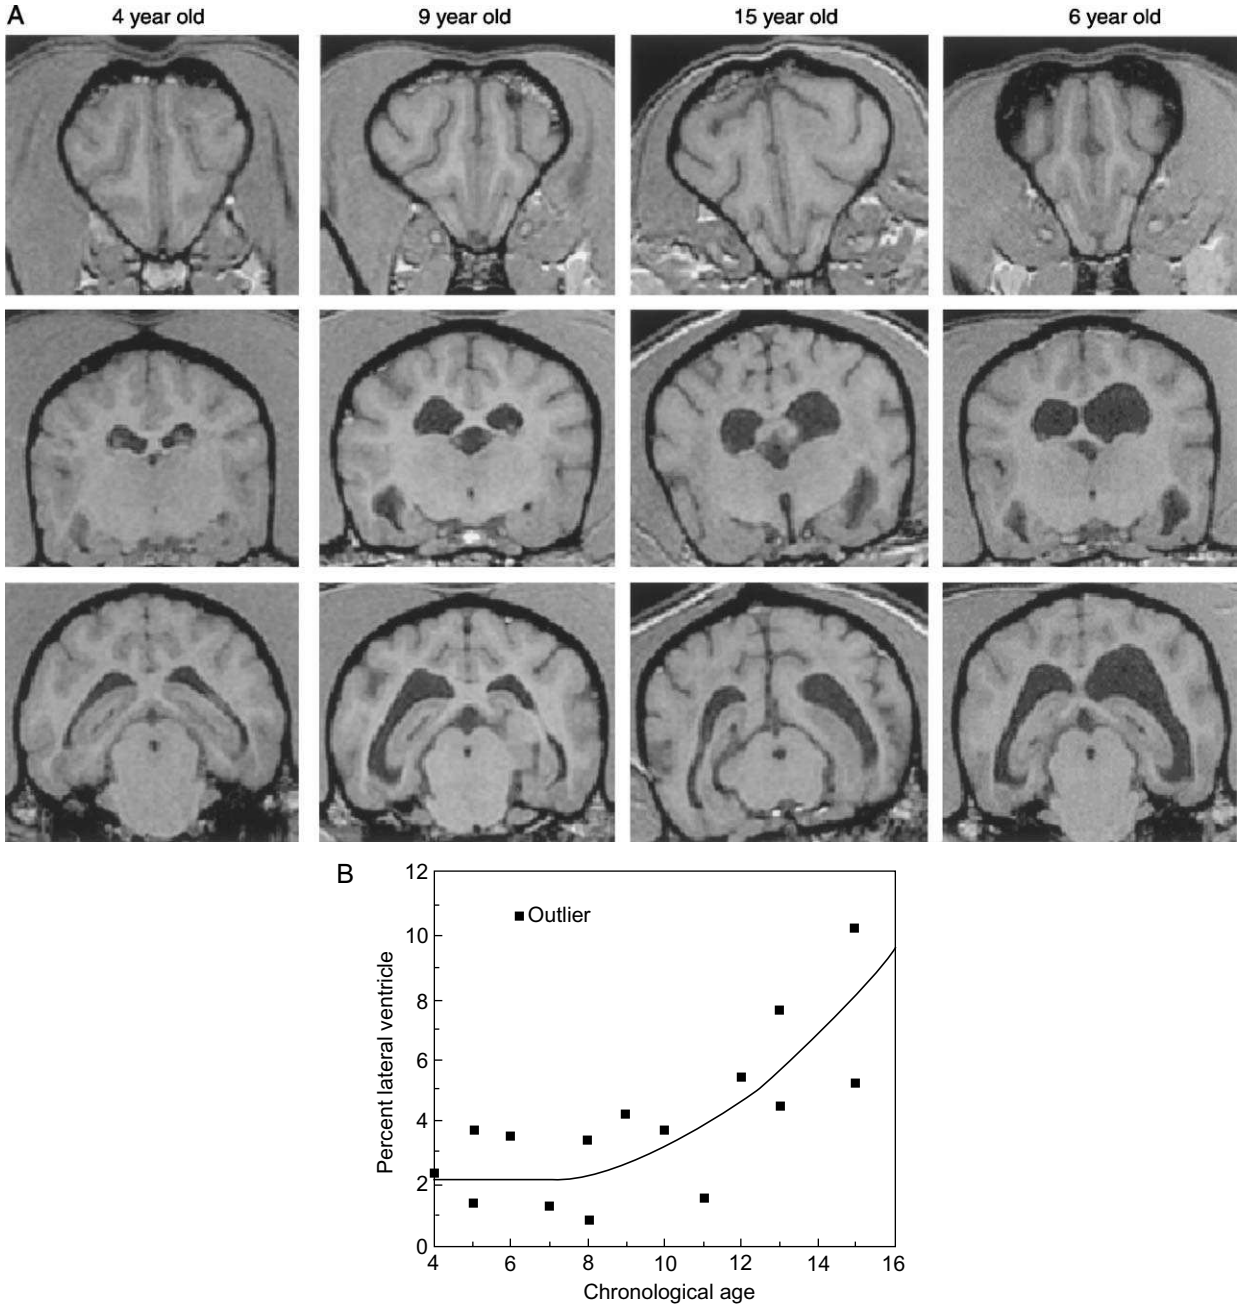

FIG. 30.2. (A) T2-weighted anatomical images obtained from a group of beagle dogs with representative samples from a 4-, a 9-, a 15-year-old dog. Note the age-associated increase in ventricular volume and cortical atrophy. The images on the far right are from a 6-year-old female beagle that showed premature Aβ deposition. (B) Graph illustrating that ventricular volume increases with age in an exponential function with volumes increasing dramatically after 11 years of age. Reprinted from Su *et al*. (1998), with permission from Elsevier Science.

in at least one aged beagle dog that had extensive Aβ deposition and was cognitively impaired (Fig. 30.3, see color insert).

B. β-Amyloid Deposition Is a Consistent Feature of Aging in Dogs

One of the hallmarks of pathology in the human brain is the formation of senile plaques in several cortical and subcortical brain regions. Aβ, the principal component of senile plaques, is a hydrophobic 39- to 43-amino-acid peptide that can adopt a β-pleated sheet configuration. Aβ is derived from the proteolytic processing of a longer amyloid precursor protein (APP), a member of a large family of 70 kDa transmembrane glycoproteins derived from alternative splicing of precursor mRNA (Kang *et al*., 1987; Price *et al*., 1991; Selkoe, 1994, 1996). The sequence of the APP is identical in dogs and humans (Johnstone *et al*., 1991). In addition, there are several cleavage products of APP but dogs deposit predominantly the longer

42/43-amino-acid-long peptide rather than the shorter 39/40 protein (Cummings *et al*., 1996b; Wegiel *et al*., 1996; Wisniewski *et al*., 1996; Nakamura *et al*., 1997). There are many features of Aβ deposits in the dog brain that parallel those seen in human brain, including similar morphology, extent of deposition with age, the pattern of deposition, the types of proteins associated with these deposits, and association with blood vessels.

The morphology of Aβ deposits in aged dog brain is that of a diffuse subtype (Fig. 30.4, see color insert). These plaques are not stained by thioflavin S and therefore probably lack β-pleated sheet formation (Cummings *et al*., 1993). These diffuse deposits appear to contain intact neurons, which are also seen in the brains of individuals with Down syndrome and in normal elderly human brain (Fig. 30.4). The extent of Aβ deposition in the dog brain does not appear to vary significantly with age in studies where a number of different breeds of dogs are included in the sample (Wegiel *et al*., 1996; Yoshino *et al*., 1996). However, in studies where a single breed of dog is used with a broad range of ages, the correlation between extent of Aβ and age at death is significant (Cummings *et al*., 1993; Cummings *et al*., 1996b; Russell *et al*., 1996; Head *et al*., 1998). The lack of an age association most likely reflects the fact that a heterogenous population of dogs was used and there is evidence of breed differences in the rate and age of onset of Aβ deposition in dogs (Bobik *et al*., 1994). Breed differences may also be a consequence of differential aging rates in large breeds of dogs as compared to smaller breeds where typically the former have a shorter life span. Thus, making the assumption that a 10-year-old larger breed of dog is the same ''biological age'' as a smaller breed may not be entirely valid and emphasizes the importance of controlling for variability due to breed.

Although Aβ deposition in the dog brain increases with age, as with human aging, not all old dogs are affected to the same extent. Another factor that contributes to the individual variability in Aβ deposition is dependent upon the brain region sampled. The pattern of deposition of Aβ as a function of age in dogs is similar to that of humans in terms of regional vulnerabilities (Braak *et al*., 1993; Head *et al*., 1998, 2000). The earliest and most consistent site of Aβ deposition is in the prefrontal cortex, with the development of senile plaques in the parietal and occipital lobe at a later age. In the entorhinal cortex, early deposition of Aβ is seen only in a subset of aged dogs. Within individual cortical layers, Aβ is first deposited in deep layers adjacent to white matter and these clouds appear to coalesce into more compact deposits, later appearing in more superficial layers with increasing age (Satou *et al*., 1997). Unlike humans with AD, diffuse plaques are rarely, if ever, seen in the molecular layer (layer I) of cortex in the dog (Fig. 30.4).

Aβ deposition in the canine also varies within brain structures. In the hippocampus, a cloud of diffuse deposition has been consistently found in the outer molecular layer (Cummings *et al*., 1993; Osmand and Switzer, 1992). This is the terminal field of the perforant pathway, which are the axons and terminals of layer II entorhinal neurons (Steward, 1976; Steward and Scoville, 1976). Diffuse deposition in this brain region strongly suggests a neuronal origin for Aβ; deposition can occur as a result of aberrant processing of APP within neurite terminals (Koo *et al*., 1990). In addition, more recent reports show that entorhinal cortex lesions given to PDAPP transgenic mice lead to a loss of Aβ deposition in the outer molecular layer (Chen *et al*., 1998).

Several proteins coexist within senile plaques in the dog brain that may play a role in the formation of these lesions. The sequence of APP, for example, contains domains that are homologous to Kunitz-type serine protease inhibitors (Kitaguchi *et al*., 1988; Ponte *et al*., 1988; Tanzi *et al*., 1988). APP is deposited in swollen neurites in senile plaques of both aged dog and human brain (Catteruccia *et al*., 1990; Younkin, 1991; Okuda *et al*., 1994). This is in addition to the presence of other factors that are associated with senile plaques in the aged dog brain, which are listed in Table 30.1.

Aged dogs also develop Aβ angiopathy, which has been reviewed in more detail elsewhere (Walker, 1997). Aβ angiopathy in the dog consists of both the longer and the shorter Aβ species as reported in Alzheimer's disease brain and in cats (Cummings *et al*., 1996b). We have also noticed that the occipital lobes of aged dogs are particularly vulnerable to this form of pathology, which is also the case in the human brain (Katzman and Terry, 1992). Aβ angiopathy in the dog brain is also associated with intense ApoE immunoreactivity (Uchida *et al*., 1997), which is interesting in light of the fact that ApoE is a risk factor associated with Alzheimer's disease in humans (Saunders *et al*., 1993).

C. Aged Dogs Do Not Develop Neurofibrillary Tangles

Neurofibrillary tangles consist of abnormally phosphorylated tau proteins, which, in their normal state, bind to microtubules and stabilize them to form a functioning cytoskeleton in neurons (Goedert, 1993; Trojanowski *et al*., 1993a,b;

Tucker, 1990). In the human literature, several studies demonstrate a relationship between cognitive status and the extent of neurofibrillary degeneration in aging human brain and in Alzheimer's disease (Dayan, 1970b; Alafuzoff *et al*., 1987; Braak and Braak, 1991, 1995; Dickson *et al*., 1995; Dournaud *et al*., 1995; Langui *et al*., 1995; Duyckaerts *et al*., 1997). One of the drawbacks to almost all animal models studied to date, except possibly the bear, wolverine, goat, and sheep (to be discussed at the end of the chapter) and in the mouse lemur (see Chapter 27), is the lack of spontaneously occurring neurofibrillary tangle formation with age. Dogs do not develop full-blown tangles (Ball *et al*., 1983; Selkoe *et al*., 1987; Giaccone *et al*., 1990; Wisniewski *et al*., 1990; Cummings *et al*., 1993). Although aged dogs do not develop full-blown neurofibrillary tangles, several reports suggest the development of early tangle formation (Ball *et al*., 1983; Selkoe *et al*., 1987; Giaccone *et al*., 1990; Wisniewski *et al*., 1990; Cummings *et al*., 1993). Another study reported neurofibrillary targles in dogs but the morphology of these were not identical to those seen in human brain at the ultrastructural level of analysis (Fisher *et al*., 1986). Our studies of aging dog brain have used the marker for early neurofibrillary tangles, AT8, and our preliminary data indicate that middle-aged dogs, but not old dogs, appear to have hyperphosphorylated tau in select populations of neurons (Fig. 30.5, see color insert). These never appear to progress to full neurofibrillary tangles.

One possible explanation for a lack of neurofibrillary tangle formation in aged dog brain is that the tau protein itself is different from the human tau protein. A preliminary RT-PCR analysis certainly suggests isoform differences from human tau with apparent excesses in four repeat sequences, which is similar to transgenic mice that also do not develop neurofibrillary tangles despite extensive Aβ deposition (M. Hutton, personal communication).

IV. Functional Neurobiology of Aging in the Dog

Can we account for the selectivity in age-associated cognitive dysfunction by selectivity in the development of neuropathology? As discussed previously, not all aged dogs are cognitively impaired, and chronological age is not the best predictor of cognitive status, which parallels human aging (Rowe and Kahn, 1987; Albert and Funkenstein, 1992). There must be some other factor rather than age *per se* that can account for the variability in the aging process in dogs as it does in humans. To approach this question, the fact that not all old dogs are impaired, becomes a useful tool for identifying markers of neuropathology that can differentiate the two groups.

Our first study of the relationship between cognition and neuropathology examined the extent of Aβ deposition in a group of cognitively characterized dogs. A group of 29 dogs ranging in age from 1.6 to 12.3 years had been tested for reward and object approach learning, visual discrimination and reversal, and spatial and object recognition memory. The prefrontal cortex, hippocampus, and entorhinal cortex was examined for the extent of Aβ deposition using image analysis techniques. A discriminant analysis of the cognitive test scores indicated that two major clusters were present in the behavioral data, one that we termed procedural-type tasks (reward and object approach learning) and the second termed declarative-type tasks (visual discrimination, reversal, and memory tasks). The declarative-type tasks, but not the procedural-type tasks were strongly correlated with Aβ deposition in both the prefrontal and entorhinal cortices. In fact, up to 68.9% of the variability in cognitive test scores could be accounted for by the amount of Aβ deposition.

In a second study, a more detailed examination was made of 20 beagle dogs ranging in age from 4.5 to 15.3 years of age. In these dogs, we tested object and reward approach learning (which we previously established to be independent of Aβ deposition), object discrimination learning using either a preferred or a nonpreferred object, and size discrimination learning along with long-term retention. Based on the nonhuman primate literature, we predicted that some tasks would be sensitive to prefrontal lobe pathology (reversal learning, object discrimination learning with a nonpreferred object) and that others would be sensitive to temporal lobe function (size discrimination task). Dogs were first classified as being impaired or unimpaired based upon individual error scores obtained from the cognitive tasks listed previously. An impaired dog was defined as an animal that obtained an error score falling outside the range of error scores obtained by the young dogs. If dogs are separated on this basis then those old dogs that were impaired had higher amounts of Aβ deposition. In addition, as illustrated in Fig. 30.6, dogs with impairments in reversal learning and in object discrimination learning with a nonpreferred object accumulated significantly more Aβ in the prefrontal cortex than unimpaired dogs. This was also true for size discrimination and reward approach learning; impaired dogs had higher amounts of Aβ in the entorhinal cortex. Thus, it may be possible to predict the presence of Aβ deposition in specific brain regions based upon cognitive test scores (Head *et al*., 1998).

Significant associations between extent of Aβ pathology and cognitive dysfunction in the dog parallels that reported in humans (Blessed *et al*., 1968; Dayan 1970a; Wisniewski, 1979; Alafuzoff *et al*., 1987; Duyckaerts *et al*., 1990; Price *et al*., 1991; Cummings and Cotman, 1995; Dickson *et al*., 1995; Langui *et al*., 1995; Cummings *et al*., 1996c). The fact that not all old dogs are impaired is consistent with taking a random sample of old individuals: we would expect a mix of successfully aging individuals in addition to those suffering from some type of neurodegenerative disorder resulting in increasing individual variability with increasing age.

V. Aging Cats: Behavior and Neuropathology

Behavioral information on aging cats is primarily anecdotal. The most common behavioral problems noted in geriatric pet cats are related to secondary age-related diseases such as arthritis, cardiovascular or renal disease, and diabetes. In addition, sensory decline in visual and auditory ability occurs with age in cats (Harrison and Buchwald, 1982). Aged cats show a heightened sensitivity to changes in the environment, which can cause changes in eating or patterns of elimination or possibly even aggression (Houpt and Beaver, 1981). Other age-linked behavioral deficits include reduced classical condi-

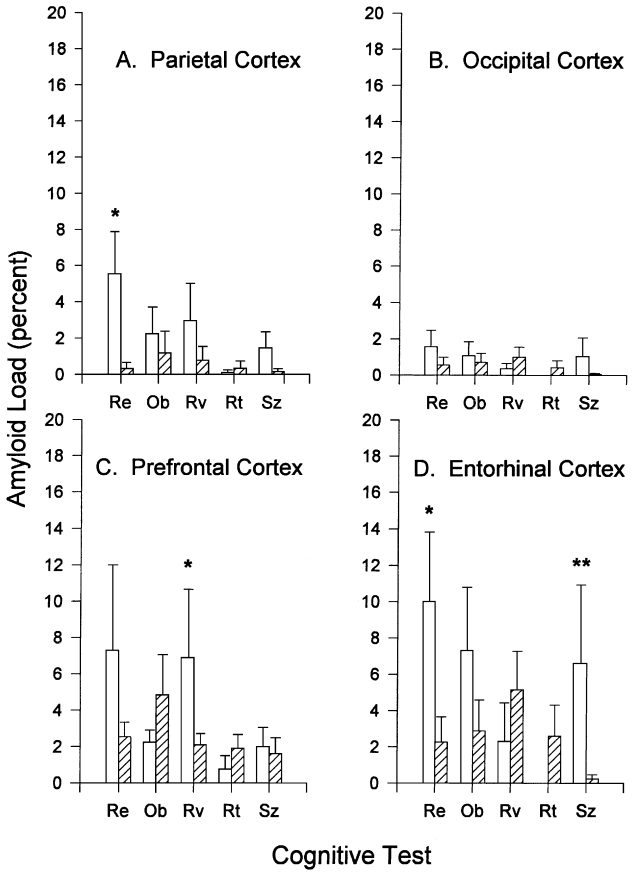

FIG. 30.6. The relationship between cognitive task, cognitive status, and Aβ accumulation is represented as a function of brain region: (A) parietal cortex, (B) occipital cortex, (C) prefrontal cortex, and (D) entorhinal cortex. Aged dogs were classified as being impaired or unimpaired for each behavioral task and the amount of Aβ present in each brain region was compared. Re, reward approach learning; Ob, object approach learning; Rv, reversal learning; Rt, retention testing; Sz, size discrimination learning. $^{*}p < 0.05$;$^{**}p < 0.075$. tioning and disturbances in patterns of habituation in tests of locomotor activity and auditory reactivity (Harrison and Buchwald 1983; Levine *et al.*, 1987). In the latter study, three groups of cats (1–3, 5–9, and 11–16 years of age) were tested for locomotor activity, fine motor coordination, reactivity to auditory stimuli, and spatial reversal learning. The rather surprising finding of improved spatial reversal learning in aged cats relative to younger cats may reflect previous experience variables—or poorer motivation in the young cats. The results of this study highlight a potential problem in working with cats, a difficulty in obtaining reliable behavior during the test situation. The authors suggest that these changes in behavior may be associated with caudate dysfunction since impairments in habituation are a symptom of caudate-lesioned cats (Villablanca *et al.*, 1978). On the other hand, the lack of spatial reversal impairments in aged cats suggest that caudate dysfunction does not contribute to the age-dependent cognitive dysfunction (Olmstead *et al.*, 1976).

Very few studies of the neuropathology of the aging cat exist. The presence of Aβ, the protein constituent of senile plaques has been observed in some studies and not others. Visualizing Aβ in the cat brain, as for the dog, is dependent upon the staining technique used. For example, in silver stains, no senile plaques have been found in cats up to the age of 17 years (Braak *et al.*, 1994). On the other hand, more sensitive immunohistochemical techniques consistently identify diffuse senile plaques in cats over 16 years (Cummings *et al.*, 1996b; Nakamura *et al.*, 1996; Kuroki *et al.*, 1997; E. Head, unpublished observations—Fig 30.4). In addition, the longer form of Aβ, 42 to 43 amino acids long, is found in diffuse senile plaques of aged cat brain, which is consistent with the dog and with human brain tissue (Cummings *et al.*, 1996b). No evidence for early tangle formation has been found in aged cat brain (Kuroki *et al.*, 1997).

The age range for the development of senile plaques (>16 years) suggests that very old cats would be the most appropriate for studies of age-dependent cognitive decline. The relationship between neuropathology and behavioral dysfunction has not been well explored in cats, however, in the Cummings *et al.* (1996b) study, the three aged cats with diffuse senile plaques were reported to be exhibiting abnormal behavior such as wandering, confusion, and inappropriate vocalization.

VI. Neuropathology of Aging Sheep, Goats, Bears, Wolverines, Camels, and Birds

In contrast with many other animal models of aging, goats, sheep, bears, and possibly wolverines are the few vertebrates where there are reports of naturally occurring neurofibrillary tangle-like formations but in the former two cases, a lack of senile plaque formation. Silver staining in aged goats and sheep up to 10 years of age was negative for Aβ (Braak *et al.*, 1994) and this was confirmed in a second study of sheep using immunohistochemical techniques (Nagata, 1997). On the other hand, there are several reports of neurofibrillary tangle-like formations in these two species (Braak *et al.*, 1994; Nelson *et al.*, 1994; Nagata, 1997). Antibodies against hyperphosphorylated tau (AT8, PHF-1, and Alz-50), a component of neurofibrillary tangles, reveal tangle-like structures in aged sheep (Braak *et al.*, 1994; Nelson *et al.*, 1994). A recent study has demonstrated the occurrence of tangle-like lesions in the brains of other large artiodactyls such as llamas and bison (Härtig *et al.*, 2000). However, another study, involving samples from sheep between the ages of 2 and 14 years was negative for neurofibrillary tangles (Kuroki *et al.*, 1997). In addition to sheep and goats, bears and wolverines may also exhibit neurofibrillary tangle-like structures (Cork *et al.*, 1988; Roertgen *et al.*, 1996; Härtig *et al.*, 2000). Reports of amyloid angiopathy in a 16-year-old woodpecker and senile plaques in a 20-year-old camel suggest that in fact, birds and many artiodactyls may also develop some of the characteristic lesions of human brain aging (Nakamura *et al.*, 1995; Nakayama *et al.*, 1999). To our knowledge no information is available regarding behavioral decline as a function of age in these animals.

VII. Summary

Both aged cats and dogs develop senile plaques in many brain regions that very likely have functional consequences.

In aged dogs, the relationship between the extent of Aβ deposition and the extent of cognitive dysfunction shows a strong association. However, we do not account for all behavioral dysfunction with Aβ accumulation alone, suggesting that other factors likely contribute. The potential role for environment, breed, previous experience, and genetics all highlight the utility of the dog as a model of human aging. In addition, particularly with respect to the dog, genetic contributions to both brain and cognitive aging can be studied by taking advantage of the presence of different breeds of dogs and studying littermates (Russell *et al*., 1992; Bobik *et al*., 1994). Our own studies have evaluated these factors to some degree but we are currently studying aging in a colony of beagle dogs that are extremely well-characterized clinically with health records maintained since birth. This colony of dogs is also unique in that all animals have been raised and maintained in the same environment, given the same diet and water, and housed with the same kennelmate for their entire lives. Thus, we are able to eliminate many potential variables that can confound experimental studies of aging.

Estrogens and Alzheimer's Disease

I. Introduction

Risk factors for the development of Alzheimer's disease (AD) include age, family history, low level of education, head trauma, and gender. Epidemiological studies indicate that AD afflicts women one-and-a-half to three times as frequently as men (Jorm *et al*., 1987; Aronson *et al*., 1990). The prevalence for AD in women remains higher even after adjusting for their longer life span compared to men (Gao *et al*., 1998).

The role of estrogens in the prevention and treatment of osteoporosis is well established (Riggs and Melton, 1992; Lindsay, 1993), and observational studies suggest a reduction of risk for coronary heart disease among women receiving postmenopausal hormone replacement therapy (Grondstein and Stampfer, 1998; Sites, 1998; Oparil, 1999). Investigators have also attempted to gather evidence of a possible effect of estrogens on cognition. Specifically, a presumed role of estrogen deficit in postmenopausal women is a subject of much study. In particular, basic science and clinical studies have suggested an association between estrogens and memory. In this chapter we will review the results from studies that have investigated the role of estrogen in cognition and AD.

II. Estrogen Effects on Cognition and AD

A convergence of evidence demonstrates that a central cholinergic deficiency plays an important role in AD (Bartus *et al*., 1982; Coyle *et al*., 1983). Cholinergic neurons projecting from the nucleus basalis of Meynert to the cortex, amygdala, and hippocampus are critically involved in the performance of learning and memory tasks in humans and animal models (Deutsch, 1971; Drachman and Leavitt, 1974; Fibiger, 1991; Ceyla, 1998). One of the more consistent neurobiological finding is the presence of aromatase (the enzyme that transforms testosterone to 17β-estradiol) and estrogen receptors in the basal forebrain (nucleus basalis of Meynert, septum nuclei, nucleus accumbens), limbic, paralimbic regions, and the gray matter (Terasawa and Timiras, 1968; McLusky *et al*., 1987; McEwen,1988; Loy *et al*., 1988; Toran-Allerand *et al*., 1992; McEwen *et al*., 1997). Experiments have demonstrated that gonadal hormones can affect the activity of both choline acetyltransferase (ChAT) (Luine *et al*., 1980; Luine, 1985; Kaufman *et al*., 1988) and acetylcholinesterase (AChE) (Iraman *et al*., 1980), enzymes involved in the synthesis and degradation of acetylcholine. Moreover, studies with ovariectomized rats have shown that estrogen affects acetylcholine release (Gibbs *et al*., 1997). Colocalization of estrogen receptors with nerve growth factors in cholinergic neurons of the basal forebrain (Toran-Allerand *et al*., 1992) opened a new area of interest regarding the possible importance of estrogen–neurotrophin interaction in neuronal viability (Gibbs, 1994; Singh *et al*., 1995; Mudd *et al*., 1998). Several lines of work have suggested that estrogens play a major role in synaptic formation during the perinatal period and in the plasticity of the adult brain (Matsumoto *et al*., 1985; Matsumoto, 1991; Chung *et al*., 1988; Gould *et al*., 1990; Cordoba-Montoya and Carrer, 1997).

Recent evidence also links estrogen to the metabolism of amyloid precursor protein (APP). The accumulation of β-amyloid protein, which is derived from APP, in the senile plaque cores of the brain is considered a histopathological hallmark of AD (Jaffe *et al*., 1994; Xu *et al*., 1998).

The apolipoprotein E4 (APOE4) allele encoding for plasma apolipoprotein E (apoE) has been associated with increased risk for late-onset, familial, and sporadic AD (Corder *et al*., 1993; Saunders *et al*., 1993; Strittmatter *et al*., 1993). Recent studies have suggested that APOE4 may be a risk factor for early-onset AD (Okuizumi *et al*., 1994; Van Duijn *et al*., 1994). Estrogen modulates the expression of apoE (Srivastava *et al*., 1996) and enhances the synaptic sprouting via an apoE-dependent mechanism (Stone *et al*., 1998).

Other functions of estrogen have also been reported. In experiments with cell cultures it has been demonstrated that estrogens confer protection against oxidative stress-induced neurodegeneration (Behl *et al*., 1995; Goodman *et al*., 1996). In addition, estrogens can increase the cerebral glucose metabolism (Bishop and Simpkins, 1992) and cerebral blood flow, especially in the right lower frontal area suggesting that the increased metabolism may be related to estrogen's enhancement of cholinergic projections (Ohkura *et al*., 1994a,b).

Behavioral studies with animal models have suggested a role for estrogen in facilitating memory and learning. Most animal experiments have used maze task (a spatial memory

task), or avoidance behavior paradigms in ovariectomized rats to determine whether gonadal steroids, notably estrogens, counteract the deficits induced by the anticholinergic agent scopolamine (Farr *et al*., 1995; O'Neal *et al*., 1996; Daniel *et al*., 1997; Fader *et al*., 1998). Estrogen administration has been shown to improve performance in cognitive tasks in ovariectomized rats (Singh *et al*., 1994). Specifically, estrogen replacement not only enhanced performance in the active avoidance tasks, but also accelerated learning. It was consequently hypothesized that chronic exposure to low doses of 17β-estradiol may play a positive role in long-term memory. These studies underscore the importance of estrogen in memory and learning.

III. Clinical Trials of Estrogen Treatment

Several placebo-controlled clinical trials have evaluated the effects of estrogen on the cognitive function of postmenopausal women. Six of the nine most frequently cited studies (Caldwell and Watson, 1952; Campbell and Whitehead, 1977; Fedor-Freybergh, 1977; Hackman and Galbraith, 1977; Sherwin, 1988; Phillips and Sherwin, 1992) concluded that estrogens might benefit the cognitive performance of the participants, whereas three studies (Rauramo *et al*., 1975; Vanhulle and Demol, 1976; Ditkoff *et al*., 1991) failed to detect any hormonal benefits. Although the above studies were very intriguing and suggested a positive role of estrogen in cognition, they were not specifically designed to assess patients with dementia. Other limitations of these studies were the following: First, they did not always compare measure outcomes with the placebo-controlled group. Second, a small number of subjects (< 70) were tested in each study. Third, patients were followed for a brief duration (< 6 months). Fourth, they used a variety of not standardized psychometric instruments. Finally, the authors did not always adjust or match estrogen users with controls for age, education, and depression. Therefore it is not possible to draw general conclusion about the effectiveness of estrogen in postmenopausal women or to translate these results into women with dementia.

Five observational studies (three cross-sectional, one prospective, and one case–control nested in a large prospective study) have been conducted recently with the goal of detecting the purported benefit of estrogen use in healthy postmenopausal women. Three investigations (Kampen and Sherwin, 1994; Robinson *et al*., 1994; Kimura, 1995) suggested a positive association between estrogens and cognitive performance, while the other two (Barrett-Connor and Kritz-Silverstein, 1993; Paganini-Hill and Henderson, 1996a) failed to detect any association. The Barrett-Connor and Kritz-Silverstein (1993) study needs further mention because it was the only prospective study of these five trials with the largest cohort of 800 elderly women and mean duration of 15 years of follow-up. The design of the study provided cognitive assessment of the participants with an array of neuropsychological instruments, which are currently used to evaluate demented patients. The researchers adjusted the scores for age and education but not for depression. The authors concluded that their study offered no evidence that replacement estrogen therapy preserves cognitive function in older postmenopausal women.

Unfortunately, the studies reviewed so far do not unequivocally answer the question whether estrogen enhances cognitive performance in postmenopausal women. Also, it is not clear if positive results represent an independent effect or are secondary to an improvement of mood and somatic relief.

In a meta-analysis (Yaffe *et al*., 1998) of 10 observational studies in which AD, based on any criteria, was associated with estrogen replacement therapy, the summary odds ratio was 0.71, indicating an almost 30% reduction of risk in estrogen users compared with nonusers. The authors commented on the heterogeneity of the above trials (8 case–control, 2 prospective); however, 4 (Broe *et al*., 1986; Henderson *et al*., 1994; Mortel and Meyer, 1995, Paganini-Hill and Henderson, 1996b) of the 8 case–control studies suggested that estrogen therapy lowered the risk of AD (summary odds ratio range 0.3–0.7). In contrast, two studies (Heyman *et al*., 1984; Amaducci *et al*., 1986) noted an almost twofold risk for AD in estrogen users, while two failed to demonstrate any risk reduction (Graves *et al*., 1990; Brenner *et al*., 1994). It is of importance, though, that the two prospective studies (Tang *et al*., 1996; Kawas *et al*., 1986) suggested that estrogen replacement therapy may reduce the risk of AD.

Specifically, the Manhattan study, conducted by Tang and his associates, found 167 patients with probable AD in a cohort of 1124 community-based women with up to 5-year follow-up and 7 years mean duration of estrogen replacement therapy. Women who took estrogen had a reduced relative risk for AD of 0.40. A significant linear trend suggesting that the duration of estrogen use affected the risk for AD was also noted. The Baltimore study, by Kawas and colleagues, identified 34 cases of probable AD in a cohort of 472 community-dwelling women, followed up to 16 years, and reported a reduced relative risk of 0.46, indicating again a protective effect of estrogen therapy. This study was unable to detect any increase in protection depending on the duration of estrogen replacement therapy. These results were replicated in a 3-year longitudinal study of 1568 Italian women who were included in the risk factor analysis (Baldereschi *et al*., 1998). This investigation also reported that the risk of AD for estrogen replacement therapy users was reduced three-fourths below that of women who had never used estrogen (summary odds ratio, 0.24). All prospective studies used standard National Institute for Neurological and Communicative Disorders and Stroke/Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) criteria for the clinical diagnosis of AD. The protective effect of estrogen remained after adjusting for other covariates (usually age and education).

There have been four trials examining the effect of estrogen in the treatment of AD. Two of the above were uncontrolled and studied only seven subjects. The other two studies were controlled (one of which was double blinded, randomized) and analyzed a total of 58 women. All studies were less than 6 weeks in duration of treatment and varied in the severity of dementia. Specifically, in an open, uncontrolled trial (Fillit *et al*., 1986) with seven women, carrying the diagnosis of AD and being treated with low dosages of estradiol over a 6-week period, significant improvement over baseline in attention, orientation, mood, and social interaction was noted in three patients. In another uncontrolled study (Honjo *et al*., 1989), it was reported that five of seven AD subjects treated

with 1.25 mg/day of conjugated equine estrogen for 6 weeks showed improvement in Hasegawa Dementia Scale and 6 women improved in the New Screening test for dementia. The same group of researchers in a later 3-week, placebo-controlled, double-blind study (Honjo *et al*., 1993) with 14 AD elderly women treated with 1.25 mg/day of conjugated equine estrogen reported an improvement in cognition as measured by the Hasegawa Dementia Scale, but not in the Mini Mental State Exam or the New Screening test. In a 6-week, open, nonrandomized trial (Ohkura *et al*., 1994b) with 15 AD patients, treated with 1.25 mg/day of conjugated equine estrogen and 15 controls, an improvement in the dementia symptoms was noted in the estrogen-treated group. There was a significant elevation of the mean Mini Mental State Exam score in 10 patients and an increase in the Hasegawa Dementia Scale in 11 subjects at both 3 and 6 weeks. The authors reported that the apparent changes were also noted by the caregivers of the patients, and the test scores returned to baseline after dicontinuation of estrogen replacement therapy. Okhura and his associates published in 1995 a case report with seven subjects treated with low-dose estrogen over an extended time period. Four of seven patients improved dramatically, as was shown by psychometric and behavior rating scales, with reversal of benefits upon termination of treatment.

IV. Summary

In summary, the role of estrogens in AD is supported by basic research, observational, epidemiological, and clinical studies. However, the efficacy of estrogen for AD has yet to be confirmed in large-sample, double-blind, controlled studies. Research centers are conducting two ongoing placebo-controlled, double-blind trials (The Women' s Health Initiative Randomized Trial and the Alzheimer's Disease Cooperative Study Unit) in order to clarify the putative role of estrogen replacement therapy in AD.

Cholinergic Treatments of Alzheimer's Disease

I. Introduction

A gradual degenerative process of the central nervous system characterizes Alzheimer's disease (AD). Although the pathogenesis of AD is not completely understood, advances in research have led to the development of several therapeutic strategies. The conceptualization of treatments for AD is in accordance with preclinical and basic science findings. In this chapter we review the evidence supporting the use of therapies targeting the cholinergic system. Several lines of evidence suggest a critical role of the cholinergic mechanisms involved in AD.

1. Cholinergic innervation and neurotransmission are pivotal in the execution of complex cognitive tasks (Deutsch, 1971; Bartus *et al*., 1982, 1987).

2. Rodents, monkeys, and humans subjected to anticholinergic treatments, such as scopolamine (Ostfeld and Aruguette, 1962; Crow and Grove-White, 1973; Drachman and Leavitt, 1974; Bartus *et al*., 1987) or cholinergic lesions (Irle and Markowitsch, 1987; Berger-Sweeney *et al*., 1994; Leanza *et al*., 1996; Walsh *et al*., 1996), manifest cognitive impairments.

3. These deficits can be effectively restored with cholinergic agents (Davis *et al*., 1978; Bartus, 1979; Aigner *et al*., 1987; Bartus *et al*., 1987; Dokla and Thal, 1988). Experiments with cholinergic-rich fetal tissue transplants, grafted in rats with lesions of the nucleus basalis of Meynert, support the role of acetylcholine (ACh) in restoring learning and memory deficits following basal forebrain damage (Winkler *et al*., 1995).

4. Postmortem studies of patients with AD demonstrate a significant reduction of cholinergic neurons in the basal forebrain (Davies and Maloney, 1976; Whitehouse *et al*., 1981) and a profound decline in the activity of choline acetyltransferase (ChAT) in the neocortex and hippocampus (Davies and Maloney, 1976; Perry *et al*., 1977).

5. AD brains demonstrate no change or an increased number of muscarinic receptors and a decreased number of high-affinity nicotinic receptors (Nordberg and Winblad, 1986; Nordberg, 1992; Shimohama *et al*., 1986).

6. Significant correlation exists between cholinergic deficits and the severity of dementia (Perry *et al*., 1978).

All these findings suggest the potential therapeutic value of agents that enhance cholinergic neurotransmission for AD.

II. Acetylcholinesterase Inhibitors

Different strategies, including ACh precursor loading (lecithin, choline), ACh releasers, cholinometics, and acetylcholinesterase (AChE) inhibitors have been actively pursued as therapeutic options over the past decades. Trials with choline or lecithin have had equivocal outcomes (Etienne *et al*., 1978, 1981; Thal *et al*., 1981). Most promising results have been observed with cholinesterase inhibitors, several of which have been tested in phase III clinical trials in the United States and Europe. Currently, two of the above drugs (tacrine and donepezil) have been approved by the Food and Drug Administration (FDA). However, several others AChE inhibitors (rivastigmine, galanthamine, metrifonate, and physostigmine) are at different stages of FDA authorization. The FDA guidelines recommend that the clinical studies accompanying new drug applications for AD use the Alzheimer's Disease Assessment Scale, Cognitive Subscale (ADAS-Cog), the Clinician Interview-Based Impression of Change (CIBIC) or the Clinical Global Impression of Change (CGIC) scale as primary efficacy variables. The ADAS-Cog is an 11-item psychometric instrument assessing different aspects of cognitive performance. Scores in ADAS-Cog range from 0 (no errors) to 70 (severe impairment) with an expected average decline of 8 points over a 1-year period. An improvement of four points or more in ADAS-Cog with drugs would be considered a clinically significant effect (U.S. Department of Health and Human Services, 1989). Both the CIBIC and the CGIC are seven-point ordinal scales ranging from 1 (marked improvement) to 7 (marked deterioration), which provide a more global assess-

ment of the patient's clinical condition, and unlike the ADAS-Cog are not standardized. A drug to be considered for approval should result in a clinically and statistically significant improvement of the core cognitive symptoms of AD compared to placebo.

A. Tacrine (THA)

Tacrine (9-amino-1,2,3,4-tetrahydroacridine) was the first cholinesterase inhibitor approved by the FDA for the treatment of AD. Tacrine is a synthetic compound, known since 1949, that has a structural similarity to the K^+ channel blocker 4-aminopyridine (Osterrieder, 1987). This agent is a mixed-type (competitive/noncompetitive) (Catalan *et al*., 1993), reversible inhibitor of cholinesterase that binds close to the catalytically active serine in the active site of the enzyme. In addition to its inhibition of AChE and butyrylcholinesterase, tacrine has an effect on muscarinic (M1, M2) and nicotinic receptors (Flynn and Mash, 1989; Adem *et al*., 1990; Xiao *et al*., 1993). Tacrine is rapidly absorbed from the gastrointestinal tract and easily crosses the blood–brain barrier. It is metabolized in the liver by the P450 system (CYP1A2, CYP2D6) and excreted by the kidneys with a 3 hr elimination half-life (Parnetti, 1995; Physician's Desk Reference, 1999a). Tacrine has nonlinear pharmacokinetics, with significant variability in pharmacokinetic parameters after oral, intravenous, and rectal administration. This compound has potential drug interactions with cimetidine and theophylline.

Following the pilot trials with tacrine (Summers *et al*., 1981, 1986), more than a dozen (Chatellier and Lacomblez, 1990; Gauthier *et al*., 1990; Ahlin *et al*., 1991; Molloy *et al*., 1991; Davis *et al*., 1992; Farlow *et al*., 1992; Wilcock *et al*., 1993; Knapp *et al*., 1994; Maltby *et al*., 1994; Wood and Castleden, 1994; Forette *et al*., 1995; Foster *et al*., 1996) randomized, double-blind, placebo-controlled trials have been published. The majority of them used standardized psychometric instruments and demonstrated that tacrine in a dose above 80 mg/day improves the cognition and function in patients with mild to moderate-stage AD. A large percentage of patients had to be discontinued from the studies because of the development of liver function tests elevations (Knapp *et al*., 1994; Watkins *et al*., 1994; Samuels and Davis, 1997; Gracon *et al*., 1998). Many of these abnormalities may have been due to forced uptitration. More than 25% of patients developed clinically significant hepatic enzyme elevations (>3 times the upper limit of normal) and severe liver enzyme abnormalities (>20 times normal) occurred in 2% of patients. These elevations occurred mostly during the first 9 weeks of treatment and they were reversible, with patients recovering within 3–4 weeks after discontinuation of treatment. They were almost always asymptomatic, more common in women, and related to the duration of the treatment. Fatal hepatotoxicity has not been reported yet. It is of interest that 88% of patients were successfully rechallenged with tacrine. Other common adverse effects related to the cholinomimetic profile of tacrine include gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain) and rarely myalgia and dizziness.

Because of tacrine's liver toxicity, monitoring of the liver function is required during the course of treatment and careful uptitration of the medication is recommended (Samuels and Davis, 1997). Tacrine has been widely used after its FDA approval and pharmacoeconomic studies (Lubeck *et al*., 1994; Knopman *et al*., 1996) have demonstrated that tacrine delays institutionalization, suggesting the economic utility of this medication. Moreover tacrine has provided a benchmark against which other cognitive enhancers can be compared. The need for liver function monitoring and four-time dosing schedule of tacrine has led to its limited use.

B. Donepezil (E2020)

Donepezil is the second AChE inhibitor approved in 1996 for the treatment of AD (Physician's Desk Reference, 1999b). Donepezil is a noncovalent, highly selective inhibitor of AChE (donepezil's inhibition of AChE is 1250 times more than that of butyrylcholinesterase). It is a reversible inhibitor of mixed type with a favorable pharmacokinetic profile (Ohnishi *et al*., 1993; Shintani and Uchida, 1997).

Donepezil is well absorbed after oral administration with an almost 100% bioavailability, and it is not affected by the presence of food. It has a 70 hr elimination half-life (60 hr in young adults, 104 hr in elderly) and it is metabolized by CYP2D6, CYP3A4 hepatic enzymes, without evidence of liver toxicity—in contrast to acridine based AChE inhibitors. It manifests linear pharmacokinetics with a plateau of inhibition at plasma concentration >50 ng/ml and the recommended dose is 5–10 mg/day. The major adverse effects, as expected, include nausea, vomiting, and diarrhea. Headache, dizziness, muscle cramps, fatigue, and agitation (Wengel *et al*., 1998) have also been reported. Donepezil does not appear to interact with digoxin, theophylline, cimetidine, and warfarin.

In the first phase II/III, double-blind, placebo-controlled study (Rogers and Friedhoff, 1996), a sample of 161 AD patients were randomized to different fixed doses (1, 3, and 5 mg daily) versus placebo. The trial was 14 weeks in duration (12 weeks double-blind donepezil or placebo, and 2 weeks placebo washout phase). More than 80% of the cohort completed the study with the 5 mg group showing statistically significant improvement on ADAS-Cog and MMSE relative to the placebo group. Comparable incidences of adverse effects among the three dose groups and placebo (68% vs 65%) were noted. In an open-label study, with 133 patients who had completed the previous 14 week trial and were followed up to 192 weeks, a long-term benefit of donepezil was noted (Rogers and Friedhoff, 1998). Donepezil was well tolerated without liver abnormalities. A 30 week, randomized, double-blind, placebo-controlled trial (24 week active medication and 6 week placebo washout phase) of 473 patients suggested statistically significant improvements in cognitive performance outcomes with both 5 and 10 mg/day doses, mostly in favor of the 10 mg dose at the end point (Rogers *et al*., 1998a). This study confirmed that there is a dose–response effect with 16% of patients in the 10 mg group discontinuing the study because of serious adverse effects compared to 7% in the placebo or 6% to the 5 mg group, possibly related to the greater degree of AChE inhibition. It is worthwhile to mention here that 68% of the 10 mg group completed the study and half of these patients achieved at least four-point improvement in ADAS-Cog scores. These findings compare very favorably

with the high doses of tacrine (160 mg/day), where the dropout percentage reached 75 at the end of the 30 week trial (Knapp *et al*., 1994).

A 15 week (12 week active and 3 week washout phase), double-blind, placebo-controlled, parallel group study (Rogers *et al*., 1998b) with 468 patients replicated the results of previous trials with donepezil. Statistically significant correlations were detected between donepezil plasma concentrations and AChE inhibition, ADAS-cog, and CIBC with caregiver input (CIBIC-plus) scores. The adverse effects with both 5 and 10 mg dosages were comparable to the ones observed with placebo. Transient nausea, diarrhea, and insomnia were more common with the 10 mg dose and there was no association with liver toxicity. The efficacy of donepezil has been reevaluated in a multinational 24 week, placebo-controlled study of 818 patients, which demonstrated significant improvement in cognitive and global function, suggesting also a greater benefit in the 10 mg daily regimen, for the treatment of mild to moderate AD (Burns *et al*., 1999).

Donepezil's once-a-day dosing schedule and its mild side-effect profile has provided a safe alternative to tacrine. No direct studies comparing tacrine with donepezil have been performed as yet. Currently, the potential utility of donepezil for patients who exhibit mild cognitive impairment, but do not meet criteria for frank dementia, is under investigation.

C. Galanthamine

Galanthamine is a naturally occurring alkaloid of the common snowdrop plant and it is structurally related to codeine (Cozanitis *et al*., 1983). Galanthamine is a selective, reversible, competitive, carbamate inhibitor of AChE (Thomsen and Kewitz, 1990). This compound, like other homologous alkaloids, can act as a noncompetitive agonist of nicotinic acetylcholine receptors (nAChR) by binding to sites that are different from the ACh receptors (Storch *et al*., 1995). It has two major metabolites (epigalanthamine and galanthaminone) with negligible potency (>130 times) in comparison with the parent compound (Bickel *et al*., 1991). The drug has a mean half-life of 5.7 hr and is safe. The most common adverse effects are nausea and vomiting; hepatotoxicity has not been reported to date. Galanthamine has been used in anesthesia to reverse the paralytic effect of tubocurarine-like muscle relaxants (Cozanitis *et al*., 1981). Its long half-life and its proven efficacy in reversing the cognitive deficit of rats with basal forebrain lesions (Sweeney *et al*., 1988) suggested its role, as a cognitive enhancer, for patients with AD (Dal-Bianco *et al*., 1991). A recent phase II trial suggested a beneficial role for this agent with clinical improvement on the ADAS-cog (Wilcock and Wilkinson, 1997). Multicenter clinical trials are currently conducted in the United States and in Europe and the results have not been published yet.

D. Physostigmine

Physostigmine was one of the first agents studied as treatment for the cognitive impairment produced by the cholinergic deficit in AD (Drachman and Leavitt, 1974; Davis *et al*., 1978; Bartus *et al*., 1982). Physostigmine, a natural alkaloid, is a reversible, nonselective cholinesterase inhibitor, being more selective for AChE than butyrylcholinesterase. It can be administered orally and parenterally with a variable dose response and a narrow therapeutic window. Physostigmine, when taken orally, exhibits a high but variable bioavailability with an elimination half-life of 20–30 min (Whelpton, 1983; Whelpton and Hurst, 1985; Johansson and Nordberg, 1993). Due to the very short half-life, administration every 2 hr was required in the initial trials (Beller *et al*., 1985; Stern *et al*., 1987). Earlier reports relied on the intravenous administration of physostigmine (Christie *et al*., 1981; Davis and Mohs, 1982). Studies with the oral route of administration (Mohs *et al*., 1985; Beller *et al*., 1985, 1988; Jenike *et al*., 1990) reported cognitive enhancement with this agent. Several of these pilot studies were not controlled; they tested a small number of subjects and used different routes of physostigime administration, and a variety of psychometric tools. Yet, investigators consistently demonstrated cognitive improvement in a subgroup (30%) of patients. Variability in the absorption, metabolism, central nervous system penetration, and plasma concentration, along with a short half-life with an inverted U-shaped response curve have hampered the use of physostigmine as a viable choice in the treatment of AD. However, a long-acting physostigmine is currently under investigation and the reported results are encouraging. Specifically, in a 6 week, placebo-controlled, double-blind study (Thal *et al*., 1996) with an initial cohort of 1111 subjects treated with controlled-release physostigmine, a subset (366) of AD patients, showing some improvement during the initial dose titration period, entered the active phase and were randomized to placebo versus their ''best dose'' of physostigmine. At the end of the 6 week period physostigmine-treated patients scored higher than placebo-treated patients on the ADAS (1.75 points) and CGIC (0.26 points) scores. In a 24 week, parallel-group trial (Thal *et al*., 1999) with 475 patients randomized to three groups—placebo and controlled-release physostigmine at 30 or 36 mg daily—a 2.9-point difference in ADAS-Cog and a 0.3-points difference in favor of this agent versus placebo was noted. In both trials a significant number of patients withdrew prior to completion of the study, while more than 40% reported nausea and vomiting, raising questions about the clinical utility of this drug. Hepatotoxicity or blood dyscrasias did not occur. A recently published, 24 week, placebo-controlled study of 204 patients treated with transdermal administration of two different doses of physostigmine (30 and 60 mg) failed to show any beneficial effect (Moller *et al*., 1999).

Data, suggesting that pharmacological manipulations of the noradrenergic system may improve cognition, have led in studies investigating a possible role of α2-agonists—such as clonidine or guanfacine—and the α2-antagonist, yohimbine, in the cognitive processes of learning and memory (Coull, 1994). In accordance with the above, trials with physostigmine in combination with noradrenergic system modulators as clonidine (Davidson *et al*., 1989), or selegiline (Marin *et al*., 1995) have been conducted, in order to achieve augmentation of both cholinergic and noradrenergic neurotransmission. These studies proved the efficacy and safety of combination treatments. However, they were too small to provide a definite answer regarding the potential utility of combination treatments. The efficacy of the above treatments is still being explored.

E. Eptastigmine

Eptylphysostigmine (eptastigmine) is a carbamate, derivative of physostigmine. The medication after oral administration has rapid distribution, with an inverted U-shaped dose–response curve and good penetration of the blood–brain barrier (Parnetti, 1995), although food can reduce its bioavailability (Bjornsson *et al*., 1998). It causes a long-lasting, dose-dependent, sigmoidal red blood cell AChE inhibition of the competitive type and its action on butyrylcholinesterase is weak and not dose dependent (Imbimbo *et al*., 1995). Phase I studies in healthy elderly subjects have shown that oral doses up to 32 mg are safe and well tolerated (Auteri *et al*., 1993; Sramek *et al*., 1995; Mant *et al*., 1998). In a multicenter, double-blind, placebo-controlled, parallel group, 4 week study (Canal and Imbimbo, 1996) of 103 subjects receiving 40–60 mg/day of eptastigmine, 34% of AD patients versus 0% in the placebo group improved on the CGIC and the Instrument of Activities of Daily Living Scales (IADLS). Marginal improvements were shown in other cognitive tests. The drug was well tolerated and moderate cholinergic side-effects were noted in one-third of patients, predominantly in patients with 50% acetylcholinesterase inhibition. In 25 week, controlled trial (Imbimbo *et al*., 1998) of 320 patients receiving placebo versus 10 or 15 mg of eptastigmine three times daily a statistically significant difference of 2.0 points on ADAS-Cog was noted only in the 15 mg three times daily group, while the CIBIC-plus score did not reach statistical significance in any group. The drug was well tolerated and more than 90% completed the protocol. A recently published, controlled study (Imbimbo *et al*., 1999) of 491 patients, randomized in three groups (placebo and 15 and 20 mg three times daily) demonstrated that 20 mg three times daily of eptastigmine can reach statistically meaningful improvement on the ADAS-Cog, CIBIC-plus, and IADL. The majority of patients (>85%) completed the trial and only 8% of patients on eptastigmine versus 7% on placebo had to discontinue the study due to adverse effects. The researchers noted that these results compared favorably with tacrine, donepezil, and metrifonate but a dose-dependent neutropenia in about 5% of treated patients may limit the clinical utility of this agent.

F. Rivastigmine

Rivastigmine (ENA, 713, carbamoylatine) is a novel, ''pseudoirreversible,'' selective, noncompetitive, carbamate AChE inhibitor (Enz and Floersheim, 1996; Polinsky, 1998). This agent preferentially inhibits in a dose-dependent fashion (Cutler *et al*., 1998a) the G1 enzymatic form of AChE, which predominates in the central nervous system. It has a long duration of action and results in up to 10 hr of enzyme blockade after a single dose. The drug demonstrates nonlinear pharmacokinetics with rapid and almost complete absorption and low bioavailability (35% of the administered dose), with primarily renal metabolism. Rivastigmine lacks hepatic toxicity or interaction with medications metabolized by CYP-450 isoenzymes. Rivastigmine has been shown to improve cognitive performance in animal models with basal forebrain lesions (Niigawa *et al*., 1995). Phase I/II trials have shown the efficacy and safety of the medication (Anand *et al*., 1996; Sramek *et al*., 1996; Forette *et al*., 1999). In phase II/III clinical studies it appeared that rivastigmine 6–12 mg/day may confer statistically significant cognitive improvement to recipients of the drug compared to placebo (Spencer and Noble, 1998). A randomized, double-blind, placebo-controlled, 26 week study (Rosler *et al*., 1999) with 1–4 mg/day or 6–12 mg/day doses of rivastigmine in 725 AD patients demonstrated that higher doses resulted in cognitive improvement as measured by ADAS, CIBIC-plus, MMSE, and the Global Deterioration Scale (GDS). The adverse effects were cholinergic in nature, occurred in a dose-dependent fashion, and affected predominantly the gastrointestinal system. Headaches, malaise, fatigue, and dizziness have also been reported. Specifically, half of patients in the higher dose (6–12 mg) group developed nausea and one-third from the same group vomiting. A statistically significant decrease in body weight (mean change, -1.39 kg) was noted in the higher rivastigmine group. Apart from nausea there was no significant difference in adverse effects between placebo and the low-dose group. The percentage of patients who discontinued treatment for any reason reached 33% in the higher dose arm versus 14% for the other two groups, whereas the proportion of patients who dropped out because of adverse effects was 23% versus 7%, respectively. Similar results have been reported by an earlier randomized study in North America (Corey-Bloom *et al*., 1998). The medication has already been approved in some countries in Europe and South America.

G. Velnacrine (HP-029)

Velnacrine maleate, or L-hydroxytacrine, is an acridine-based derivative and a principal metabolite of tacrine (Truman *et al*., 1991). Velnacrine is a reversible, lipophilic cholinesterase agent that exerts both AChE and butyrylcholinesterase inhibition. It can be taken orally (Puri *et al*., 1989, 1990), is metabolized primarily by the liver, has limited renal excretion, and manifests nonlinear pharmacokinetics (Turcan *et al*., 1993; Parnetti, 1995). This compound has been associated with improvement of memory in primates (Jackson *et al*., 1995). In two, double-blind, placebo-controlled studies conducted by the Mentane Study Group (Antuono, 1995; Zemlan, 1996), patients achieved better scores in the ADAS-cog and CGIC scales. Most improvement was observed in doses greater than 150 mg per day. The most common adverse effects were consistent with the cholinergic properties of the drug (diarrhea, nausea, vomiting). A few patients developed white blood cell abnormalities. Velnacrine caused a reversible, dose-dependent, asymptomatic elevation of liver transaminases in about 30% of patients versus 3% in the placebo group. Liver enzyme elevations occurred between 6 and 8 weeks and led to termination of treatment in a third of the studied patients. These findings invite a comparison between velnacrine and tacrine, given the structure similarities of these agents.

H. Metrifonate

Metrifonate is a nonselective almost irreversible phosphorylating agent, which has been used for decades against schistosomiasis (Cerf *et al*., 1962). Its therapeutic efficacy for the treatment of schistosomiasis is due to the fact that AChE is present in abundance in the muscle system of the schistosomes

(Camacho *et al*., 1994). Metrifonate is a long-acting cholinesterase inhibitor, with no anticholinesterase activity, that exerts its action through a slow transformation to 2,2′-dichlorovinyldimethyl phosphate (DDVP or dichlorvos) (Hinz *et al*., 1996). This compound inhibits butyrylcholinesterase more than AChE (Pacheco *et al*., 1995). The administration of metrifonate achieves a high degree of cholinesterase inhibition (70%) without the need for dose adjustment. The active compound is released in a slow sustained mode, and steady state takes 6–8 weeks in the absence of loading dose (Cutler *et al*., 1998b). Metrifonate is not dependent on the P450 enzyme system and undergoes less than 15% protein binding, which limits the possibility of drug interactions. Phase I/II studies have demonstrated that the drug has a safe profile with minimal drug interactions and is well tolerated. Clinical trials with patients diagnosed with mild to moderate AD have demonstrated the role of this agent in enhancing cognitive performance. In a 3 month double-blind, placebo-controlled trial (Becker *et al*., 1996) with 50 patients who completed the study, the authors reported a mean 50% inhibition of red blood cell AChE activity and a 2.6-point difference in ADAS-Cog. No difference was found in other outcome measures and the authors questioned the clinical value of their findings. Adverse effects were uncommon, although two patients were diagnosed with lymphoma but reviews of use of metrifonate have not linked this compound with increased risk of malignancy (World Health Organization, 1989). In a 6 month double-blind study, conducted by the same researchers in a cohort of 47 AD patients the results suggested a clinically meaningful cognitive improvement in the metrofinate group (Becker *et al*., 1998).

In a 12 week, placebo-controlled, double-blind study (Cummings *et al*., 1998) of 480 patients, of whom more than 90% completed the trial, improvement in cognition was demonstrated in ADAS-cog and the CIBIC-plus. In a 26 week, placebo-controlled study (Morris *et al*., 1998) of 408 subjects, a beneficial effect of metrofinate was observed in both ADAS-Cog and CIBIC-plus subscales. Again, more than 80% of patients completed the active period and 12% discontinued due to adverse effects. The low attrition reflects the favorable safety and tolerance profile of the drug. The above results have been replicated in a 26 week, double-blind study of 264 patients (Raskind *et al*., 1999). The later two studies suggested that metrifonate benefits not only the cognition and global function but may also attenuate the behavioral disturbances of AD patients (Morris *et al*., 1998, Raskind *et al*., 1999). Similar findings have been noted in a preliminary report of the Metrifonate in Alzheimer Trial study (McKeith, 1998). Due to the unique pharmacokinetic profile of metrifonate, with delay in reaching steady-state, patients in clinical trials are dosed initially with a loading regimen of the drug. It appears though that the no-loading dose regimen is equally efficacious and better tolerated in comparison to the loading dose regimen (Jann *et al*., 1999). Overall, the adverse events have been mild and primarily gastrointestinal in nature, and less than 10% of patients discontinued the treatment because of adverse effects. The most common adverse events associated with the drug included diarrhea, nausea, abdominal pain, leg cramps, and rhinitis. Liver toxicity or elevations of hepatic enzymes have not been observed and the drug is in the process of FDA approval.

I. MSF

MSF (methanesulfonyl fluoride) is a highly selective, long-lasting AChE inhibitor with low toxicity, which was able to attenuate scopolamine-induced in Sprague–Dawley rats (Palacios-Esqivel *et al*., 1993). In the first double-blind, placebo-controlled, phase II/III study of 21 patients (Moss *et al*., 1999), this agent demonstrated a safe pharmacodynamic profile without gastrointestinal side-effects and a statistical improvement in ADAS-cog and MMSE compared to placebo, which endured for 8 weeks after termination of treatment. The small number of patients and the short duration of treatment (8 weeks double-blind, placebo-controlled and 8 weeks washout period) do not permit generalization of the above results. Further clinical trials with larger cohorts are needed to support the notion of less toxicity and equal or better efficacy of this agent, compared to placebo.

III. Cholinergic Agonists

Another potential strategy for boosting cholinergic function in patients with AD involves the administration of selective cholinergic receptor agonists. It is known that the cholinergic receptors fall into two major categories, muscarinic and nicotinic. Four muscarinic receptor subtypes (M1, M2, M3, M4) (Waelbroeck *et al*., 1990) have been identified pharmacologically and five receptor subtypes (M1–M5) have been detected through cloning (Bonner *et al*., 1988; Hulme *et al*., 1990; Dorje *et al*., 1991). Studies with antisera (Yasuda *et al*., 1992) demonstrate a substantial overlap between the pharmacologically and the molecularly defined subtypes of muscarinic receptors. The muscarinic receptors are slow, and they bind to G proteins. Specifically the M1, M3, and M5 are coupled to phosphoinositide hydrolysis and cause cell excitation, whereas M2 and M4 are coupled to cyclic AMP and cause inhibition (Peralta *et al*., 1988; Cooper *et al*., 1996). Localization studies have shown that M1 receptors are found preferentially in the neocortex and hippocampus (Levey *et al*., 1991; Flynn *et al*., 1995), areas crucial for cognition and memory. M2 receptors are found in the cardiac tissue and M3 subtype receptors are detected in secretory glands (Waelbroeck *et al*., 1991). M4 receptors have a distribution almost similar to M1 and their pharmacological properties have not been defined very well (Yasuda *et al*., 1992). M5 receptors levels are very low in rat brains (Yasuda *et al*., 1992) and their role is not clear yet. In most studies with postmortem brain tissue from AD patients it was demonstrated that the density of M1 receptors remains unaltered or even increased in AD (Whitehouse and Kellar, 1987; Giacobini, 1990; Nordberg, 1992), whereas M2 receptors are relatively decreased (Mash *et al*., 1985). Stimulation of the presynaptic M2 receptors inhibits Ach release. Because M1 is the more abundant receptor in the neocortex and hippocampus and most of the peripheral adverse effects are caused by activation of M2 and M3 subtypes, the development of agents with high specificity for the M1 receptors has a potential clinical value. In addition, *in vitro* studies have shown that M1 agonists increase the synthesis of nonamyloidogenic forms of APP (Nitsch *et al*., 1992) and regulate tau phosphorylation (Sadot *et al*., 1996). These agents may be involved in neurotrophic mechanisms in the brain (Pinkas-Kramarski *et al*.,

1992), affecting the development, plasticity, and preservation of brain tissue. Muscarinic agonists without specificity have been studied in the past with little or no success. Moreover, since M2 receptor agonists can inhibit Ach release, the blockage of M2 receptors would result in increased levels of acetylcholine. At present studies with selective muscarinic agonists are being conducted with the objective of restoring the cholinergic deficit and possibly succeeding in modifying the course of this disease. However, the tonic stimulation by the above agents does not reflect the phasic physiological mechanism of AChE release and may pose limitations to the benefits gained by these agents.

A. Bethanechol

Bethanechol is a synthetic β-methyl analog of Ach with M1 and M2 agonist properties. This compound has been studied extensively in the past decades and has demonstrated limited efficacy (Harbaugh *et al*., 1989; Wilson and Martin, 1988), a narrow therapeutic window (Penn *et al*., 1988), and variable response with severe adverse effects in higher doses (Read *et al*., 1990). A major limitation has been the inability of bethanechol to penetrate the blood–brain barrier, thereby requiring intrathecal administration with a high risk of perioperative complications (seizures, hematoma, and infections).

B. Arecoline

Arecoline is a natural alkaloid of the Taiwanese betel nut. The compound has cytomodulating effects and has been implicated in the pathogenesis of oral cancer and oral submucous fibrosis (Van Wyck *et al*., 1994; Tsai *et al*., 1997). This agent has been also used in *Echinococcus* screening testing due to its strong purging activity (Craig *et al*., 1995). Arecoline is a nonselective M1 and M2 agonist with nicotinic properties. It has been evaluated for enhancing memory and learning in rats (Molinengo *et al*., 1995) and primates (Buccafusco *et al*., 1995a) and for its ability to increase brain glucose utilization (Maiese *et al*., 1994). Arecoline infusion in patients with probable AD produced a dose-dependent response in cognitive tests (Rafaele *et al*., 1996). In a randomized, double-blind study (Tariot *et al*., 1988) with 12 AD patients, no improvement was found in an array of cognitive psychometric tests. However, with a low-dose infusion (1–2 mg/hr), an arousal effect and psychomotor activation was observed, whereas infusions with a higher dose (4 mg/hr) produced psychomotor retardation, dysphoria, and difficulty with verbal expression. It was postulated that the lower dose activation was a muscarinic phenomenon and the higher dose retardation was a nicotinic phenomenon. Overall, this agent has not been recently studied as a cognitive enhancer for AD.

C. RS-86

RS-86 (2-ethyl-8-methyl-2,8-diazospiro-4,5-decart-1,3-dianhydrobromide) is a nonselective muscarinic agonist with higher affinity for M1 than M2 receptors. It can be taken orally, penetrates the blood–brain barrier, has a long half-life, and has the tendency to induce hypothermia in mice (Freedman *et al*., 1989). RS-86 has been administered in sleep studies as it has been hypothesized that REM sleep disinhibition in depression is associated with muscarinic hypersensitivity (Berger *et al*., 1989; Gann *et al*., 1992). A double-blind, crossover study (Foster *et al*., 1989) of 10 patients with progressive supranuclear palsy who were treated with RS-86 did not improve motor activity or cognition. In a controlled study (Wettstein and Spiegel, 1984) with RS-86, a subset of patients with AD showed minimal changes in mood, social behavior, and cognition. These results have not been replicated in other trials (Bruno *et al*., 1985; Hollander *et al*., 1987).

D. AF Compounds

AF-series compounds, are structurally rigid, synthetic analogs of Ach (Fisher *et al*., 1993, 1996). They were designed to act on specific muscarinic subtype receptors and they have been shown to exert both agonistic and antagonistic activity. The action of AF agents on muscarinic receptors depends on the tissue, the muscarinic receptor subtype, and the functional assays. They demonstrate variable degree of receptor selectivity and efficacy (Fisher *et al*., 1993, 1996). AF102B, AF150, and AF151 are selective M1 agonists and AF125 is mostly a M2 agonist. AF compounds have demonstrated a beneficial effect on cognition in experiments performed with various animal models with a relatively wide safety margin. The activity of AF compounds is coupled with phosphoinositides hydrolysis and enhances the secretion of APP. Observations in cultured cells have suggested that these drugs may act in concert with nerve growth factor to enhance APP processing, since the secreted form of APP are instrumental in decreasing the production of β-amyloid (Nitsch *et al*., 1992; Haring *et al*., 1995). Other *in vitro* data (Sadot *et al*., 1996) suggest that these muscarinic ligands decrease the amount of phosphorylated tau protein, the principal component of neurofibrillary tangles.

E. AF102B

AF102B is highly selective for M1 receptor agonist. The compound has a long-lasting activity and in experiments with rats (Fisher *et al*., 1989; Nakahara *et al*., 1989; Vincent and Sepinwall, 1992) and primates (O'Neill *et al*., 1998) has been shown to enhance cognitive performance with a safe therapeutic index. In a 6 week, single-blind, placebo-controlled study (Fisher *et al*., 1994), AF102B, administered in 20 to 60 mg three times daily doses, was found to improve cognitive performance, measured with the ADAS-cog and ADAS-word recognition scales. Diaphoresis and excessive salivation were the most common side-effects in the higher dose (60 mg three times daily) group. Double-blind studies will provide more definitive evidence regarding the efficacy of AF102B.

F. Xanomeline

Xanomeline is a functionally selective M1/M4 agonist that has shown a promising therapeutic profile in preclinical trials (Shannon *et al*., 1994). Xanomeline is well absorbed orally, crosses the blood–brain barrier, and undergoes extensive liver metabolism with at least six metabolites (Andersen and Hansen, 1997). In earlier phase II studies (Medina *et al*., 1997) the oral formulation was found to reduce the blood pres-

sure and was associated with an increased risk for syncope. A 6-month, double-blind, placebo-controlled study (Bodick *et al*., 1997) of 343 AD patients, randomized to receive 75, 150, or 225 mg/day versus placebo, demonstrated a significant improvement in ADAS-cog and CIBIC-plus, with the higher dose of xanomeline (225 mg/day). The analysis of Treatment Emergent Signs and Symptoms (TESS) disclosed a dose-dependent reduction in behavioral disturbances and psychotic symptoms. Favorable effects were reported in the Nurse's Observation Scale for Geriatric Patients (NOSFGP). These findings were more pronounced in the high-dose group. However 59% of patients in the 225 mg group discontinued therapy compared to 35% in the placebo group. Half of them dropped out predominantly due to gastrointestinal adverse effects, while 12.5% patients in this group experienced transient syncope. Overall 34 patients (13%) receiving xanomeline developed moderate, reversible elevations of transaminases. As a result of the hypotensive episodes and other side-effects the oral formulation has been discontinued. The efficacy of xanomeline through transdermal delivery is now being investigated.

G. Sabcomeline

Sabcomeline is a functionally selective M1 partial agonist, which has been tested in rats and marmoset monkeys and show improved cognitive performance in doses that did not cause the common cholinergic adverse effects (Harries *et al*., 1998; Hatcher *et al*., 1998).

H. Milameline (CI-979)

Milameline is a nonselective M1/M4 partial agonist of muscarinic receptors, which in animal models has shown to reverse scopolamine-induced amnesia (M'Harzi *et al*., 1995). It appears that milameline has a safe cholinergic profile in doses used in both healthy subjects and probable AD. A multicenter clinical study of the role of milameline in patients with mild, moderate AD is currently under way.

IV. Cholinergic Agonists with Nicotinic Affinity

Muscarinic receptors have been the target of the cholinergic replacement strategy due to their abundance in comparison to the nicotinic receptors and the well known cognitive impairment produced by muscarinic antagonists. Nonetheless, there is convergence of evidence that nicotinic acetylcholine receptors play an important role in the cognitive deficits that characterize AD (Vidal, 1996; Levin and Simon, 1998). Postmortem studies of AD brains have shown a significant reduction of nicotinic receptors in both neocortex and hippocampus (Perry *et al*., 1987; Nordberg *et al*., 1992). Basic research has shown that nicotine receptor stimulation might protect neurons from a β-amyloid (Kihara *et al*., 1997) and glutamate toxicity (Seguela *et al*., 1993; Akaike *et al*., 1994).

A. Nicotine

Nicotine has been repeatedly found to improve cognitive performance of aged rats (Levin and Torry, 1996) and primates (Terry *et al*., 1993). It has also been shown that the nicotinic antagonist mecamylamine induces significant impairment of working memory performance of rats (Decker and Majchrzac, 1992) and cognitive dysfunction in humans (Newhouse *et al*., 1992).

Preliminary studies in humans also suggest the potential efficacy of nicotine as a cognitive enhancer (Rusted *et al*., 1995; Foulds *et al*., 1996). Metaanalysis (Lee, 1994) of 19 case–control studies demonstrated a significant negative association between AD and smoking, with an overall estimate of 40% risk reduction of AD in smokers compared to nonsmokers. It has been argued though that this protective effect of smoking reflects a survival disadvantage for nonsmokers (Riggs, 1996).

A pilot study (Newhouse *et al*., 1988) with intravenous administration of nicotine in six nonsmokers with probable AD demonstrated a reduction of intrusion errors. Unfortunately, significant behavioral effects occurred, such as anxiety, depression, and dysphoria. Trials with subcutaneous (Sahakian *et al*., 1989; Jones *et al*., 1992) or dermal (Wilson *et al*., 1995; Snaedal *et al*., 1996) administration of nicotine have been inconclusive, and more selective agents are being investigated.

B. ABT-418

ABT-418 is a selective, channel ligand for nicotinic acetycholine receptors, which has been tested with success in rats with lesions in the septal nuclei (Decker *et al*., 1994a) and in macaque monkeys (Buccafusco *et al*., 1995b), improving performance on cognitive tasks. This compound has anxiolytic effects (Brioni *et al*., 1994; Decker *et al*., 1994b). It has also been shown to protect human cell lines against glutamate toxicity and might slow the rate of neurodegeneration of the aged brain (Arneric *et al*., 1995; Donnelly-Roberts *et al*., 1996). Tests with humans are necessary to determine the efficacy of ABT-418 as a cognitive enhancer.

V. Summary

In summary, several compounds that target the potentiation of cholinergic neurotransmission have been studied with AD patients. Acetylcholinesterase inhibitors are associated with significant cognitive improvement in a subgroup of patients with dementia. These drugs have been tested in well designed clinical trials in patients meeting inclusion criteria for mild to moderate dementia. The potential value of these agents in patients with incipient dementia is currently under investigation. Less is known, however, about the effects of selective muscarinic agonists and nicotinic ligands on the neuropsychiatric manifestations of AD, and studies with these agents are ongoing.

Anti-inflammatory and Antioxidant Therapies in Alzheimer's Disease

I. Introduction

The primary treatment of Alzheimer's disease (AD) may be considered to consist of two categories of therapy: symptomatic therapy that boosts cognitive performance and disease-modifying therapy that prevents or slows the disease process. The drugs approved thus far by the Food and Drug Administration (FDA) for the treatment of AD fit into the first category; they provide modest but measurable symptomatic benefit, without altering the rate of long-term decline. Much effort at present is devoted to seeking treatments in the second category to favorably alter the process of neurodegeneration. The development of transgenic mouse models of amyloid deposition in brain offer methods for screening potential anti-amyloid therapies; the result is likely to be human trials of agents that alter processing of the amyloid precursor protein into amyloidogenic fragments or otherwise interfere with the generation or deposition of β-amyloid peptide (Aβ). The recent report of dramatic effect of Aβ immunization in blocking plaque formation in a mouse model (Schenk *et al.*, 1999) represents one exciting example.

Symptomatic treatment, such as cholinesterase inhibitors, augment neurotransmission to improve cognitive performance. Disease-modifying treatment strategies, on the other hand, promote neuronal survival. While anti-amyloid strategies target events specific to the pathogenesis of AD, it may also be fruitful to seek non-disease-specific neuroprotective therapy. For example, treatments that increase the generation or effectiveness of neurotrophic factors may promote neuronal survival in the face of multiple stressors.

Anti-inflammatory and antioxidant treatment strategies fall into this latter category: approaches to improving neuronal survival in the face of nonspecific neurodegenerative stress. This chapter reviews evidence that inflammatory mechanisms and oxidative stress contribute to neurodegeneration in AD and outlines current efforts to develop anti-inflammatory and antioxidant treatment strategies.

II. The Inflammatory Hypothesis of AD

Though clinical features of inflammation are absent, on a molecular level it is apparent that an inflammatory response accompanies the neuropathologic features of AD (Aisen and Davis, 1994; Rogers *et al.*, 1996). Amyloid plaques are surrounded by reactive microglia and astrocytes; the former have the characteristics of antigen-presenting tissue macrophages, including HLA-DR surface markers. There is clear evidence of an acute phase response, with upregulation of inflammatory cytokines such as interleukins 1 and 6 and tumor necrosis factor α (TNF-α) accompanied by an increase in acute-phase proteins such as α1 antichymotrypsin and α2 macroglobulin. The complement system is active in the AD brain (Pasinetti, 1996), with generation of the lytic membrane attack complex, and presumably with release of anaphylatoxins. Upregulation of cyclooxygenase-2 in AD neurons (Pasinetti and Aisen, 1998) suggests that inflammatory lipids may also be involved in the pathogenesis of the disease. On the other hand, there is no acute neutrophilic inflammation in the AD brain, and little evidence of lymphocytic involvement or a humoral response.

Do inflammatory processes represent an ''innocent bystander'' reaction to AD neurodegeneration, induced by neuronal damage without contributing to it? Or do inflammatory mechanisms actually combat amyloid deposition and promote neuronal survival? There is no definitive answer to these pivotal questions, but evidence suggests that inflammation may play an active role in the disease process. Certainly, inflammatory cytokines, microglial activation, and complement activation are potentially neurotoxic, *in vitro* and *in vivo*. Inflammatory cytokines (Fagarasan and Aisen, 1996) and complement components (Oda *et al.*, 1995) augment the toxicity of Aβ protein in cell culture systems. Activated microglia secrete neurotoxins (Giulian *et al.*, 1994) and also augment amyloid toxicity in hippocampal slice cultures (London *et al.*, 1996). Inflammatory cytokines may be directly neurotoxic: overexpression of

IL-6 in the brain of a transgenic mouse leads to neurodegeneration (Campbell *et al.*, 1993). However, recent studies indicate that the role of inflammatory mediators may be complex. It has been assumed that complement activation in the AD brain is destructive, with anaphylatoxin release contributing to the recruitment and activation of microglia, and with generation of the membrane attack complex leading to neuronal membrane lysis. Indeed, suppression of anaphylatoxin release has been considered as a therapeutic goal in AD (Fagarasan *et al.*, 1997). Evidence derived from mice deficient in the complement component C5 (Pasinetti *et al.*, 1996) and studies of C5a receptor knockout mice (Osaka *et al.*, 1999) suggest that the anaphylatoxin C5a may actually play a neuroprotective role. Thus, it is not clear whether broad suppression of complement system activity is beneficial or harmful in AD. It may, therefore, be necessary to develop targeted anti-inflammatory strategies. Specific inflammatory processes that contribute to neuronal failure must be identified, so that selective interventions can be designed.

III. Cyclooxygenase and Brain Inflammation

Some evidence suggests that cyclooxygenase (COX)-2 may be such a specific target for anti-inflammatory therapy. COX catalyzes the conversion of membrane-derived arachidonic acid to prostanoids, a number of which are potent inflammatory mediators (Abramson and Weissmann, 1989). There are two distinct isoforms of COX, called COX-1 and COX-2. COX-2, the inducible form of the enzyme, is most important in inflammatory pathways. Inhibition of the constitutive COX-1, on the other hand, may be responsible for the adverse effects of NSAIDs (Vane and Botting, 1995).

Surprisingly, COX-2 apparently plays a role in mechanisms of neuronal death apart from inflammatory pathways (Pasinetti, 1998). Thus, in animal models of neurodegeneration (using lesions produced by kainic acid and by colchicine, for example) there is marked neuronal upregulation of COX-2 associated with apoptotic mechanisms (Tocco *et al.*, 1997; Ho *et al.*, 1999; Kelley *et al.*, 1999). In cell culture studies, amyloid toxicity is associated with induction of COX-2, and selective COX-2 inhibitors are cytoprotective (G. M. Pasinetti, unpublished data). COX-2 inhibitors also protect against ischemic and excitotoxic neuronal injury (Graham *et al.*, 1996; Nakayama *et al.*, 1996). It appears that COX-2 is involved in programmed cell death and that COX-2 inhibitors are neuroprotective. There is neuronal expression of COX-2 in the AD brain (Pasinetti, 1998). While an initial report indicated reduced levels of COX-2 mRNA in AD cortex (Chang *et al.*, 1996), we have demonstrated upregulation of COX-2 mRNA and protein, primarily associated with neurons, in AD frontal cortex (Pasinetti and Aisen, 1998). Recent studies also show COX-2 upregulation in AD hippocampus (Ho *et al.*, 1999; Yasojima *et al.*, 1999).

Selective COX-2 inhibitors have been developed by several pharmaceutical companies, because these drugs share anti-inflammatory efficacy with older nonselective COX inhibitors (such as indomethacin) with fewer side-effects. A selective COX-2 inhibitor with central nervous system penetration would be a good candidate for therapeutic trials in AD. While NSAIDs inhibit the enzyme's catalytic activity, glucocorticoids downregulate COX-2 expression. If the hypothesis that COX-2 contributes to apoptotic neuronal death in AD is correct, then a glucocorticoid might have synergistic benefit with a selective COX-2 inhibitor. It should be noted that COX-1 may also play a role in the pathophysiology of AD. Although it may not be upregulated, COX-1 is expressed in neurons and glia in the AD brain (Pasinetti and Aisen, 1998; Yasojima *et al.*, 1999). Both COX-1 and COX-2 may be a source of prostanoids that contribute to inflammation and neurodegenerative stress, and both may be targets for pharmacologic intervention. A cartoon depicting the possible role COX isoforms in neuronal–glial interactions in AD is shown in Fig. 33.1.

IV. Oxidative Stress and AD

Free radicals are molecules with unpaired electrons, formed as byproducts of metabolic processes (Halliwell and Gutteridge, 1989). They are highly reactive with macromolecules including lipids and thus can readily damage cell membranes. When the balance between free radical production and cellular anti-oxidant defenses is lost, cellular damage may ensue; such an imbalance has been invoked to explain age-related deterioration in many tissues. The theory that oxidative stress contributes substantially to neuronal damage in AD has received substantial attention (Simonian and Coyle, 1996; Markesbery, 1997; Behl, 1999). Nitrotyrosine, a marker of oxidative damage to proteins, has been demonstrated in association with neurofibrillary tangles in AD (Good *et al.*, 1996). Lipid peroxidation may be most notable in the AD temporal cortex (Marcus *et al.*, 1998). Oxidative damage to nuclear DNA occurs in the AD brain (Lyras *et al.*, 1997), particularly in neocortex (Gabbita *et al.*, 1998), along with a reparative response (Love *et al.*, 1999). Altered expression of superoxide dismutases, antioxidant enzymes, in areas of AD neurodegeneration has been demonstrated (Furuta *et al.*, 1997). Regional increase in iron levels in AD hippocampus could contribute to oxidative damage (Deibel *et al.*, 1997; LeVine, 1997). Malonaldehyde

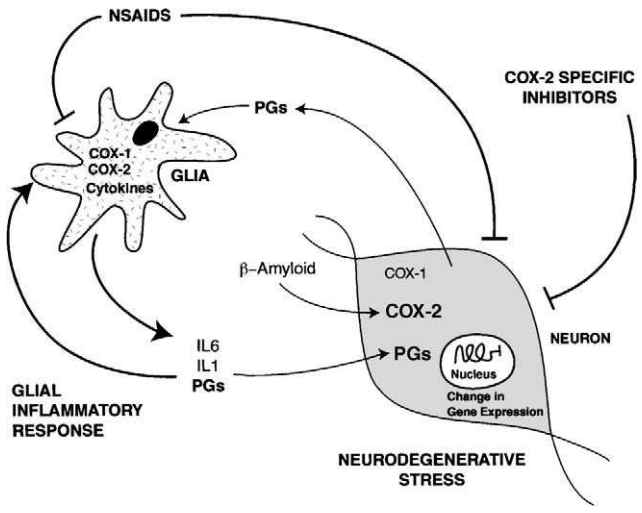

FIG. 33.1. Hypothetical role of COX isoforms in neuronal–glial interactions in Alzheimer's disease neurodegeneration.

levels in erythrocytes are elevated in AD compared to that seen in age-matched controls (Bermejo *et al.*, 1997), while levels of antioxidant enzymes and plasma antioxidant capacity are altered (Famulari *et al.*, 1996; De Leo *et al.*, 1998), consistent with systemic oxidative stress in the disease.

In vitro studies also support a possible link between free radicals and AD. Aβ protein generates free radicals in cell culture and in cell-free solution (Hensley *et al.*, 1994), and the toxicity of Aβ *in vitro* can be limited by antioxidants (Bruce *et al.*, 1996; Tomiyama *et al.*, 1996; Hirai *et al.*, 1998). Mitochondrial dysfunction, with cytochrome oxidase deficiency and impaired function of the electron transport chain, may contribute to free radical accumulation (Beal, 1998; Cassarino and Bennett, 1999). If free radicals play a significant role in neuronal loss in AD, then antioxidants that penetrate cell membranes within the brain would be expected to slow the neurodegeneration (Hall, 1992; Schulz *et al.*, 1996). The results of the multicenter trial of vitamin E and selegiline in AD (Sano *et al.*, 1997) provide encouraging support to this hypothesis.

V. Specific Interventions

A. Glucocorticoids

Glucocorticoids are the most potent anti-inflammatory/immunosuppressive drugs available, and are the primary treatment of many inflammatory disorders of brain. If the hypothesis that suppression of inflammation in brain will slow the progression of AD is correct, glucocorticoid therapy should be considered. The major concern with this approach has been the potential toxicity in the AD population. High-dose steroid regimens (e.g., prednisone 60 mg daily or more) are typically used to suppress brain inflammation in disorders such as multiple sclerosis, lupus cerebritis and vasculitis; such regimens are associated with significant toxicity in elderly subjects, and AD patients may be particularly susceptible to adverse effects on bone and behavior. It is known that glucoroticoids are actually toxic to the hippocampus in rodents (Sapolsky *et al.*, 1985), though perhaps not in primates (Leverenz *et al.*, 1999). Cognitive testing in normal volunteers suggests that glucocorticoids may adversely affect declarative memory (Newcomer *et al.*, 1994), though interestingly this effect diminishes with age (Newcomer *et al.*, 1995). On the other hand, in the presence of an inflammatory disease such as systemic lupus erythematosus, glucocorticoid therapy may improve cognitive function (Denburg *et al.*, 1994).

The Alzheimer's Disease Cooperative Study group (ADCS), a consortium of academic centers conducting clinical trials in AD with support from the National Institute on Aging, conducted the first multicenter trial of anti-inflammatory therapy for AD (Aisen *et al.*, 2000). Based on pilot studies that demonstrated the tolerability (Aisen *et al.*, 1996a) of low-dose prednisone in the AD population, and the efficacy of this treatment in suppressing peripheral markers of inflammation in AD (Aisen *et al.*, 1996a; Fagarasan *et al.*, 1997), the ADCS opted to study the effect of low-dose prednisone treatment on cognitive decline in subjects with mild to moderate AD. In this double-blind placebo-controlled parallel design study, 138 subjects were randomized to receive a regimen of low-dose prednisone or matching placebo. Subjects received an initial dose of 20 mg daily for 4 weeks, tapered to a maintenance dose of 10 mg daily for the duration of 1 year. After 1 year of treatment, medication was slowly tapered over an additional 16 weeks. The primary outcome measure for this study was the cognitive component of the Alzheimer's Disease Assessment Scale (Rosen *et al.*, 1984). The results of the prednisone trial were negative: the low-dose prednisone regimen did not influence the rate of cognitive decline. This may indicate that the regimen of prednisone studied is insufficient to suppress destructive brain inflammatory activity. Much higher doses are used to treat inflammatory diseases of brain such as lupus cerebritis and central nervous system vasculitis. However, higher doses may not be tolerable for prolonged treatment, particularly in the elderly, as indicated by the serious toxicity associated with high-dose glucocorticoids in the treatment of temporal arteritis. Adverse effects on behavior, and on blood sugar and bone density, of the prednisone regimen studied in the ADCS trial suggests that higher doses of glucocorticoids will cause serious toxicity in the AD population.

It is also possible that the diverse actions of glucocorticoids produced deleterious effects that nullified a beneficial anti-inflammatory effect. Thus, hippocampal toxicity may have canceled out a palliative effect on the disease. Further, recent evidence suggests that some inflammatory mediators, such as the anaphylatoxin C5a (Pasinetti, 1996; Osaka *et al.*, 1999) and the cytokine TNF-α (Mattson *et al.*, 1997), may have both neurodegenerative and neuroprotective effects. A more specific, targeted anti-inflammatory strategy may prove successful despite the nagative result of the prednisone trial.

B. Nonsteroidal Anti-inflammatory Drugs (NSAIDs)

The most widely discussed class of anti-inflammatory drugs with regard to AD is the NSAIDs. This interest is fueled by a large number of epidemiologic studies that support the theory that exposure to NSAIDs offers some degree of protection with regard to AD. Rheumatoid arthritis and AD are rarely diagnosed in the same individual (McGeer *et al.*, 1990); one interpretation of this finding is that NSAIDs, the most commonly used drugs to treat rheumatoid arthritis, reduce the subsequent incidence of AD. Studies of twins (Breitner *et al.*, 1994) and sibling pairs (Breitner *et al.*, 1995) discordant for AD also suggest a protective effect of NSAIDs. Numerous other cross-sectional and longitudinal surveys provide further evidence for NSAID neuroprotection (McGeer *et al.*, 1996). A small pilot study of indomethacin treatment in AD suggested that this NSAID slowed the rate of disease progression (Rogers *et al.*, 1993). This study generated a great deal of interest, but the results have been interpreted with caution because of the small number of subjects involved and a large number of drop-outs in the active drug group. Indeed, concern about the tolerability of traditional NSAIDs in the AD population has delayed the development of confirmatory studies. A study using a similar design, but testing the combination of diclofenac and misoprostol (a prostaglandin that reduces the risk of NSAID-induced ulceration), suffered from a similar high drop-out rate (50% in the active drug group) (Scharf *et al.*, 1999).

If long-term treatment with full anti-inflammatory doses of traditional NSAIDs is not feasible in population at risk for AD, there are at least two alternative approaches. One is to test a

low-dose NSAID, reducing the toxicity; the epidemiologic studies cited above suggest that casual use of low-dose NSAIDs may be neuroprotective. The second approach is to use new classes of COX inhibitors, which appear to be safer than older NSAIDs. Two pharmaceutical companies are currently conducting studies of new selective COX-2 inhibitors for the prevention or treatment of AD. In addition, National Institute on Aging-funded studies of both low-dose NSAIDs and selective COX-2 inhibitors have been initiated. Finally, newly developed drugs which combine NSAID activity with nitric oxide release appear to be safer than traditional NSAIDs and may represent candidates for testing in AD.

C. Other Anti-inflammatory Agents

There are other classes of anti-inflammatory drugs that merit consideration for trials in AD. Selection of agents for such trials will depend on evaluation of the contribution of specific mechanisms to neuronal stress. Activated microglia appear to play a prominent role in plaque maturation and may contribute to neuronal damage. If this is the case, agents which target mononuclear cell function may be useful. Colchicine and chloroquine both may be more effective than glucocorticoids in suppressing microglial accumulation and activation (Giulian and Robertson, 1990). Colchicine is also anti-amyloidogenic, highly effective in the secondary amyloidosis of familial Mediterranean fever (Zemer *et al.*, 1992), and perhaps effective in other amyloidoses. A pilot study of colchicine in AD demonstrated excellent tolerability (Aisen *et al.*, 1996b). A multicenter trial of hydroxychloroquine in AD is in progress in the Netherlands (van Gool, personal communication). The activity of propentofylline, a compound under development for the treatment of AD as well as vascular dementia, may work in part by suppressing microglial activity (Rother *et al.*, 1998). On the other hand, some evidence suggests that microglial function plays a beneficial role in the AD brain, scavenging amyloid deposits (Schenk *et al.*, 1999); drugs which inhibit microglial activity could prove harmful.

D. Antioxidants

Inflammatory and oxidative mechanisms overlap, and some therapeutic modalities have both anti-inflammatory and antioxidant properties. For example, potentially toxic free radicals may be generated during the activity of COX, and COX inhibitors may have antioxidant effects. However, interest in the agents discussed below for the treatment or prevention of AD is based primarily on putative antioxidant effects.

E. Vitamin E/Selegeline

The ADCS has reported the results of a multicenter trial of the antioxidants selegeline and vitamin E (α-tocopherol) for the treatment of moderate stage AD (Sano *et al.*, 1997). This trial investigated the effect of treatment of subjects at an initial Clinical Dementia Rating (Morris, 1993) of 2 with vitamin E (1000 IU twice daily), selegeline (5 mg twice daily), or both for 2 years. While there was no evidence of an effect of either agent on cognitive measures, treatment with either (or both) agents was associated with a delay in clinical markers of disease progression (death, institutionalization, progression of and loss of activities of daily living). Interestingly, there was no additive benefit of administering the two agents together. These results support the theory that antioxidant therapy can favorably influence the progression of AD.

F. Ginkgo Biloba

Substantial interest has developed in the use of ginkgo biloba, a botanical antioxidant, in the treatment of AD since publication of a study showing a small but statistically significant cognitive benefit with treatment for 12 months (Le Bars *et al.*, 1997). The study has been criticized over methodologic concerns, such as a very high dropout rate and the use of a last observation carried forward analysis. A recent review suggested that there is a small cognitive benefit to ginkgo treatment (Oken *et al.*, 1998), and the NIH is currently supporting a trial of ginkgo for the prevention of AD.

G. Idebenone

Interest in idebenone as a treatment for AD is based on both its antioxidant properties (Yamada *et al.*, 1999) and its capacity to increase brain production of nerve growth factor (Nitta *et al.*, 1993; Yamada *et al.*, 1997). One trial has reported that treatment of AD patients with idebenone for 6 months results in a slowing of cognitive decline (Weyer *et al.*, 1997). A controlled trial of idebenone to slow the progression of Huntington's disease did not demonstrate benefit (Ranen *et al.*, 1996).

VI. Conclusion

It is likely that specific inflammatory mechanisms, along with oxidative stress, contribute to neuronal damage in AD. Available agents which penetrate into brain tissue and inhibit these mechanisms are now undergoing testing for prevention and treatment of the disease. Further research into the inflammatory and oxidative pathways that influence neuronal survival in neurodegenerative conditions will increase the likelihood that these treatment strategies will succeed.

The Retina in Aging and in Alzheimer's Disease

I. Changes in the Retina

Defective vision and visually guided behavior is a frequent complaint in the elderly and in patients with neurodegenerative disorders, which may be due to eye pathology—including the retina—and a variety of processes affecting the central visual pathways. Elucidating the underlying mechanisms is a complex task, especially under conditions where several regions mediating vision are involved, such as Alzheimer's disease. In fact, impairments of visual perception and eye movements have been repeatedly demonstrated in many patients with Alzheimer's disease (AD). These defects include, but are not limited to, anomalies in color vision, spatial contrast sensitivity, susceptibility to visual masks, electroretinographic and visual evoked potential abnormalities, saccadic and eye tracking dysfunction, and deficits in stereoacuity (Hutton *et al*., 1984; Fletcher and Sharpe, 1988; Katz and Rimmer, 1989; Cronin-Golomb *et al*., 1991). The precise basis for these deficits remains elusive, since senile plaques, neurofibrillary tangles, and neuropil threads, among other lesions, occur in multiple regions that collectively mediate vision (Kuljis, 1994), but not in the retina itself (Hinton *et al*., 1986; Blanks *et al*., 1989; Sadun, 1989; Sadun and Bassi, 1990). Here we focus on one of the putative mechanisms for some of the above clinical manifestations, i.e., retinal ganglion cell loss, postulated on the basis of electroretinographic abnormalities, reduction in the numbers of these cells, and axonal loss in the optic nerve of patients with AD (Hinton *et al*., 1986; Blanks *et al*., 1989; Katz *et al*., 1989). However, this is still a controversial field because virtually all of the postulated Alzheimer-specific histopathological abnormalities in the retina and optic nerve have been found by others to be indistinguishable from age-associated degenerative changes and may not be specific to AD (Price *et al*., 1990; Curcio and Drucker, 1993).

The general problem of visual defects in AD exhibits several levels of complication because traditional accounts of AD have tended to neglect the involvement of the visual system in this condition. However, many different types of visuoperceptive and visuomotor manifestations—and histopathologically demonstrable lesions—have been increasingly recognized or claimed in recent years (Hutton *et al*., 1984; Hutton, 1985; Hinton *et al*., 1986; Beach and McGeer, 1988; Fletcher and Sharpe, 1988; Beach *et al*., 1989; Hof *et al*., 1989, 1990a,b, 1993; Katz and Rimmer, 1989; Katz *et al*., 1989; Méndez *et al*., 1990a,b; Sadun and Bassi, 1990; Cronin-Golomb *et al*., 1991; Hof and Bouras, 1991; Kuljis, 1992, 1994; Fletcher, 1994; Hof and Morrison, 1994). It has since become apparent that involvement of the visual system is both common and multifocal in AD, raising important questions about the precise substrates underlying each of the specific visual manifestations in this condition. The marked heterogeneity in the clinical, neuropsychological, and histopathological manifestations among individual patients, however, have conspired against the elucidation of the precise relationship between these various aspects of involvement and visual impairment in AD.

One of the areas in which efforts at elucidating these mechanisms have concentrated is the possibility of retinal pathology in AD. This is a relatively new area of inquiry, in which most of the relevant work has taken place within a decade and a half. In 1986, it was stated that "whether neuritic plaques are present in the axonal terminations of [retinal] ganglion cells in the lateral geniculate nucleus or the superior colliculus is not known" (Hinton *et al*., 1986). This statement was motivated by focused attention on retinal and optic nerve anbormalities, suggesting possible Alzheimer-specific pathology (Hinton *et al*., 1986; Blanks *et al*., 1989; Sadun, 1989; Sadun and Bassi, 1990). Specific abnormalities originally reported in AD patients include: (1) increase in the glia/neuron ratio throughout the retina, (2) 25–40% ganglion cell loss, (3) "frothy" degeneration in ganglion cells, (4) thinning of the optic nerve fiber layer, and (5) degeneration of predominantly large-diameter axons in the optic nerve. These findings appeared compatible with clinical and electrophysiological abnormalities supporting a retinal disturbance in patients with AD, such as electroretinographic abnormalities and funduscopic changes in the retina and optic nerve (Katz *et al*., 1989; Trick *et al*., 1989; Sadun and Bassi, 1990; Tsai *et al*., 1991; Fletcher, 1994). However, subsequent examinations

have cast doubt on some of these early claims on retinal histopathology, as some investigators have been unable to distinguish quantitatively and qualitatively between the preceived abnormalities in patients with AD and age-matched, presumably normal elderly individuals (Price *et al*., 1990; Curcio and Drucker, 1993).

More recent studies, however, have supported some aspects of the original reports of both neuronal and glial alterations in AD, with proper comparisons with age-matched, presumably eye-disease-free controls (Blanks *et al*., 1996a,b). In particular, these improved reassessments indicate that there is a 25–43% decrease in the total number of ganglion cells, and that the percentage of cell loss is regionally variable. Thus, neuronal loss is greatest in the central retina (52%), especially in its temporal region, and decreases away from the fovea (24%). This phenomenon seems to affect all classes of ganglion cells, and not predominantly large ones as previously suggested (Sadun and Bassi, 1990). There is also loss of additional neuron types throughout the retina (an average of 36%), which is most severe in the peripheral regions (up to 59%). Furthermore, while there is a modest and perhaps insignificant increase in absolute astrocyte numbers (16%), there is a statistically highly significant ($P < 0.0008$) increase in the ratio of astrocytes to neurons (82%). There are also indications of additional changes in Müller glial cells (e.g., increased labeling in their end-feet) in patients with AD.

II. Summary

Virtually all of the histopathological studies in the retina of patients with AD to date have been performed with quite small number of patients, and many of the initial studies did not employ stereological methodology. This, coupled with disconfirming evidence from other laboratories led to controversy as to whether retinal lesions occur or not in AD. There seems to be a consensus, however, that: (1) retinal ganglion cell loss—and other retinal changes—occur in normal aging, which must be distinguished from any changes attributable to AD or any neurodegenerative disorder potentially affecting the brain, and (2) no changes resembling those in the brain—such as senile plaques, neurofibrillary tangles, and amyloid protein deposits—have ever been reported in the retina of patients with AD. Nevertheless, the most recent histopathological findings (Blanks *et al*., 1996a,b), summarized above, lend credence to those postulating that AD results in retinal degeneration.

Future work in this field will hopefully include larger numbers of patients to ascertain to what extent retinal pathology is truly characteristic of AD. In addition, since increasing attention is being paid to AD with visual manifestations—clearly a subgroup of patients with the disorder (Hof *et al*., 1989, 1993; Levine *et al*., 1993; Blanks *et al*., 1996a,b)—it would be most helpful to have information about eye abnormalities in these patients in whom unusually severe involvement of association visual cortices has been recognized. This information is important not only to improve our understanding of the pathobiology of the disease, but is also relevant to the understanding and management of both visual deficits as well as hallucinations frequently observed in patients with AD (Chapman *et al*., 1999).

Pathogenesis of Glaucomatous Optic Neuropathy

I. Introduction

A. Primary Open-Angle Glaucoma

Glaucoma is an optic neuropathy characterized by loss of retinal ganglion cells, cupping or excavation of the optic disc, and a characteristic defect and progressive changes in the visual field. Loss of vision in glaucoma is due to the progressive and irreversible loss of the axons of the retinal ganglion cells. Glaucoma is usually, but not always, associated with impaired aqueous humor outflow, which results in elevated intraocular pressure (IOP). Elevated IOP is considered the major risk factor for glaucoma. Depending on the mechanism of aqueous outflow obstruction, glaucoma is subdivided into open-angle, closed-angle, and congenital or developmental glaucoma. The causes of glaucoma can be primary or secondary, depending on the nature of the pathophysiological events leading to impairment of the flow of aqueous humor. In primary open-angle glaucoma, there is no visible obstruction in the trabecular meshwork; whereas, in secondary glaucoma or in angle closure glaucoma, there are clinically observable causes that impede the flow of aqueous humor.

Primary open-angle glaucoma (POAG), the most common form of glaucoma, is a major cause of blindness worldwide. The prevalence of POAG increases with age markedly, with an estimated age-adjusted prevalence of 1.8% in Caucasians and 5.2% in persons of African descent over the age of 40 (Quigley and Vitale, 1997). POAG is often bilateral, although it may develop in one eye first, and is asymptomatic until later in the disease when patients lose central vision.

The retinal ganglion cells are found in the ganglion cell layer that is the innermost neural layer of the retina bordering the vitreous humor. The retinal ganglion cells have large somas that send dendritic processes into the inner plexiform layer and synapse with bipolar cells and amacrine cells. The retinal ganglion cells carry visual information that has been processed by the retina into the central nervous system by way of long axons that arise from the soma to make up the nerve fiber layer of the retina. These axons run centripetally along the vitreous surface in the nerve fiber layer and, when reaching the optic nerve head, make a right-angle turn to form the optic nerve. In humans, the optic nerve is made up of approximately one million axons from the retinal ganglion cells.

In glaucoma, the loss of neural tissue is believed to be exclusively that of retinal ganglion cells. Clinically, this is seen by biomicroscopy as progressive loss of tissue in the optic nerve head (cupping or excavation) and loss of birefringence in the nerve fiber layer. By visual field testing, the functional loss of retinal ganglion cells can be followed. The statement that only retinal ganglion cells are lost in glaucoma is based on pathological examination of retinas from patients with glaucoma that were done many years ago. However, this question has not been revisited with contemporary techniques. Nevertheless, we will focus on the loss of retinal ganglion cells in this disease.

There is general agreement in the field that damage to the optic nerve axons occurs at the level of the lamina cribrosa in the anterior, nonmyelinated portion of the optic nerve known as the optic nerve head (for comprehensive reviews, see Hayreh, 1978; Kolker and Hetherington, 1983; Quigley, 1992; Hernandez and Pena, 1997). The lamina cribrosa is composed of stacks of connective tissue plates, the cribriform plates, with holes that are aligned in register to form channels through which the axons pass as they exit the globe. In the glaucomatous optic nerve, cupping of the optic disc and compression, stretching and rearrangement of the cribriform plates of the lamina cribrosa occur in response to elevated IOP (Quigley *et al.*, 1983). The changes in the optic disk can be seen clinically by ophthalmoscopy.

The relationship between IOP and glaucomatous optic neuropathy has been extensively studied. Optic nerve changes occur throughout the entire range of IOP levels and damage to the optic nerve shows individual variability. There are many patients with elevated IOP in which optic nerve damage does not occur (ocular hypertension) and there are patients with IOP within the normal range in which optic nerve head damage does occur (normal pressure glaucoma) (Werner, 1996).

Nevertheless, the tendency to develop optic nerve damage and the diagnosis of glaucoma increase with increasing IOP and with each decade over the age of 40. Thus, there seems to be a relationship between age and optic nerve damage, and elevated IOP and optic nerve damage. A less frequent form of primary open-angle glaucoma may occur before age 40 and is referred as a separate entity: juvenile primary open-angle glaucoma. In addition to increasing age and IOP, other important risk factors for glaucoma are race and family history. Persons of African descent are at higher risk for developing more severe glaucoma and at a younger age (Tielsch *et al*., 1991; Leske *et al*., 1995).

B. Human Genetics of Glaucoma

Some forms of early-onset glaucoma are inherited as autosomal-dominant, autosomal-recessive traits or as complex traits involving multiple gene defects and environmental factors. Undoubtedly, many of the risk factors underlying the pathogenesis of glaucoma are also inherited. Ocular parameters such as optic cup size, level of IOP, outflow facility, ocular dimensions, and sensitivity to steroids appear to have a genetic component (Johnson *et al*., 1996). Major advances in glaucoma genetics have led to the discovery and chromosomal location of several genes that cause early-onset glaucoma.

Of interest in this chapter are genes associated with adult onset POAG. The first major gene loci for POAG, GLC1A, and GLC1B, were described by Stone and collaborators (1997) and by Sarfarazi and collaborators (Stoilova *et al*., 1996). GLC1A, also known as myocilin or Trabecular Meshwork Inducible Glucocorticoid Responsive (TIGR), is a gene that is localized on chromosome 1 and expressed in the trabecular meshwork of the outflow pathway. Many families affected with juvenile open-angle glaucoma (JOAG) and 2–4% of patients that are affected with adult-onset POAG show mutations in GLC1A (Alward *et al*., 1996, 1998; Fingert *et al*., 1999). In the laboratory, expression of this gene is induced by chronic treatment of cultured trabecular meshwork cells with glucocorticoids, thus an early name of this gene was TIGR (Polansky *et al*., 1997). The sequence of myocilin suggests a protein with multiple leucine zipper motifs, PEST regions susceptible to intracellular degradation, and regions with homology to the myosin heavy chain. Studies are underway to determine whether there is an association of myocilin with the cytoskeleton and/or the microtubules (Takahashi *et al*., 1998; Mertts *et al*., 1999).

The expression pattern of myocilin in ocular tissues indicates that the outflow pathway is probably the site where the mutation causes the elevated IOP found in these patients (Polansky *et al*., 1997; Takahashi *et al*., 2000). However, the function of myocillin in the outflow tissue is unknown. Myocilin is also expressed in many tissues of the body, including the optic nerve head. Nevertheless, to date there is no evidence that correlates mutations in myocilin with retinal ganglion cell loss or optic nerve damage, the hallmarks of the optic neuropathy in glaucoma.

The GLC1B locus is located on chromosome 2 and is associated with normal to moderately elevated IOP and with optic nerve damage (Stoilova *et al*., 1996). The GLC1C locus was mapped to chromosome 3 and is associated clinically with elevated IOP, cup/disc ratios larger than 0.7, and visual fields defects (Wirtz *et al*., 1999). Other loci for adult onset POAG have been reported in the literature (GLC1D–GLC1F); however, the genes have not been identified. To date, only the GLC1A gene has been identified as causative for glaucoma. Future work in this field may uncover genes that affect retinal ganglion cell or optic nerve susceptibility to elevated IOP.

II. The Optic Nerve Head as the Site of Glaucomatous Damage

A. Structure

The optic nerve head is the intraocular portion of the optic nerve and extends from the vitreal surface of the optic disc to the posterior scleral surface. The axons of the retinal ganglion cells are not myelinated as they traverse through this region. The prelaminar region of the nerve head is where the axons of the retinal ganglion cells converge and turn 90° to form the optic nerve. Columns of astrocytes, which contain blood vessels, separate the nonmyelinated axons into bundles (Anderson, 1969).

The lamina cribrosa is posterior to the prelaminar region and is composed of about 10 fibroelastic plates, cribriform plates, stretched across the scleral canal. The cribriform plates are perforated by several hundred openings, aligned in register to permit the exit of the nerve bundles (Anderson, 1969).

In normal human optic nerve heads, the lamina cribrosa is fibroelastic and formed by stacks of connective tissue, the cribriform plates, which are organized in lamellae perpendicular to the axons and are lined by astrocytes (Elkington *et al*., 1990; Hernandez and Gong, 1996). The extracellular matrix (ECM) of the lamina cribrosa, together with the astrocytes, provides mechanical and biological support to the axons from the retinal ganglion cells as they exit the eye (Hernandez and Pena, 1997).

The postlaminar region of the nerve head is posterior to the lamina cribrosa and is where the axons of the retinal ganglion cells become myelinated. The axon bundles are separated by pial septae containing blood vessels and lined by astrocytes.

B. Pathological Changes in Glaucoma

The human optic nerve head has biomechanical properties, which may be altered irreversibly during the glaucomatous process. These biomechanical properties are provided at the level of the lamina cribrosa. In the glaucomatous optic nerve head, cupping of the optic disc, notching and thinning of the neuroretinal rim, disc hemorrhages, and loss of the retinal nerve fiber layer are common pathological observations by the clinician. At the tissue level, compression, stretching, and remodeling of the cribriform plates occur, in many patients in response to IOP (Quigley *et al*., 1983) (Fig. 35.1). Early glaucomatous changes in the lamina cribrosa include an outward movement and vertical compression of the cribriform plates. The bowing of the lamina cribrosa is hinged at the insertion of the lamina in the sclera and at the insertion of the lamina into the wall of the central vessels of the retina. This results in the change from U-shaped lamina in normal eyes to a W-shaped lamina in glaucomatous eyes (Varma and Minckler, 1996).

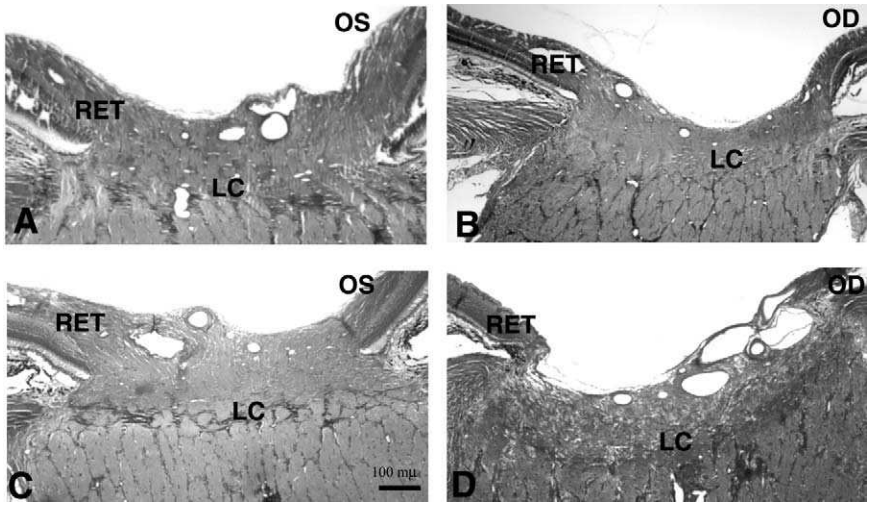

FIG. 35.1. Low magnification of sagittal views of the macaque monkey optic nerve head in experimental glaucoma. Right eyes (OD) of two Rhesus monkeys were exposed to chronic elevation of intraocular pressure at ~29.4 mm Hg for 32 weeks (B) and at ~39 mm Hg for 12 weeks. Left eyes (OS) were left untreated and used as controls; intraocular pressures were ~19 mm Hg (A) and ~11 mm Hg (C), respectively. Note in (B) a slight excavation of the optic nerve head and displacement of the central retinal vessels to the margins of the cup. Note in (D) a marked excavation of the nerve head and posterior bowing of the lamina cribrosa (LC). RET, retina. Trichromic staining.

There are changes in the quantity and composition of several matrix macromolecules, which must significantly affect the biomechanical properties of the optic nerve head. Astrocytes, the major cell population in the optic nerve head, become reactive and are probably responsible for the remodeling of the optic nerve head in glaucoma. Changes in the support component of the optic nerve head in the initial stage of glaucoma will account for irreversibility and perhaps increased susceptibility to optic nerve damage from IOP during the progression of the disease.

The remodeling of the optic nerve head in glaucoma is accomplished through the properties of ECM macromolecules, which generate a large array of structures, allow interactions between protein and nonprotein macromolecules, modulate cellular behavior and phenotypes, bind growth factors and cytokines, thus acting as a source of potent modifiers of cellular responses, and provide the scaffold for cell migration and cell–cell interactions (Raghow, 1994).

C. Role of the Extracellular Matrix in Glaucoma

Wound healing and remodeling of ECM in the brain involves several cell types. These include reactive astrocytes, microglia, and vascular endothelia, invading macrophages and oligodendrocytes, all of which contribute to the formation of a glial scar. After neural injury, reactive astrocytes synthesize ECM proteins, e.g., tenascin, laminin, and chondroitin sulfate proteoglycan, that are not expressed in adults but are expressed at high levels during development. Synthesis of these ECM macromolecules by reactive astrocytes causes remodeling of the microenvironment of the neural tissue and may provide boundaries to isolate the damaged neurons, prevent migration of inflammatory cells due to failure of the blood–brain barrier, serve as storage sites for growth factors, and deter regrowth of brain axons after injury (Fitch and Silver, 1997). Although the responses in the glaucomatous optic nerve head have components of wound healing that are similar to those seen after neural injury in the central nervous system, there is no invasion of inflammatory cells. A true glial scar does not form; nevertheless, extensive remodeling of the ECM does occur, affecting most of the major groups of ECM macromolecules.

Several laboratories, including ours, have used immunohistochemistry and molecular biological techniques to document the changes in the macromolecular components of the ECM in the human glaucomatous optic nerve head compared to age-matched normals. Previous work has demonstrated changes in different collagen types, basement membrane components, glycosaminoglycans, elastin, tenascin, and fibrillin (Morrison *et al*., 1989, 1990; Hernandez *et al*., 1990, 1994a,b; Quigley *et al*., 1991; Fukuchi *et al*., 1992, 1994; Hernandez, 1992; Pena *et al*., 1996, 1998, 1999; Gong *et al*., 1997; Varela and Hernandez, 1997).

1. Structural Extracellular Matrix

In POAG, there is enhanced expression of collagen type IV mRNA by astrocytes in the prelaminar region and *de novo* expression of elastin mRNA by laminar astrocytes (Hernandez *et al*., 1994a,b). These observations of the differential expression of ECM macromolecules, dependent on the area of the optic nerve head, strongly suggest reactivation of astrocytes and regional responses to their microenvironment.

Collagen fibers, elastic fibers, basement membranes, and proteoglycans form the ECM of the lamina cribrosa. The three-dimensional organization of the ECM in the lamina must contribute to the ability of this tissue to adapt to the diurnal changes in IOP that occur normally. However, in glaucomatous neuropathy a marked disruption of the ECM occurs. In POAG, there are marked changes in elastic fibers at the level of the lamina cribrosa, involving elastotic degeneration

(Hernandez, 1992; Netland *et al*., 1995; Pena *et al*., 1998) and upregulation of tropoelastin mRNA, indicating reactivation of synthesis of this macromolecule in glaucoma (Hernandez *et al*., 1994b). However, elastotic fibers are predominantly formed in glaucomatous optic neuropathy.

The ultrastructural morphology of elastotic fibers in the lamina cribrosa varies from large irregular masses of ribbons of elastin-labeled material to moth-eaten large fibers, with irregular distribution of elastin and microfibrils (Fig. 35.2). In the monkey model of glaucoma in use in our laboratory, elastotic fibers are also present in the ECM of the lamina cribrosa in the eye with elevated pressure but not in the contralateral eye. However, in the lamina cribrosa of the monkey model of optic nerve transection, elastotic fibers are absent in the ECM of both the transected and the contralateral eyes. These studies strongly suggest that the enhanced elastin synthesis and assembly of elastotic fibers in glaucoma represent a specific response to elevated IOP and not a response to the mere loss of axons from the optic nerve head.

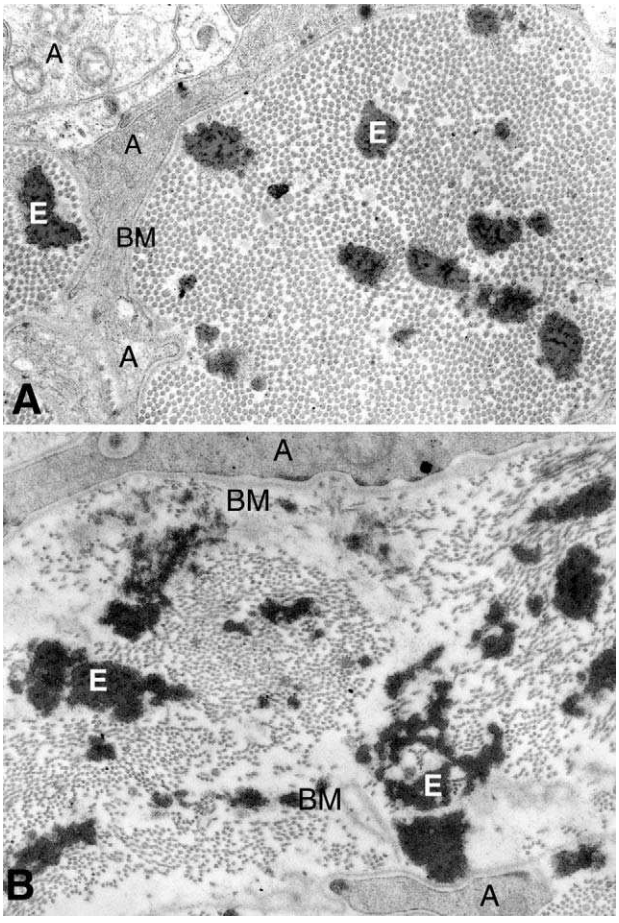

FIG. 35.2. Electron micrographs of the human lamina cribrosa of a normal eye (A) and an age matched glaucomatous eye (B). (A) In the normal eye, the fibroelastic matrix of the laminar plates consists in tightly packed collagen fibers surrounding elastic fibers (E). A well-defined basement membrane (BM) separates the astrocytes and their process (A) from the underlying matrix. (B) In glaucoma, elastic fibers (E) appear fragmented and strongly electron dense. The density of collagen fibers is markedly reduced around the elastic fibers. Note the presence of basement membrane material (BM) in the matrix. Original magnification, $\times 26,000$.

The increased area of elastin-labeled material in glaucoma (Pena *et al*., 1998) suggests that elastotic fibers may consist of newly synthesized elastin as demonstrated by the increased tropoelastin mRNA detected in the lamina cribrosa of glaucomatous eyes (Hernandez *et al*., 1994b; Pena *et al*., 1996). There is no apparent defect in the primary sequence or in the alternative splicing of tropoelastin mRNA in glaucomatous optic nerves (Pena *et al*., 1996), suggesting that the derangement of elastic fibers in the glaucomatous lamina cribrosa results from extracellular processing of tropoelastin and/or assembly into the microfibrillar scaffold.

The changes in elastic fibers are accompanied by changes in the collagen network. Qualitative changes in density and distribution of collagen fibers in the laminar plates and loss of collagen fibers around elastic fibers, as detected by morphometry, have been described (Quigley *et al*., 1991; Hernandez, 1992). Recently, a three-dimensional study using the scanning electron microscope further demonstrated the disorganization of the collagen network in the lamina cribrosa of glaucomatous monkeys. In normal eyes, a thin cushion of collagen fibers covers the surface of the laminar plates and a smooth layer of well-packed collagen fibers covers the inner surface of the laminar pores. In contrast, in glaucomatous eyes the inner surface of the pores is irregular and the pores are narrower (Sawaguchi *et al*., 1999).

In most connective tissues, elastic fibers and collagen fibers act as parallel mechanical elements to applied stress or strain. At low levels of strain, collagen fibers are easily extended with most of the strain borne by the elastic fibers. At high levels of strain, the collagen fibers limit the distension, providing strength and support to the tissue (Mercer and Crapo, 1990).

In conclusion, the changes in the ECM of the glaucomatous optic nerve head are extensive and may be caused by reactive astrocytes. As these cells alter the microenvironment, some of the changes in ECM may not be supportive of normal axons in the immediate area. Furthermore, changes in the elastic and collagen components will have an impact on the tissue's ability to respond normally to pressure, resulting in a less compliant optic nerve head. These changes in the biomechanical properties will produce a remodeled tissue with a tendency to collapse under elevated pressure, as suggested by changes in the compliance of the optic disc related to elevated IOP in human and monkey glaucomatous eyes.

2. Reactive Extracellular Matrix in Glaucoma

Reactive astrocytes synthesize new ECM proteins in areas of neural degeneration that provide boundaries to isolate damaged axons from healthy axons, that prevent hematogenous cells from invading the injured neural tissue, that affect survival of remaining axons, and that prevent axonal regrowth. Recently, we demonstrated gene expression and synthesis of tenascin, an ECM protein, synthesized by optic nerve head astrocytes (Pena *et al*., 1999). Tenascin is synthesized in development and by reactive astrocytes in central nervous system injury (Bartsch *et al*., 1992, 1994). Other ECM proteins that may be induced in glaucoma are laminin, sulfated glycoprotein 2 (SPG2), and chondroitin sulfate proteoglycans (Fitch and Silver, 1997).

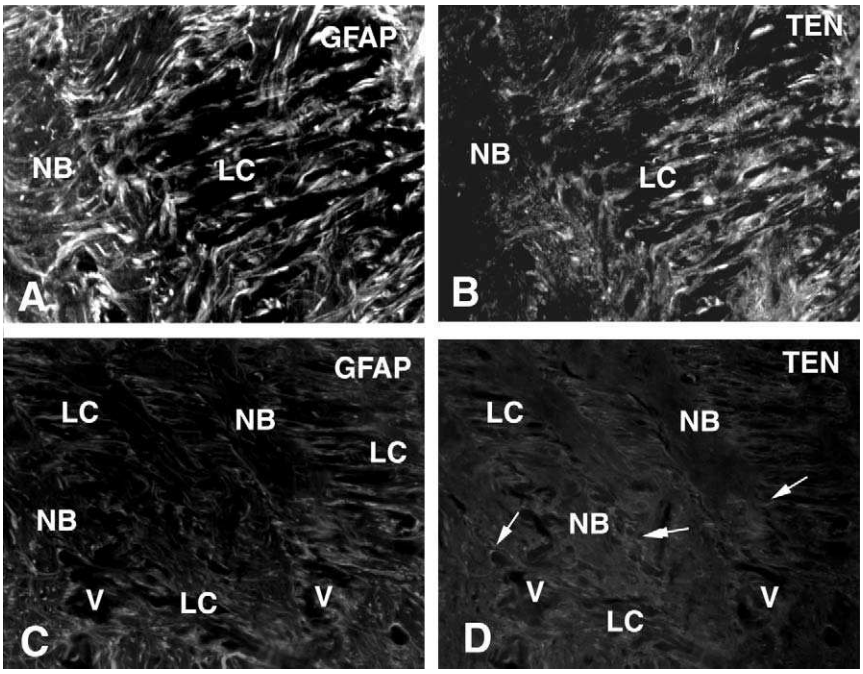

FIG. 35.3. Sagittal sections of the lamina cribrosa (LC) immunostained with antibodies against GFAP and tenascin. (A) In the normal eye, astrocytes stained with GFAP form lamellae oriented perpendicular to the nerve bundles (NB). Tenascin staining is present in the cribriform plates and around blood vessels but not in the nerve bundles. (B) In the glaucomatous eye, astrocytes bearing thick processes stained intensely with GFAP occupy the nerve bundle area. Tenascin staining is present inside the nerve bundles. Scale bar, 50 mμ.

Tenascin synthesis, a minor component of the ECM in normal optic nerve head, is upregulated in human and monkey glaucomatous optic nerve head (Pena *et al*., 1999) (Fig. 35.3). In the lamina cribrosa of human glaucomatous eyes, tenascin immunoreactivity and gene expression were localized to astrocytes in the cribriform plates and inside the nerve bundles. It is interesting to note that the promoter region of the tenascin gene contains an enhancer element responsive to mechanical stress (Chiquet-Ehrismann *et al*., 1994; Chiquet *et al*., 1996). Glaucoma is characterized by IOP, and it has been proposed that elevated IOP-related stress in the optic nerve head affects astrocytes within the tissue (Hernandez and Pena, 1997). Although, the role of tenascin in the nerve head is unknown, one can speculate that upregulation of tenascin synthesis by astrocytes in glaucoma may be partially due to IOP-related mechanical stress.

3. Extracellular Matrix Degradation

Proteolysis cleaves extracellular domains of ECM macromolecules, regulates assembly and remodeling of the tissue and releases growth factors. Through these functions, ECM-degrading enzymes participate in development, morphogenesis, growth of tissues and organs, tissue repair, and pathological processes (Parks and Sires, 1996; Werb, 1997). The major families of ECM-degrading enzymes are the matrix metalloproteinases (MMPs), the tissue inhibitors of MMP, the tissue serine proteinases, e.g., as thrombin, tissue plasminogen activator, urokinase-type tissue plasminogen activator, and plasmin. Certain ECM-degrading enzymes have been identified in brain injury, tumor invasion, and neurodegenerative disease in the brain (Romanic and Madri, 1994; Rosenberg, 1995; Pagenstecher *et al*., 1998; Uhm *et al*., 1998).

A recent study in the normal and inflamed mouse brain documented differential expression of several MMP and tissue inhibitors of MP genes. MMPs are expressed constitutively at very low levels, whereas tissue inhibitors of MPs 2 and 3 are expressed at high levels in the central nervous system of normal animals. In the inflamed brain tissue, microglia and leukocytes invading the lesions expressed high levels of MMPs. Reactive astrocytes surrounding the lesions expressed tissue inhibitors of MPl (Pagenstecher *et al*., 1998). This study indicates that in the normal central nervous system, astrocytes maintain low MMP activity by high constitutive expression of tissue inhibitors of MPs and that in response to inflammation, reactive astrocytes isolate lesions to protect healthy neurons (Pagenstecher *et al*., 1998).

MMPs may also be a component of astrocyte reactivation, which requires a change in cell shape and migration through the ECM. MMP activities are likely to be involved in the transition of quiescent astrocytes to the reactive phenotype by degrading cell surface adhesion molecules and, through disruption of the extracellular domains, by altering the cytoskeleton (Parks and Sires, 1996; Werb, 1997). Activation of growth factors, such as TGF-β, can also be mediated by proteolysis of ECM-binding proteins. The extensive remodeling of the ECM of the optic nerve head that is characteristic of glaucoma strongly suggests the presence of ECM-degrading enzymes contributed by reactive astrocytes. Studies are underway in several laboratories, including ours, to determine which MMPs

may be involved in the remodeling of the ECM in glaucoma. A preliminary screening of MMPs indicate that there are several such enzymes associated with reactive astrocytes that may account for ECM remodeling. For example, a cell membrane-associated MMP, MT-MMPl, is localized to hypertrophic astrocytes in the glaucomatous lamina cribrosa suggesting a role for these enzymes in the disease.

D. Glial Cells in Glaucoma

1. Astrocytes in the Optic Nerve Head

Astrocytes are the major glial cell type in the nonmyelinated optic nerve head in most mammalian species. In the lamina cribrosa and prelaminar region of the optic nerve head, astrocytes provide cellular support functions to the axons form the interface between connective tissue surfaces and surround blood vessels (Anderson, 1969).

In the prelaminar, lamina cribrosa, and retrolaminar axons, there are regional and functional heterogeneities of astrocytes that provide cellular support to the axons and synthesize ECM macromolecules. In the human optic nerve head, two subpopulations of astrocyte type 1 are distinguished. Type 1 A astrocytes are interpersed in the glial columns and at the edges of the cribriform plates. They express glial fibrillary acidic protein (GFAP), a cytoskeletal marker of astrocytes, but do not express neural cell adhesion molecule (NCAM). Type 1B astrocytes express both GFAP and NCAM. They are the major glial cell population in the region and are the primary sources for the synthesis of ECM in the optic nerve head during development and throughout life (Hernandez *et al*., 1991; Hernandez, 1992; Ye *et al*., 1994; Pena *et al*., 1996). Type 1B astrocytes line the vitreal surface of the optic disc, form the glial columns, surround blood vessels in the prelaminar region, form the cribriform plates in the lamina cribrosa, and separate the sclera from the optic nerve in the insertion area.

In the lamina cribrosa, astrocytes form lamellae oriented perpendicular to the axons. A well-defined basement membrane separates the astrocytes from the underlying collagen and elastic matrix. Astrocytes extend cell processes into the ECM core and establish contacts with processes of other astrocytes and lamina cribrosa cells (Fig. 35.3).

2. Reactive Astrocytes in Glaucoma

Astrocytes are a significant component of the response to injury in the central nervous system (Hatten *et al*., 1991; Eddleston and Mucke, 1993; Faden, 1993; Norenberg, 1994, 1996; Ridet *et al*., 1997; Aschner, 1998). In the brain, mature, quiescent astrocytes become ''reactive'' after injury and participate in formation of a glial scar, which does not support axonal regrowth (Ridet *et al*., 1997). The glial scar represents the scar tissue in the central nervous system. The major hallmark of the glial scar is the increased expression of GFAP by accumulation of hypertrophic astrocyte cell bodies and a thick network of processes (Hatten *et al*., 1991). Depending on the type of injury and the region of the central nervous system, glial scars also contain microglia, macrophages and other blood-borne cells, meningeal cells, fibroblasts, and oligodendrocytes. Newly formed blood vessels may also be present in the scars (Bartsch *et al*., 1992, 1994; Ajemian *et al*., 1994). Abundant ECM proteins are synthesized in the glial scars by reactive astrocytes or by invading meningeal cells (Hirsch and Bahr, 1999). Reactive astrocytes form a barrier around the injured neural area, isolating intact neural tissues from secondary lesions, which may also lead to inhibition of axonal growth.

By light microscopy, the cardinal morphologic features of reactive astrocytes are cellular hypertrophy, hyperplasia, and increased expression of GFAP and vimentin (Hatten *et al*., 1991; Eddleston and Mucke, 1993; Ridet *et al*., 1997). Studies on activity indicate that reactive astrocytes increase the synthesis of ECM macromolecules, cell adhesion molecules, and recognition molecules, a variety of growth factors and cytokines, and cell mediators and receptors. In humans, reactive astrocytes contribute to the pathogenesis of several neurodegenerative disorders including Alzheimer's disease (Tomimoto *et al*., 1997), schizophrenia (Arnold *et al*., 1995), AIDS dementia (Aschner, 1998), and acute injury (Brodkey *et al*., 1995). Reactive astrocytes exhibit regional variability of activities depending on the nature of the injury, the microenvironment at the injured site, and the distance to the injured site (Malhotra and Shnitka, 1994).

Recent studies in human glaucomatous optic neuropathy and in a rat model of elevated IOP have demonstrated synthesis of inducible nitric oxide synthase, NOS-2, by reactive astrocytes in the optic nerve head (Neufeld *et al*., 1997, 1999). NOS-2 is a powerful enzyme that generates excessive amounts of nitric oxide, which may be neurotoxic to the axons of the retinal ganglion cells (Neufeld, 1999b). These observations underscore the importance of the reactive astrocytes in the glaucomatous process.

3. Reactive Astrocyte Cytoskeleton

Changes in expression of intermediate filaments in the astrocyte cytoskeleton are characteristic of the transition of a quiescent astrocyte to the reactive phenotype Ridet. GFAP and vimentin are type III cytoplasmic intermediate filaments characteristic of astrocytes (Galou *et al*., 1997). Both proteins are developmentally regulated; e.g., in rodents, vimentin is expressed early in development in radial glia. In most astrocytes in the central nervous system, expression of vimentin ceases and GFAP expression begins at birth (Oblinger and Singh, 1993; Galou *et al*., 1996). Vimentin is expressed in immature and in reactive astrocytes, both of which are mobile cells (Galou *et al*., 1997; Takamiya *et al*., 1988). However, astrocytes in the optic nerve retain expression of both GFAP and vimentin in adulthood (Calvo *et al*., 1990). Nestin is a type IV intermediate filament that is expressed in multipotent neural progenitor cells and in reactive astrocytes rapidly after central nervous system injury, where it lasts for a prolonged period (Frisen *et al*., 1995). In addition to the transcriptional regulation of the expression of GFAP (Brenner, 1994) and vimentin in reactive astrocytes, posttranslational modifications of intermediate filaments, such as phosphorylation by protein kinases, are also part of the reorganization in reactive astrocytes (Harrison and Mobley, 1992).

Increased expression of GFAP by reactive astrocytes after neural injury is an early response that can occur in the absence

of astrocyte proliferation and is related to cell hypertrophy (Hatten *et al*., 1991). Once a glial scar is formed in the site of injury, GFAP levels decrease at the site of injury and astrocytes become quiescent. In moderate and advanced POAG in humans and in monkey eyes with chronically elevated IOP, increased immunoreactivity of GFAP was evident in astrocytes of the prelaminar region and lamina cribrosa, suggesting astrocyte reactivation. The tissue remodeling of the optic nerve head in glaucoma is associated with changes in distribution and cellular characteristics of astrocytes (Hernandez and Pena, 1997). The changes in distribution included loss of the glial columns in the prelaminar optic nerve and apparent migration of astrocytes into the nerve bundles in the lamina cribrosa (Fig. 35.4).

In addition to increased GFAP immunoreactivity, the cellular changes included hypertrophy of the cell body, thicker and longer cellular processes in the prelaminar region, and round-shape cell body and loss of processes in the lamina cribrosa (Fig 35.4) (Varela and Hernandez, 1997). Recently, specific markers for reactive astrocytes have been reported (Malhotra and Shnitka, 1994; Ridet *et al*., 1997). The monoclonal antibody J1-31 recognizes a protein associated with glial intermediate filaments in reactive astrocytes, which are adjacent to areas of neural tissue damage (Malhotra and Shnitka, 1994; Ridet *et al*., 1997). In addition, the cytoskeleton-associated stress protein, Hsp-27 (Renkawek *et al*., 1994; Kato *et al*., 1995), is also upregulated in reactive astrocytes proximal to a lesion. In human glaucoma, Hsp27 is upregulated in astrocytes in the optic nerve head (Tezel *et al*., 2000).

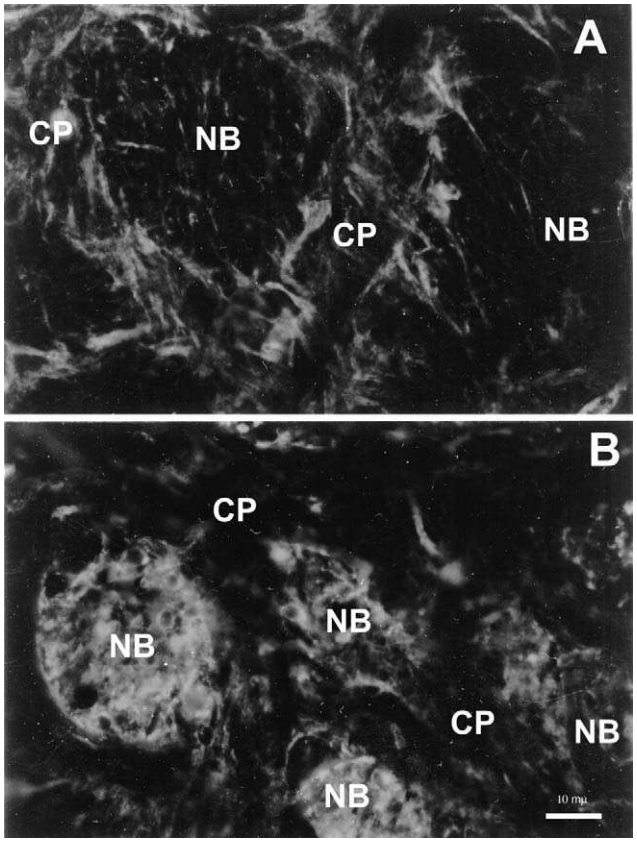

FIG. 35.4. Cross sections of the human lamina cribrosa immunostained with an antibody against GFAP. (A) In the normal lamina cribrosa, astrocytes stained with GFAP are located in the cribriform plates (CP) and extend processes into the nerve bundles (NB). (B) In the glaucomatous lamina cribrosa, astrocytes appear rounded and are located inside the nerve bundles (NB). Note that the cribriform plates are devoid of astrocytes and their processes.

4. Expression of Neural Cell Adhesion Molecule in Reactive Astrocytes

NCAMs are a family of cell surface glycoproteins that accomplish Ca^{2+}-independent adhesion, either through homophilic or heterophilic binding, between molecules on neighboring cells or between cell and ECM proteins. Changes in NCAM expression are considered a sign of reactive astrocytes (Le Gal La Salle *et al*., 1992; Lehmann *et al*., 1993; Jucker *et al*., 1995; Wolf *et al*., 1995; Roche *et al*., 1997; Cotman *et al*., 1998).

NCAMs are abundantly expressed in the central nervous system during development (Edelman, 1986a,b; Walsh and Doherty, 1997). A single gene encodes NCAMs but alternative splicing of the pre-mRNA produces at least three major isoforms, $NCAM_{180}$, $NCAM_{140}$, and $NCAM_{120}$ (Hemperly *et al*., 1990; Walsh and Doherty, 1996). These isoforms differ in the size of their cytoplasmic domains and in the mode of association to the membrane. $NCAM_{120}$ lacks a cytoplasmic domain and is attached to the membrane by a glycosylphosphatidylinositol moiety. $NCAM_{140}$ and $NCAM_{180}$ possess transmembrane and intracytoplasmic domains (Hemperly *et al*., 1990; Pan *et al*.,1992).

Previous studies have demonstrated that type 1B astrocytes constitutively express NCAM in the optic nerve head and also in culture (Ye and Hernandez, 1995; Kobayashi *et al*., 1997). In glaucoma, increased NCAM immunoreactivity is observed in most astrocytes in the lamina cribrosa and prelaminar regions, consistent with astrocyte reactivation (Varela and Hernandez, 1997). Recent studies in our laboratory indicate that $NCAM_{140}$ mRNA is constitutively expressed in normal optic nerve head, whereas $NCAM_{180}$ mRNA is the predominant isoform expressed in glaucomatous optic nerve head. *In situ* hybridization experiments localized $NCAM_{180}$ mRNA to reactive astrocytes in the glaucomatous tissue. (Ricard *et al*., 1999).

Dynamic changes in astrocytes are associated with changes in NCAM expression. $NCAM_{180}$ is more adhesive and associates with cytoskeletal molecules thus influencing cell anchoring and shape. $NCAM_{180}$ physically couples with the cytoskeleton, using actin-associated proteins such as vinculin and actinin, at the long cytoplasmic domain (Pollerburg *et al*., 1986, 1987). This may be relevant to differentiation of neural cells during central nervous system development and in adult central nervous system remodeling in response to injury (Hortsch *et al*., 1998). Furthermore, deletion of $NCAM_{180}$ exon 18 in mouse produces defects in cell migration in certain regions of the central nervous system including the retina (Tomasiewicz *et al*., 1993). Such interactions between NCAM and the cytoskeleton may be required for the migration of reactive astrocytes during optic nerve remodeling. Movement of astrocytes requires initial separation from neighboring cells and ECM substrate and subsequent adhesion and readhesion to the substrate during locomotion. We hypothesize that new, selective expression of the $NCAM_{180}$ isoform that permits

rapid changes in adhesive interactions is a necessary part of the transition of quiescent to reactive astrocyte.

5. Microglia

Microglia are a subtype of glia in the central nervous system that are activated in response to neuronal injury (Perry *et al*., 1995; Raivich *et al*., 1999; Streit *et al*., 1999). In normal tissue, microglia are quiescent and have a stellar shape with a small nucleus and a cell body with several ramified processes. Microglia are distributed in a regularly spaced array throughout neural tissue and are found within the perivascular space, surrounded by the glia limitans, and paravascular or encircling the glia limitans. There is currently some debate about whether the perivascular cells are truly microglia or monocytes. Microglia are also found in the central nervous system, not associated with blood vessels.

Recent studies in the human optic nerve head have identified the presence of quiescent microglia in normal optic nerve heads and of activated microglia in the glaucomatous nerve (Neufeld, 1999a). Stellate cells with thin, ramified processes, positive for HLA-DR and CD-45 but negative for GFAP, were identified as quiescent microglia in the human optic nerve head. These cells were found throughout the normal optic nerve head in the walls of large blood vessels and surrounding capillaries in the glial columns and the cribriform plates (Fig. 35.5). In glaucomatous eyes with moderate and severe optic nerve head damage, microglia were present as clusters of large ameboid, activated cells in the compressed lamina cribrosa and as formations of concentric circles surrounding blood vessels. In the parapapillary chorioretinal region of glaucomatous optic nerve heads, large, activated microglia were present as single cells or clusters on the termination of Bruch's membrane (Fig 35.5). Activated microglia, as clusters of cells in the parapapillary chorioretinal region, appear to form a discontinuous, linear barrier in the parenchyma near the vassels of the choriocapillaris bordering the neural tissue. The parapapillary chorioretinal region is considered a potential defect in the blood–retinal barrier. In addition, along the optic nerve/choriocapillaris–scleral interface, activated microglia appeared to form liner arrays near the choriocapillaris vessels. These cells were parenchymal and not in close association with the vasculature.

In glaucomatous tissue, activated microglia appear to be strategically positioned in relationship to blood vessels and the blood–retina barrier. In medium-sized vessels in the compressed prelaminar region, activated microglia form concentric rings in the parenchyma around the vasculature. As the glaucomatous optic nerve becomes compressed, disorganized, and remodeled, blood vessels may become leaky and compromise the blood–retinal barrier. Also, the distribution and activation of microglia in the parapapillary chlorioretinal region of glaucomatous eyes may provide, at least in part, a cellular explanation for the progressive parapapillary chlorioretinal atrophy that has been seen biomicroscopically, described clinically, and associated, by many authors, with glaucoma (Fantes and Anderson, 1989; Jonas and Grundler, 1996; Nicolela and Drance, 1996).

III. Mechanisms of Optic Nerve Damage

A. Role of Elevated Intraocular Pressure

Elevated intraocular pressure remains the most prominent risk factor in the development and progression of glaucoma. In normal individuals *in vivo*, tissues of the lamina cribrosa of the optic nerve head are exposed to a hydrostatic pressure gradient between the intraocular compartment IOP and the retrolaminar tissue pressure (Morgan *et al*., 1998). This hydrostatic pressure gradient fluctuates normally, a small amount, due to the ocular pulse and the diurnal changes in IOP (Zeimer *et al*., 1991). In glaucoma, there are elevated IOP as well as daily fluctuations and spikes of IOP. Under such conditions, the lamina cribrosa undergoes significant deformation in response to changes in IOP, which generates biomechanical stress on astrocytes and other cell types of the lamina cribrosa (Zeimer and Chen, 1987; Zeimer and Ogura, 1989; Burgoyne *et al*., 1995). *In vivo*, the nature of the IOP-related biomechanical stress that affects astrocytes or retinal ganglion cell axons is unknown but shear, tensile, or compressive forces may be involved. Similarly, the mechanisms by which IOP-related

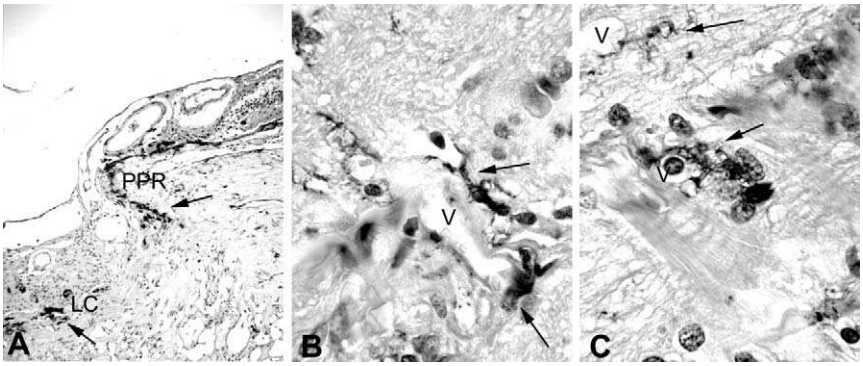

FIG. 35.5. Microglial cells in the human optic nerve head. Microglia cells were stained with anti-human HLA-DR antibody and detected with HRP. (A) Glaucomatous optic nerve head showing clusters of microglia in areas of degeneration in the lamina cribrosa (LC) and in the peripapillary region (PPR). Note the accumulation of microglia along Bruch's membrane (BM) (×150). (B) Perivascular microglia, shown at higher magnification, in an optic nerve head with glaucoma (arrows). Note the characteristic "spiny" processes of microglial cells (×1200). V, blood vessel. (C) Perivascular microglia in an age-matched normal optic nerve head (arrows). Note that the perivascular microglia are similar to perivascular microglia shown in B (×1200). From Hernandez (2000).

stress affects optic nerve head astrocytes leading to the reactive astrocyte phenotype, optic nerve head remodeling, and loss of retinal ganglion cell axons in glaucoma remain elusive.

Many other cellular functions may be affected by IOP-related physical stress including cell adhesion, transmembrane transport, and RNA processing (Wright *et al*., 1992; Maniotis *et al*., 1997; Kaarniranta *et al*., 1998). *In vitro* studies on cells of the optic nerve head may contribute to the understanding of the impact of abnormally elevated IOP in the pathophysiology of glaucomatous neuropathy.

B. Role of the Vasculature in Glaucoma

Although there is overwhelming clinical and experimental evidence that elevated IOP is a critical player in the structural changes and in retinal cell ganglion cell loss in glaucomatous optic neuropathy, a subset of patients develop glaucomatous changes at normal levels of IOP, a condition called normal-tension glaucoma (Werner, 1996). Investigators in the field point out several examples of glaucomatous damage that cannot be explained by the IOP theory: In Japan, the average IOP tends to decrease with age, in contrast in the West, where IOP levels tend to be higher in the aging population. However, the frequency of glaucomatous optic neuropathy in the Japanese population is similar to that seen in the West. There are more females than males affected by normal-tension glaucoma despite having similar IOP levels. Between blacks and whites, the levels of IOP are similar; however, the prevalence of glaucomatous optic neuropathy is four times higher in blacks (Flammer, 1994). To account for these differences, hemodynamic factors, such as ocular blood flow, decreased blood pressure, and increased prevalence in individuals suffering from cardiac ischemia have been investigated. Blood flow in the optic nerve head may be altered as a consequence of optic nerve tissue loss secondary to chronic elevation of IOP.

The nature and basis for physiological control and pathological mechanisms in the optic nerve head and related retinal circulation are unknown. However, the vasculature in the retina and optic nerve head appears to autoregulate to maintain blood flow, despite changes in perfusion pressure (Anderson, 1996). A deficit in blood flow autoregulation leading to transient ischemia may cause increased susceptibility to the damaging effects of IOP (Cioffi and Van Buskirk, 1998). Microvascular factors such as the endothelins, a family of potent long-acting vasoconstrictor peptides, are produced by the vascular endothelium to control vascular tone and regulate blood flow. Endothelin-1 may play a role in the autoregulation of blood flow of the retina and the optic nerve head (Cioffi *et al*., 1995; Oku *et al*., 1999). Endothelin-1 may cause hypoxia due to local ischemia and thereby contribute to tissue damage in glaucoma.

Hypoxia due to ischemia and decreased vascular perfusion has been proposed as a factor leading to axonal damage, retinal ganglion cell loss, and remodeling of the optic nerve head in glaucoma. Due to the clinical relevance of ischemic brain damage the effects of hypoxia on central nervous system neurons and astrocytes *in vivo* and in culture have been studied extensively (Hori *et al*., 1994; Silver *et al*., 1997; Krasney, 1999). Recent studies have demonstrated that cells respond to hypoxia via cellular oxygen sensors that regulate glycolytic genes and the cascades that regulate vascular perfusion (Semenza *et al*., 1997). To date, the role of hypoxia in the optic nerve head in glaucoma has not been defined on a cellular level. Hypoxia causes increases in ECM synthesis, gene expression of growth factors and cytokines, release of mediators, cellular activity, and neovascularization in many systems including normal and diseased ocular tissues (Shima *et al*., 1995). Hypoxia is thought to be a key regulator of angiogenesis and subsequent neovascularization (D'Amore, 1994; Aiello *et al*., 1995). Because neovascularization does not occur in glaucomatous optic neuropathy, astrocytes and vascular cells in the optic nerve head may be inhibited from making certain responses to hypoxia.

IV. Experimental Studies Relevant to Glaucomatous Optic Neuropathy

A. Animal Models

1. Primate Models of Glaucoma

Work in primates has provided most of the experimental data in glaucomatous optic neuropathy. The monkey model of laser-induced elevated IOP is probably the animal model most closely reflecting POAG, which is unique to humans. The model is based on raising IOP by argon or diode laser photocoagulation of the trabecular meshwork, resulting in decreased outflow of aqueous humor (Quigley and Hohman, 1983; Pederson and Gaasterland, 1984; Wang *et al*., 1998). The relationship between elevated IOP and cupping of the optic disc was demonstrated in a primate model of glaucoma in the early 1980s in Quigley's laboratory. Recently, two more laboratories have reported extensive studies on the histopathological changes in the optic nerve head in the monkey model of experimental glaucoma, confirming the validity of the model (Hayreh *et al*., 1999; Jonas and Hayreh, 1999; Yucel *et al*., 1999). Clinical evaluation of the model has shown a linear correlation between axonal loss and increase in cup/disc ratio (Varma *et al*., 1992). However, measurement of finer parameters of visual functions using perimetry using either a monochromatic or white stimuli indicated that the model does not provide information on retinal ganglion cell loss until a large number have died (Harwerth *et al*., 1999).

Experimental glaucoma in monkeys with chronically elevated IOP demonstrated the axonal transport was slowed down at the level of the lamina cribrosa. The retinal ganglion cells projecting to the magnocellular layer of the lateral geniculate nucleus appeared to be affected earlier in the disease (Dandona *et al*., 1991). Recently, it was shown that the pattern of degeneration of midget and parasol retinal ganglion cell in glaucoma was initiated with the reduction of the dendritic fields and ended with the decrease in size of the soma, suggesting that early functional deficits and retinal ganglion cell atrophy (Weber *et al*., 1998). The challenge of this work is to develop early detection systems that will identify patients in early stages of the disease in which neuroprotection is beneficial.

Glutamate excitotoxicity has been postulated as one of the possible factors leading to retinal ganglion cell loss in glaucoma. Elevated glutamate levels were found in the vitreous of monkeys with experimental glaucoma, suggesting that excitatory glutamate excitotoxicity may play a role on retinal

ganglion cell loss in glaucoma (Dreyer *et al*., 1996). Additional studies using the monkey model of glaucoma have shown that retinal ganglion cell populations labeled with antibodies to the neurofilament triplet were more affected by elevated IOP in glaucoma whereas amacrine, horizontal, and bipolar neurons were not affected. Large retinal ganglion cells located in the periphery of the nasal and temporal retina were lost preferentially in this study (Vickers *et al*., 1995). More recently, loss of retinal ganglion cells expressing GluR2 and NMDAR1 glutamate receptors was reported in monkey eyes with elevated IOP; however, there was no difference between retinal ganglion cells in labeling between different populations of retinal ganglion cells (Hof *et al*., 1998). The authors concluded that loss of neurofilaments by a particular population of retinal ganglion cells was a better marker of vulnerability to glaucomatous damage than expression of glutamate receptor subtype.

2. Rat Models of Glaucoma

Recently, two laboratories (Garcia-Valenzuela *et al*., 1995; Moore *et al*., 1995) reported methods for chronically increasing IOP in rat eyes to moderately elevated levels and have observed optic nerve degeneration and retinal ganglion cell loss. In one method, hyperosmotic solution is injected into the limbal venous plexus (Moore *et al*., 1995) in the other method, limbal derived veins are cauterized (Garcia-Valenzuela *et al*., 1995). These methods produce similar elevations of IOP and have demonstrated loss of nerve fibers from the optic nerve, changes in the extracellular matrix of the optic nerve head, and degeneration of retinal ganglion cells at moderately elevated IOP.

In a series of more than 130 animals, some observed over a 6-months period, we have found that an approximately 1.6-fold elevation of IOP causes a rate of retinal ganglion cell degeneration in the peripheral retina of approximately 1.4%/week. On the other hand, we have found less change of retinal ganglion cell density in central retinal areas over the 6-month period. Cupping of the optic disk was observable by ophthalmoscopy in these animals (Neufeld *et al*., 1999).

3. Inherited Glaucoma in Mouse

The use of mice as a glaucoma model is being tested (John *et al*., 1991). Measuring IOP in mice has been a major obstacle in the use of the model (Chang *et al*., 1999). John *et al*. identified mice strains that exhibit elevated IOP. The DBA/2J (D2) mice develop spontaneous age-related secondary glaucoma with elevated IOP associated with severe iries atrophy and anterior synechiae formation (Hawes *et al*., 1999). Optic nerve atrophy and retinal ganglion cell death occur in a substrain of DBA/2 mice. The difficulty of these experiments is that the IOP has to be measured invasively by cannulation of the anterior chamber of the eye. Ideally a noninvasive IOP measurement would allow performing longitudinal sudies in these animals.

B. Cell Culture Models

1. Retinal Ganglion Cell Culture

Studies on the mechanisms necessary for retinal ganglion cell survival are critical to developing neuroprotective therapies in glaucomatous optic neuropathy. Several laboratories have successfully accomplished purification and maintenance in culture of rat retinal ganglion cells isolated from developing postnatal retinas (Barres *et al*., 1988; Jo *et al*., 1999; Morgan *et al*., 1999). Recently, an *in vitro* study using cultured retinal ganglion cells confirmed *in vivo* observations that nitric oxide production from astrocytes was involved in retinal ganglion cell axonal loss in a rat model of glaucoma (see below). Anoxia-induced retinal ganglion cell death was significantly blocked by *N*-nitro-L-arginine, an inhibitor of NOS, in cocultures of rat retinal ganglion cells and astrocytes (Morgan *et al*., 1999).

Potentially relevant studies to glaucoma are those on retinal ganglion cell survival and responsiveness to trophic factors. Recent studies reported that retinal ganglion cell responsiveness to trophic factors such as BDNF, CNTF, and IGF-1 was enhanced by increasing the levels of cAMP in cultured purified retinal ganglion cells and subsequently in retinal ganglion cells *in vivo*. These studies demonstrated that retinal ganglion cells die after axotomy not only because of deprivation of trophic factor stimulation but because of concomitant loss of responsiveness to trophic factors due to loss of trophic receptors (Shen *et al*., 1999). The implication is that neuroprotective therapies for retinal ganglion cells using trophic factors must take in account that retinal ganglion cell death in glaucoma is probably due to a combination of events, which may or may not include deprivation of neurotrophic factors.

2. Optic Nerve Head Astrocyte Culture

Cultured astrocytes from the rodent optic nerve are used in many laboratories to study many aspects of astrocyte cell biology and physiology that may impact optic nerve regeneration, myelination, astrocyte axon interactions, etc. Astrocytes in the central nervous system and in the optic nerve mediate responses to injury and to chronic neurodegenerative disease. Glaucomatous optic neuropathy is not an exception and different aspects of astrocyte behavior need to be characterized. *In vitro* models using optic nerve head astrocytes from humans provide such a model system. Well-characterized astrocyte culture methods from humnan optic nerve head have become available and cultured astrocytes can be generated in sufficient numbers to perform experiments. The optic nerve head astrocyte cultures express cellular markers present *in situ* such as GFAP and NCAM (Kobayashi *et al*., 1997).

Researchers who study stress forces on cells have postulated that because of the interconnections among the ECM, cell attachments and the cytoskeleton, a physical deformation in the ECM triggers cellular responses by activating signaling cascades and gene expression (Banes *et al*., 1995; Chiquet *et al*., 1996; Galou *et al*., 1997; Ingber, 1997). For example, hydrostatic pressure, when applied as a mechanical stress to cells in culture results in deformation of the cell membrane and cytoskeleton due to the fixed cellular adhesions to the matrix, causing activation of mechanosensitive ion channels and signaling enzymes sequestered in the membrane (Bray *et al*., 1991; Zucca *et al*., 1991; Acevedo *et al*., 1993; Yang *et al*., 1993; Klein-Nulend *et al*., 1995, 1997; Schwartz *et al*., 1999). Thus, a mechanical signal at the cell membrane is transduced into an intracellular event (Maniotis *et al*., 1997). Biomechanical stress may alter the kinases associated with the

ECM–integrin–cytoskeleton system to trigger responses that change cell behavior and phenotype. In a variety of cell types, cell surface ion channels are activated or inactivated in response to mechanical tension on the membrane (Banes *et al*., 1995; Verkhratsky and Kettenmann, 1996; Sachs, 1997). At least five mechanically responsive channels have been described in astrocytes by patch clamp experiments (Bowman *et al*., 1992).

Studies indicate that increased production of prostaglandin E_2, prostacyclin, or cAMP may mediate the effects of compressive pressure on cells in culture (He and Grinnell, 1994; Klein-Nulend *et al*., 1995; Yousefian *et al*., 1995; Glantschinig *et al*., 1996). Increased synthesis of cell adhesion molecules, such as I-CAM and integrins, has been reported in response to a variety of mechanical stimuli including hydrostatic pressure (Haskin and Cameron, 1993; Davies, 1995; Resnick and Gimbrone, 1995; Salwen *et al*., 1998). Cell surface adhesion molecules have been proposed to participate in the coupling of cells to the ECM or between neighboring cells, with the cell cytoskeleton allowing mechanical stress to be transmitted intracellularly (Banes *et al*., 1995; Ingber, 1997), thus activating signaling cascades and turning on new gene expression (Bowman *et al*., 1992; Verkhratsky and Kettenmann, 1996; Oishi *et al*., 1998). The gene for ICAM-1 has a specific sequence in the promoter region, which responds to mechanical stimulation. Similar sequences have been found in the promoter region of other genes relevant to vascular pathophysiology, such as TGF-β, PDGF, and tissue plasminogen activator (Resnick *et al*., 1993).

Astrocytes in the lamina cribrosa are attached to the fibroelastic ECM and to neighboring astrocytes by cell surface adhesion molecules, which, through their transmembrane domains, are connected to the cytoskeleton. Thus, ECM changes in the microenvironment can be transmitted into the intracellular compartment. Because the cortical cytoskeleton is coupled to cell adhesion molecules, to membrane-bound enzymes, and to ion channels, biomechanical stress will cause intracellular responses in astrocytes.

Rearrangement of the actin cytoskeleton in response to hydrostatic pressure or other forms of mechanical stress occurs in many cell types (Acevedo *et al*., 1993; Haskin and Cameron, 1993; Sumpio *et al*., 1994; Crenshaw *et al*., 1996; Smith *et al*., 1996; Oluwole *et al*., 1997). The effect of pressure on actin stress fibers suggests depolymerization of filamentous actin, which has been described in cultured chondrocytes exposed to hydrostatic pressure and in cultured astrocytes in response to cyclic AMP (Parkkinen *et al*., 1995; Yousefian *et al*., 1995; Wright *et al*., 1996). In addition, we have recently demonstrated increased adenyl cyclase activity and disorganization of the actin cytoskeleton in optic nerve head astrocytes exposed to hydrostatic pressure (Wax *et al*., 2000).

V. Retinal Ganglion Cell Degeneration in Glaucoma

A. Neuronal Cell Death by Apoptosis

Various animal models, particularly those with rats and mice, have been used to study the degeneration of retinal ganglion cells. A large number of studies using optic nerve transection, optic nerve crush, and chronic, moderately elevated intraocular pressure, a glaucoma model, all indicate that retinal ganglion cells die by apoptotic mechanisms (Garcia-Valenzuela *et al*., 1995; Quigley *et al*., 1995). By examining human retinas, Quigley observed a relatively small, but nevertheless greater, number of TUNEL-positive retinal ganglion cells in glaucomatous compared to normal eyes (Kerrigan *et al*., 1997). The small number of positive cells is not surprising considering the slow progression of the disease. In tissue sections taken for pathology, there is a notable absence of inflammatory cells in glaucomatous optic nerves and retinas. Most investigators in the field believe that it is reasonable to hypothesize that the death of retinal ganglion cells in glaucoma is by apoptosis.

B. Glutamate Excitotoxicity

Glutamate is a neurotransmitter throughout the CNS and is the major neurotransmitter used by the neurons of the retina. In a variety of *in vitro* and animal models of neurodegeneration, excessive glutamate leads to apoptosis and necrosis of neurons. Similar results using *in vitro* and animal models of ischemia and optic nerve transection have been observed in the retina. Indeed, the first demonstration of glutamate neurotoxicity by Olney (1969), which led to the coining of the term ''excitotoxicity,'' was based on observations of retinal tissue, particularly the retinal ganglion cells.

Over the past few years, glutamate excitotoxicity has been implicated as a component cause of the loss of retinal ganglion cells in glaucoma. Dreyer originally demonstrated that glutamate was elevated in the vitreous humor of glaucoma patients collected at the time of surgery compared to similarly collected samples from patients that did not have glaucoma (Dreyer *et al*., 1996). Although the work in humans has not been confirmed, animal models (monkey, cat, rabbit, dog, and rat) of elevated IOP in which there is loss of retinal ganglion cells are associated with elevated glutamate in the vitreous humor (Vorwerk *et al*., 1999).

The origin of increased levels of glutamate in glaucomatous eyes is unknown. Glutamate could be released from dying retinal ganglion cells or there may be, in glaucomatous eyes, a malfunction of one of the glutamate uptake systems that normally keeps extracellular glutamate levels low. Whether such elevated glutamate could contribute in a primary or secondary manner to the death of retinal ganglion cells over several decades as glaucomatous damage progresses remains to be determined. Nevertheless, there is an ongoing pharmaceutical clinical trial with memantine, a glutamate receptor antagonist, to determine whether this drug can accomplish neuroprotection in the treatment of glaucoma.

C. Nitric Oxide Synthase

Nitric oxide is formed from L-arginine by nitric oxide synthase (NOS). Molecular cloning has identified three distinct genes expressing NOS isoforms: neuronal NOS (nNOS or NOS-1), endothelial NOS (eNOS or NOS-3), and inducible NOS (iNOS or NOS-2). The nomenclature was derived from the tissue in which they were first studied and the numbering was derived from the order in which they were cloned (Bredt and Snyder, 1994). NOS-1 and NOS-3 are constitutive, present

physiologically and calcium dependent. Under conditions of degeneration and inflammation, both isoforms may be upregulated. In contrast, NOS-2 is not constitutive, is Ca^{2+} independent, and is induced after immunological challenge and neuronal injury (Dawson *et al*., 1993; Yun *et al*., 1996).

The constitutive isoforms of NOS, NOS-1, and NOS-3 are present in the normal and glaucomatous human optic nerve heads. In contrast, the inducible isoform, NOS-2, appears in the optic nerve head of patients with primary open-angle glaucoma (Neufeld *et al*., 1997). The NOS-2 found in glaucomatous optic nerve tissue is predominantly in reactive astrocytes (Liu and Neufeld, 2000). These findings suggest induction of NOS-2 in glaucoma. Excessive NO, synthesized by NOS-2, may be neurodestructive through a peroxynitrite mechanism in the optic nerve heads of patients with glaucoma (Neufeld, 1999b). The presence of NOS-2 in reactive astrocytes in glaucomatous tissue is consistent with the optic nerve head being an early site of focal neuronal degeneration of the axons of the retinal ganglion cells in glaucoma.

The NOS-2 isoform is also induced in the rat optic nerve head in an animal model of chronic, moderately elevated IOP and is not present at all in normal tissue (Shareef *et al*., 1999). In a 6-month pharmacological experiment using this rat model of glaucoma, aminoguanidine, a relatively specific inhibitor of NOS-2 which had no effect on the elevated IOP, significantly blocked the loss of retinal ganglion cells, the cupping of the optic disk, and the degeneration of axons in the optic nerve (Neufeld *et al*., 1999).

D. Neurotrophic Factors

The survival of any nerve cell is believed to be dependent on neurotrophic factors, such as BDNF and CNTF. This is certainly true for embryonic, neonatal, and cultured nerve cells and has been postulated, and in some cases demonstrated, for adult neurons *in vivo* (Barde, 1989). Neurotrophic factors are released by postsynaptic neurons, bind to specific trk receptors in the nerve terminals, and are carried by their receptors, via retrograde axoplasmic transport, to the cell soma. There is also anterograde axoplasmic transport of neurotrophic factors and other important cellular components from cell soma to nerve terminals.

The axons of the retinal ganglion cells form synapses with neurons in the superior colliculus, the lateral geniculate nucleus, suprachiasmatic nucleus, and the pretectal nuclei and, therefore, may receive neurotrophic factors from neurons in these regions of the CNS. In glaucoma, compression of the axons of the retinal ganglion cells at the level of the lamina cribrosa may cause a blockade of axoplasmic transport and thus deprive these neurons of their target derived neurotrophic factors. Retinal ganglion cell degeneration in glaucoma may occur by apoptosis in response to deprivation of neurotrophic factors (Quigley *et al*., 1995). In support of this hypothesis, there is a large body of work demonstrating enhanced survival of retinal ganglion cells following axotomy in the rat when exogenous neurotrophic factors are administered (Mansour-Robaey *et al*., 1994). Nevertheless, there is no supporting evidence for deprivation of neurotrophic factors as a causative factor in human glaucoma. Recently, loss of NT4/5 and BDNF immunostaining was reported in the optic nerve head and retina in a rat model of glaucoma, suggesting interruption of axonal transport at the level of the nerve head or loss of endogenous production of neurotrophins (Johnson *et al*., 2000).

Color Vision, Object Recognition, and Spatial Localization in Aging and Alzheimer's Disease

Alzheimer's disease affects multiple brain areas that are devoted to the processing of basic visual capacities and to higher-order visual cognition. This chapter describes the effect of this disorder on the basic visual capacity of color discrimination and on the visuocognitive domains of object recognition and spatial localization. For each function—color discrimination, object recognition, and spatial localization—the review begins with documentation and a discussion of the behavioral evidence for deficits in Alzheimer's disease relative to normal aging. The next topics are the relation of basic visual deficits to cognitive impairment and their brain bases, focusing on the occipitotemporal and occipitoparietal visual processing streams. The finding that basic visual deficits predict visuocognitive performance has implications for determining the brain substrates of cognitive dysfunction. The next section evaluates the relative dysfunction of object recognition and spatial localization in Alzheimer's disease, including subgroups defined by specific behavioral and neuropathological profiles. It is clear that both visual processing streams are affected in this disease. In many patients, deficits in object recognition may be more pronounced than deficits in spatial localization, whereas in subgroups such as patients exhibiting the symptoms of Bálint's syndrome, this pattern may be reversed. Finally, consideration is given to the clinical relevance of impaired vision and visual cognition in normal aging and Alzheimer's disease. Understanding fundamental disorders in visual processing may lead to interventions that restore visual capacities with the goal of enhancing cognitive ability.

I. Introduction

Alzheimer's disease (AD), the most common cause of dementia in elderly adults, is viewed as a disorder primarily of memory by patients and their caregivers. Although the memory deficit in AD is usually predominant, researchers have long known that the disease is characterized by impairments in multiple additional domains, including visual cognition. In his original case study, Alois Alzheimer described abnormalities in object discrimination and recognition and in spatial localization:

> (S)he could not find her way about her home ...She was disoriented as to time and place... She suffered from serious perceptual disorders ...While reading she would omit sentences... She did not remember the use of particular objects. (Alzheimer, 1907)

More recently, researchers have attained a consensus that even lower-level visual functions are impaired in a large number of patients with AD, although these findings have not yet made the leap to the diagnostic manuals. For example, the most recent edition of the Diagnostic and Statistical Manual of Mental Disorders states that few sensory signs occur early in AD (American Psychiatric Association, 1994).

In accordance with their own observations, and expectations, of the prominence of the memory impairment, as well as those of the clinical staffs with whom they come into contact, patients with AD report vision problems to their physicians less frequently than do healthy elderly individuals (McCormack *et al*., 1994). Nevertheless, visual dysfunction is prevalent in AD (Mendola *et al*., 1995). The neuropathology of this disorder affects several brain areas that are devoted to visual processing of low-level visual functions as well as higher-order visual cognition.

The goal of this chapter is to summarize what is known about one relatively low-level visual function in AD, color discrimination, and the two principal domains of visual cognition, object recognition and spatial localization. This summary includes discussion of the behavioral evidence for deficits, the relation of visual dysfunction to cognitive impairment, the brain bases of the deficits, and the clinical relevance of

impaired vision and higher-order visual cognition in this disorder.

II. Color Discrimination

A. Evidence for Color Discrimination Deficits

Color discrimination deficits occur in a significant proportion of individuals with AD. These deficits are usually subtle enough that patients rarely complain in the clinic about losses of color vision. Use of clinical tests of color discrimination or psychophysical assessments reveals the impairments, principally along the tritan (blue-yellow) color axis. We have reported that patients with AD, but not healthy elderly adults, show a disproportionate deficit in the discrimination of short wavelengths relative to medium and long wavelengths on three clinical tests of color vision: the City University Colour Vision Test (Cronin-Golomb *et al*., 1991, 1993a) and the Farnsworth D-15 and Lanthony New Color Tests (Cronin-Golomb *et al*., 1993a).

The City University Colour Vision Test (Fletcher, 1980) consists of 10 trials, each depicting a central color circle surrounded by four comparison colors on a black background. Observers point to the surrounding circle that is most similar in hue to the target, though none is in fact identical to the target. The test is short and has low cognitive demands, making it possible to assess color discrimination in even severely demented patients. There are four response types: correct, protanomalous-like error, deuteranomalous-like error, and tritanomalous-like error. The terms protan, deutan, and tritan refer to errors in red, green, and blue hue discrimination, respectively, and are used commonly in discussions of dysfunctions of retinal photoreceptors. Because the optic media and the retinocalcarine pathway are usually normal in AD (Rizzo *et al*., 1992; Davies *et al*., 1995), we use terms such as tritanomalous-like in order to avoid implicating the retina and to raise the possibility that color discrimination deficits in AD have a cortical basis. None of the participants in our studies reported a history of color blindness or other historical difficulty in perceiving colors. The AD patients' self-report was corroborated by their accompanying caregivers. All had normal binocular acuity ranging from 16/20 to 20/40 Snellen.

In our initial study (Cronin-Golomb *et al*., 1991), 54% of the 37 patients with AD made one or more errors, whereas the 12 healthy elderly adults performed at or near ceiling level. There was an unequal distribution of error types in the AD group, with tritanomalous-like errors exceeding other types. In the replication study (Cronin-Golomb *et al*., 1993a), hue discrimination errors were made by 66% of the 32 AD patients, with the 32 control participants performing at or near ceiling. Again, tritanomalous-like errors exceeded other error types. In both studies, there was no significant correlation between test performance and dementia severity as measured by mental status exam.

Our finding of a tritanomalous-like deficit in AD has been replicated in another laboratory using this same test (Gilmore *et al*., 1993). We have observed a similar pattern of tritanomalous-like color discrimination deficit in Down syndrome (Rocco *et al*., 1997), a disorder that shares with AD numerous neuropathological (Hof *et al*., 1995) and metabolic (Pietrini *et al*., 1997) characteristics in visual association cortex. Of 21 adults with Down syndrome, 48% made one or more errors on the test, with tritanomalous-like errors exceeding others. Their performance contrasted with the near-ceiling level attained by mentally retarded adults without Down syndrome, even when subgroups were matched for IQ. The similarity in pattern of performance of patients with AD and adults with Down syndrome is depicted in Fig. 36.1.

Because our findings of a selective color discrimination deficit in AD were based on a single clinical color discrimination test, the City University, we broadened our investigation to include other clinical measures in an effort to assess how general the findings might be. The same 32 AD patients described above for the City University replication study (Cronin-Golomb *et al*., 1993a) were also administered two tests that required the arrangement of color caps in a smooth, uninterrupted hue sequence. For the Farnsworth D-15 test (Farnsworth, 1947), there are 16 caps of desaturated hues including a blue starting cap. For the Lanthony New Color Test, chroma 8 (Lanthony, 1978), there are 25 caps, 10 of which represent the gray scale and the other 15 of various saturated hues, with no designated starting cap. Observers pick out and sequence the gray scale caps and then sequence the color caps as per the Farnsworth test. Error analysis for both tests provides the number of each hue-discrimination error type. The Lanthony test additionally provides information on brightness discrimination through use of the gray scale. Such information is valuable because deficient brightness discrimination alone may lead to poor performance on color vision tests even in the absence of a genuine impairment in the ability to discriminate hues.

The tritanomalous-like pattern of performance that we observed for the City University Test was repeated, strikingly, for the sequencing tests. Major hue sequencing errors, defined

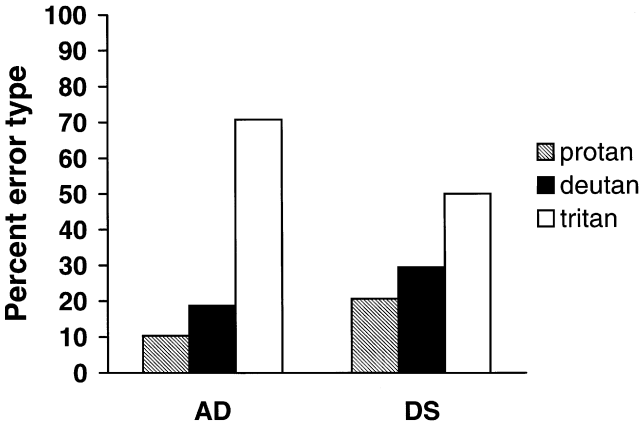

FIG. 36.1. Percentage of each hue discrimination error type on the City University Colour Vision Test for patients with Alzheimer's disease (AD) and Down syndrome (DS). The AD group ($n = 32$, of whom 21 made a total of 34 errors) and DS group ($n = 21$, of whom 10 made a total of 48 errors) each committed a disproportionately large number of tritanomalous-like errors relative to protanomalous- or deuteranomalous-like errors. The control groups made relatively few errors. Results for the AD and elderly control groups are described in Cronin-Golomb *et al*. (1993a). Results for the DS and mentally retarded (non-DS) control group are described in Rocco *et al*. (1997).

as errors falling along a specific axis (protan, deutan, or tritan) that went beyond transpositions of adjacent caps, were made by 50% of the 32 AD patients but less than 16% of the 32 control participants on the Farnsworth test and by 52% of the 29 AD patients and 25% of the control participants on the Lanthony hue test. Only tritanomalous-like errors significantly differentiated the groups for both tests. Across tests, tritanomalous-like errors by the AD patients exceeded protoanomalous- and deuteranomalous-like errors, combined, by a ratio of 2:1, whereas the distribution of error types was relatively even across hue axes for the control participants. Importantly, the AD and control groups did not differ in their ability to sequence the Lanthony gray caps, indicating that the AD patients had normal brightness discrimination and therefore implying that poor performance on the hue sequencing tests was due to poor color discrimination rather than to problems with luminance sensitivity or the cognitive demands of the tests. In accordance with the latter assertion, there was no significant correlation between hue-discrimination performance and dementia severity in the AD group for either test.

Our reports of a tritanomalous-like deficit in color discrimination in AD have been supported by the results of detailed psychophysical assessments (Kurylo *et al*., 1994a), which showed that a significantly larger proportion of AD patients than age-matched healthy adults were impaired at discriminating between blue and violet hues, whereas there was no group difference in discriminating between yellow and orange hues.

The behavioral findings indicate that AD is not simply an exaggeration of the normal aging process. Although age-related yellowing of the lens can result in mild color discrimination deficits along the tritan axis in healthy elderly relative to younger adults (Matjucha and Katz, 1994), the AD patients in the studies described above were matched for age to the control group, and neuro-ophthalmological examination did not reveal obvious group differences in the appearance of the ocular media, including the lens. The disproportionate tritanomalous-like impairment seen in AD was mirrored in adults with Down syndrome, a disorder that shares with AD numerous behavioral and neuropathological characteristics.

B. Relation of Color Discrimination Dysfunction to Cognitive and Functional Deficits

Poor performance of AD patients on the Stroop Color-Word Test is well established (e.g., (Koss *et al*., 1984; Binetti *et al*., 1996; Spieler *et al*., 1996) and exceeds normal age-related decrements (reviewed in Spieler *et al*., 1996). This test is widely used as a measure of executive function and attention and is thought to reflect the integrity of the frontal lobes (Lezak, 1995). The goal of the test is to assess the ability to inhibit one response in favor of another. First, on the word reading subtest, an observer reads as quickly as possible color words (''red,'' ''green,'' ''blue'') printed in black ink on a white background. Second, on the color identification subtest, the observer reads aloud the ink color (red, green, or blue) of ''X'' symbols on a white background. Finally, on the interference subtest, the observer reads aloud the ink color (red, green, or blue) for color words that are incongruent with the ink color (for example, read ''green'' when the ink color is green for the printed word ''blue''). Two studies have reported poor performance by individuals with AD on the color identification subtest specifically (Cohen *et al*., 1988; Fisher *et al*., 1990). In a third study using somewhat different methodology, it was noted that that color confusion errors, though few in number, may have complicated comparisons of error rates across the groups of AD and healthy young and old participants (Spieler *et al*., 1996). None of these studies examined basic color vision in the same participants. The findings raised the question of whether a color discrimination impairment in AD was influencing performance on the color identification subtest, which might then contribute to compromised performance on the critical interference subtest.

We examined the relation between a wide variety of basic visual capacities and cognitive capacities in participants with probable AD in order to test the general hypothesis that visual dysfunction predicts cognitive performance (Cronin-Golomb *et al*., 1995). In regard to the question of sources of poor cognitive performance on the Stroop Color-Word Test, we found for 38 AD patients who had received both the City University Colour Vision Test and the Stroop test that tritanomalous-like errors on the City University test accounted for 7% of the variance in performance on the color-naming subtest of the Stroop and for 2% of the variance on the interference subtest. Although the predictive value is low overall, the prevalence of the color discrimination deficit in AD is significant, and it is therefore likely in individual patients that this deficit may contribute to poor performance on various cognitive tests that coincidentally require normal color discrimination. Our AD prevalence estimate for the City University test is 28%, based on the performance of 74 AD patients and 54 age-matched control participants, and using a strict cutoff score such that the probability of a healthy elderly control participant obtaining that score was 1% or less (Mendola *et al*., 1995).

Knowledge about abnormalities in color perception in AD may lead not only to an understanding of certain cognitive impairments, but may also be employed to enhance cognition and daily function in individuals with AD. In a study of ingestive behavior in severely demented inpatients with probable AD, Dunne and Neargarder (1999) reported that enhanced color contrast of tableware (bright red plates and cups substituted for institutional white) resulted in significant increases in the volume of food and liquid ingested relative to baseline. The volume ingested declined again in the postintervention (white) phase. This pattern held for each of the nine tested participants. Dunne and Neargarder based their study on the premise that enhancement of color contrast in AD may enhance behavioral performance, and that the color selected for manipulation should be one outside of the compromised blue-yellow axis. Koss and Gilmore (1998) likewise reported that enhanced contrast of dinnertime tableware affected behavior, specifically resulting in increased food intake and decreases in the frequency of night-time agitation (''sundowning'') in 13 residents of an inpatient dementia unit. The amount of food ingested at dinner was significantly different across intervention conditions, with more food consumed during the dinner intervention, whereas there was no change in amount of food ingested at lunchtime, when no intervention was effected. The frequency of agitated nighttime behaviors decreased dramatically during the intervention condition.

C. Brain Bases of Color Discrimination Impairment

The color discrimination deficits observed in individuals with AD are likely to be of cortical origin. Neuroophthalmological examination including electrophysiological testing yielded age-appropriate results in a large sample of the AD participants in our studies. These same patients showed significant impairments on vision tests, including color discrimination (Rizzo *et al*., 1992). The findings indicated that defects in the anterior visual structures up to and including the optic radiations did not account for the observed visual impairments. In normal aging, optical changes account for about 40% of the decline in sensitivity of short-wavelength-sensitive (blue) cones. The rest of the decline has been attributed to receptor and postreceptor neural changes that do not affect blue cones preferentially (reviewed in Matjucha and Katz, 1994).

Examination of autopsy tissue suggests that, in the very late stages of AD, some cases may show degeneration of retinal ganglion cells (Hinton *et al*., 1986; Blanks *et al*., 1991, 1996a,b). Other investigators have found no evidence of retinal ganglion cell or optic nerve degeneration (Curcio and Drucker, 1993; Davies *et al*., 1995). In living patients, it is reportedly difficult to obtain and to evaluate reliably photographs of the retinal nerve fiber layer, especially in cases with severe dementia (Hedges *et al*., 1996). Tsai and colleagues (1991) reported no significant difference in retinal nerve fiber layer abnormalities, nor in optic disc pallor, in AD relative to control eyes, though they found more AD abnormalities on topographic measures of the optic nerve head.

Whereas the status of the retina and optic nerve is inconclusive, it is clear that there is significant AD pathology in subcortical and cortical brain regions devoted to color processing. As described in the next sections on Object Recognition and Spatial Localization, behavioral studies suggest that AD affects both the ventral (occipitotemporal) and the dorsal (occipitoparietal) visual processing streams. The ventral stream receives input from the parvocellular, or color-opponent and magnocellular, or broadband pathways that extend from the retina to visual association cortex. Color processing is dependent upon the parvocellular pathway. In AD, neuritic plaques are found in the parvocellular regions of the lateral geniculate nucleus (Leuba and Saini, 1995). Of note, pathological changes occur in the specific sublayer of the primary visual center that receives color information from the lateral geniculate nucleus (Beach and McGeer, 1988) as well as in the pulvinar and superior colliculus (Leuba and Saini, 1995), subcortical regions that along with the lateral geniculate nucleus may be involved in chromatic processing (Barbur *et al*., 1998).

AD neuropathological changes are more widespread in visual association cortices than in the retinocalcarine pathway, based on histological examination (Pearson *et al*., 1985; Lewis *et al*., 1987; Arnold *et al*., 1991) and electrophysiological assessment (Wright *et al*., 1984, 1987; Aguglia *et al*., 1991; Rizzo *et al*., 1992; Celesia *et al*., 1993; Martinelli *et al*., 1996). Extensive pathology occurs in occipital and inferotemporal cortex (Lewis *et al*., 1987), and it is this pathology, particularly in the fusiform gyrus, that presumably underlies the observed changes in color discrimination (Cronin-Golomb *et al*., 1993a; McKeefry and Zeki, 1997; Zeki and Marini, 1998). In type and extent, the abnormalities seen in AD go well beyond the loss of neurons in striate cortex described in normal aging (Polidori *et al*., 1993). Some investigators even dispute whether there is any age-related reduction of neuronal density in striate cortex (Spear, 1993).

III. Object Discrimination and Recognition

A. Evidence for Deficits in Object Discrimination and Recognition

The ability to discriminate and recognize objects is disrupted in patients with AD relative to healthy elderly adults. By ''objects,'' we mean letters, words, faces, and patterns, as well as common objects such as animals and manufactured items. Difficulties in reading letters and words are well documented in the AD literature (Cogan, 1979, 1985; Appel *et al*., 1982; Cummings *et al*., 1986; Butter *et al*., 1996; Furey-Kurkjian *et al*., 1996; Gilmore *et al*., 1996).

Object and pattern discrimination deficits are common in AD (Mendez *et al*., 1990a,b). They include difficulties in identifying line drawings of overlapping or masked objects (Mendez *et al*., 1990a,b; Butter *et al*., 1996; Giannakopoulos *et al*., 1999), fragmented objects (Corkin, 1982; Mendez *et al*., 1990a,b; Mendola *et al*., 1995; Mielke *et al*., 1995; Butter *et al*., 1996), pattern contours (Kurylo *et al*., 1996), figures embedded in noise (Kurylo *et al*., 1994b; Kurylo, 1999), or complete objects (Huff, 1990; Mendez *et al*., 1990a,b; Jacobs *et al*., 1995; Furey-Kurkjian *et al*., 1996; Giannakopoulos *et al*., 1999).

The prevalence of object discrimination deficits may be high in individuals with AD, and the degree of impairment substantially exceeds normal age-related decrements in performance on tasks such as visual closure (Read, 1988), word discrimination (Lawrence *et al*., 1998), and pattern completion (Esposito *et al*., 1999). In our study, the prevalence rate for dysfunction was 30% for identification of incomplete pictures alone (14/46 AD patients) (Mendola *et al*., 1995). Even more striking were the findings of Mendez and colleagues (1990a), who reported that 57% of patients (17/30) were unable to visually recognize actual common objects, and 100% were impaired on figure–ground analysis, including those with the mildest dementia severity. Classic visual agnosia occurs in a subgroup of patients (Cogan, 1979, 1985; Hof and Bouras, 1991; Mendez *et al*., 1990b). Curiously, a history of visual agnosia may be associated with visual hallucinations in AD patients, possibly suggesting common cortical substrates (Cogan, 1985; Holroyd and Sheldon-Keller, 1995). Alternatively, the combination of impaired object recognition and paranoid thinking may predispose some patients to the experience of hallucinations (Mendez *et al*., 1990b).

Face discrimination deficits in AD presumably arise at multiple stages of information processing, including levels such as memory (Wilson *et al*., 1982; Bäckman and Herlitz, 1990; Ricker *et al*., 1994), semantic knowledge (Hodges *et al*., 1993; Greene and Hodges, 1996), naming (Becker *et al*., 1995), or cognitive interpretation (Mendez *et al*., 1992). Mendez and colleagues (1992) evaluated the records of 217 patients with AD and found that 25% showed cognitive interpretation deficits. Of these 55 patients, 34 exhibited transient misidentifications of familiar persons; 11 showed Capgras syndrome, in

which they denied the identity of their caregiver and substituted an imposter; five misidentified themselves in mirrors; three showed overt prosopagnosia; and two had other unusual deficits in person identification. Cogan (1985) described multiple face recognition impairments within a single case. Difficulties with both famous faces (Mendez *et al*., 1990a) and unfamiliar faces (Kurylo *et al*., 1996) have been reported. In accordance with theories that distinct pathways are involved in the processing of familiar and unfamiliar faces (Bruce and Young, 1986), double dissociations occur in AD, with some patients more impaired on the recognition of familiar faces and others on the discrimination of unfamiliar faces (Della Sala *et al*., 1995). It is clear, however, that a large percentage of patients are impaired at processing both types of faces (Becker *et al*., 1995). Age-related decrements in face discrimination and recognition occur in the healthy population (Eslinger and Benton, 1983; Koss *et al*., 1991), to a lesser degree than in AD.

Perceptual organization may be another stage of information processing contributing to performance on tasks of face discrimination and recognition. It has been reported that facial processing in AD is related to the ability to identify objects from a complex array (Ricker *et al*., 1994), a capacity that is dependent on figure–ground discrimination and featural synthesis, both of which are impaired in AD (Mendez *et al*., 1990a; Kurylo *et al*., 1994b). Patients also have difficulty with perceptual grouping that uses the cues of proximity and global organization. The perceptual grouping deficit along with the impaired ability to identify degraded forms are correlated with deficits in face discrimination in AD (Kurylo *et al*., 1996; Kurylo 1999).

B. Relation of Visual Dysfunction to Deficits in Object Discrimination and Recognition

There is evidence that basic-level visual deficits, specifically in low spatial frequency contrast sensitivity, may contribute significantly to the difficulty that healthy elderly as well as demented individuals have with face discrimination. Contrast sensitivity reflects the minimum amount of contrast that an individual needs to resolve a stimulus of a given size. Standard stimuli are sinusoidally modulated gratings, the number (cycles) of which varies within a set overall width, conventionally one degree of visual angle. The measure of this spatial frequency is cycles per degree. Stimuli of different spatial frequencies have different contrast thresholds. For most human observers, contrast sensitivity is less acute at low and high relative to mid-range frequencies, producing the characteristic contrast sensitivity curve. When the stimulus is a face, it is conventional to use a face width as the measure of overall size. The unit of measure is cycles per face rather than cycles per degree. Cycles per face is defined as the number of sinusoidal repetitions that can be placed within the eye-level width of the face. In order to distinguish between spatial frequency as measured in cycles per degree and face measurements in cycles per face, we refer to the latter as the facial frequency. Faces contain low frequency information in their general shape, shading, and contours, as well as higher frequency information in fine details. In normal observers, contrast sensitivity at low spatial frequencies is related to the ability to detect and discriminate faces. Healthy older adults require higher contrast than young adults to detect and discriminate photographed faces (Owsley *et al*., 1981).

Contrast sensitivity at low spatial frequencies is salient to face discrimination in patients with AD (Nissen *et al*., 1985). We have reported that contrast sensitivity is impaired in AD, especially at low spatial frequencies (Cronin-Golomb *et al*., 1991, 1995; Mendola *et al*., 1995). Because changes in face size result in shifts in the sensitivity curve, we hypothesized that by adjusting the size of face stimuli presented, we could use the natural frequency response of the visual system to enhance the perception of the low facial frequency content and thereby enhance discrimination of face stimuli in AD patients. We found that reducing face size in order to enhance relatively the contrast sensitivity at low facial frequencies resulted in normal face discrimination in AD. Relative enhancement of middle or high facial frequencies, however, through use of medium- and large-sized faces, respectively, was associated with impaired performance (Cronin-Golomb *et al*., 2000).

It is counterintuitive that a reduction in face size should lead to better performance, because in normal older individuals, small angular character size for stimuli such as letters and words (under 0.3 degrees) often leads to impaired performance, such as on tests of reading speed (Akutsu *et al*., 1991). For faces, however, the important information shifts into a lower spatial frequency range as the size of the face increases. The control participants had good sensitivity for the lower spatial frequencies, as shown by their scores on the contrast sensitivity test, and may have been able to use that information for face discrimination. By contrast, the patients with AD had relatively poor sensitivity in that range. They would therefore have been less able to use that critical band of information and consequently performed the face discrimination task more poorly than did the control group.

For the group of 18 control participants reported in our study, age was strongly correlated with the ability to discriminate faces of any size. No such correlation was present for our sample of 18 AD patients matched to the control group for age, education, binocular central acuity, and ratio of men to women (8 men and 10 women in each group), indicating that in this sample, contrast sensitivity status was much more salient to face discrimination than were age effects. It is worth commenting on a different pattern of results in an additional 10 AD patients who were not included in the final study because they were not as well matched to the control group for the demographics of age, education, and ratio of men to women. In this excluded sample, the AD patients were somewhat older, less educated, and most were men (8 of 10). They were more demented than the final study group, though not so demented that their ability to understand task instructions was significantly compromised (mean score of 19.7 on Mini-Mental State Exam, compared to 21.6 in the final study group). Their contrast sensitivity at the high spatial frequency of 18 cycles per degree was relatively depressed (mean log sensitivity 0.54, compared to 0.75 in the final study group), as was Snellen acuity (median 20/30, compared to a median of 20/20 in the final study group). They did not show the effect of low-frequency enhancement on face discrimination, performing equally poorly with all three face sizes. Though their performance with large (mean score 11.3 correct of 17) and medium

sizes (mean score 10.1) was comparable to that of the final study sample (mean scores of 11.0 and 10.6 respectively), they were substantially impaired with the small faces (mean score 9.3), whereas the final study sample attained scores that were not significantly different from those of the control group (mean AD score 12.1). Although these excluded patients were few in number, their failure to demonstrate the pattern of performance shown by the control-matched study sample suggests that some constellations of demographic and visual features permit while others may prevent the visually mediated enhancement of cognitive performance. It will be important to investigate further these feature constellations.

Whereas contrast sensitivity appears to be relevant to understanding face discrimination deficits in AD, low-level visual symptoms associated with dorsal-stream dysfunction, such as optic ataxia, oculomotor apraxia, and simultanagnosia, do not seem related to poor face discrimination (Furey-Kurkjian *et al*., 1996).

In regard to the discrimination and recognition of nonfacial stimuli, we have reported that performance on a pattern masking task accounted for at least 25% of the variance on tests of object identification (Gollin Incomplete Pictures, 50%), word identification (Stroop Color-Word Test, 46%), and pattern completion (Raven's Coloured Progressive Matrices, 25%). Low spatial frequency contrast sensitivity was also a good predictor of performance on object-based cognitive tasks (Cronin-Golomb *et al*., 1995). Mendez and colleagues (1990a) likewise found strong correlations of visual symptoms with performance on tests of figure–ground discrimination and object recognition.

C. Brain Bases of the Impairment in Object Discrimination and Recognition

Object discrimination and recognition are subserved by the temporal lobes, as shown in humans by lesion studies (Milner, 1958; Meier and French, 1965; Lansdell, 1968; Newcombe and Russell, 1969; Newcombe *et al*., 1987) and by studies of regional cerebral blood flow (Haxby *et al*., 1991, 1994; Esposito *et al*., 1999). The temporal lobes undergo a loss of volume as a concomitant of normal aging (Coffey *et al*., 1992), which may be related to some of the mild age-related declines in performance described above (section III,A). Brain activation as measured by cerebral blood flow may be extended with increased age. For example, like young adults, elderly adults recruit temporal regions during a pattern-completion task, but unlike young adults, they fail to suppress prefrontal regions (Esposito *et al*., 1999).

The primary source of dysfunction in object discrimination and recognition in AD is the direct disruption of the object recognition pathway from the occipital to the temporal lobes, including extensive neuropathological damage to the temporal lobe itself (Brun and Englund, 1981; Pearson *et al*., 1985; Lewis *et al*., 1987; Braak *et al*., 1989; Arnold *et al*., 1991; Hof and Bouras, 1991). Relative to primary visual cortex, the density of neurofibrillary tangles increases 20-fold in parastriate cortex (Brodmann's area 18) and doubles again in inferotemporal cortex (Brodmann's area 20). The tangle distribution correlates positively with the regional distribution of pyramidal neurons that give rise to long corticocortical projections, which appear to be disrupted in AD (Lewis *et al*., 1987). Tangle density in occipital and occipitotemporal cortices (Brodmann's areas 18, 19, and 37) also correlates with a history of associative visual agnosia (Giannakopoulos *et al*., 1999). Within the temporal lobes, AD patients with a variety of visual complaints show reduced glucose metabolism relative to normal individuals (Pietrini *et al*., 1996). Although AD patients exhibit increased regional cerebral blood flow in the temporal lobes that is comparable to that seen in healthy elderly adults on a face-matching task, there may be abnormal functional connectivity in the AD group, who, compared to the control group, show additional activation in occipital and frontal cortices (Grady *et al*., 1993). Right temporal and hippocampal volume reduction in AD, as shown on structural imaging, are associated with impaired performance on a test of face recognition, whereas left hippocampal reduction of volume is related to word recognition memory (Cahn *et al*., 1998).

The occipitotemporal visual processing stream receives input from the parvocellular and magnocellular pathways that extend from the retina to visual association cortex. Functions associated mainly with the magnocellular pathway, the principal input to the occipitoparietal stream, are described in the section on spatial localization below. Those functions dependent upon the parvocellular pathway, such as color and texture discrimination, are impaired in many individuals with AD (Cronin-Golomb *et al*., 1991, 1993a; Kurylo *et al*., 1994a; Mendola *et al*., 1995). Parvocellular pathway dysfunction is supported by findings of a greater density of senile plaques in parvocellular than in magnocellular regions of the lateral geniculate nucleus (Leuba and Saini, 1995).

IV. SPATIAL LOCALIZATION

A. Evidence for Deficits in Spatial Localization

Spatial localization, broadly defined, includes the ability to orient oneself to aspects of the environment and to relate spatially those aspects of the environment external to the self. Clinical observations and research findings indicate that AD leads to severe impairments in numerous aspects of spatial localization (Mendez *et al*., 1990a,b; Ogden, 1990; Cronin-Golomb *et al*., 1993b; Kurylo *et al*., 1996), many of which are preserved in normal aging. The various aspects of spatial function may be categorized as constructional abilities, personal (egocentric) localization, extrapersonal (allocentric) localization, and spatial cognition.

Constructional apraxia includes deficiencies in copying or drawing two- or three-dimensional designs, and in assembling whole forms from elements. It occurs in the early as well as later stages of AD (Henderson *et al*., 1989; Mendez *et al*., 1990b; Ogden, 1990; Ricker *et al*., 1994; Cahn-Weiner *et al*., 1999). Complex form copying often is preserved in normal elderly adults (Koss *et al*., 1991; Janowsky and Thomas-Thrapp, 1993). By contrast, three-dimensional construction such as measured with the Block Design Test may be less accurate for old than for young adults (Plude *et al*., 1986; Koss *et al*., 1991) and may furthermore become less accurate with age within an elderly sample (Wahlin *et al*., 1993; Libon *et al*., 1994). An understudied possible concomitant of constructional difficulty in some patients with AD is unilateral spatial neglect, which may arise early (Ishiai *et al*., 1996) or late in the disease course (Venneri *et al*., 1998) and may affect visual search of objects in space (Mendez *et al*., 1997).

Personal (egocentric) orientation refers to the judgment of the spatial relation of one's own body to objects external to it, whereas extrapersonal (allocentric) orientation refers to the assessment of the spatial relation between objects external to the body. Patients with AD show impairments in both types of orientation. The disruption of personal orientation in AD is demonstrated by patients' poor use of a road map that requires them to negotiate directions in relation to their own body position (Mendola *et al*., 1995; Armstrong and Cloud, 1998). Although normal elderly adults significantly outperform patients with AD, they tend to be slower and less accurate at some types of map reading and perspective-taking than are young adults (Ohta *et al*., 1981; Aubrey and Dobbs, 1990; Aubrey *et al*., 1994). In healthy adults ranging in age from 50 to 85, age correlated significantly with performance. It is noteworthy that healthy women are slower at making map-position decisions than are age-matched men, though they are not less accurate (Aubrey *et al*., 1994). Gender differences often are not examined in the literature for either normal aging or AD, although they have been documented even in basic visual capacities such as motion perception (Gilmore *et al*., 1994). Environmental familiarity effects also are salient in normal aging (Kirasic, 1989) and remain mostly unexplored.

Extrapersonal orientation deficits are shown by difficulties in manipulating objects in space and in relating environmental landmarks to each other spatially. A common sign in AD is the tendency to become lost in familiar surroundings (Cogan, 1979, 1985; Henderson *et al*., 1989) or to follow unfamiliar routes. This problem may arise from an inability to judge one's position or self-movement in relation to the environment (personal orientation), or to judge spatial landmarks in the environment in relation to each other (extrapersonal orientation), or both (Mendez *et al*., 1990b; Tetewsky and Duffy, 1999).

Spatial cognition comprises such abilities as form matching, mental rotation, judgment of line orientation, and object location. Form matching is impaired in very early (Kaskie and Storandt, 1995) and midstage AD (Rosen and Mohs, 1982). AD deficits in mental rotation include the inability to rotate objects in order to effect form matching (Mendola *et al*., 1995; Kurylo *et al*., 1996) as well as the failure to detect object rotations (Mendez *et al*., 1990a; Kaskie and Storandt, 1995). Normal older adults tend to be slower than young adults on tests of mental rotation (Dollinger, 1995), but the age groups may be equally accurate if the tests are untimed (Cerella *et al*., 1981; Sharps and Gollin, 1987; Grady *et al*., 1994). Judgment of at least some aspects of line orientation is impaired in AD (Ska *et al*., 1990; Ricker *et al*., 1994; Finton *et al*., 1998), whereas findings in the normal aging literature are mixed. Equivalent performance has been reported across the wide age range of 55 to 84 years (Ska *et al*., 1990) and in groups ages 64–74 *versus* 75–94 (Libon *et al*., 1994). Others find age-related decrements in performance over a span of 65 to 94 years (Eslinger and Benton, 1983). AD patients also show a reduced ability to scan fields in order to locate objects and to reach for them (Mendez *et al*., 1990a).

The prevalence of spatial dysfunction may be high. We reported prevalence rates of 39% for a test of mental rotation (14/36 AD patients) and 29% for a test of map reading (10/35 AD patients) (Mendola *et al*., 1995). Spatial localization may be especially impaired in a subgroup of patients (Ross *et al*., 1996), including those with symptoms of Bálint's syndrome or other such prominent visual symptoms (Kiyosawa *et al*., 1989; Trick *et al*., 1989; Mendez *et al*., 1990a,b,c; Pietrini *et al*., 1996; see Chapters 10 and 18). Common types of deficits in these patients include difficulties in driving, following lines of text when reading, telling time from a watch, writing, and drawing (Pietrini *et al*., 1996).

B. Relation of Visual Dysfunction to Deficits in Spatial Localization

Relatively low-level visual deficits may contribute to the difficulty that AD patients have with some aspects of spatial localization. The perception of optic flow, which is related to motion perception, was found to be impaired in some individuals with AD and was correlated both with dementia severity and with memory for a real-world spatial navigation task (Tetewsky and Duffy, 1999). Some patients with AD plus Bálint's syndrome show deficient contrast sensitivity at low spatial frequencies relative to AD patients without this visuospatial syndrome (Mendez *et al*., 1990c).

The presence of visual symptoms has been reported to correlate with performance on tests of eye–hand coordination, a spatial function (Mendez *et al*., 1990a). We have reported rather weak correlations of visual abilities with performance on higher-order spatial localization tests (Cronin-Golomb *et al*., 1995). Specifically, the best visual predictor, low spatial frequency contrast sensitivity, accounted for only 11% of the variance on a mental rotation task, and for only 2% of the variance on a test of road-map reading.

C. Brain Bases of the Impairment in Spatial Localization

Spatial localization is subserved by the parietal lobes, as shown by human lesion studies (Butters and Barton, 1970; Butters *et al*., 1970, 1972; Newcombe *et al*., 1987) and functional imaging (Cohen *et al*., 1996; Richter *et al*., 1997). The same tasks supported by the parietal lobes often are not supported by the temporal lobes (Butters *et al*., 1972; Newcombe *et al*., 1987; Cohen *et al*., 1996), with the exception of tasks that require semantic knowledge as well as visuospatial abilities, such as clock drawing (Cahn-Weiner *et al*., 1999). Temporal areas appear to be important in drawing of complex figures (Mega *et al*., 1998). In normal individuals, performance of a localization task resulted in increased regional cerebral blood flow in superior parietal cortex (Haxby *et al*., 1991, 1994). On this type of task, brain activation patterns change with age, with cerebral blood flow increased in temporal as well as parietal regions in healthy elderly adults. By contrast, young adults recruit parietal regions relatively exclusively. The fact that the older adults perform the task as well as younger adults indicates that changes in activation patterns with age do not translate directly into changes in cognitive performance (Grady *et al*., 1994).

The main source of dysfunction in spatial localization in AD is the disruption of the dorsal pathway from the occipital to the parietal lobes (Grady *et al*., 1993), including extensive neuropathology in the parietal lobe itself (Brun and Englund, 1981; Pearson *et al*., 1985; Lewis *et al*., 1987; Braak *et al*., 1989; Arnold *et al*., 1991). In regard to metabolic function,

AD patients with a variety of visual complaints showed reduced glucose metabolism relative to normal individuals in some occipital and parietal regions (Kiyosawa *et al*., 1989; Pietrini *et al*., 1996). In the case of unilateral spatial neglect, imaging scans provide evidence of asymmetric parietal atrophy in AD (Kaida *et al*., 1998; Venneri *et al*., 1998).

The main input of the dorsal stream is the magnocellular pathway. Some visual capacities that are dependent upon the magnocellular pathway and dorsal stream may be performed normally by AD patients. For example, normal performance is seen for motion perception at some speeds (Kurylo *et al*., 1994a; Mendola *et al*., 1995) and for flicker perception (Cronin-Golomb *et al*., 1991; Mendola *et al*., 1995). Poor performance by patients with AD on some tasks of motion perception (Trick and Silverman, 1991; Gilmore *et al*., 1994) may reflect relatively high cognitive demands of those tasks (Cronin-Golomb, 1995).

Even with minimal cognitive demands, however, tests of dorsal-stream dysfunction may reveal impairments in AD. Mentis and colleagues (1996), using passive visual stimulation, described abnormal AD response to high-frequency pattern flash and to apparent motion, findings that are suggestive of dysfunction of striate cortex and the middle temporal area, MT, respectively. An understanding of whether or not AD patients are impaired on motion tasks will need to take into account not only task demands but also the possibility of dissociations. For example, one study reported normal motion detection (unconscious) and abnormal motion perception (conscious) in AD (Silverman *et al*., 1994), a dissociation that supports the proposition that the source of most visual dysfunction in AD occurs beyond striate cortex. The medial superior temporal area of the dorsal stream, MST, is the likely substrate of the processing of optic flow, which in turn is associated with memory for spatial navigation (Tetewsky and Duffy, 1999).

Disproportionate compromise of the occipitoparietal stream and its input, the magnocellular pathway, appears to occur in AD patients who show visual symptoms characteristic of Bálint's syndrome (Hof *et al*., 1989, 1990, 1997; Mendez *et al*., 1990c), as well as in some AD patients who exhibit suggestive electrophysiological abnormalities (Trick *et al*., 1989). The neuropsychological profile of such patients is distinguishable from that of AD patients without the symptoms of extensive occipitoparietal dysfunction. For example, constructional difficulties, such as in complex figure drawing and block construction, may be significantly worse in the Bálint's subgroup than in other AD patients (Furey-Kurkjian *et al*., 1996). Biparietal atrophy may be prominent in the subgroup of patients with visuospatial difficulties that in the early stages of the disease are out of proportion to deficits in other domains, such as memory and language (Ross *et al*., 1996).

V. Comparison of Object and Spatial Function

A. Evidence for Deficits in Object and Spatial Function

On spatial tasks, normal aging, speed or accuracy of performance often is reduced relative to performance on tasks of object discrimination and recognition (Koss *et al*., 1991; Grady *et al*., 1994; Lawrence *et al*., 1998). In one study, the degree of dissociation in performance between object discrimination (assessed with the Benton Facial Recognition Test) and spatial localization (assessed with Judgment of Line Orientation) increased with age. Specifically, spatial localization was worse in 9 of the 12 healthy elderly adults who showed a dissociation of 2 or more standard deviations. It was noteworthy, however, that dissociations occurred in quite few of the 178 normal individuals tested (Eslinger and Benton, 1983).

Most patients with AD perform poorly on tests of object discrimination and recognition and also on tests of spatial localization (Mendez *et al*., 1990a,b; Coslett *et al*., 1995; Butter *et al*., 1996; Kurylo *et al*., 1996). Some comparison studies suggest that within and across patients, object recognition is more impaired than spatial localization in AD patients without specific visual symptomatology (Butter *et al*., 1996; Kurylo *et al*., 1996), though others report more severe impairment in spatial localization (constructional abilities) than in object discrimination (face perception) (Haxby *et al*., 1990). It often is difficult to match object and spatial tests for difficulty, as pointed out by Mentis and colleagues (1996).

Because of the heterogeneity of cognitive performance from patient to patient, different AD samples may well give different results, making it difficult to infer relative preservation and impairment of performance in various domains of visual cognition. Some AD patients appear to be unimpaired on a test of face perception but unable to perform a dot location test (Mentis *et al*., 1996). By contrast, Kurylo and colleagues (1996) reported that the same tests yielded the opposite pattern of results in their AD sample: abnormal face discrimination and normal dot location. These investigators attempted to compare AD performance on tests of object recognition and spatial localization (four of each) by conducting separate discriminant analyses for each test type. They found that even though the patients were significantly impaired on both sets of tests, the object recognition tests were better at discriminating AD patients from healthy elderly adults than were the spatial tests (Fig. 36.2).

B. Relation of Visual Dysfunction to Deficits in Object and Spatial Function

Lower-level visual dysfunction may contribute differentially to downstream dysfunction in object recognition and spatial localization, suggesting that AD may affect the two cortical visual processing streams in different ways. Our correlative study of vision and cognition in AD (Cronin-Golomb *et al*., 1995) indicated that deficits in pattern masking and contrast sensitivity accounted for substantially more performance variance on tests of object completion, pattern completion, and word identification (25–50%) than on tests of mental rotation or map reading (2–11%). A similar finding was reported by Mendez and colleagues (1990a), who found the strongest correlation of some visual symptoms to be with performance on tests of figure–ground discrimination ($r = 0.72$) rather than on tests of spatial localization. These investigators did report, however, that eye–hand coordination, a spatial function, was as strongly correlated with visual symptoms as was performance on tests of object recognition ($r = 0.63$ for both).

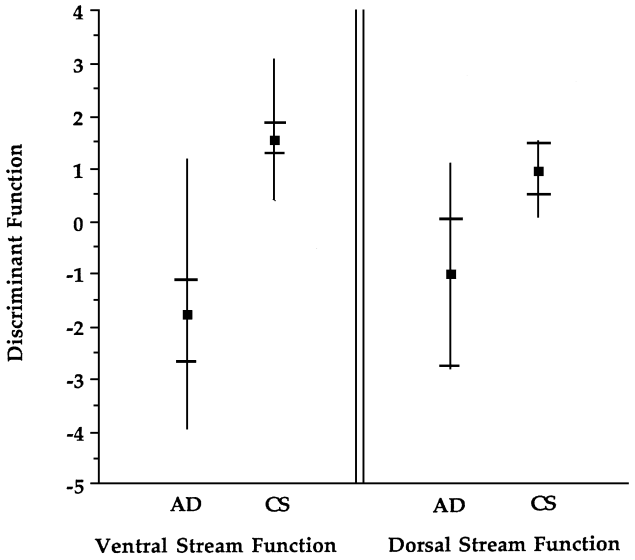

FIG. 36.2. Distribution of discriminant function scores for each of two test categories (ventral stream, object recognition *versus* dorsal stream, spatial localization) from the standardized discriminant function that best differentiated patients with Alzheimer's disease (AD) and healthy elderly control participants (CS). Distribution mean (filled square), 25th and 75th percentiles (short horizontal lines) and range (vertical lines) are indicated for each group. From Kurylo *et al.* (1996). C. Brain Bases of the Impairment in Object and Spatial Function

Comparison studies such as those of Butter and colleagues (1996) and Kurylo and colleagues (1996), which suggest that object recognition is more impaired than spatial localization in AD patients unselected for visual symptomatology, are in accordance with studies showing greater density of AD neuropathology in inferotemporal relative to posterior parietal cortex (Arnold *et al.*, 1991; Bouras *et al.*, 1994) and the greater density of senile plaques in parvocellular than in magnocellular regions of the lateral geniculate nucleus (Leuba and Saini, 1995). By contrast, in normal aging there is some suggestion that age-related differences in brain activation were more widespread for a spatial task (mental rotation) than for an object (face) discrimination task (Grady *et al.*, 1994).

Subgroups of AD patients showing "visuoperceptual" or "visuospatial" impairments out of proportion to deficits in memory, language, and other domains may represent two different clinical syndromes, depending on the specific locus of bilateral posterior atrophy. Whereas the biparietal subgroup may be characterized by impairments of spatial localization and visually guided movement with or without Bálint's syndrome, the occipitotemporal subgroup may be characterized by visual agnosia, alexia, and difficulties in the processing of color and faces (Ross *et al.*, 1996).

Although the evidence points to disruption of both the dorsal and ventral visual processing streams across the AD population as a whole, the relative and possibly differential vulnerability of the respective streams to the AD process in individuals and subgroups remains mostly unknown. One single-case study reported no difference in the density of neurofibrillary tangles in the dorsal versus the ventral regions of parastriate and peristriate cortex (Levine *et al.*, 1993). To date, more extensive pathology in one stream relative to the other in extrastriate cortex has been documented only in cases of AD with Bálint's syndrome, with the dorsal stream more affected than the ventral (Hof *et al.*, 1990).

On the basis of the available histological, metabolic, and behavioral evidence, we conclude that in AD there is dysfunction at multiple sites along the ventral and dorsal visual processing streams. We interpret the behavioral results as implicating the posterior parietal cortex as the primary locus of the spatial localization deficit in AD, and the inferior temporal lobe as the primary locus of the object recognition deficit in AD. Pathological changes in these cortical areas are presumed to disrupt cognitive capacities directly. The convergence of evidence further suggests that an additional source of cognitive dysfunction in AD is upstream in the extrastriate occipital cortex as well as the magno- and parvocellular pathways that provide input to the dorsal and ventral cortical visual streams.

VI. Clinical Relevance of Impaired Vision and Visual Cognition

Information on vision and visual cognition may be useful in functional assessment and intervention for the individual patient with AD as well as for relatively normal elderly adults. Clinicians and family members need to be alerted to the possibility that an older adult may experience difficulties in activities of daily living that are attributable to specific visual dysfunctions, especially in light of our findings that prevalent visual deficits can strongly predict cognitive impairment. For example, evidence of impaired color discrimination in AD may contraindicate the use of color coding to help a patient distinguish between different room doors, pill bottles, or other objects important to everyday activities.

Poor object recognition resulting from impaired inputs to temporal cortex and degeneration of that cortex itself leads to the expectation of deficient functional interaction with everyday objects. Deficits in spatial localization, arising from pathological change in parietal cortices and their inputs, may render an individual unable to orient effectively to the environment. This difficulty may manifest itself as decreased locomotion in some patients and wandering in others, and is especially likely to occur after a change from processing a long-known spatial layout (such as a home) to a new, unfamiliar layout (a relative's home, or an institution). Even after months or years in the relatively new environment, there may be little accommodation by the patient because of the impaired ability to encode as well as retrieve spatial information.

Recognizing that the source of difficulties in daily function may be at least in part visual can provide clinicians and researchers with new ways to develop and apply interventions. The goal would be to enhance cognitive performance through interventions aimed at restoring visual capacities. For example, as described above, enhancing color contrast may improve aspects of daily function in institutionalized AD patients, including increases in the amounts of food and liquids ingested, and decreases in the frequency of night-time agitated

behaviors (Koss and Gilmore, 1998; Dunne and Neargarder, 1999). Designers of living spaces for patients with AD have made great strides in recent years in attempting to minimize visuocognitive deficits (Brawley, 1997; Warner, 1998). Strategies include use of living areas that are highly differentiated (to employ residual object discrimination and recognition) and abolishment of long corridors and maze-like walking paths (to minimize difficulties in spatial localization). The application of basic findings on vision and visual cognition in AD to everyday life is relatively recent and encourages further research to aid in this effort.

Acknowledgments

I am grateful to Melissa Amick for her critique of an earlier draft of this chapter and especially for pointing me to relevant literature on normal aging and spatial abilities. I thank Dan Kurylo for permission to reproduce Fig. 36.2 from his paper. This work was supported by the Alzheimer's Association (IIRG-98-043) and the National Institute on Aging (5 R01 AG15361).

Anatomical and Neurochemical Bases of Presbycusis

Age-related hearing loss—presbycusis—is associated with two major symptoms: loss of sensitivity to sound, especially for high pitches, and a reduced ability to understand speech in background noise. Ultimately, these functional sensory perceptual problems result from neurological changes in the ear and brain that occur as we age. This chapter focuses upon neuroanatomical and biochemical degradations in the inner ear and central auditory system that may underlie hearing problems associated with old age. The basic findings to date suggest that sensitivity deficits result from the loss of cochlear sensory cells, metabolic cells, microvasculature, and neurons of the eighth cranial nerve that occur as a result of aging and age-related environmental insults. In addition, the problem of comprehending speech in acoustically noisy environments is exacerbated by alterations in the normal number, structure, and biochemistry of neurons in the parts of the central nervous system used for hearing. The latter deficits can result from direct aging effects on the brain, or as a response to reduced inputs to the central auditory system resulting from the age-related pathologies of the inner ear.

I. Introduction

This chapter will focus on the possible etiologies of permanent, progressive age-related sensorineural hearing loss that resides in the inner ear or brain. If taken in conjunction with other chapters on presbycusis in this volume, the present chapter provides some of the possible neuroanatomical or neurochemical bases for the behavioral and physiological characterizations of age-related hearing loss described elsewhere. It is only with this knowledge of the underlying anatomy and neurochemistry that therapeutic interventions involving gene therapy or biochemical medications can be developed and implemented.

II. Inner Ear

A. High-Pitch Hearing Loss: Declines in Hair Cells and Spiral Ganglion Cells

It has been known for some time that the primary cause of the high-frequency audiometric threshold decline in sensitivity characteristic of presbycusis—age-related hearing loss—is the destruction of hair cells in the basal (high-frequency) turn of the cochlea (auditory portion of the inner ear). From an aging perspective, this decline in the number of hair cells begins with the loss of outer hair cells, which are generally more susceptible than inner hair cells to age-related insults such as hypoxia, fever, noise, antibiotics, or other internal and external environmental insults. Losses of inner hair cells also occur with age, which can decrease the number of neural channels carrying information to the brain, thus reducing or distorting information relayed to the brain about complex sounds such as speech. In advanced age groups, nearly complete loss of inner hair cells can result in profound hearing loss and can be accompanied by severe reduction of spiral ganglion cells (neural information channels to the brain).

1. Animal Models

a. Genetically Inbred Mouse Strains. Neurobiologists and hearing scientists investigating the neural bases of presbycusis have found it useful to utilize different strains of inbred mice that lose their hearing at different rates. The hearing characteristics of these strains are described in more detail in other chapters of this handbook dealing with age-related hearing loss. Briefly, two of the most commonly utilized strains are the CBA and C57 mice. The CBA mouse loses its hearing at a slow rate as a function of age and loses sensitivity at all frequencies. In contrast, the C57 strain loses its hearing very rapidly as a function of age, and tends to lose hearing first in the high frequencies due to hair cell loss in the basal turn of the cochlea. The CBA is a model of the human condition in that its slow progressive hearing loss occurs on a time scale similar to that of humans suffering from presbycusis if one corrects for the absolute difference in the average life spans of mice and men, i.e., 2 years versus seven decades, respectively. The

C57 mouse model mimics the high-frequency component of human age-related hearing loss, and has been used effectively to determine the central effects of peripheral hearing loss. Taken together, these two strains along with other mouse strains can help delineate central versus peripheral aging effects in the auditory system. For example, a 6-month-old C57 mouse has a relatively young brain but an ''old'' ear. The young brain, however, has undergone a peripherally induced reduction in physiological inputs superimposed upon it due to the death of auditory nerve fibers from the basal turn of the cochlea that normally would provide input. An old CBA mouse has an old brain and an old ear, which in many ways resembles the situation in a presbycusic patient with an old ear and brain.

Hair cell loss takes place rapidly, starting at about 2 months of age, initially in the basal turn of the cochlea in C57 mice. Specific pathologies of the organ of Corti in the age range of 3 to 12 months include significant decline, clumping, and distortion of outer hair cells; degeneration of pillar cells; but little loss of inner hair cells (Henry and Chole, 1980; Willott, 1991). At 2 years of age, very little is left of the organ of Corti in the basal turn. Spongr *et al*. (1997a,b) performed systematic counts of inner and outer hair cells for C57 mice of four different age groups. Data for the 26-month-old group are presented in Fig. 37.1A. Notice that hair cell loss is most extreme in the basal turn (furthest from the apex). Also, observe that losses of both hair cell types are 100% in the base in these old animals, whereas in the apex outer hair cell declines are about 80%, and inner hair cell reductions are at approximately 20% in the C57 cochlea.

C57 mice have reductions in spiral ganglion cells that accompany the hair cell losses (Willott, 1991). At the end of the second year of life, there is a 40% loss in the apical turns (low frequency) of the cochlea and 80% or more in the basal turns (high frequency). Degeneration of spiral ganglion neurons goes through several steps (Cohen *et al*., 1990): (1) demyelination, including loosening and unraveling of myelin sheaths; (2) pathological contact with fusion of cells that are partly demyelinated; (3) clumping of demyelinated cell bodies that become surrounded by cytoplasmic processes; (4) resorption; (5) disappearance of basal lamina at contact sites; (6) encircling of clumped ganglion cell bodies by Schwann cells; (7) extensive mitochondrial death; (8) formation of empty spaces where ganglion cell bodies used to be.

Compared to the C57, the CBA mouse strain loses hair cells and spiral ganglion cells at a much slower rate, with very little loss at even 16 months of age (Henry and Chole, 1980). Spongr *et al*. (1997a) confirmed this and demonstrated that at 18 months of age, a 30–50% loss of outer hair cells was present only in the extreme basal and apical portions of the cochlea, with no loss of inner hair cells. The old-age configuration of hair cells for CBA mice is shown in Fig. 37.1B. Notice that the functions are U-shaped, with significant losses present only in the most apical and basal portions of the cochlea. These 26-month data show that there are no hair cell losses in the middle turns of the CBA cochlea, whereas outer hair cell losses occur at 50–60% in the cochlear extremes, and inner hair cell losses reach 10–30% in the most apical and basal portions.

Loss of spiral ganglion neurons is not as severe or frequency-specific as in the C57. For example, in 2-year-old

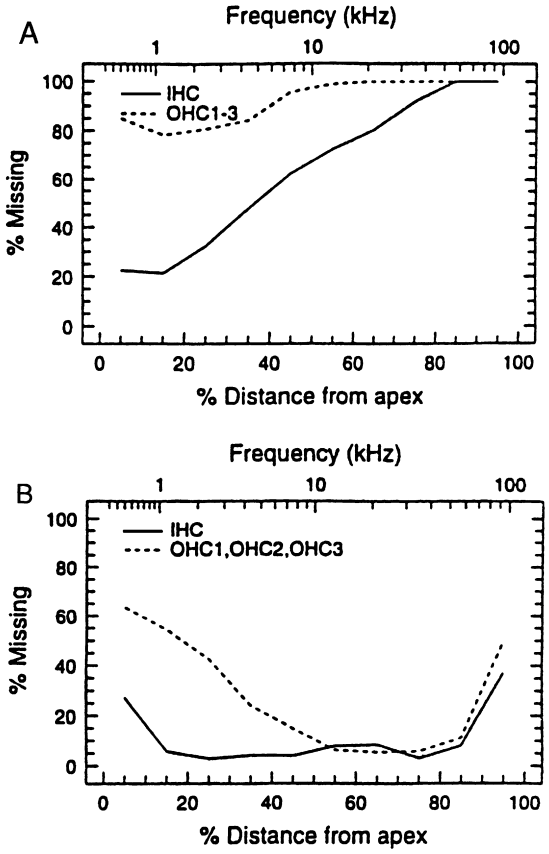

FIG. 37.1. Cytocochleogram displaying pattern of hair cell loss in the old (26-month) C57 and CBA cochlea. (A) Notice that for C57 mice, both inner and outer hair cells have the most significant declines in the cochlear base (furthest distance from the apex). (B) For CBA mice, the functions are U-shaped in that most losses are in the base and apex. For each graph, the data represent the mean of cytocochleograms from 10 animals. This format displays the percentage of missing inner and outer hair cells in 10% intervals as a function of distance from the apex. From Spongr *et al*. (1997a) with permission from the American Institute of Physics and the author.

CBA mice, the density of spiral ganglion cells in Rosenthal's canal declines by only 5–20%, and in 30-month-old mice, declines at all frequencies are only about 30% (Willott, 1991).

Willott and Erway (1998) more recently have evaluated hearing and cochlear cell losses in 25 different recombinant inbred mice derived from C57 and DBA strains. The DBA strain has an accelerated peripheral hearing loss that occurs at a rate even faster than the C57, and is also high-frequency in nature (Willott *et al*., 1984). These recombinant inbred mice, referred to as BXD strains, were derived by successive brother–sister mating from original F1 hybrids of a C57 mouse and a DBA mouse. Evidence suggests (Erway *et al*., 1993; Willott *et al*., 1995) that C57 and DBA mice share a common age-related-hearing loss gene (*Ahl*) on chromosome 10. DBAs, with the more severe hearing loss, are homozygous for two additional age-related-hearing-loss genes: *Ahl2*, also on chromosome 10, and *Ahl3*. Thus, they postulate that each BXD strain is composed of one of four possible genotypes: (a) homozygous for *Ahl* only, like C57s; (b) homozygous for all three, like DBAs; (c) homozygous for *Ahl* and *Ahl2*; (d) homo-

zygous for *Ahl* and *Ahl3*. Given a large enough sample, it was hypothesized that a quarter of the mice would be like C57s, a quarter like DBAs, and half in between. This hypothesis was supported in the Willott and Erway (1998) study, as three distinct phenotypes in appropriate proportions emerged in the BXD recombinant mice: one with an age-related hearing loss and spiral ganglion cell diminution like C57 mice, another with the more severe losses of the DBA strain, and the rest with intermediate levels of hearing and spiral ganglion cell loss as a function of age, presumed to be homozygotic for two of the three age-related-hearing-loss genes.

b. Other Rodents. Bohne *et al.* (1990) examined age-related declines in hair cells of the laboratory chinchilla, an outbred rodent with a life span of 12–20 years. A slow, progressive pattern similar to the CBA mouse strain was observed in that through middle age (8–11.5 years), declines in all turns of the cochlea were less than 10% for outer hair cells and less than 5% for inner hair cells. In old age (12–19 years), although less severe than in mice, losses were most prevalent in both the apex (17% decline) and the base (25% fall) for outer hair cells, with declines of 11–15% for the middle turns. For inner hair cells, the reductions were 6% in the base and apex of the cochlea and 4% for the middle turns. Clumping and tangled stereocilia were not common in the young animals, but increased with age. Chinchilla pillar cells also degenerated with age, starting with losses of cuticular plate substance. Degeneration of spiral ganglion cells was associated with loss of inner hair cells, but rarely occurred in regions with just outer hair cell loss.

McFadden *et al.* (1997) performed an interdisciplinary investigation of age-related hearing loss in chinchillas by comparing a young group with a "young" elderly group with an age range of 11–15 years. Their hair cell counts were similar to Bohne *et al.* (1990), as shown in Fig. 37.2, which was correlated with a modest decline in hearing sensitivity, especially in the high frequencies. They also showed increases in the prevalence of phalangeal scars and a wider distribution of pigmented granules (lipofuscin or melanin) in the organ of Corti of old animals, as displayed here in Fig. 37.3.

As demonstrated by the Medical University of South Carolina's hearing research team headed by Mills and Schmiedt, the gerbil, with a life span of about 3 years, is a useful model for peripheral studies of age-related hearing loss. Unlike most rodents, but like the chinchilla, gerbils have good low-frequency hearing. Gerbils have a slow, progressive hearing loss that reaches about 20 dB for low frequencies and 30 dB in high frequencies in old age (36 months; Schmiedt, 1993). There is almost no loss of inner hair cells in aged gerbils, and interestingly, the loss of outer hair cells is most significant in the apex of the cochlea, whereas the greatest hearing loss is in the high frequencies (Tarnowski *et al.*, 1991). Keithley *et al.* (1988) report that spiral ganglion cell loss in gerbils starts at about 24 months, and in the oldest animals (36–42 months) reductions of 15–25% occurred throughout the cochlea.

Covell and Rogers (1957) and Ingham *et al.* (1999) have investigated age-related changes in the cochlea and their relationships to hearing loss in guinea pigs. The guinea pig, having a maximal life span of 6–7 years, shows very slow, minimal loss of hair cells and auditory sensitivity with age. In very old animals, the only significant loss of outer hair cells occurs in the apical turn of the cochlea. There are very slight declines in inner hair cells and spiral ganglion cells. The outer hair cell losses of the apex increased from the first to the third row: first row, 20%; second row, 25%; third row, 30%. In terms of a model for presbycusis, the rate of age-related loss in guinea pigs would be slower than that seen in most humans, and except for the oldest group of presbycusics with significant cochlear apex damage, the guinea pig has the opposite configuration of hair cell damage from classic presbycusis. Last, hearing loss in old guinea pigs is relatively minimal (30–40 dB) and constant across frequencies, suggesting, as for gerbils, that loss of outer hair cells outside the basal turn is not generally a good predictor of elevations in hearing thresholds.

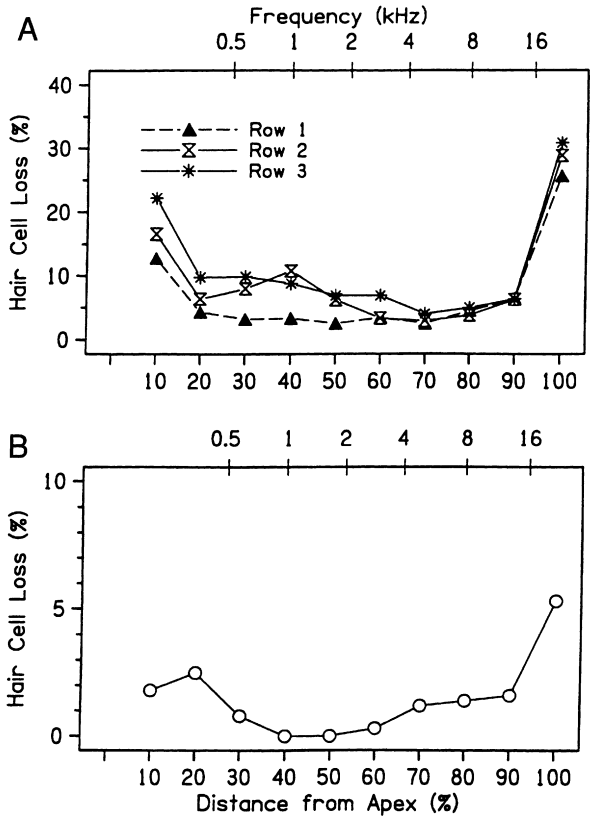

FIG. 37.2. Hair cell declines in chinchillas are U-shaped, reminiscent of findings in old humans and CBA mice. (A) Outer hair cells have their greatest losses in the extreme base, with severity of decline increasing from the 1st row to the 3rd row. (B) Inner hair cells also show a U-shaped function, although it is less concave (flatter loss than the outer hair cells). Cytocochleogram format same as the previous figure. From McFadden *et al.* (1997) with permission from Elsevier Science and the author.

As a means for evaluating the usefulness of inbred mouse strains, comparisons have been made of spiral ganglion cell loss in wild-type mice and other rodent outbred strains including guinea pigs and gerbils. Spiral ganglion cell loss in middle aged (18– to 19-month-old) wild type mice ranged from 16 to 49%, with the greatest loss in the basal turn (Dazert *et al.*, 1996). For old-age wild types (28–31 months) the drops relative to the young mice ranged from 50 to 76%, with the most loss in the apex and base, which were about the same. This time-dependent pattern of ganglion cell loss in the wild type

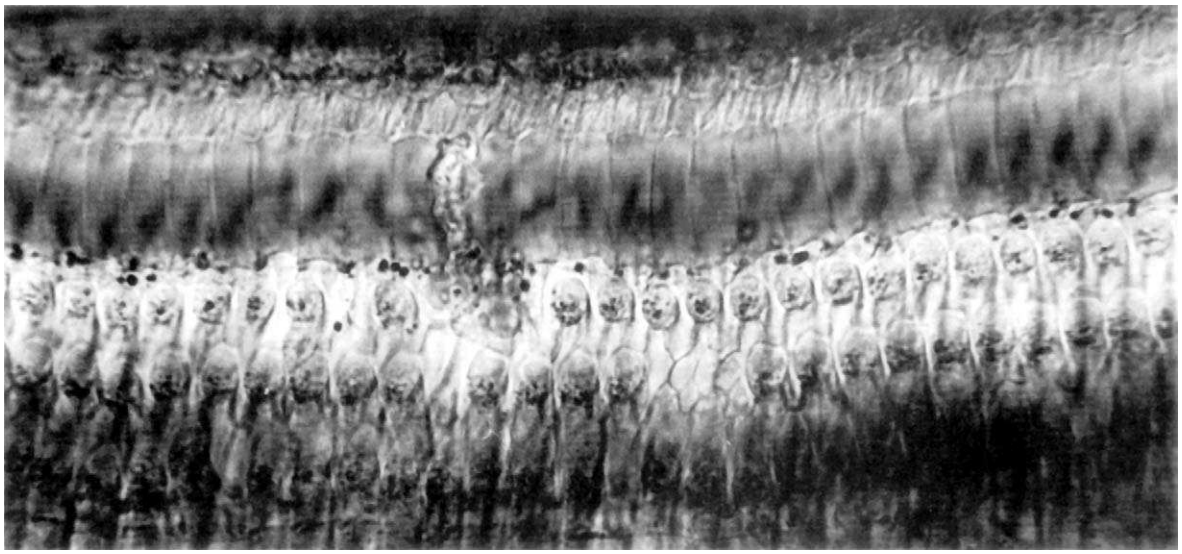

FIG. 37.3. Old chinchillas displayed increased occurrences of phalangeal scars and pigmented granules such as lipofuscin and melanin, throughout the extent of the organ of Corti. This photomicrograph displays a surface preparation from the basal turn of an 11-year-old chinchilla. From McFadden *et al.* (1997) with permission from Elsevier Science and the author.

mice, as shown in Fig. 37.4, was very similar to the pattern seen in gerbils, guinea pigs, and different strains of rats, where noticeable diminutions start to occur in middle age, and in old age the greatest losses are in the basal and apical turns of the cochlea (Keithley and Feldman, 1979; Keithley *et al*., 1989, 1992).

Last, Hoeffding and Feldman (1988) demonstrated in Sprague–Dawley rats that the median number of healthy, normal auditory nerve fibers (axons of spiral ganglion cells connecting the ear to the brain) was reduced by 21% at 27 months of age and by 24% at 36 months. The number of degenerating nerve fibers went up by 6 months of age, peaked at 27 months, and went back down at 36 months. Although the auditory nerve cross-sectional area rose over the life span due to increasing thickness of myelin sheaths, the packing density of healthy nerve fibers declined with age. Glial cells in the nerve were constant across the life span.

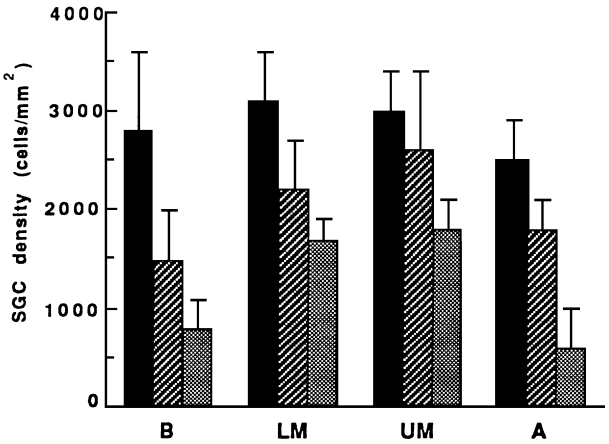

FIG. 37.4. Cochlear spiral ganglion cells decline with age in mice, with the greatest declines in the base and apex. This histogram displays the mean and standard deviation of the number of ganglion cells/mm^2 in the four half-turns of the mouse cochlea. Left bar (solid), young; middle bar (hatched), middle age; right bar (shaded), old; B, base; LM, lower middle turn; UM, upper middle turn; A, apex. Each turn was found to have a significant (ANOVA, $P < 0.001$) decline in spiral ganglion cells with age. From Dazert *et al.* (1996) with permission from Elsevier Science and the author.

c. Other Mammals and Primates. The usefulness of the rodent studies has precluded the necessity of performing extensive inner ear aging studies in other mammals. This is primarily due to the fact that what is known about presbycusis in other mammals is consistent with the findings of the rodents. For example, neuroanatomical studies of the aging cochlea conducted in monkeys, cats, and dogs (summarized by Willott, 1991) show slow progressive declines in the condition of the organ of Corti and in numbers of hair cells and spiral ganglion cells. In the absence of noise exposure and other environmental insults, higher mammals lose hair cells slowly, with the greatest losses in old age occurring in both the cochlear apex and base, and with outer hair cell diminutions exceeding and preceding inner hair cell degeneration. This was demonstrated quite exquisitely in the rhesus monkey by Hawkins and Johnsson (1985) whose cytocochleograms based on data from 15 monkeys aged 4–31 years showed the same U-shaped function as the chinchilla data displayed here in Fig. 37.2.

2. Human Studies

Elderly individuals, unlike laboratory animals housed in university vivariums, undergo environmental insults, which are overlaid or interact with general biological aging processes and any genetic susceptibilities to insults to the cochlea or brain coming from internal or external bioenvironments. Therefore, investigations of temporal bones from aged individuals have shown sensory and spiral ganglion cell losses throughout the cochlea, with usually the greatest severity in

the cochlear base and apex, and anomalies of the stria vascularis and inner ear microcirculation. For instance, Bredberg's (1968) study of old humans showed that inner hair cell loss was confined to the base and can be greater than a 50% reduction. However, organ of Corti abnormalities and outer hair cell loss generally took place throughout the auditory sensory epithelium with the greatest changes in both apex and base. Specifically, Bredberg (1968) reported a 75% reduction of outer hair cells in the base, and a 65% decrease in the apex. In some individuals, perhaps suffering from noise-induced hearing loss, patterns of degeneration did not follow the norm and were restricted to isolated points along the cochlear partition.

Bredberg (1968) along with Schuknecht (1974), also noted a finding that has been substantiated in animal models as mentioned above: destruction of outer hair cells generally starts with the outermost row, proceeds to the middle row, and finally reaches the inner row. Subsequently reported in animal preparations, Johnsson and Hawkins (1972) noted the presence of phalangeal scars in the organ of Corti of old humans. The scar apparently results from the growing together of apical processes of phalangeal (supporting) cells in the gap where the hair cell used to be. Johnsson (1971) in a study of the human Reissner's membrane (separating scala vestibuli [perilymph] from scala media [endolymph]), noted that in presbycusis the membrane degrades, producing vacuoles 5–10 μm in diameter which may be the product of pinocytosis. Breakdown of Reissner's membrane, which has been reported in some old animals, could compromise the separation of endolymph from perilymph, thus decreasing the endocochlear potential and interfering with normal hair cell functioning and the auditory mechanical-to-electrical transduction cascade. Engström *et al*. (1987), in a study of hair cell loss in the aged human cochlea, also reported abnormalities and fusing of stereocilia on the apical surfaces of hair cells that were still present.

In general, loss of spiral ganglion cells occurs sooner and to a greater degree with age in the base of the human cochlea relative to other turns of the cochlea, and is rarely seen in the absence of sensory-cell degeneration. An exception is the patchy loss of ganglion cells in certain restricted foci of the cochlea reported by Johnsson and Hawkins (1972), similar in configuration to the local hair cells losses mentioned in the previous paragraph. Schuknecht (1993) reports that in very old individuals (81–90 years old), ganglion cell loss is 54% in the apical turn and 48% in the basal turn, in contrast to ''younger'' old who have the greatest spiral ganglion cell losses in the basal turn of the cochlea. Felder and Schrott-Fischer (1995) also investigated relations between hair cell loss and myelinated nerve fiber degeneration in the human cochlea. They found that reductions of up 40% in spiral ganglion cells in aged (above 60 years of age) human temporal bones relative to cochleas from middle-aged persons with normal hearing. Interestingly, the spiral ganglion losses were throughout the cochlea, but the outer hair cell losses were most severe in the apex (up to 80% reductions), and declines in inner hair cells were minimal relative to the middle-aged controls. This study exemplifies another case where subjects have a classic, high-frequency presbycusic hearing loss that cannot be entirely understood in terms of hair cell or auditory nerve fiber degeneration, which themselves were not well correlated.

As Willott (1991) summarizes, in aging humans degeneration of spiral ganglion cell processes or cell bodies can occur sometimes where organ of Corti pathology or hair cell loss has not occurred. Therefore, it appears that loss of hair cells can induce ganglion cell loss with age, but the latter can also occur in some cases where a relatively healthy organ of Corti exists. It appears that organ of Corti pathology is a sufficient but not necessary condition for the atrophy of spiral ganglion cell distal (peripheral) dendrites or their perikarya. One possible mechanism for auditory nerve fiber death independent of organ of Corti pathology is destruction of nerve fibers due to disruption of their central projections to the cochlear nucleus resulting from central nervous system aging degeneration there (to be discussed later in this chapter). Indeed, consistent with reports of spiral ganglion cell loss, Rasmussen (1940) and Spoendlin and Schrott (1989, 1990) have counted nerve fibers in the auditory division of the eighth cranial nerve as a function of age in humans and found reductions of 8–25% and noted the presence of pathological axons in the old temporal bones.

An important ramification of ganglion cell loss, because their axons have the singular property of carrying all information about sound to the brain, is that decrements in speech recognition performance have been correlated with spiral ganglion cell degeneration in aged human subjects (Belal, 1975; Otte *et al*., 1978). These correlations are stronger than for pure tone sensitivity but can be quite variable overall. Interestingly, Pauler *et al*. (1986) found a surprisingly strong relationship between ganglion cell loss in the region of the human cochlea corresponding to sensitivity to 1–2 kHz (15–22 mm from the base) and speech recognition. This is intuitively appealing in that this frequency region is the most important band for human speech perception.

B. Metabolic and Blood-Flow Changes Affect Overall Sensitivity

In contrast to sensory and spiral ganglion cell losses that tend to occur in specific regions of the inner ear with age, metabolic and blood flow deficits with age can have a more generalized effect on the functioning of the cochlea. The stria vascularis is a highly vascularized region on the lateral wall of the cochlea whose primary function is to extract potassium chloride from cochlear capillaries to maintain the electrochemical gradient in scala media necessary for normal conversion of sound energy to nerve cell impulses.

1. Animal Models

The most systematic study of age-related metabolic and blood flow deficiencies of the cochlea have been accomplished by Schmiedt and Schulte's South Carolina investigative team using the gerbil as an animal model. For example, Schmiedt and Adams (1989), Schulte and Schmiedt (1993), and Gratton *et al*. (1997) demonstrated almost all of the reductions in the normal endocochlear potential with age can be accounted for by declines in ion transport capabilities of the stria vascularis marginal cells as visualized by Na,K-ATPase immunoreactivity in the gerbil inner ear. Figure 37.5 displays this functional relationship for 25 gerbil cochleas ranging in age from 3 to 32 months of age. The endocochlear potential is the voltage pre-

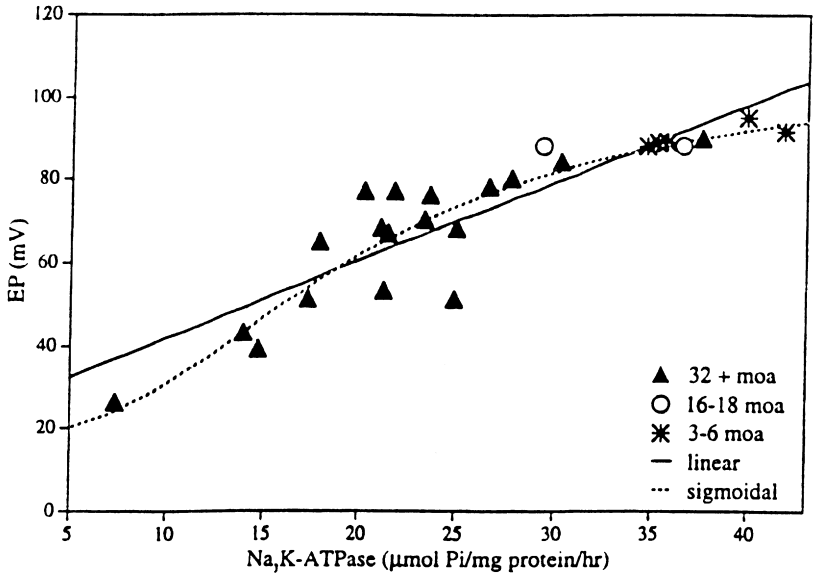

FIG. 37.5. A positive correlation was found for the magnitude of the endocochlear potential and the extent of Na^+,K^+-ATPase activity in gerbils of different ages. These data come from 25 ears, with the solid line representing the linear regression results while the dashed curve embodies a sigmoidal regression analysis. Data from 18 old gerbil (triangles), 2 middled age gerbils (circles), and 5 younger animal (asterisks) ears are displayed; moa, months of age. From Gratton *et al.* (1997) with permission from Elsevier Science and the author.

sent in scala media that provides the basis for acoustico-mechanico-electrical transduction (conversion of sound energy to the electrochemical code of the central nervous system). Another article reports, similar to what was explained above for hair cell loss, that aging gerbils first display stria vascularis lesions in the cochlear apex and base, rather than the middle turns, which then spread with age (Gratton and Schulte, 1995).

Gratton *et al.* (1996) looked for relations between changes in cochlear vasculature in quiet-aged gerbils at 36 months of age and their endocochlear potentials. The density and diameter of strial capillaries were assessed in wholemount preparations, and then histopathologic changes were studied with light and transmission electron microscopy. In the same animals, endocochlear potentials from all turns of the cochlea were recorded along with the endocochlear potential at the round window. No strong relations were found between the endocochlear potential in each turn and the amount of microvascular damage. However, there was a significant correlation between the overall, mean endocochlear and the amount of *normal* strial vasculature throughout the cochlea, both of which decline with age (see Fig. 37.6). In related investigations, Schmiedt (1993, 1996) found that despite age-related declines in the endochoclear potential (92 mV [$\pm$5.7 mV] in young adult gerbils to 65 mV [$\pm$15.8 mV] in 30-month-old animals to 61 mV at 36 months), scala media K^+ concentrations remained within normal limits until endocochlear potential voltages became very low (below 60 mV). Below, 60 mV, there was always a K^+ concentration below the normal range.

To better understand the etiology and temporal sequencing of age-related strial degeneration, the integrity of the basement membrane unique to strial capillaries was investigated in the gerbil inner ear. In general, the basement membrane is a thin layer associated with the plasmalemma of endothelial and epithelial cells as they contact other cell types, and provides mechanical support for proper cell attachment and differentiation, especially during development. It has many structural components, but a primary one is laminin, a multidomain glycoprotein composed of eight distinct chains. Sakaguchi *et al.* (1997) and Thomopoulos *et al.* (1997) found that starting in the cochlear apex of 6-month-old gerbils, the presence of laminin increased above normal levels in the basement membrane, causing it to become pathological. With advanced age (33 months and older), the cochlear base and apex showed abnormal basement membrane thickening in 65–85% of strial capillaries, which is about seven-fold the occurrence seen in young adult animals. This pathology was followed by capillary obstruction (in some ways similar to atherosclerotic closure of blood vessels with age), that resulted in degeneration of marginal cells and complete strial atrophy.

Fibrocytes of the spiral ligament, which contain K^+ transport enzymes, also play a critical role for endolymph homeostasis in scala media (Schulte and Adams, 1989; Spicer and Schulte, 1991). Spicer *et al.* (1997) demonstrated that changes in the concentration of K^+-ion transport enzymes are complex with age, but related to strial damage that starts first in the apical and basal regions, and then spreads to the middle turns in old age. For example, carbonic anhydrase isoenzyme II first upregulates itself in regions of strial damage, or regions adjacent to areas of strial damage, presumably to compensate for the failure of other ion transport systems and decreased blood flow. As presbycusis proceeds in gerbils, this upregulation ceases, and in very old gerbils with strial damage in most areas of the cochlea, the carbonic anhydrase immunoreactivity declines to levels below those of young adult animals.

Studies of stria vascularis integrity and patency of cochlear microcirculation in other animals, although not as comprehen-

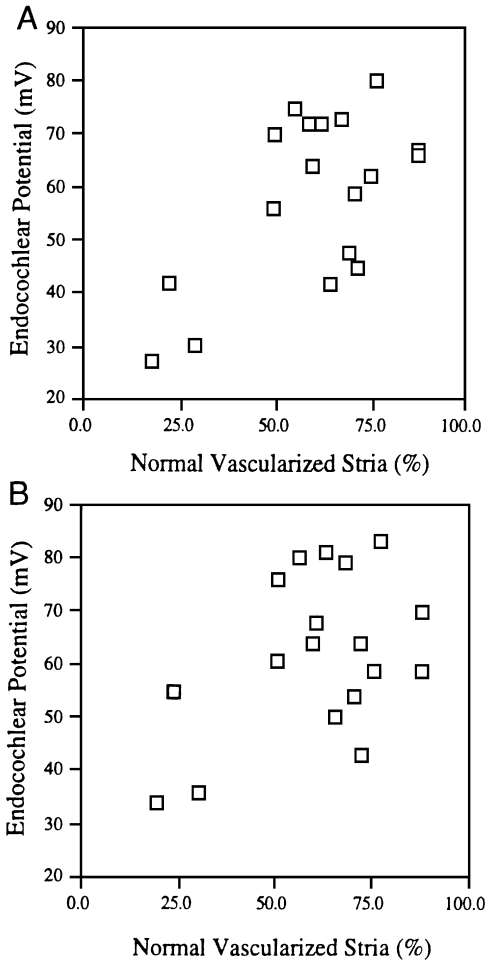

FIG. 37.6. Declines in the endocochlear potential follow reductions in the capillary integrity of the stria vascularis. Here endochoclear potential values are plotted versus the amount of normal capillary structure of the stria vascularis. (A) Data are from scala media of 18 gerbil inner ears ($P < 0.01$, $r = 0.61$, $n = 18$). (B) Similar data except data were collected at the round window, outside the cochlea ($P < 0.05$, $r = 0.44$, $n = 18$). sive and systematic, are important because they confirm that such changes discovered in the gerbil work are probably present to some degree in all mammals and therefore play a key role in understanding certain aspects of the biological bases of human presbycusis. For example, Bohne *et al.* (1990) performed a comprehensive investigation of cochlear changes involving over 80 chinchillas ranging in age from birth to 19.2 years. They found that substantial strial degeneration involving all three types of strial cells and capillaries occurred in 14% of chinchillas over 3 years of age. Willott (1991) reports increases in abnormal pigment inclusions in old C57 and CBA mice, with the occurrence much greater in the C57s, and summarizes the presence of age-induced strial degeneration in cats, dogs, and sometimes in old rhesus monkeys and chimpanzees. Ding *et al.* (1998) report aging effects in the cochleas of C57 and CBA mice regarding dehydrogenase activity and glycogen levels that in many aspects support the conclusions drawn from the gerbil studies.

2. Human Studies

Cochleas from persons suffering from presbycusis display pathologies of the stria vascularis as well as anomalies in cochlear microcirculation that parallel the age-related pathologies investigated in gerbils and other mammals. Based upon abnormalities of the stria vascularis and cochlear blood vessels in human temporal bones from elderly patients with hearing loss, Schuknecht (1964) and Schuknecht *et al.* (1974) put forth the concepts of "metabolic presbycusis" and "vascular presbycusis." Consistent with this are reports of significant loss of blood vessels in the spiral ligament, stria vascularis, and even in the organ of Corti in presbycusic ears (Johnsson and Hawkins, 1969). Like most mammals, these losses were greatest in the apical and basal turns of the cochlear spiral, and were accompanied by strial atrophy and declines in the diameters of remaining vessels. Interestingly, these vascular degenerations resemble those reported for the aging human retina. In addition, Fischel-Ghodsian *et al.* (1997) report that mitochondrial DNA from spiral ganglion cells and membranous labyrinths from old human cochleas had from 1 to 26 sequence changes in mitochondrial chromosomes versus a range of 1–3 sequence changes from control tissue (tissue from subjects with no hearing loss). These additional DNA sequence changes could disrupt normal oxidative phosphorylation in the ears of elderly patients, thus interfering with normal cochlear transduction functioning.

C. Summary of Cochlear Findings

The inner ear work shows some noteworthy similarities between the animal investigations and the human reports. In human pathological studies, hair cell loss occurs as a function of age, with declines first occurring in the cochlear base. The configuration of this degeneration is modeled well by hair cell loss in the C57 mouse strain. The rate of hair cell loss in humans, a slow progressive process with age, is better modeled by the slow decline of hair cells over the life span seen in the CBA mouse, the chinchilla, and other rodents. However, the animal losses for these species generally are more flat than that seen in classic cases of presbycusis. It appears that the high-frequency component of human presbycusis is due primarily to age-related loss of hair cells and spiral ganglion cells in the basal turn of the cochlea, starting with outer hair cells which are more susceptible to physiological insults such as noise, hyperthermia or other ototoxic agents. Superimposed on this may be a more general loss of sensory hair cells, and to a lesser extent spiral ganglion cells, from an aging process that affects the integrity of the stria vascularis or cochlear microcirculation, which may affect the entire cochlea. Strial atrophy and reductions in inner ear capillaries has been observed in many aged animals and demonstrated in detail in the gerbil. For reasons not completely understood, these vascular changes can induce hair cell loss in both the cochlear base and apex. Extensive apical damage is seen in most of the nongenetically inbred animal models and in the very old human temporal bones. Deficiencies in cochlear microcirculation have been reported in old human temporal bones, and in animal models such as the gerbil and the dog. Finally, an important lesson from these aging studies is that outer hair cell loss

in the cochlear base results in declines in hearing sensitivity, whereas reductions in outer hair cells in other turns of the cochlea are generally not well correlated with hearing loss.

III. Central Auditory System: Peripherally Induced Changes

Aging can affect the central auditory nervous system directly, by causing age-related problems in the structure and neurochemistry of brain cells. However, age can also cause damage to the inner ear, ultimately inducing degeneration of spiral ganglion cells and eighth nerve fibers that constitute the information channels connecting the cochlea to the cochlear nucleus, the first processing stage of the auditory central nervous system. At this point, peripherally induced central effects will be focused on first, and then this chapter will conclude with aging problems of the central auditory system that appear to be independent of damage to the inner ear. These concepts of differential effects of age on the auditory nervous system are explained graphically in another chapter (see Chapter 39, Fig. 1).

A. Animal Models Demonstrate Reorganization of the Brain Due to Reduced Peripheral Inputs

Contrary to classical notions of a hard-wired central nervous system in adult organisms, more recent neuroscientific research has unequivocally shown that the adult mammalian brain is capable of reorganization in response to normal or abnormal sensory input. In contrast to synaptic and pathway reorganizational capabilities of the brain, it is still the case that under normal conditions central nervous system nerve cells cannot regenerate themselves when lethally damaged or destroyed. In this section, we will focus on studies of the C57 mouse strain by Willott and colleagues and by our group. The rapid cochlear hearing loss of the C57 as a function of age provides a relatively unique model for investigating the effects of reduced peripheral input to the auditory central nervous system. A 6-month-old C57 mouse has an "old ear" with significant reductions in the information that gets relayed to the auditory central nervous system, but still has a young brain. In some sense then, the effects of an old ear can be studied for a brain that does not have its own age-related degradation.

1. Gross and Cellular Anatomical Measures of Central Nuclei

Anatomical measurements of the anteroventral cochlear nucleus were made by Willott *et al*. (1987) in C57 and CBA mice of different ages. No changes in anteroventral cochlear nucleus volume or dimensions were noted with age. For nerve cell number and packing density, there is a decline in the first 7 months of life for C57s and little change thereafter. However, these parameters do not decline in CBAs until the second year of life. C57 spherical and globular cells increase in size with age, whereas multipolars decline, and these changes take place earlier and largely in dorsal regions of anteroventral cochlear nucleus. These dorsal areas receive severely declining peripheral inputs as a function of age from the base (high-frequency turn) of the cochlea. All three cell types become smaller as a function of age for CBAs. These strain differences were interpreted to be the result of the different rates of hearing loss across the two strains. A follow-up study comparing anatomical changes in the AVCN for C57 and DBA mice revealed that for the DBA strain, which possesses a more rapid peripheral loss than the C57, neuronal losses were more rapid than in C57 mice, paralleling the accelerated time course of the peripheral hearing loss in DBAs (Willott and Bross, 1996). It was instructive to note that the final reductions in neuron size and packing density were of similar magnitude at the age of about 1 year for both strains. This suggested that although the rate of hearing loss is greater in the DBAs re the C57s, the anatomical changes asymptote at about the same level as both strains enter middle age, as shown here in Fig. 37.7.

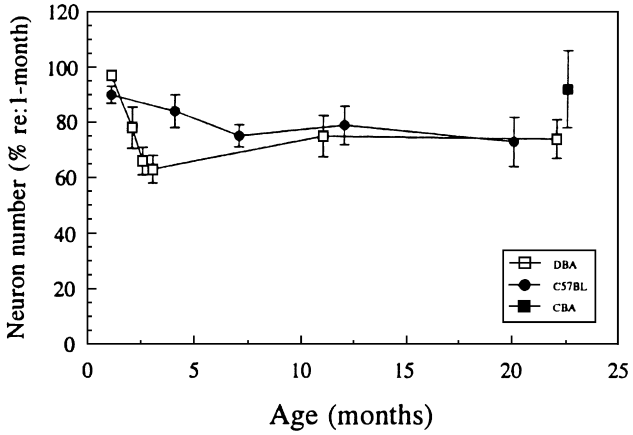

FIG. 37.7. Anteroventral cochlear nucleus neurons decrease in number with age at a faster rate in DBA mice compared to C57. The long-term reduction in DBA and C57 mice is the same (20+ months). For the DBA and C57 data, percentages are relative to 1-month-old values. Only 22-month-old CBA data are plotted, since CBA mice do not lose anteroventral cochlear nucleus neurons with age. From Willott and Bross (1996) with permission from Elsevier Science and the author.

Willott *et al*. (1992) measured properties of the dorsal cochlear nucleus layers I, II and III. They found that dorsal cochlear nucleus volume declined dramatically with age in C57s, but increased during the first year of life in CBAs and then declined slightly in very old age for CBAs; and declines in nerve cell numbers were greater for the C57 (primarily in layer III) than for the CBA. Comparison of the findings from the two strains suggests that loss of peripheral inputs that are exaggerated in the C57 cause the more noticeable reductions in this strain relative to the CBA. It makes sense that the changes were most evident in layer III of the dorsal choclear nucleus, since it is this lamina that receives inputs from the cochlea.

An important issue in presbycusis research, of which little is known, has to do with interactions between age and environmental insults such as noise exposure. Are old animals more susceptible to noise damage? Willott *et al*. (1994b) shed some light on this matter by exposing CBA mice of different ages to very loud, wideband noises of different magnitudes and then looked at the morphology of the cochlear nucleus at various time periods following the noise exposures. CBAs of the same age that were not exposed to noise served as controls.

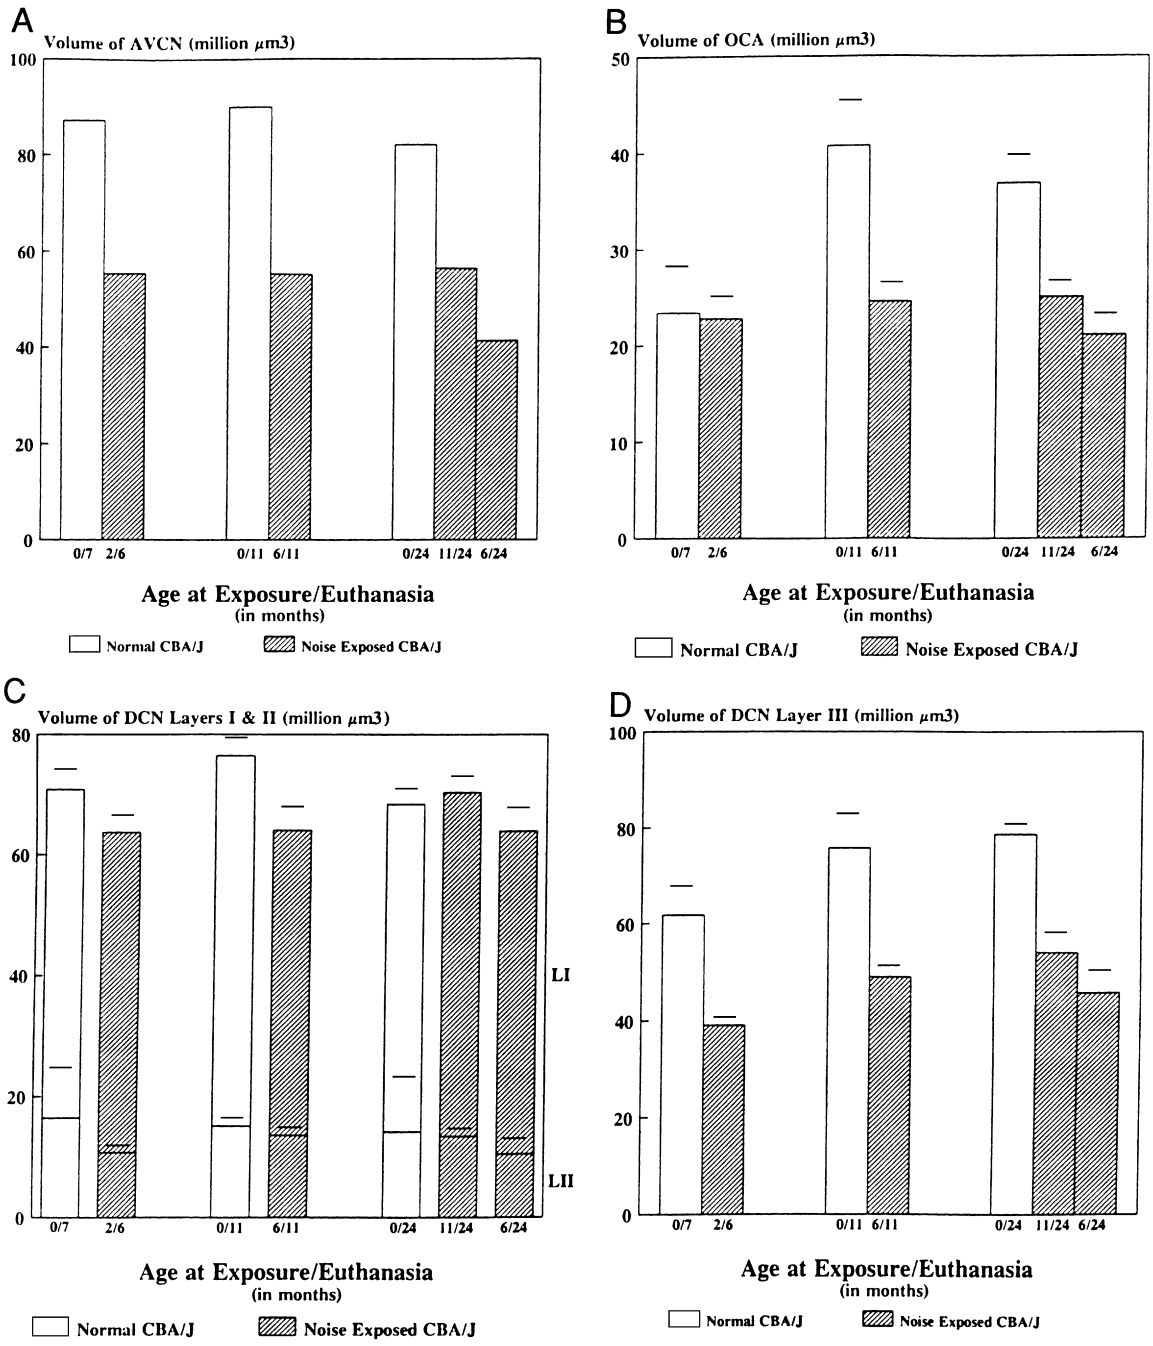

FIG. 37.8. Cochlear noise damage results in declines in volume of anteroventral cochlear nucleus (AVCN), octopus area (OCA), and dorsal cochlear nucleus (DCN) layer III in CBA mice. However, the age of the animals at the time of the noise exposure had no effect on the amount of damage (volume reductions). (A) Histograms showing relations between ages of noise exposure/euthanasia and the volume of the AVCN. (B) Same for the OCA. (C) Same for layers I and II of the DCN. Note that cochlear noise damage has little effect here because these portions of the DCN receive most inputs from noncochlear sources. (D) Similar to A and B for layer III of the DCN. Horizontal bars, standard deviations. From Willott *et al.* (1994b) with permission from Elsevier Science and the author.

They discovered that regions of the cochlear nucleus that are heavily innervated by peripheral inputs, such as the anteroventral division, the octopus cell area and layer III of the dorsal cochlear nucleus showed reductions in neuropil volume, declines in neuron size, and increases in neuron packing density, see Fig. 37.8. Only small declines in neuron number were present in all divisions, despite massive cochlear sensorineural damage. Relevant to the present chapter, there was no effect or interaction of age with the noise damage, i.e., a given noise-damage stimulus (peripheral pathology) produced the same amount of cochlear nucleus damage regardless of the animal's age.

Saada *et al.* (1996) examined differences in the light microscopic properties of the cochlear nucleus in congenitally deaf

white cats possessing early onset cochlear receptor loss with the cochlear nuclei of normally hearing pigmented cats, however, the ages of the subjects were not reported. They discovered that for the deaf cats (relative to the controls): the ventral and dorsal cochlear nucleus volumes were reduced by about 50%, spherical bushy cells of the anteroventral nucleus and pyramidal cells of the dorsal division were reduced in size by 31–40% (nonauditory neurons from adjacent brain areas were not changed), and astrocyte density was elevated in the anteroventral division by 40% and by 5% in the dorsal nucleus.

At the level of the inferior colliculus Kazee and colleagues (1995) demonstrated, using young adult, middle-aged, and old C57 mice, that there was a significant reduction in the number and size of synaptic contact areas on principal nerve cells of the central nucleus of the inferior colliculus and that the size of the principal cells declined with age. Interestingly, there was no difference in the magnitude of these age effects in different quadrants of the inferior colliculus. This means that the same synaptic reductions occurred in ventral (high-frequency) regions of the inferior colliculus that now receive more low-frequency information, as occurred in the dorsal (low frequency) areas. A follow-up investigation, using the same quantitative electron microscopy neuroanatomical procedures, found that no such age-related reductions occur in the inferior colliculus central nucleus of the CBA mouse (Kazee and West, 1999). Taken together, these two studies suggest that reductions in synaptic efficacy in the central nucleus of the auditory midbrain are a result of, or are in response to, synaptic reorganization or degradation caused by reductions in peripheral inputs, not to the aging brain itself. Put another way, it may be that to preserve the number and size of synaptic inputs to inferior colliculus nerve cells, relatively normal input from the auditory periphery is required.

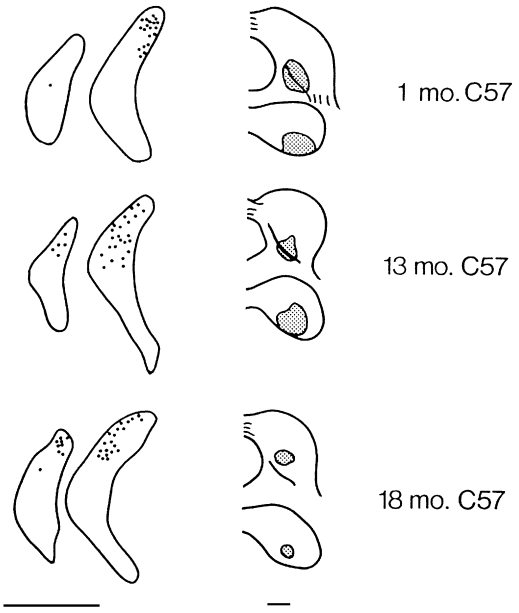

FIG. 37.9. Inputs to the ventral central nucleus of the inferior colliculus from the dorsal region of the anteroventral cochlear nucleus (AVCN) remain stable with age for C57 mice. (Right) Location of injection sites in the ventral region of the inferior colliculus in C57 mice of different ages. The upper inferior colliculus section is more rostral. (Left) Locations of retrogradely labeled cell bodies in dorsal regions of the contralateral AVCN. The left AVCN section is more rostral. Scale bars, 500 μm. From Willott *et al.* (1985) with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc., and the author.

2. Changes in Connectivity between Auditory Centers

Willott (1986) has shown that there is a functional reorganization of the tonotopic or cochlear map in the central nucleus of the inferior colliculus of the C57 mouse. The reorganization consists of nerve cells in the ventral portions of the inferior colliculus, most sensitive to high frequencies in normal hearing young animals, becoming preferentially sensitive to lower frequencies in old C57 mice, a phenomenon not seen in old CBA mice with a milder flat hearing loss. These physiological findings are explained in more detail in Walton and Burkard (Chapter 40). One important question concerning this functional reorganization is: at what level of the auditory central nervous does the transformation from high frequency sensitivity to low frequency sensitivity take place? To begin to answer this question, Willott *et al.* (1985) placed relatively focal horseradish peroxidase (a central nervous system anatomical tracer) injections into dorsal, intermediate, and ventral regions of the central nucleus of inferior colliculi of young adult, middle-aged, and old C57 mice. If the modification of inputs occurred above the level of the cochlear nucleus, then injections into the ventral inferior colliculus should label nerve cells of the ventral portions of the ventral cochlear nucleus, rather than the dorsal regions of the ventral cochlear nucleus as occurs in normal young adult mammals. As shown here in Fig. 37.9, Willott and colleagues found that regardless of the animal's age, horseradish peroxidase injections into ventral regions of inferior colliculi always retrogradely labeled nerve cell bodies in dorsal regions of the ventral cochlear nucleus. This suggests that the transformation of high-frequency pathways of the central auditory system to carry lower frequency information in old C57 mice takes place in the cochlear nucleus. It may be that auditory nerve axons or axonal collaterals reroute from the ventral portions of the ventral cochlear nucleus as a function of an age-related decline of auditory nerve fibers from the base of the C57 cochlea to innervate and synaptically terminate on nerve cells located more dorsally in the ventral cochlear nucleus. It could also be that the neuronal pathways are already present in young C57 mice, but they do not become preferentially activated until the high-frequencies inputs become attenuated and less dominant with age.

3. Neurochemical Responses in Auditory Neurons

Zettel *et al.* (1997) investigated the presence of the calcium-binding proteins calbindin and calretinin in the inferior colliculus of young and old C57 mice. The exact function of these proteins is not known; however, the available evidence suggests that they play critical roles in intracellular calcium regulation crucial for proper nerve cell functioning. Not unexpectedly, since declines in calbindin immunoreactivity have been reported in other systems of the aging brain of mammals, there was a statistically significant reduction in the number of nerve cells labeled with calbindin in the old C57s, with no change in calretinin. These quantitative data are shown in Fig. 16 of Fri-

sina *et al*. (Chapter 39). O'Neill *et al*. (1997) performed a similar investigation in the medial nucleus of the trapezoid body of C57 and CBA mice of different ages. O'Neill and coworkers found that the number of calbindin-immunoreactive neurons declined in the C57 strain but not in the CBA mouse. In addition, they measured the total number of nerve cells in the medial nucleus of the trapezoid body with age and found minimal declines that could not account for the more dramatic reductions in calbindin immunostaining. They concluded that for the medial nucleus of the trapezoidal body, the downregulation of calbindin was a result of the decline in peripheral inputs in the C57 with age.

B. Summary of Peripherally Induced Effects

Age-related reductions in peripheral inputs to the central auditory system oftentimes result in reductions in neuron numbers or size in regions of the cochlear nucleus that are heavily innervated by the synaptic endings of auditory nerve fibers. There may also be rewiring of axonal terminations and ramifications in response to reduced activity in high-frequency auditory nerve fibers with age. At the electron microscopy level, comparison of C57 and CBA strains indicate that synaptic reductions in the auditory midbrain may be primarily determined by declines in peripheral inputs, rather than a consequence of aging itself. The immunocytochemical studies examining the presence of calcium-binding proteins revealed that declines in calbindin sometimes occur with age in the central auditory system, but in other instances appear to be a result of reduced input from the cochlea.

IV. Central Auditory System: Aging Brain

A. Animal Models Exhibit Changes That Differ from Those Induced by the Aging Periphery

1. Alterations in Size and Pathway Connectivity

In an investigation of the octopus region of the posteroventral cochlear nucleus of CBA and C57 strains, Willott and Bross (1990) measured nerve cell sizes, packing density, and other light microscope features. Although there were differences in absolute numbers between the strains, both showed the same age-related trends, including declines in the overall volume of this area, loss of nerve cells, declines in nerve cell size, increases in glial cell packing density, and highly variable reductions in the size and presence of primary dendritic branches. In this case, taking results from the two strains into account, significant reduction in peripheral inputs did not exacerbate any central nervous system aging effects occurring in the brains of both strains.

Willott *et al*. (1994a) examined gross morphological features of the inferior colliculus as a function of age for CBAs and C57s. They measured the overall size of the inferior colliculus, the size of the inferior colliculus nerve cells, and the packing density of these cells and found no significant changes in either strain with age. They concluded that for these gross measures, declining peripheral input in the case of the C57s was not detrimental, and the aging of the brain itself did not affect these measurements either.

Frisina *et al*. (1997, 1998) explored the connections of the dorsomedial region of the CBA auditory midbrain, examples of which are displayed here in Fig. 12 of Frisina *et al*. (see Chapter 39). The anatomical region under study had previously been functionally characterized in a single-unit neurophysiological study by Walton *et al*. (1997) and explained in more detail in Chapters 40, and 39 (Fig. 8). Here, since the anatomy and physiology were conducted in the same animals, physiological maps could be literally overlaid with harsenadish peroxidase injection sites, as shown in Chapter 39 (Fig. 11). Walton *et al*. (1998) then went on to demonstrate that the sound gap encoding capabilities of single nerve cells in this region of the inferior colliculus became degraded with age. These neurophysiological temporal processing declines with age are more fully described in Chapters 39 (Figs. 9 and 10) and 40. We then examined how the inputs to this functionally characterized region changed with age in the CBAs. We found that some major inputs to dorsomedial inferior colliculi, such as those from the ipsilateral superior olivary complex and the ipsilateral nuclei of the lateral lemniscus remained stable with age, (see Figs. 14 and 15 in Chapter 39). Whereas the number of retrogradely labeled cell bodies from all three divisions of the contralateral cochlear nucleus and ipsilateral anterolateral periolivary nucleus declined dramatically as the CBAs aged, with statistically significant reductions starting in the middle-aged group of mice. These age-related drops are displayed in Figs. 13 and 14 in Chapter 39.

2. Changes in Intracellular Calcium Regulators

Zettel *et al*. (1997) examined the presence of the calcium-binding proteins calbindin and calretinin in the inferior colliculi of young and old CBA mice. Declines in calbindin immunoreactivity have been reported in other systems of the aging brain of mammals. Consistent with this, there was a statistically significant reduction in the number of nerve cells labeled with calbindin in the old CBAs. However, surprisingly, Zettel and coworkers observed a dramatic increase, or upregulation, in the number of principal cells labeled with a calretinin antibody. These data are shown in Fig. 16 in Chapter 39. Such upregulation as a function of age is much less common in the aging mammalian brain and had not been previously reported for any proteins that regulate intracellular calcium concentrations. Taken together with the Zettel *et al*. discovery that the number of calbindin-containing nerve cells in this region decline with age in C57 mice (described above), it appears that maintenance of peripheral input, sustenance of hearing in old age, is required or causes the upregulation of calretinin, but that the downregulation of calbindin may result from cellular aging processes of the central auditory system that occur on both mouse strains who have widely differing inputs in old age.

3. Declines in Inhibitory Neurotransmitters

Utilizing a variety of neuroanatomical and biochemical methodologies, Caspary, Helfert, and colleagues have uncovered evidence suggesting that there are significant declines in inhibitory synaptic circuitry in the rat auditory brain stem (Caspary *et al*., 1995). Specifically, in the cochlear nucleus,

glycine is the predominant inhibitory neurotransmitter and is likely essential for optimal auditory processing of biologically relevant acoustic signals in background noise. Milbrandt and Caspary (1995) showed that strychnine, a glycine antagonist, binding to glycine receptor sites significantly declined in the anteroventral and dorsal cochlear nucleus of old rats, with no significant change in affinity.

GABA (γ aminobutyric acid) is a primary inhibitory neurotransmitter in the central auditory system that is particularly prominent in nerve endings and nerve cells in the inferior colliculus, especially its central nucleus. It is very likely that this inhibitory transmitter plays a crucial role in several aspects of auditory functioning such as binaural coding, temporal processing, and discrimination of sounds from background noise. Caspary *et al*. (1990) immunolabeled inferior colliculus nerve cells against GABA in young (2- to 7-month) and old (18- to 29-month) Fischer-344 rats. Cell counts showed that in the ventrolateral central nucleus of the inferior colliculus (high-frequency region) the number of labeled neurons decreased by 36% with age. Neurochemical experiments measured the basal (resting) and K^+-evoked efflux of GABA from the central nucleus of the inferior colliculus. Tissue from central nucleus of the inferior colliculus old animals showed statistically significant reductions in both basal and K^+-evoked release of GABA relative to young rats. As a control, release of excitatory neurotransmitters, such as glutamate and aspartate, as well as another endogenous amino acid, tyrosine, and the inhibitory neurotransmitter acetylcholine, were measured and found to remain stable with age.

In a follow-up study, Caspary's group demonstrated an age-related decline in GABAB receptor binding in the rat inferior colliculus (Milbrandt *et al*., 1994). Using quantitative receptor autoradiography, reductions were demonstrated in the central nucleus, dorsal cortex, and external nucleus, (Fig. 37.10),

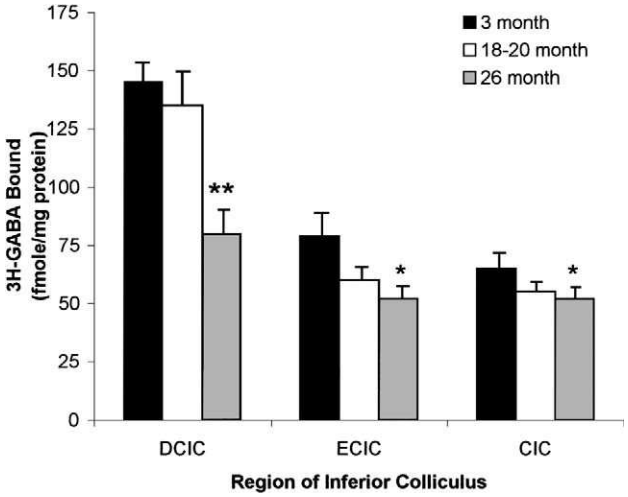

FIG. 37.10. GABAB receptor binding in the inferior colliculus declines with age in rats, with the biggest reduction occurring between middle age (18–20 months) and old age (26 months). Binding was significantly greater in the dorsal cortex nucleus of the inferior colliculus than in the other two divisions studied here. **, $P < 0.05$; *, $P < 0.05$; CIC, central nucleus of IC; DCIC, dorsal cortex of IC; ECIC, external nucleus of IC. From Milbrandt *et al.* (1994) with permission from Elsevier Science and the author.

whereas no age-related deficits were observed in neighboring cerebellar tissue. The inferior colliculus changes were seen despite no change in the cross-sectional area of the rat inferior colliculus with age. Milbrandt *et al*. (1994) went on to show that GABAB receptor binding decreased in old rats. In contrast, the number of GABAA receptors increased with age, perhaps as a partial compensation for the GABAB losses (Milbrandt *et al*., 1996).

Using immunogold electron microscopy methodologies, Helfert *et al*. (1999) quantitatively compared changes in the organization of GABA-containing and GABA-free terminals and synapses in the rat inferior colliculus. They discovered that the density of both types of terminals and synapses declined with age by 24–33% in old rats relative to young adults, with the range reduced by 9% if the densities are corrected for overall shrinkage of the inferior colliculus with age. The synaptic declines were correlated with reductions in dendritic size for inferior colliculus neurons, with the synaptic density remaining stable on those portions of GABA-negative dendrites that remained in old age. In GABA-containing dendrites, the pattern of synapses shifted to larger diameter dendrites, presumably closer to the cell body in the old animals. Since the age-related declines were similar for GABA-containing and GABA-free synaptic densities, the results of this study suggest that excitatory and inhibitory inputs decline proportionately with age, avoiding an age-related imbalance. In another investigation, Milbrandt *et al*. (1997) examined the GABAA receptor subunit composition. They found that this changes with age in the rat inferior colliculus such that enhanced responses to GABA can occur. Specifically, the gamma1 protein subunit *increased* with age, and the α_1 *decreased* with age (Caspary *et al*., 1999). They also found an age-related increase in GABA-mediated chloride influx, which is a functional consequence of these changes in the subunit composition. These varying effects are summarized in terms of functional implications (Fig. 37.11). If similar redistributions occur for excitatory synapses which enhance their responsiveness, then the relative balance and strength of excitation and inhibition could be somewhat maintained with age as an attempt to help preserve normal functioning of the inferior colliculus in the face of other age-related structural and neurochemical declines, such as those involving GABAB receptors.

An informative summary of Caspary and Helfert's investigations is given in an article by Caspary *et al*. (1995), (Figs. 37.12 and 37.13). The general finding is that there are declines in most aspects of GABA biochemistry in the inferior colliculus, including the presence of GABA, its receptors, and its activity levels. A limitation of this line of research is that these reductions in the presence of inhibitory neurotransmitters and their activity levels have rarely been reported in other species, so it is not clear how these results apply to auditory systems of other mammals and the human condition.

4. Other Neurochemical Investigations

Cransac *et al*. (1996) examined the presence of several important central nervous system neurotransmitters in the rat cochlear nucleus and medial vestibular nucleus as a function of age. They found that noradrenaline levels increased in the anteroventral cochlear nucleus and decreased in the vestibular nucleus. Serotonin levels were elevated with age in all divi-

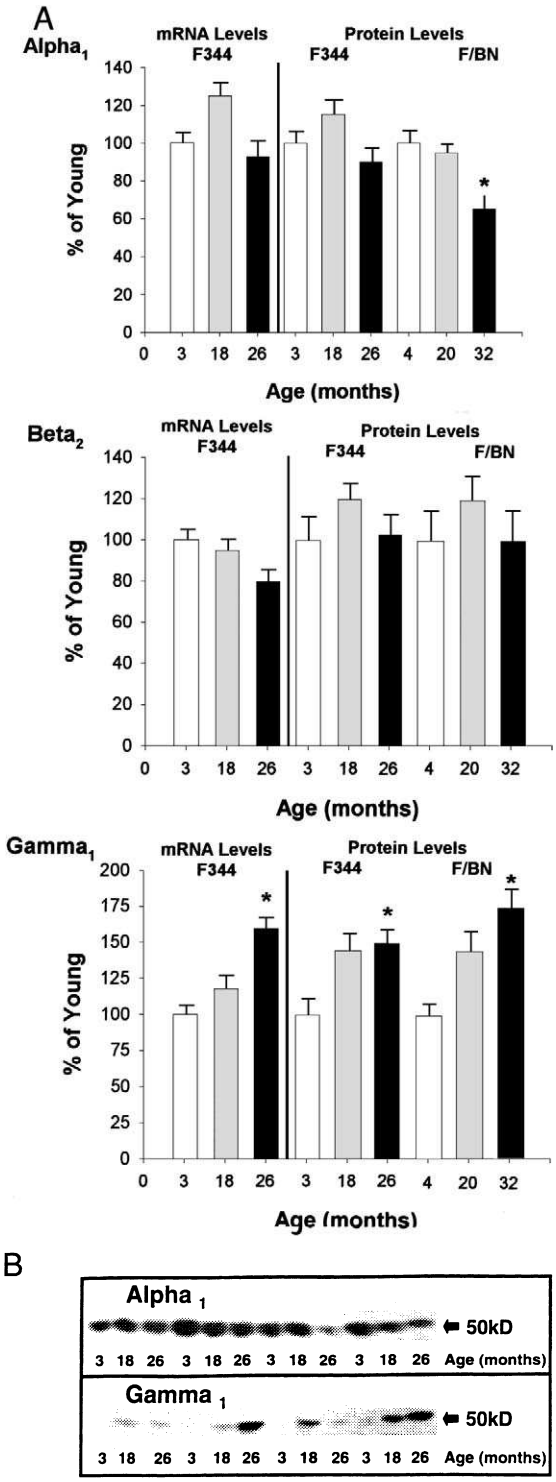

FIG. 37.11. GABAa receptor subunit composition changes with age in the rat central nucleus of the inferior colliculus, as demonstrated by Western blot and *in situ* hybridization studies. (A) For the α_1 subunit, mRNA and protein levels rise by middle age and then fall for old age. β_2 mRNA levels fall with age, and protein levels rise for middle age and then fall in the old animals. Gamma$_1$ mRNA and protein levels all rise with age. Only the γ_1 increases in old age, and the F/BN protein decline in old age were statistically significant (*). F/BN = Fischer 344/Brown-Norway F1 hybrid rats. (B) Western blot findings for FBN rats indicate age-related decreases for the α_1 subunit, and increases for the γ_1 subunit. From Caspary *et al*. (1999) with permission from Elsevier Science and the author.

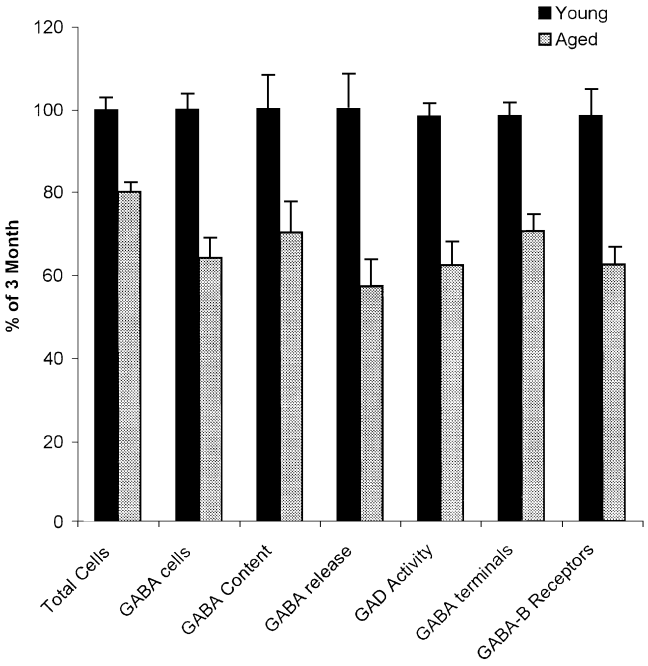

FIG. 37.12. Most aspects of GABA biochemistry in the rat inferior colliculus decline with age, as summarized on this histogram where aged (19–28 months) data are plotted as a percentage of levels from young animals (2.5–4 months). Differences between young and old data for each experiment are significant at the $P < 0.05$ level; the bars represent the standard errors of the mean. From Caspary *et al*. (1995) with permission from Elsevier Science and the author.

sions of the cochlear nucleus and the vestibular nucleus. These investigators concluded that elevation of serotonin may be widespread, whereas the noradrenaline changes are more varied in primary sensory centers of the brain stem with age. Increased levels of these modulatory neurotransmitters could be one way to compensate for decreased peripheral inputs that

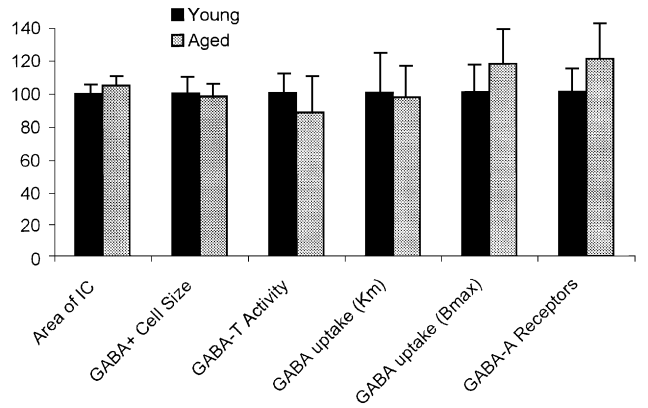

FIG. 37.13. Some aspects of the gross anatomy and GABA biochemistry in the rat inferior colliculus remained stable with age, as summarized on this histogram where aged (19–28 months) data are plotted as a percentage of levels from young animals (2.5–4 months). Differences between young and old data for each experiment were not statistically significant; the bars represent the standard errors of the mean. From Caspary *et al*. (1995) with permission from Elsevier Science and the author.

occur with age in the auditory and vestibular systems to improve the processing of acoustic signals in background noise.

Astrocytes and glial cells were traditionally thought to provide only a supportive, trophic function for nerve cells in the brain. However, more recent evidence suggests that they may play more active roles in real-time neural processing, as related to neurotransmitter uptake and regulation of synaptic density. Jalenques *et al*. (1995) analyzed the presence of glial fibrillary acidic protein (GFAP) immunoreactivity in the cochlear nuclei of young adult (3-month-old) and old (24-month-old) Sprague–Dawley rats, which have a mild peripheral hearing loss with age. GFAP is selectively located in astrocytes (Malhatra *et al*., 1990) and is an intermediate filament protein in astrocytes (Eng *et al*., 1971) that is differentially expressed in the face of brain aging or trauma (Eng, 1988). Jalenques and coworkers reported that there was a quantitative increase in GFAP immunoreactive astrocytes and processes with age and that the topographic distribution of label was altered. In the young adult animals, there is a concentration in the granular cell region, whereas this specificity disappears in the old rats and takes on a more homogenous distribution throughout the cochlear nucleus (Jalenques *et al*. 1997), (Fig. 37.14). The age-related increase in GFAP immunoreactive astrocytes actually peaks in middle age (12 months of age) and then declines a little with further aging. As a backdrop, they measured the total number of nerve cells in the cochlear nucleus and found no change with age, except for a decline in the anteroventral division with age.

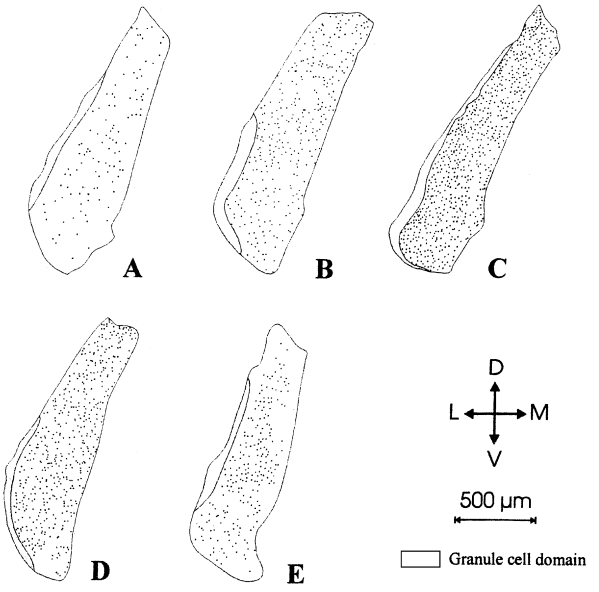

FIG. 37.14. In the anteroventral cochlear nucleus, GFAP-immunoreactive astrocytes increase in number and become topographically patterned from youth to middle age (3–12 months). As animals age beyond middle age to old age (18–24 months), the topographic distribution of GFAP astrocytes disappears and the number of astrocytes declines: (A) 3 months old, (B) 6 months old, (C) 12 months old, (D) 18 months old, (E) 24 months old. From Jalenques *et al*. (1997) with permission from Elsevier Science and the author.

B. Human Investigations

Relative to the major efforts put into anatomical and neurochemical studies of the aging brain related to age-related neurodegenerative disorders such as Alzheimer's and Parkinson's diseases (e.g., Flood, 1993), very little is directly known about such matters for the human central auditory nervous system. However, what is known suggests that what has been discovered in the animal studies of the aging central auditory system probably occur to some extent in human presbycusis. For instance, in the human cochlear nucleus, age results in a reduction in ventral cochlear nucleus volume (Königsmark and Murphy, 1970, 1972) and neuron size (Seldon and Clark, 1991), without any significant reductions in neuron number, relative to that seen in young adults. However, increases in lipofuscin and decreases in the number of capillaries/unit area were reported with age.

In the lateral lemniscus, the major input tract to the inferior colliculus, Ferraro and Minckler (1977) report a significant decline in the number of nerve fibers with age, based upon analysis of 15 human brains ranging in age from birth to 97 years. At the midbrain level, McGeer and McGeer (1975) examined postmortem presence of GAD, a precursor to GABA important for its synthesis in neurons, and found that it significantly declines with age. At the level of the auditory cortex in the superior temporal gyrus, Brody (1955) reported a striking decline in the number of neurons with age (correlation coefficient $= -0.99$). This decline was much greater than reductions in neighboring cortical areas such as the inferior temporal cortex, striate (visual) cortex, and pre- and postcentral cortex.

Another hypothesis that has more recently been put forth states that mitochondrial DNA (mtDNA) deletions or point mutations, which result in declines of oxidative phosphorylation activity, play an important role in the eventual demise of postmitotic nerve cells (Corral-Debrinski *et al*., 1992), including those of the central auditory system (Keithley *et al*., 1999). The high metabolic requirements of nerve cells make mitochondrial dysfunction quite harmful for auditory system neurons. mtDNA is quite susceptible to mutation because it is exposed to high concentrations of free radicals that are byproducts of the respiratory chain reactions that take place in mitochondria.

C. Summary of Changes Due to the Aging Brain

As age occurs, one of the lessons learned from the animal model and human investigations is that loss of sensory cells and auditory nerve fibers is much greater in magnitude than the declines in numbers of nerve cells in the central auditory system, even at the level of the cochlear nucleus which directly receives the synaptic endings of the eighth nerve. Rather, age-related changes in the brain appear to be more subtle, such as shrinkage of nerve cells and overall volume, alterations in connectional pathways, or changes in the neurochemical makeup of nerve cells with age. For the neurochemical studies, like the anatomy, most changes are in the negative direction. For example, when we observed changes in the presence of calbindin with age, the alterations always involved a decline in the presence of calbindin. The same can be said for the inhibitory neurotransmitter studies at the level of the auditory midbrain.

Interestingly, whenever we have observed changes in calretinin in the aging auditory system, an *upregulation* has been discovered.

V. Overview and Future Directions

An understanding of the structural and chemical changes in the ear and the brain underlying presbycusis allows for development of prevention therapies and curative regimes to avoid or reverse age-related hearing loss. As with most biomedical aging problems, sorting out whether auditory pathologies are due to internal factors (i.e., cellular or systemic aging phenomena ultimately determined or programmed genetically) or external environments (such as noise, ototoxic drugs, fever, or diet) is important for moving toward effective ameliorations. Many of the structural and, to a lesser extent, chemical changes in the aging ear and brain are now known. However, the common and quintessential etiologies of these degradations are still poorly understood. Future successes of genetic therapeutic interventions—turning genes on and off to prevent or correct age-related pathologies—will depend on adequate knowledge of the causative chain of events that results in age-related deficits in sensory end organs like the ear and the sensory portions of the central nervous system.

Acknowledgments

The author is grateful to Drs. Robert Burkard and Robert Frisina, Sr., who made constructive criticisms of this chapter in draft form. Work was supported by the National Institute on Aging at NIH, Grant P01 AG09524; and the International Center for Hearing and Speech Research, National Technical Institute for the Deaf, Rochester (NY) Institute of Technology.

Age, Noise, and Ototoxic Agents

As the population ages and life expectancy increases, more and more individuals will be at risk for developing age-related hearing loss, or presbycusis. Presbycusis can greatly impair interpersonal communication and lead to social isolation in the elderly. Age-related damage to various sensory and structural elements in the inner ear gives rise to different types of hearing loss. The type of damage that develops in the ear and the rate at which presbycusis progresses undoubtedly have a genetic basis. Rapid advances in molecular biology and in sequencing the human and mouse genomes will enhance our understanding of the genes that contribute to age-related hearing loss. Hearing loss in the elderly can have other causes as well. In particular, hearing loss can be caused by exposure to loud sounds and various therapeutic drugs, including several antibiotics and anti-tumor agents. Importantly, it is likely that these three agents—biological aging, noise exposure, and exposure to ototoxic drugs—interact in some manner (e.g., additive, subadditive, multiplicative). Regardless of the exact nature of the interaction, the hearing loss is likely to occur earlier and be more severe than that produced by any one agent alone. Strategies for reducing the risk of age-related hearing loss, ototoxicity and noise-induced hearing loss require an understanding of the underlying mechanisms of cell death in the inner ear. Recent studies with neurotrophic compounds and antioxidants may lead to new intervention strategies.

I. Introduction

The auditory system, like other sensory and motor systems, shows a gradual deterioration in function over time. Presbycusis, or the age-related decline in hearing function, is presumably the result of many factors, some endogenous and others exogenous. For example, the deterioration of other systems in the body, such as the cardiovascular system or the kidneys, could conceivably exacerbate age-related deterioration of cellular components in the inner ear. Several exogenous factors are likely to contribute to the loss of hearing with advancing age. For example, the accumulative effect of many years of noise exposure or short-term treatments with ototoxic drugs could simply add to the effect of age-related hearing loss or it could exacerbate age-related hearing loss. Because humans are constantly bombarded by different environmental stressors, it is difficult to distinguish what proportion of hearing loss is purely the result of aging or environmental factors (Corso, 1976; Gates *et al*., 1989; Cruickshanks *et al*., 1998). In highly industrialized societies, one important environmental factor that causes hearing loss is incessant exposure to a barrage of environmental sounds. Hearing loss can also be caused by certain drugs used to treat life-threatening illnesses. For example, several anti-cancer and anti-microbial drugs are ototoxic, causing permanent damage to the delicate sensory hair cells in the inner ear. These three agents—aging, noise, and ototoxic drugs—can each cause hearing loss independently. However, hearing loss in the elderly is probably always due to a combination of factors, or to interactions among them. Like aging, noise exposure and ototoxic drugs exert their primary effects on the inner ear. Therefore, it is instructive to begin by reviewing cochlear anatomy and a model of presbycusis that is based on the types of cochlear pathologies observed in aged subjects.

II. The Cochlea and Cochlear Presbycusis

The cochlea, or inner ear, consists of a bony, spiral-shaped capsule containing the sensory epithelium. Although there are many different cell types within the cochlea, the three most essential groups are the sensory cells, cells of the stria vascularis, and the spiral ganglion neurons. The sensory cells reside in the organ of Corti, which lies on the basilar membrane (Fig. 38.1). The organ of Corti spirals around the bony modiolus from the base to the apex of the cochlea. The organ of Corti contains two types of sensory cells, inner and outer hair cells. A single row of inner hair cells and three rows of outer hair cells are separated by inner and outer pillar cells. The stereocilia bundles (actually microvilli) on the apical surface of the hair cells contain the mechanically gated ion channels respon-

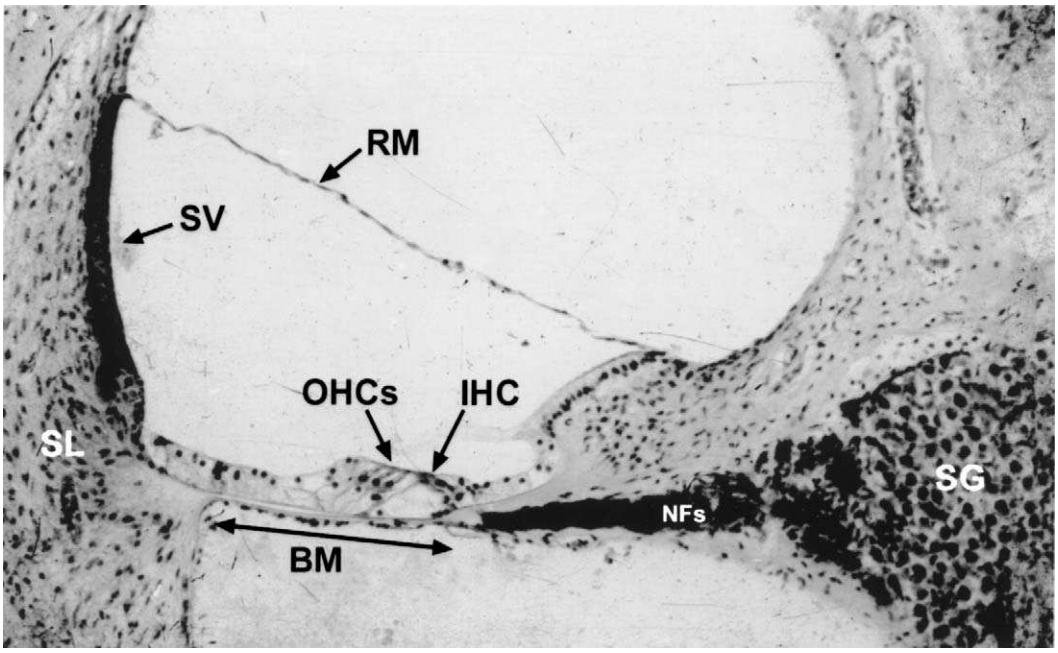

FIG. 38.1. Radial section of the cochlea showing the organ of Corti resting on the basilar membrane (BM). Inner hair cell (IHC), three rows of outer hair cells (OHCs), nerve fibers (NFs), spiral ganglion (SG), stria vascularis (SV), spiral ligament (SL), and Reissner's membrane (RM).

sible for converting the mechanical vibration of sound into a neural response. The stereocilia and apical surfaces of the hair cells are bathed by endolymph. The endolymph is a specialized extracellular fluid whose composition is regulated by marginal cells in the stria vascularis, a vascular layer of tissue that lies along the lateral wall of the cochlea. The endolymphatic space, bounded by Reissner's membrane and the reticular lamina at the top of the hair cells, contains a high concentration of potassium ions and has a potential of approximately +80 mV. This provides the hair cells with a powerful electrochemical gradient that plays a major role in generating the receptor potential when stereocilia bundles are deflected by sound-induced mechanical movement in the cochlea.

The output of the hair cells is transmitted to the central auditory system by approximately 50,000 auditory nerve fibers whose cell bodies form the spiral ganglion within the bony core of the modiolus. Most (~90%) auditory nerve fibers (type I) contact inner hair cells in a one-to-one fashion (Spoendlin, 1969) and are largely, if not exclusively, involved in transmitting acoustic information to the central auditory nervous system (Liberman, 1982). Only about 5 to 10% of auditory nerve fibers (type II) contact outer hair cells, but they do not appear to transmit information about sound to the central auditory pathway (Robertson, 1984).

Sounds that are transmitted to the cochlea cause the basilar membrane to vibrate, producing a traveling wave vibration pattern. The traveling wave vibration pattern that develops in the inner ear arises from the mass and stiffness gradient along the length of the cochlea (Bekesy, 1960). The stiffness of the basilar membrane decreases from base to apex, whereas mass increases from base to apex. As shown in Fig. 38.2, the traveling wave vibration pattern for a high-frequency sound produces its maximum vibration near the basal end of the cochlea. The maximum vibration amplitude for low-frequency sounds occurs near the apex of the cochlea whereas mid-frequency sounds, such as 2 kHz, produce maximum vibration near the middle of the cochlea. Thus, frequency is distributed spatially along the length of the cochlea.

The degenerative changes observed in the inner ear of older subjects are numerous and varied. Schuknecht (1976) origin-

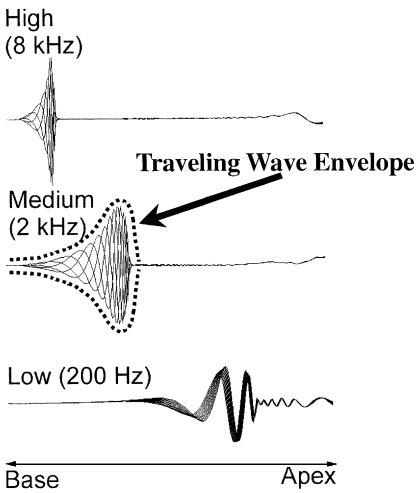

FIG. 38.2. Instantaneous traveling wave vibration pattern for a high-frequency (8 kHz), mid-frequency (2 kHz), and low-frequency (200 Hz) sound. The dotted line shows the envelope of the traveling wave vibration pattern for a 2 kHz tone. Note that high-frequency sounds produce maximum vibration near base of cochlea, whereas low-frequency sounds produce maximum vibration near the apex

ally classified the degenerative changes into four categories according to the primary target of damage—sensory cells, nerve fibers or ganglion cells, strial tissue, or structural elements of the organ of Corti and basilar membrane. Each type of inner ear histopathology would be expected to have a unique clinical outcome, as described briefly below. Schuknecht's classification of human presbycusis into four major types has been extremely helpful in conceptualizing the histopathological changes that produce hearing loss. However, it is important to keep in mind that inner ear degeneration during aging generally involves more than one type of tissue. "Pure" forms of sensory, neural, strial, and cochlear conductive presbycusis rarely, if ever, occur.

A. Sensory Presbycusis

Correlation of audiometric data with postmortem analysis of the cochleas from aged patients and animals has provided compelling evidence that degeneration of inner and outer hair cells plays an extremely important role in many cases of presbycusis (Johnson *et al*., 1997). Sensory presbycusis is generally associated with a steep high-frequency hearing loss (Fig. 38.3A). In most cases, the outer hair cells degenerate first, followed by the inner hair cells (Fig. 38.4) (Schuknecht, 1976; Spongr *et al*., 1997). In humans, sensory cell degeneration typically begins around middle age and spreads from the basal high-frequency region of the cochlea toward the apical low-frequency region with advancing age. Sensory cell loss is often accompanied by degeneration of supporting cells such as Deiters', pillar, and Hensen cells. The loss of sensory and supporting cells results in flattening of the organ of Corti.

Animal studies can provide valuable insights into the anatomical basis of presbycusis independent of extraneous variables such as noise, diet, and ototoxic drugs. From a practical viewpoint, animals with short life spans, such as mice, gerbils, and rats, allow one to study the effects of aging over a period of a few years. Mice have certain advantages because of the genetic homogeneity in inbred strains (thereby controlling for the effects of genetic background on inner ear degeneration and hearing loss), the large number of mutant and transgenic strains, and the rapid progress being made in sequencing the mouse genome. Studies with various strains of mice are likely to provide important clues regarding the genetic basis of presbycusis. CBA mice, for example, show little hair cell loss until the very late stages of life (Henry and Chole, 1980; Li and Borg, 1991; Willott and Mortenson, 1991; Spongr *et al*.,

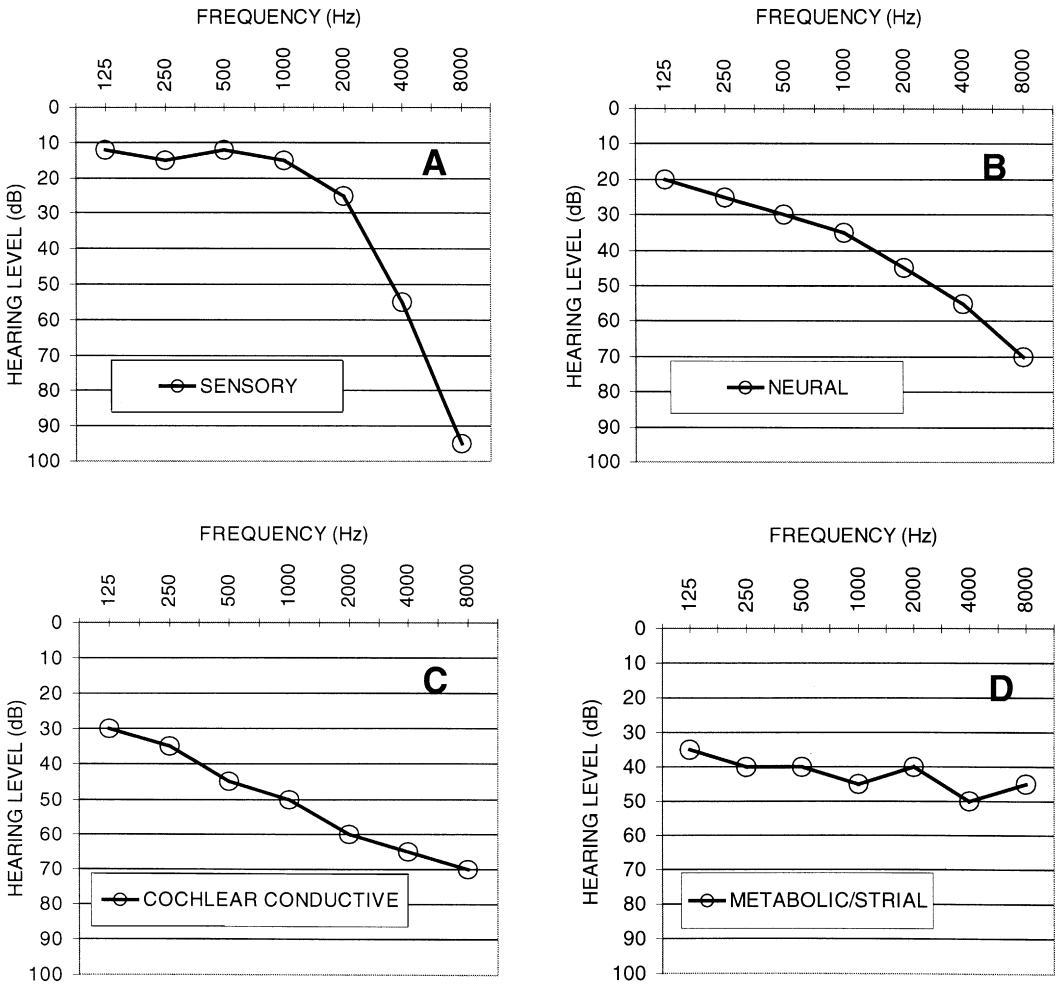

FIG. 38.3. Typical pattern of age-related hearing loss according to Schuknecht (1976). (A) Sensory presbycusis, (B) neural presbycusis, (C) cochlear conductive presbycusis, and (D) metabolic/strial presbycusis (see text for details).

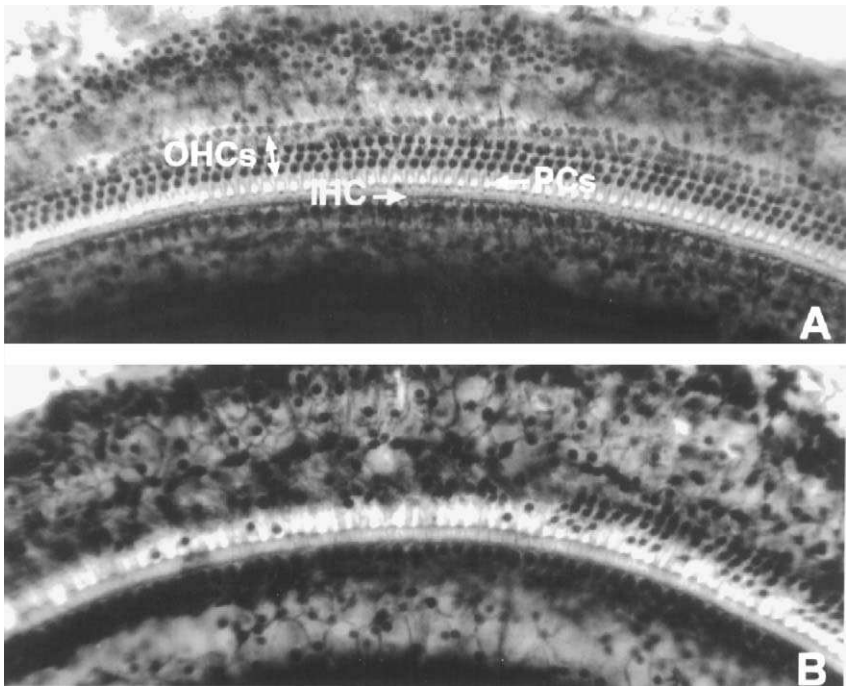

FIG. 38.4. (A) Surface preparation view of the organ of Corti from a young wild type SOD1 mouse. Note three rows of outer hair cells (OHC) and one row of inner hair cells (IHC) separated by pillar cells (PCs). (B) Surface preparation of the organ of Corti from an old wild type SOD1 mouse. Compare to (A). Note absence of outer hair cells.

1997). C57BL/6J mice, by contrast, start to exhibit hair cell loss in the base of the cochlea in early adult life. The lesion begins in the basal cochlea and rapidly progresses toward the apex of the cochlea with advancing age (Mikaelian, 1979; Henry and Chole, 1980; Li and Borg, 1991; Spongr *et al*., 1997). The sensory cells in the Bronx Waltzer mutant mouse also begin to degenerate in early adulthood. However, the lesion pattern is unique in that the inner hair cell loss precedes outer hair cell damage (Schrott *et al*., 1989, 1991).

Rats are also commonly used in studies of aging, and the effect of aging on hair cell integrity has been examined in a few strains. Some strains, such as Sprague–Dawley, show minimal hair cell loss, confined mainly in the apex of the cochlea, around 30 months of age (Keithley and Feldman, 1982). Other strains, such as the Wag–Rij rat, exhibit significant outer and inner hair cell loss around 30 months of age. The damage in this strain decreased from base to apex, a pattern typical of humans and many strains of mice.

Although hair cell loss is likely to play an important role in presbycusis, it is not clear how prevalent this type of hearing loss is in the human population. In addition, it is not clear what proportion of presbycusis is due to sensory cell damage versus some other functional or structural deficits in the inner ear. Finally, while animal models can provide some insights into the mechanisms underlying presbycusis, it is not clear which animal model is most relevant to the human condition.

B. Neural Presbycusis

Presbycusis of a neural basis was proposed on the basis of human studies showing speech discrimination scores far worse than expected from the hearing loss (Schuknecht, 1976). Hearing losses often have a steeply sloping or gradually sloping configuration (Fig. 38.3B). Analysis of temporal bones in these patients revealed a disproportionate loss of spiral ganglion neurons (Fig. 38.5) (Bredberg, 1968; Nadol, 1979). A disproportionately large loss of spiral ganglion cells has also been seen in some cases with steep high-frequency hearing loss (Suga and Lindsay, 1976). While hair cells are often missing, the ganglion cell loss is far greater than would be expected from the hair cell lesions. Neuronal losses were generally more severe in the base of the cochlea than in the apex; however, losses in the apex are clearly more important for processing speech sounds that are located in the mid-to-low frequency region (Otte *et al*., 1978). In aged chinchillas, the dendrites of spiral ganglion neurons were degenerated in regions of the cochlea with intact hair cells; however, only a small proportion (5%) of animals exhibited such changes (Bohne *et al*., 1990). Thus, some cases of neural presbycusis can be found in chinchillas.

The survival of the auditory nerve probably depends on many different factors, but recent studies indicate that several neurotrophic factors promote the survival of spiral ganglion neurons. Neurotrophin 3 (NT-3), which is synthesized and released by inner hair cells, binds to trk-C receptors on spiral ganglion neurons and promotes their survival (Ernfors *et al*., 1995). Brain-derived neurotrophic factor (BDNF), which binds to the trk-B receptor on spiral ganglion neurons, also enhances the survival of spiral ganglion neurons (Zheng *et al*., 1995). Thus, the long-term survival of spiral ganglion neuron may depend in part on an intact population of inner hair cells that release neurotrophins. Deficiencies in these neurotrophins or their receptors could lead to abnormally rapid degeneration of spiral ganglion neurons.

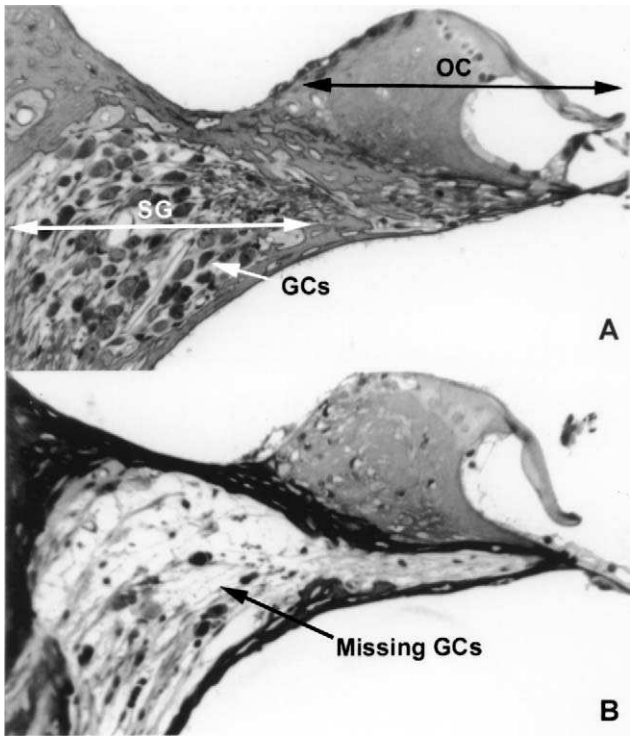

FIG. 38.5. Radial section of the organ of Corti (OC) and spiral ganglion (SG) of the modiolus. (A) Ganglion cells (GCs) present in the spiral ganglion of young SOD1 mouse. (B) Note loss of ganglion cells in old SOD1 mouse.

Certain types of health problems could exacerbate neural presbycusis. For example, ganglion cell loss seems to be extremely severe in individuals with hearing loss resulting from measles, bacterial labyrinthitis and congenital syphilis (Otte *et al*., 1978). Studies with mice lacking copper-zinc superoxide dismutase (Cu/Zn SOD), an important antioxidant enzyme found in the cytosol of virtually all cells, suggests that antioxidant levels can influence ganglion cell and nerve fiber survival during aging. Aged (13-month-old) mice lacking Cu/Zn SOD had significantly fewer ganglion cells and nerve fibers than like-aged wild type (normal) mice (McFadden *et al*., 1999a).

C. Metabolic or Strial Presbycusis

Schuknecht's model of metabolic presbycusis is based on clinical observations from patients with a relatively flat hearing loss (Fig. 38.3C) and good speech discrimination (Schuknecht and Ishii, 1966). Postmortem analysis of temporal bones revealed significant atrophy of the cells and blood vessels in the stria vascularis, which is responsible for generating the endolymphatic potential. The pattern of strial atrophy is varied. In some cases, the degeneration is patchy with the greatest atrophy in the apex and base of the cochlea (Takahashi, 1971). Strial atrophy can involve all cell types, but the marginal cells often show the greatest damage. In other cases, the atrophy is diffuse; although the stria maintains its normal thickness, there are many large intercellular spaces. Studies with aged gerbils lend support for a strial model of presbycusis (Schulte and Schmiedt, 1992; Gratton *et al*., 1996). The vascular bed of the stria showed a patchy degeneration that was most severe in the base and apex of the cochlea. Significantly, there was a strong correlation between the total stria vascular bed and the endolymphatic potential. Na,K-ATPase immunolabeling, an indirect measure of cochlear ion transport, also declined with age most notably in the apical turn followed by the middle and basal turns of the cochlea. The decline in the endolymphatic potential and Na,K-ATPase immunolabeling were positively correlated.

Another common finding in aged ears is the presence of numerous lipofusion or pigment granules (Schuknecht, 1976). Numerous pigment granules are often found in the stria vascularis of old chinchillas (Fig. 38.6). In addition, many pigment granules are found near the cuticular plate of outer hair cells and pillar cells and near the apical surface of supporting cells that line the endolymphatic space (Bohne *et al*., 1990).

Strial atrophy is sometimes considered the only form of metabolic presbycusis; however, other, more subtle, metabolic changes may also play a role. Dehydrogenase histochemistry can be used to assess the status of important enzymes involved in aerobic metabolism in normal and pathologic inner ear

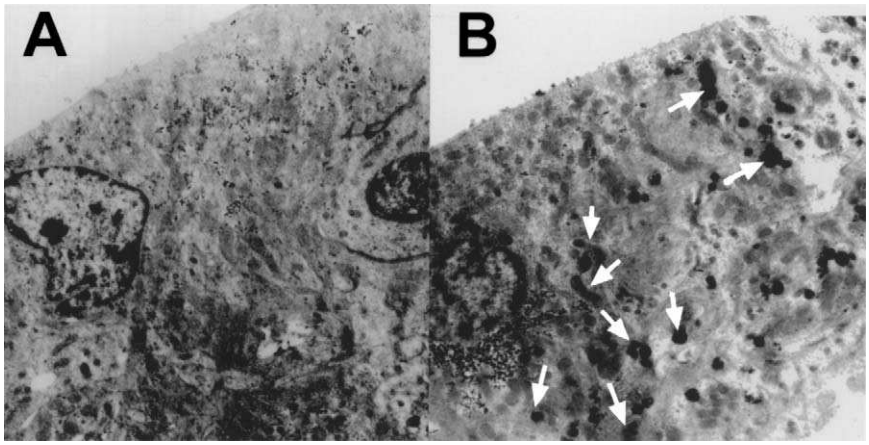

FIG. 38.6. Section of stria vascularis in young (A) and 15-year-old (B) chinchilla. Note increase in the number and size of pigment granules in old chinchilla (arrows).

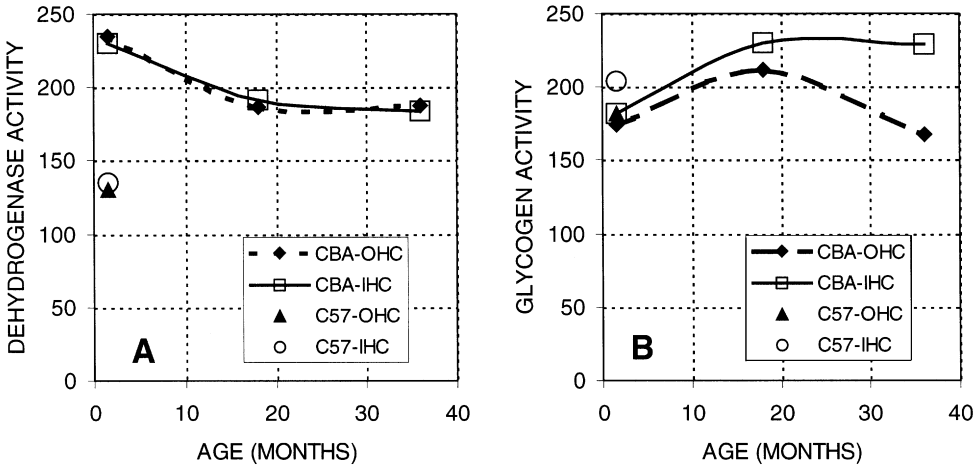

FIG. 38.7. (A) Mean dehydrogenase staining levels for outer hair cells and inner hair cells in CBA mice as a function of age. Data for young C57 mice also shown. tissue. Significant age-related changes in energy metabolism have been observed in the mitochondria of hair cells and stria vascularis with dehydrogenase and glycogen histochemistry (Ding *et al*., 1999). CBA mice, a strain that maintains normal hearing until very old age, show a significant decrease in hair cell dehydrogenase activity between young adulthood and middle age (Fig. 38.7A), coupled with increased glycogen levels in hair cell and stria vascularis over the same time period (Fig. 38.7B). Interestingly, young C57BL/6J mice, a strain that starts to show hearing loss in early adulthood, have significantly less dehydrogenase activity in hair cells than CBA mice of any age (Fig. 38.7A). Young C57 mice also showed less glycogen activity in hair cells and stria vascularis (Fig. 38.7B) than middle aged CBA mice. Changes in the metabolic activity of mitochondria in hair cells and the stria vacularis could be either a cause or a consequence of other inner ear histopathology. One possible interpretation is that impaired metabolism in C57 mice leads to increased cochlear histopathology and susceptibility to noise as compared to CBA mice.

The decline in dehydrogenase activity noted above may be related to age-related changes in the mitochondrial genes involved with energy metabolism. Damage to mitochondrial DNA (mtDNA) has been associated with a number of pathologies, including a form of nonsyndromic hearing loss in which deafness occurs only after the use of aminoglycosides. Recent studies by Seidman and colleagues (1996, 1997) have shown a correlation between a common mtDNA deletion (involving the base pair at position 4834) and age-related cochlear pathology. A corresponding mtDNA deletion in humans (involving the 4977 base pair, which is homologous to the 4834 base pair in the rat) has also been observed in temporal bones obtained from aged humans. However, the 4977-base-pair deletion is observed in humans without hearing loss as well as those with presbycusis. Thus, the common mtDNA deletion may be a better marker for aging than for presbycusis per se. Much more work is required for an understanding of the relationship between mitochondrial dysfunction and presbycusis.

D. Cochlear Conductive Presbycusis

The category of cochlear conductive presbycusis is primarily one of exclusion, reserved for cases in which there is no gross cochlear histopathology present to account for the observed hearing loss (Schuknecht, 1976; Ramadan and Schuknecht, 1989; Schuknecht and Gacek, 1993). The hearing loss associated with cochlear conductive presbycusis is usually bilateral, and gradually increases from low to high frequencies (Fig. 3D). Steeper losses in such patients are associated with poorer speech discrimination. Hearing loss of this type is presumably due to a change in the physical properties of the cochlea that modifies its mechanical response. It has been suggested that remote masking might serve as a test of cochlear conductive presbycusis (Quaranta *et al*., 1978). However, as Schuknecht notes, this category does not have a proven pathology and thus remains largely a speculative category. The only structural pathology consistently seen in ears with gradually sloping hearing loss is atrophy of the spiral ligament (Wright and Schuknecht, 1972). Recent studies suggest that subtle changes in the cochlea can contribute to cochlear conductive presbycusis. Saha and Slepecky (2000) have found age-related changes in microtubules in the guinea pig organ of Corti. Specifically, there is a shift in tubulin isoforms with increasing age that could affect the micromechanical properties of the sensory epithelium. Other recent evidence points to the involvement of fibrocytes in the spiral ligament. Fibrocytes in the spiral ligament play a fundamental role in the recycling of potassium from the organ of Corti to the stria vascularis and then to the endolymph (Minowa *et al*., 1999; Steel, 1999). Mice lacking the Brn-4 gene, which encodes a POW transcription factor, exhibit profound deafness, but do not exhibit any gross pathologies of the middle ear, hair cells, stria vascularis, or spiral ganglion. The lack of gross anatomical pathology in these ears is consistent with Schuknecht's description of patients with conductive presbycusis. However, careful ultrastructural examination revealed changes in the spiral ligament fibrocytes that were associated with a large reduction in the endolympha-

tic potential and broad hearing loss. Thus, subtle anatomical changes in the spiral ligament could conceivably be a factor in the so-called conductive presbycusis.

Viable Dominant Spotting (Wv/Wv) mutant mice show significant hearing loss which is associated with the absence of melanocytes within the stria vascularis (SV) and an endocochlear potential near zero (Cable *et al*., 1994; Kitamura *et al*., 1994). Furthermore, degree of pigmentation of the stria in other W-allele mouse strains was positively correlated with the magnitude of the endolymphatic potential (Cable *et al*., 1994). These results indicate that melanocytes are required to maintain normal stria function. Mice carrying the Light mutation (Blt), a dominant allele, show a gradual age-related whitening of hair coat color due to degeneration of melanocytes in the hair follicles (Cable *et al*., 1993). The age-related reduction in coat color was correlated with loss of melanocytes in the stria and a decline in the endolymphatic potential; no other ultrastructural pathology of the stria was noted. Thus, age-related loss of strial melanocytes associated with the Light mutation may be another factor contributing to strial presbycusis.

III. Age-Related Hearing Loss

Despite its limitations, the pure-tone audiogram remains the most commonly used metric for assessing presbycusis and other forms of hearing loss. The onset and time course of hearing loss varies considerably from one individual to the next presumably because of differences in genetic and environmental factors such as an individual's history of exposure to noise and ototoxic agents. The United States Public Health Service conducted a survey of hearing thresholds as a function of age using subjects representative of the general population (i.e., individuals not screened for hearing loss) (Glorig and Roberts, 1965). High-frequency hearing loss increases with age and is considerably greater for males than females (Fig. 38.8). The gender difference in age-related hearing loss has typically been attributed to greater exposure to noise in males. However, recent studies with chinchillas (McFadden *et al*., 1999c) suggest that factors other than noise exposure may play important roles. Careful epidemiological studies of so-called "pure" age-related hearing loss, that is, studies which exclude individuals with a history of noise exposure or hearing loss from other sources, show less age-related hearing loss (Robinson and Sutton, 1979) (Fig. 38.9). Nevertheless, it is clear that hearing loss progresses and accelerates with advancing age. Males also continue to exhibit more high-frequency age-related hearing loss than females, while females tend to show more low-frequency hearing loss than males. This has been referred to as the gender reversal phenomenon (Jerger *et al*., 1993). When considering data on the prevalence and rate of age-related hearing loss among men and women, one should keep in mind that although the subjects were screened, other subtle forms of acquired hearing loss cannot be completely ruled out.

IV. Acoustic Trauma and Age-Related Hearing Loss

Exposure to loud sounds is the most common cause of hearing loss in the industrialized societies, particularly among young people. Approximately million Americans are routinely exposed to hazardous noise in the workplace (von Gierke and Johnson, 1976; National Institute of Health (NIH), 1990, 1991). In addition, noise-induced hearing loss is rated by the National Occupational Safety and Health as one of the 10 most serious occupational hazards. An understanding of the similarities, differences, and interactions between noise-induced hearing loss and age-related hearing loss is critical for a series of important

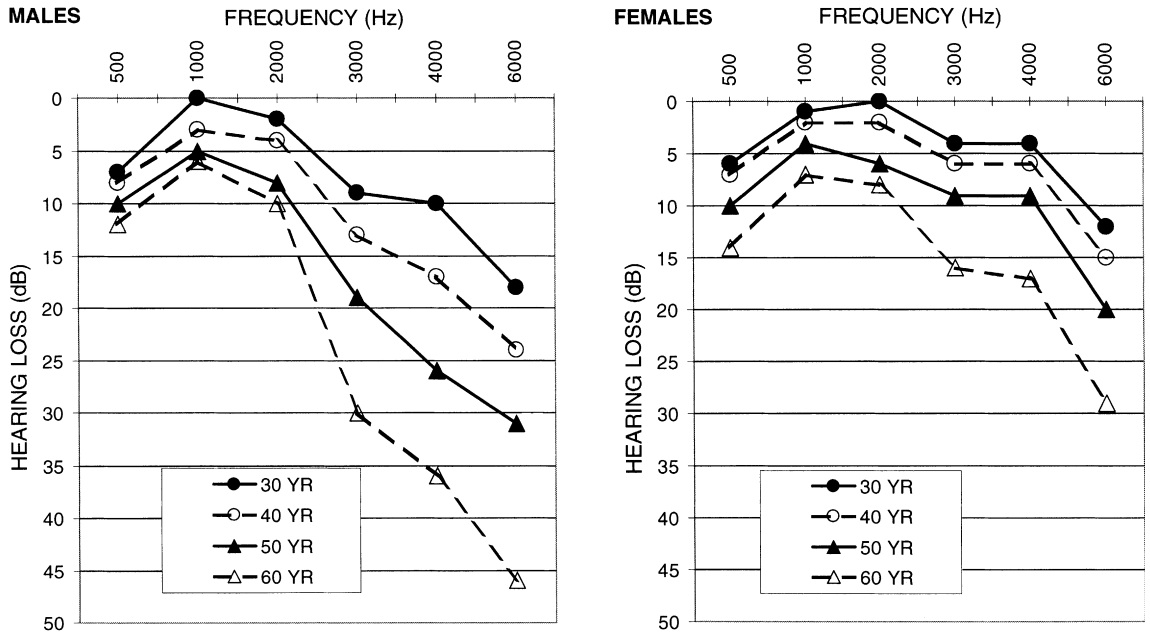

FIG. 38.8. Mean hearing loss as a function of age in male (left) and female (right) subjects representative of the general population (Glorig and Roberts, 1965). (Inset) Loss for each decade.

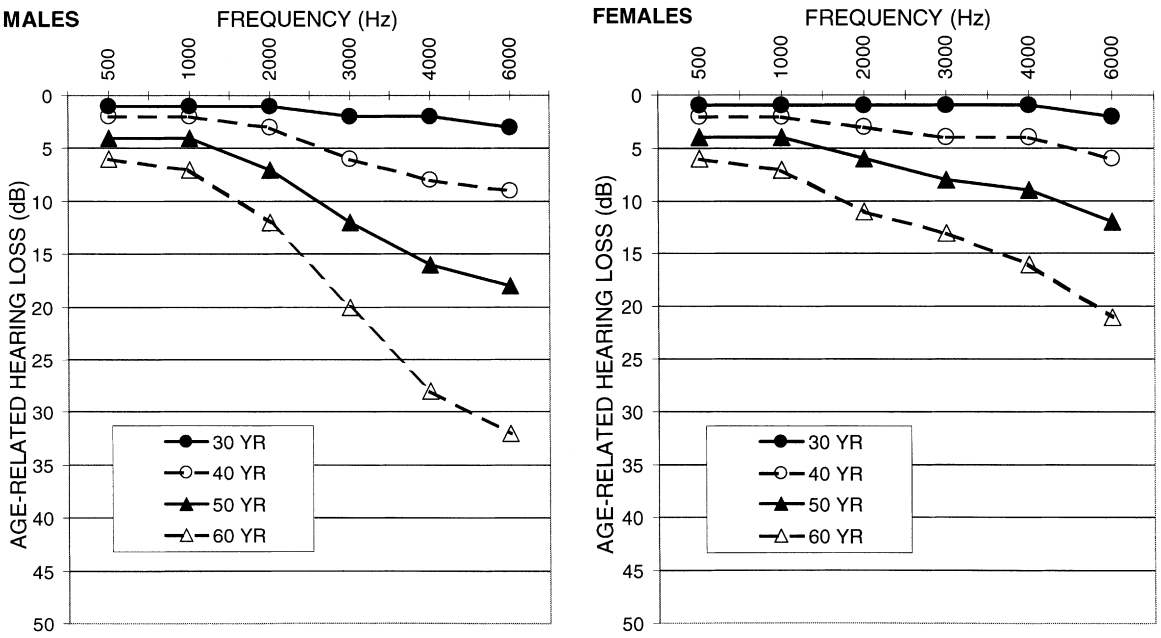

FIG. 38.9. Mean age-related hearing loss in a population of male (left) and female (right) subjects which excluded individuals with a history of noise exposures or other hearing problems (Robinson and Sutton, 1979). (Inset) Loss for each decade.

clinical legal questions. Is the aged ear more vulnerable to the effects of noise? Is an individual's susceptibility to noise-induced hearing loss and age-related hearing loss positively correlated? How does one separate the age and noise components of an individual's hearing loss? These are fundamental questions when managing risks from hearing loss in occupational settings or when one is trying to discern the degree of noise-induced hearing loss for purposes of compensation or other legal matters.

Answers to these questions are difficult to discern from human studies because the process takes place over decades. Epidemiological studies show that occupational noise exposures initially produce hearing losses around 3 to 6 kHz. The hearing loss grows to a plateau over a 10- to 15-year period. Lower and higher frequencies accumulate losses at a slower rate, but the losses continue to accumulate over a 30- to 40-year period (Burns and Robinson, 1970). In males, age-related hearing loss begins to accumulate between the ages of 20 to 30 years (Pearson *et al*., 1995). At higher frequencies (8 and 16 kHz), hearing loss accumulates at a rate of 0.8 to 2 dB per year. At low frequencies (<4 kHz), it increases at a rate of 0.2 to 0.8 dB per year. If one is interested in understanding the relation between noise-induced hearing loss and age-related hearing loss, controlled animal experiments provide a more direct and manageable perspective.

A. Animal Models of Noise-Induced Hearing Loss and Age-Related Hearing Loss

Animal studies of noise-induced hearing loss provide insights into the relation between the acoustic parameters of a noise exposure and amount of hearing loss. In addition, they provide the most direct information on the biological and pathological processes associated with high-level noise exposure. Animal studies of noise-induced hearing loss have generally been conducted with mice, rats, guinea pigs, rabbits, cats, and chinchillas. However, almost all these animals are more susceptible to the effects of noise than humans; consequently the results from animal models are difficult to extrapolate to humans.

An appropriate animal model of age-related hearing loss is difficult to choose. The most popular animal models are the Mongolian gerbil (Mills *et al*., 1990; Schmiedt *et al*., 1990; Adams and Schulte, 1997) and the C57 mouse (Henry, 1983; Willott *et al*., 1994). The gerbil's audiogram is similar to humans (Ryan, 1976; Mills *et al*., 1990). The gerbil, like humans, is outbred and, like humans, shows a tremendous variability in the amount of age-related hearing loss (Mills *et al*., 1990). In terms of shape of the audiogram and cochlear pathology, the gerbil, by 36 months, typically shows a flat hearing loss that is accompanied by a few missing outer hair cells. However, there is significant degeneration of the stria vascularis (Gratton *et al*., 1996) and a significant reduction of Na,K-ATPase and the endocochlear potential (Schulte and Schmiedt, 1992). Thus, the gerbil appears to be a good model of metabolic or strial presbycusis.

The C57 mouse begins to develop a hearing loss at 1 to 2 months of age and is essentially deaf long before the end of its life span (Henry, 1983; Kazee *et al*., 1995). The pattern of hearing loss differs from the gerbil and is more like human sensory presbycusis. C57 mice begin to lose hearing at the highest frequencies and the pattern of cochlear degeneration starts with outer hair cells in the base of the cochlea (Hunter and Willott, 1987; Spongr *et al*., 1997). The hearing loss in the C57 mouse is different from humans in that it develops faster over a very short time period.

The chinchilla is an alternative model of age-related hearing loss (McFadden *et al*., 1997). Its audiogram is similar to that of

humans (Miller, 1970) and its life span is approximately 20 years—10 times longer than the mouse and roughly 25% of the human life span. The chinchilla begins to show a hearing loss, mainly due to sensory cell loss, at about 10 years of age and it accumulates hearing loss at about the same rate as humans (Bohne *et al*., 1990; McFadden *et al*., 1997). Thus, the pattern and rate of hearing loss in the chinchilla resembles that in humans.

B. Mechanism of Hearing Loss

The mechanisms underlying noise-induced hearing loss and age-related hearing loss are not fully understood; however, recent research suggests that free radicals may be a factor in both types of hearing loss. For example, when the ear is exposed to traumatic levels of noise, the metabolic rate increases along with increased production of reactive oxygen species and ischemia (Yamane *et al*., 1995). Exposure to high levels of music reduced the number of red blood cells in the capillaries of the stria vascularis and increased free radical levels along the marginal cells of the stria in guinea pigs. Two hours after the exposure, strial capillaries and free radical levels returned to normal. Nicotera and colleagues (1999) reported that chinchillas exposed to impulse noise show evidence of outer hair cell swelling, distortion of the cell body, and an accumulation of reactive oxygen species at the perimeter of the cells. Glutathione monoethyl ester, a powerful antioxidant, reduced reactive oxygen species levels and reduced the amount of hair cell damage from impulse noise (Hight *et al*., 1999).

Free radical formation occurs during many normal physiological processes. The toxic effects of free radicals are neutralized with cellular antioxidants. Thus, a normal balance between the formation of reactive oxygen species and their inactivation by antioxidants is necessary for normal cellular function. Increasing reactive oxygen species or decreasing cellular antioxidants leads to greater cell damage (Halliwell, 1992). The effects of various antioxidant molecules on age-related hearing loss can be evaluated in transgenic mice. For example, mutant mice with a targeted deletion of the gene that codes for Cu/Zn SOD, an important endogenous antioxidant enzyme, developed greater loss of hair cells and spiral ganglion neurons than wild type mice as they aged (McFadden *et al*., 1999a,b). Homozygous mice (−/−) with 100% loss of SOD develop more hearing loss than heterozygous mice (−/+) with 50% Cu/Zn SOD and heterozygous mice develop more loss than wild type mice (+/+) with normal levels of Cu/Zn SOD (Fig. 38.10). These results suggest that reactive oxygen species can influence the magnitude of age-related hearing loss in susceptible individuals, because the absence of Cu/Zn SOD, the primary antioxidant for the superoxide radical, exacerbated cochlear degeneration.

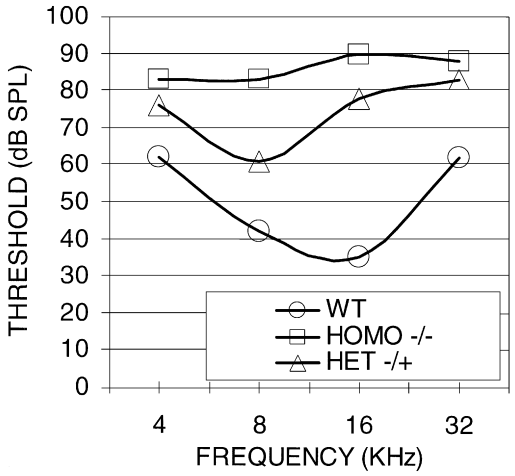

FIG. 38.10. Hearing loss in WT mice and heterozygous (HET −/+) and homozygous (HOMO −/−) Cu/Zn deficient-SOD mice (see text for details) (McFadden *et al*., 1999a).

If reactive oxygen species generation is a common factor in both noise-induced hearing loss and age-related hearing loss, then one might expect that susceptibility to noise-induced hearing loss and age-related hearing loss would be correlated. To test this hypothesis, 18-month-old gerbils were exposed to a monaural traumatizing sound. The animals were allowed to age to 36 months and then hearing was evaluated in the unexposed, aged ear. There was essentially no relationship between the amount of noise-induced hearing loss and the age-related hearing loss in the opposite, unexposed ear (F. Boettcher, personal communication). These results are consistent with data from mice lacking Cu/Zn SOD that did not show a strong relationship between susceptibility to noise and presbycusis. Clearly, this area requires further investigation before strong conclusions can be drawn.

Dietary restriction has been shown to prolong life span and reduce the incidence of cancer (Pugh *et al*., 1999). Thus, it is conceivable that dietary restriction might reduce susceptibility to age-related hearing loss. To test this hypothesis, mice were maintained on a high-energy or a low-energy diet. The low-energy diet increased longevity in several strains of mice without ameliorating age-related changes in cochlear pathology. Interestingly, caloric restriction decreased age-related cochlear degeneration in C57 mice, but had no effect on longevity in this strain (Willott *et al*., 1995). This study demonstrates the complex relationship between an individual's genetic background and the response of the auditory system to environmental factors.

C. Aging and Susceptibility to Noise-Induced Hearing Loss

How do you separate noise-induced hearing loss from age-related hearing loss? The hearing loss of a 65-year-old is most likely the combination of hearing loss and aging. ISO standard 1999 provides normative data for estimating the amount of hearing loss for aging in men and women (Kryter, 1991; Dobie, 1992). The ISO 1999 strategy is based on the assumption that noise-induced hearing loss and age-related hearing loss are additive (Mills *et al*., 1998). Consequently, the worker's noise-induced hearing is calculated to be the total hearing loss minus the hearing loss due to presbycusis. This approach is based more on logic than data; in fact, the data are equivocal in several respects. First, the average age correction is open to error because of the large variability in presbycusis. In a well-controlled laboratory study of gerbils raised in quiet, the hearing levels in 36-month-old animals ranged from normal to a

flat 65 dB loss (Mills *et al*., 1990). Thus, the range of hearing loss was extremely large despite tight control of other extraneous variable (noise exposure, diet, light–dark cycle). Second, experiments to measure the sum of age-related and noise-induced hearing loss have yielded results that agree and disagree with the additivity principle. Mills and colleagues (1997) exposed (3.5 kHz, 113 dB SPL) gerbils monaurally for 1 hr at 18 months and measured hearing levels in both ears at 36 months. If the additivity rule was appropriate, the hearing loss in the exposed ear should be the sum of the permanent hearing loss from the noise exposure and the age-related hearing loss in the unexposed ear at 36 months of age. The additivity rule significantly overestimated the total loss from noise plus aging. However, when long-duration noise exposures were used, the additivity rule was a reasonable predictor of the total hearing loss (Mills *et al*., 1996). Finally, if age-related hearing loss and noise-induced hearing loss covaried, the additivity rule would have to be modified to accommodate the degree of hearing loss. For example, for workers with a hearing loss 1 standard deviation above the mean, the correction for age-related hearing loss would need to be 1 standard deviation above the mean. Obviously, in practice, this would be a highly charged issue that would be unwise to promote given the limited and often contradictory data.

Is the aged ear more susceptible to noise? The data on this question are mixed. CBA/J mice develop normal hearing within the first 3 weeks of birth and then maintain relatively normal hearing until advanced age. Susceptibility to noise-induced hearing loss was tested from birth out to advanced age by exposing animals to a single 5 min exposure at 124 dB SPL. Susceptibility to noise-induced hearing loss increased out to 20 days of age. Susceptibility to noise-induced hearing loss remained high from 20 to 90 days, but the maximum loss shifted from 16 to 32 kHz. Between 120 days and until the end of the life span, susceptibility remained high, but the maximum hearing loss shifted to 64 kHz. These results were independent of exposure level. CBA/Ca mice also showed the same susceptibility to noise-induced hearing loss over their life span (Shone *et al*., 1991). C57BL/6, which possess a recessive gene for adult-onset age-related hearing loss (*ahl* on chromosome 10) (Johnson *et al*., 1997), were also exposed to noise and the hearing loss was compared to CBA/Ca mice were more susceptible to noise-induced hearing loss than CBA/Ca mice. This finding has been replicated in studies by Erway and colleagues (Erway and Willott, 1996; Davis *et al*., 1999), and interpreted as evidence for a common genetic predisposition to presbycusis and noise-induced hearing loss in the C57 mouse strain.

McFadden *et al*. (1998) and McFadden and Campo (1998) studied susceptibility to noise-induced hearing loss in young and old chinchillas and used two noise intensities (95 and 106 dB SPL) to determine if sound level had an effect on the age–noise interaction. The 95 dB exposure produced approximately the same amount of hearing loss in aged and young chinchillas. However, the old animals developed more hearing loss than the young animals when the high level exposure was used. In summary, the results suggest that there may be a complex interaction between age, noise, genetic background, and sound exposure level. Further work is needed to clarify the complex nature of these interaction effects.

V. Ototoxicity and Aging

The effects of drugs, both positive and negative, depend on factors such as their rate of accumulation, the concentration of the drug at its sites of action, and the duration of contact at those sites. These factors are influenced not only by the amount of drug administered, but also by pharmacokinetics—i.e., the dynamic processes involved in drug absorption, distribution, binding or localization in tissues, metabolic transformations, and excretion from the body. Many factors related to aging can have a profound impact on drug pharmacokinetics, leading to increased toxicity and the potential for negative side-effects in elderly patients. For instance, changes in fat or blood protein content can alter the transport and delivery of drugs to their sites of action; changes in kidney or liver function can alter drug clearance rates. The relationship between age and ototoxicity of commonly prescribed drugs has not been adequately explored. However, it is reasonable to expect that ototoxicity may be enhanced in elderly individuals.

A. Aminoglycoside Ototoxicity

Aminoglycoside antibiotics, such as streptomycin, gentamicin, tobramycin, and kanamycin, are potent antibiotics used in the treatment of serious infections caused by Gram-negative bacteria. The major drawbacks to their clinical use are their nephrotoxic and ototoxic side-effects. Consequently, aminoglycoside antibiotics are used sparingly in most developed countries except in cases of life-threatening illness. However, in many underdeveloped countries, aminoglycoside antibiotics are used extensively because of their ready availability and low cost. Aminoglycoside antibiotics could conceivably exacerbate sensorineural hearing loss in the aged population, particularly in individuals with impaired renal function.

Aminoglycoside antibiotics preferentially damage the sensory hair cells in the inner ear (Dallos *et al*., 1972; Worthingon *et al*., 1973; Ryan and Dallos, 1975). In general, hair cell damage progresses from the base (high frequencies) toward the apex (low frequencies) of the cochlea. In addition, aminoglycoside antibiotics tend to destroy outer hair cells before destroying inner hair cells. In cases where the dose of aminoglycoside antibiotic selectively destroys all of the outer hair cells, a hearing loss on the order of 50–60 dB will develop (Ryan and Dallos, 1975). In addition, frequency selectivity, or the ability to discriminate a signal in a background of noise will be greatly impaired (Ryan *et al*., 1979; Schmiedt *et al*., 1980). When the dose of aminoglycoside is high enough to destroy all of the inner and outer hair cells, a profound hearing loss will develop.

1. Mechanisms

The mechanisms by which aminoglycoside antibiotics exert their ototoxic effects are not fully understood; however, the progressive onset of hearing loss and hair cell degeneration provides some clues regarding the mechanism of cell death. Aminoglycoside antibiotics are rapidly taken up by the fluid compartments of the inner ear (Tran Ba Huy *et al*., 1986). However, the drugs are slowly incorporated into hair cells by

receptor-mediated endocytosis (Hashino *et al*., 1997; Richardson *et al*., 1997) and are sequestered in lysosomal-like vesicles. The vesicles increase in size and eventually rupture, releasing their toxic content into the cytoplasm, and leading to the demise of the hair cell. Sulfhydryl compounds, such as glutathione, and antioxidants can reduce aminoglycoside ototoxicity (Garetz *et al*., 1994). Moreover, transgenic mice overexpressing the antioxidant enzyme, superoxide dismutase, showed increased resistance to aminoglycoside ototoxicity (Sha *et al*., 1997). These results suggest that the antioxidant defense system may play a role in ototoxicity; however, the effects of age on the antioxidant defense system are unclear (Cristiano *et al*., 1995; Bhagwat, 1997; Campisi *et al*., 1999).

2. Effect of Age

Several studies have examined the effects of advancing age on aminoglycoside ototoxicity. One clinical study suggests that the concentration of tobramycin in serum varies with age (Cipolle *et al*., 1980). In general, the dose needed to produce a given serum concentration was higher for young patients than for old patients, because drug clearance was faster in young versus old subjects. These results suggest that aminoglycoside ototoxicity might be greater in older subjects due to slower drug clearance. However, the variability between subjects was quite high. In fact, the three factors, age, weight, and creatinine clearance, accounted for only 42% of the variance in amount of hearing loss. These results suggest that age may play only a minor role in regulating clearance rates of aminoglycosides.

Young animals show a critical period for aminoglycoside ototoxicity. Developing rats treated with amikacin between 10 and 25 days of age, during the onset and development of hearing function, showed substantially more hearing loss than younger or older animals (Carlier and Pujol, 1980). Results similar to these have also been reported for the cat, another altricial animal that develops normal hearing 2–3 weeks following birth.

Aminoglycoside ototoxicity has been examined over the life span of the CBA/J mouse (Henry *et al*., 1981). Since this strain of mouse maintains relatively normal hearing and cochlear anatomy into advanced age (Spongr *et al*., 1997), the effects of aminoglycoside antibiotics will not be confounded by any age-related hearing loss or hair cell loss. Preweanling mice treated with kanamycin showed significant hair cell loss throughout the cochlea and significant threshold shifts over a broad range of frequencies. In contrast, postweanling mice showed minimal hair cell loss and cochlear damage. Finally, post-middle-aged mice treated with kanamycin developed inner and outer hair cell lesions in the base of the cochlea and showed elevated high-frequency thresholds. These results suggest that there is a sensitive period for aminoglycoside ototoxicity around the time of onset and development of hearing. However, older subjects are more susceptible to high-frequency hearing loss from aminoglycoside ototoxicity.

The anatomical effects of the aminoglycoside antibiotic, tobramycin, were examined over a broader age range, 3 and 30 months, in the Wag–Rij rat (Dormans *et al*., 1996). Unlike the CBA mouse, the Wag–Rij rat showed increasing hair cell damage with advancing age that spread from the base toward the apex of the cochlea. Consequently, the amount of hair cell damage induced by the tobramycin must be compared to age-matched controls. As expected, hair cell loss and stereocilia damage increased with tobramycin dose. However, the amount of hair cell damage observed in old rats treated with tobramycin was not significantly different from that seen in age-matched controls. One interpretation of these results is that aging does not increase susceptibility to aminoglycoside ototoxicity if there is preexisting hearing loss or hair cell loss. However, in the case of the CBA mouse, which does not exhibit significant age-related hearing loss or cochlear pathology, aging does appear to increase susceptibility to aminoglycoside antibiotics. Clearly, the case is more complicated with elderly humans, since a host of nonauditory factors must also be taken into account.

B. Cisplatin Ototoxicity

Cisplatin (*cis*-diaminedichloro-platinum) and other platinum-based antineoplastic agents are frequently used to treat squamous cell carcinomas of the head and neck and genitourinary system. Cisplatin and its derivatives, which are inorganic, heavy metal compounds, inhibit cell division by forming intrastrand cross-links between guanine bases, thereby inhibiting DNA synthesis (Dedon and Borch, 1987). Cisplatin is taken up readily by cells in the liver, kidney, and inner ear. In humans and some animals, the hearing loss begins in the high-frequency regions and gradually spreads to the low frequencies with increasing dose (van der Hulst *et al*., 1988).

1. Mechanisms

The mechanisms underlying carboplatin ototoxicity are not fully understood; however, results from other systems have provided some preliminary insights. Histochemical studies indicate that cisplatin and its related compounds result in uncoupling of oxidative phosphorylation, inhibition of ATP synthesis, loss of calcium from mitochondria, and loss of calcium-associated transport enzymes and membrane transport enzymes. Increased calcium intake protected these enzymes and preserved kidney function (Aggarwal, 1993).

Carboplatin-induced damage to mitochondria, which may in some cases lead to an increase in the production of reactive oxygen species, could overwhelm the cell's free radical defense system and increase the risk of cell death. Cisplatin treatment of guinea pigs caused a significant hearing loss and a significant reduction of glutathione and glutathione *S*-transferase, compounds that protect against oxidative damage. Interestingly, glutathione levels in the rat auditory nerve declined by 86%, whereas cochlear levels remained unchanged (Lautermann *et al*., 1997).

Compounds that up- or downregulate the free radical defense system could modulate cisplatin ototoxicity. Buthionine sulfoximine (BSO), which inhibits glutathione synthesis, exacerbates hearing loss and inner and outer hair cell damage from carboplatin (Hu *et al*., 1999). Conversely, D-methionine, which upregulates the antioxidant defense system, provides significant protection against cisplatin and carboplatin ototoxicity *in vivo* and *in vitro* (Campbell *et al*., 1996; Gabaizadeh *et al*., 1997; Lockwood *et al*., 2000). Diethyldithiocarbamate,

which upregulates cochlear glutathione levels, also protects against cisplatin ototoxicity (Rybak *et al*., 1995). In addition to damaging sensory cells, cisplatin and related compounds can destroy spiral ganglion neurons (Zheng *et al*., 1995; Ding *et al*., 1997). BDNF, NT-3, and neurotrophin-4/5 (NT-4/5) promote the survival of spiral ganglion neurons (Zheng *et al*., 1995; Gabaizadeh *et al*., 1997). These results suggest that an age-related reduction in the level of cochlear antioxidants and neurotrophin could increase the ear's susceptibility to ototoxic drugs. For example, an age-related loss of inner hair cells would decrease NT-3 levels in the cochlea and presumably decrease the survival of spiral ganglion neurons.

2. Effects of Age

A heightened period of sensitivity to cisplatin has been observed in developing gerbils (Sie *et al*., 1999), an altricial species whose onset of hearing occurs around 12 days of age (McFadden *et al*., 1996). Decreases in high-frequency distortion product otoacoustic emissions, a measure of outer hair cell function, were greatest around 14 days after birth. These results suggest that there is a sensitive period for cisplatin ototoxicity in the developing gerbil ear. A comparable period in humans would occur *in utero* around the second trimester.

Hearing loss and cisplatin pharmacokinetics have been compared in children (1–7 years) and adolescents (12–15 years) with solid tumors (Murakami *et al*., 1990). The dose of cisplatin that caused hearing loss in the adolescent group was roughly three times higher than in children. The increased susceptibility in children was attributed to slower elimination of the drug compared to that seen in adolescents.

Many organs in the human body, such as the ear, liver, and kidney, gradually deteriorate with age. Therefore, the ototoxic effects of cisplatin and related compounds could conceivably be more severe in elderly patients. Several studies have found that the risk of hearing loss does indeed increase with age (Helson *et al*., 1978; Laurell and Borg, 1988; Hallmark *et al*., 1992) and with the drug dose (Helson *et al*., 1978). The increased susceptibility with age was not correlated with the drug dose or the use of furosemide or aminoglycosides (Hallmark *et al*., 1992).

3. Effect of Prior Hearing Loss

Is the age-related increase in cisplatin ototoxicity related to hearing loss that accompanies aging or some other factor? In gynecologic cancer patients, cisplatin ototoxicity was significantly correlated with a history of otologic problems (van der Hulst *et al*., 1988). However, others have reported that hearing loss caused by cisplatin was uncorrelated with prior hearing loss (Melamed *et al*., 1985).

VI. Summary

As the human life span continues to increase, age-related hearing loss will become an increasingly serious problem for health care professionals. Older individuals who develop severe to profound age-related hearing loss experience immense social isolation that can lead to secondary symptoms such as depression. While hearing aids can improve the threshold for hearing and sound quality in a quiet room for some individuals, they often provide little or no benefit in noisy social situations such as a restaurant. The inability to discriminate complex speech sounds in a noise background is largely due to two factors. One of the most important factors, which impacts the vast majority of patients, is damage to the outer hair cells that results in a loss of frequency selectivity and an elevation of threshold (Evans, 1976; Liberman and Mulroy, 1982). Hearing aids can overcome the threshold deficit, but cannot restore the ear's ability to distinguish one sound frequency from another particularly in moderate to high levels of background noise. The second factor that seems to have a profound impact on speech discrimination is the loss of spiral ganglion neurons (Schuknecht and Woellner, 1953; Schuknecht, 1976). Loss of inner hair cells and spiral ganglion neurons has little impact on threshold and frequency selectivity (Wang *et al*., 1997). However, the number of neuronal channels funneling information to the brain is greatly reduced, depriving the brain of the full array of information it needs to discriminate complex sounds such as speech (Salvi *et al*., 1999).

The range of hearing loss among individuals of the same age (Taylor *et al*., 1965) or individuals exposed to the same noise is enormous (Taylor *et al*., 1965). One of the factors that is likely to contribute to this enormous variability is genetic susceptibility to presbycusis, acoustic trauma, ototoxicity or some combination of these (Fischel-Ghodsian *et al*., 1993; Erway *et al*., 1996; Johnson *et al*., 1997; McFadden *et al*., 1999a,b). Rapid advances being made on the human and mouse genomes will undoubtedly accelerate our understanding of the genetic factors that predispose an individual to developing a hearing loss. Individuals armed with such information can take the necessary precautionary measures to reduce the risk of age-related hearing loss.

Over the past two decades, important advances have been made in understanding the mechanisms that can lead to cell death in the inner ear. Using this information, scientists have identified some promising intervention strategies aimed at protecting the inner ear from damage due to aging, ototoxicity and noise exposure (Boettcher *et al*., 1992; Seidman *et al*., 1993; Zheng *et al*., 1995; Campbell *et al*., 1996; Hu *et al*., 1997; McFadden *et al*., 1997; Willott and Turner, 1999). Many obstacles, such as efficacy of drugs in humans, drug delivery routes, inherent toxicity, and convenience, must be overcome before these otoprotective agents can be used to slow or prevent age-related hearing loss.

Auditory Temporal Processing during Aging

This chapter presents results of a thematic interdisciplinary approach to characterizing and determining the neural bases of presbycusis. Research audiology, psychoacoustics, behavior and experimental psychology, neuroimaging and neurology, single-cell neurophysiology, neuroanatomy and neurochemistry, and evoked potential neurophysiology contributed to cross-project experiments in humans and animals. By using psychoacoustic and evoked potential neurophysiological paradigms such as forward and backward masking (gaps), interstimulus intervals and rates, and by manipulating naturally occurring pauses and voice-onset times in speech, we were able to gain insights into age-related slowing of central nervous system timing mechanisms. The peripheral auditory system with its extensive bank of filters is responsible for the spectral analysis of simple and complex environmental sounds. Thus, inner ear dysfunction is characterized principally and initially by deficiencies in frequency analysis and sensitivity. In contrast, most sounds, and especially suprathreshold complex sounds such as speech, vary over time. Therefore, measures of temporal resolution that can reflect the integrity of the central auditory system have become especially useful in our research seeking to determine the effects of age, per se, on hearing. Here we present results of our temporal resolution research utilizing human and animal subjects aimed at determining neural sites of hearing loss due to aging. This chapter also reinforces how findings from animal models can assist in understanding the human condition and thus lead to future interventions.

I. Themes and Specific Aims of Presbycusis Research Program

Cross-project experiments in humans and animals have brought together the disciplines of research audiology, psychoacoustics, behavior and experimental psychology, neuroimaging and neurology, single-cell neurophysiology, neuroanatomy and neurochemistry, and evoked potential neurophysiology. Strengths of this multidisciplinary approach include the ability to (a) conduct parallel animal and human experiments, (b) obtain repeated measures on the same subjects (human/animal) or subject groups, (c) obtain behavioral and physiological measures on the same subjects, and (d) study central as well as peripheral components/interactions in the auditory system (see Fig. 39.1).

We examined auditory temporal resolution, which is a fundamental acoustic feature for speech perception. This auditory dimension was chosen because aged listeners have difficulty understanding speech in noisy or reverberant environments, and because temporal processing is largely the domain of the central auditory nervous system. By using psychoacoustic and evoked potential neurophysiological paradigms such as forward and backward masking (gaps) and interstimulus intervals and rates and by manipulating naturally occurring pauses and voice-onset times in speech, we were able to gain insights into age-related slowing of central nervous system timing mechanisms.

The peripheral auditory system with its extensive bank of filters is responsible for the spectral analysis of simple and complex environmental sounds. Thus, inner ear dysfunction is characterized principally and initially by deficiencies in frequency analysis and sensitivity. In contrast, most sounds, and especially complex sounds such as speech, vary over time. Therefore, measures of temporal resolution that can reflect the integrity of the central auditory system have become especially useful in our research seeking to determine the effects of age, per se, on hearing. This chapter presents results of our temporal resolution research utilizing human and animal subjects aimed at determining neural sites of hearing loss due to aging. It also represents how findings from animal models can assist in understanding the human condition and thus lead to future interventions.

II. Neurobiology of Temporal Processing: Human Subjects

A. Speech Recognition in the Elderly

We were guided in the design of our speech recognition experiments by the extensive report prepared by the Commit-

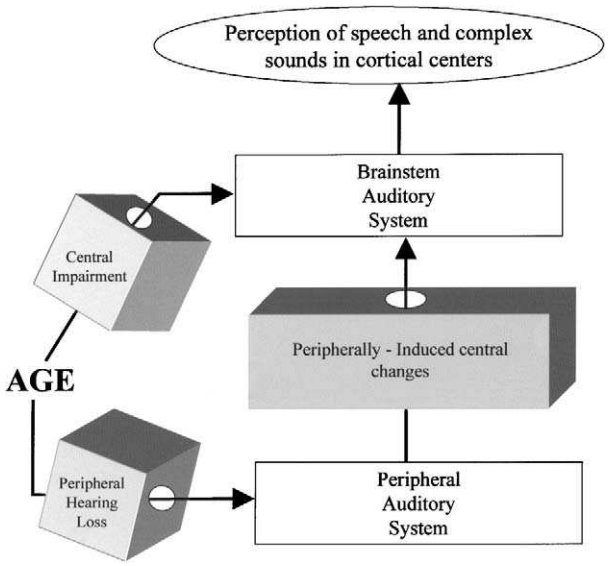

FIG. 39.1. Schematic representation of auditory system illustrating possible neural sites underlying age-related hearing loss. Age-related central changes can occur independently of peripheral hearing loss or in conjunction with peripherally induced central changes.

tee on Hearing, Bioacoustics and Biomechanics (CHABA) of the Acoustical Society of America in 1988. That report expressed the lack of certainty regarding auditory neural site(s) of biological aging because much of the prevailing research focused on the peripheral auditory system. It also encouraged more careful subject selection criteria and accurate control of materials and experimental procedures when comparing adult subject groups of different ages. In general, the committee's review of studies dealing with speech perception performance in quiet and simple tones tended to confirm the vital role played by the peripheral auditory nervous system irrespective of subject age. However, the results of studies measuring speech recognition performance in noise and complex signals were equivocal with respect to differences due to age versus those due to inner ear damage.

It is characteristic of most people 60 years of age and older to show some hearing loss for pure tones and speech stimuli (Gates *et al*., 1990). Their expressed concern, however, is difficulty in understanding the speech of others especially when in noisy or reverberant acoustic environments. In order to test for an age effect in the central auditory system, it was necessary to find those relatively few elderly subjects 60 years of age and older who demonstrated normal speech-frequency pure-tone sensitivities and speech perception thresholds in quiet. For every 100 elderly women and men screened, we found 5 or 6 women and 3 or 4 men with normal auditory sensitivity thresholds. These ''golden ears'' provided the basis for comparing speech recognition in noise performance of young and old adult normal hearers and thus helped determine the existence of a central auditory nervous system age effect. It was clear from prior research that temporal resolution dysfunction would most likely be revealed under conditions of adaptively varying background noise rather than presenting speech signals at fixed signal-to-noise levels (Gordon-Salant, 1987).

Here we evaluated the effects of age and/or hearing loss by comparing monaural speech recognition performance in five groups consisting of young adult normal listeners (ages 18–30), old adult normal listeners (ages 60–81), and three groups of old adults (ages 60–81) with sensorineural hearing loss (Frisina and Frisina, 1997a). The young and old normal listeners were matched on absolute thresholds for pure tones and speech. The old sensorineural hearing loss groups represented three levels of hearing loss. Three types of speech stimuli were employed, spondees (words of two equally stressed syllables, e.g., eardrum), sentences in which context contributed to target word identification, and sentences where context did not aid in the identification of target words. Speech perception performance results in the quiet conditions indicated that the young and old normal hearers did not differ, thereby confirming that the auditory sensitivity of these two groups was similar. By implication, peripheral auditory system function did not differ. In addition, comparisons of performance of the two groups on ability to use context yielded no difference, thereby eliminating cognitive function as causation for speech recognition (in noise) performance differences. However, when the noise background, 12-speaker multitalker noise (Kalikow *et al*., 1977), was used, the performance of the young normal hearing group was superior to that of the old normal hearers. Thus implicating age as a factor contributing to this difference. The effect of hearing loss was revealed by comparing speech-recognition performance of the old normal hearers to that of the three old hearing loss groups. The combined effects of age and hearing loss were revealed in the relative performances of the young normal hearers and the three old groups with hearing loss. These findings pointed to a neural dysfunction originating in the central auditory system. Gap detection thresholds were later obtained in these subject groups as a measure of auditory temporal resolution the results of which were consistent with these findings.

We also conducted a study of free field perception of speech in noise to test for a central effect of age on binaural hearing in a simulated everyday environment (Frisina and Frisina, 1997b). Speech recognition performance of young normal hearers and old normal hearers with equivalent hearing sensitivity similar to those in the above study were compared. Sentences from the Hearing-in-Noise Test (HINT), (Nilsson *et al*., 1994) were presented adaptively. Speech signals and speech-spectrum noise were presented simultaneously at ear level 1 m from the subject seated in a double-walled sound booth. Audiometric thresholds of the young (18–27 years of age) and old normal hearers (60–81 years of age) did not differ. Speech was presented at 0° azimuth while noise was presented simultaneously at each of three positions, 0°, 90°, or 270°. An age effect was found in each of the speech-in-noise performance comparisons between the young and the old normal hearers. Moreover, spatial separation of speech and noise resulted in greater release from masking for the younger group in all conditions. We suspect that an age effect exists because the older human listener is unable to use timing cues as effectively as the younger human listener. In addition, in both groups noise interference was less when speech was delivered at 0° and noise at 270° than when speech was located at 0° and noise at 90°. This laterality effect in which a masker is presented to the right ear (and thus favoring the left and dominant

speech cortex) was the more effective masker for both young and old subjects. Of added importance was the finding (in a companion study, Ison *et al*., 1998) that it was a significantly more effective masker for the oldest of the old subjects. This result occurred in a context in which there was no significant relationship within this particular older group of subjects between age and audiometric loss. This suggests that the processing of speech signals in noise lateralized to the right ear is particularly affected by old age, strongly implicating a central effect in the genesis of this aspect of presbycusis.

In summary, most adults beyond the age of 60 years experience difficulty in understanding speech when conversing in the presence of background noise. One obvious reason for this difficulty is a change in the spectral resolving capacity of the inner ear. However, our findings utilizing ''golden ear'' subjects suggest that changes in the central auditory nervous system, characterized as temporal resolution dysfunction, is due to biological aging and exists independently or in conjunction with peripheral changes in the inner ear. To test this hypothesis further, our colleagues in psychoacoustics, evoked potential neurophysiology, behavior and experimental psychology, and neurology and neuroimaging conducted parallel studies in humans. In this way, we hoped to identify and elucidate the neural substrates underlying speech recognition problems reported by and corroborated in older adults.

B. Psychoacoustic Declines in Temporal Gap Detection

We explored declines in processing rate by examining temporal acuity on an elemental level in a simple paradigm, an auditory gap-detection task. We did so because age-related changes in the processing of speech, especially in acoustically complex conditions (van Rooij and Plomp, 1992), had been linked to declines in rate processing.

Because gap resolution had been demonstrated to be strongly dependent on the audibility of high-frequency energy in a test signal (Buus and Florentine, 1985) and generally gap thresholds in people with cochlear hearing loss were reported to be higher (Moore and Glasberg, 1988), the need to measure temporal acuity in older adults without hearing loss was clear. Other investigators who explored temporal resolution in older subjects using a gap-detection paradigm (e.g., Moore *et al*., 1992; Schneider *et al*., 1994) noted the importance of not confounding age and hearing loss. Nevertheless, the absolute thresholds of older subjects in previous studies were usually poorer than those of young subjects. Thus, it remained unclear whether the decreased temporal acuity reported for the older subjects reflected age-related changes alone or interactions between age and hearing loss.

Also, previous studies of gap detection and aging used sinusoidal signals (Moore *et al*., 1992, with 400 msec sinusoids; Schneider *et al*., 1994, with tone pips). While frequency specificity is often desirable, age-related changes in temporal resolution measured in tasks other than gap detection have been reported to increase with the complexity of the stimulus condition (Fitzgibbons and Gordon-Salant, 1995). This finding is consistent with those of other studies which indicated that the magnitude of the age-related slowing was proportional to task complexity (Sliwinski *et al*., 1994). Therefore, the use of more complex sets of conditions in studying gap detection in aging adults increases the likelihood of detecting age-related differences. Of practical consequence, results with acoustically complex signals in complex background may be more directly relevant to understanding the speech perception problems of older adults (CHABA, 1988).

Our study sought to clarify and extend understanding of age-related changes in temporal resolution by matching pairs of young and old subjects for absolute sensitivity across a wider range of frequencies than in previous studies and by measuring temporal resolution in conditions varying in stimulus and background complexity. If previously reported age-related differences reflected primarily differences in absolute sensitivity or its interactions with age, groups matched audiometrically should have comparable gap thresholds in all conditions. On the other hand, comparable gap detection in quiet and group performance differences in complex backgrounds would be consistent with reports of relatively greater difficulty understanding speech in noisy or complex listening environments that cannot be explained by audiometric thresholds alone. Finally, differences between groups in all conditions would support the hypothesis that a more generalized age-related change occurs in the speed of auditory processing.

One of our recent studies (Snell, 1997) demonstrated that gap detection is strongly influenced by age; i.e., mean gap thresholds of the younger subjects were smaller than those of older subjects. Mean gap thresholds appeared to be especially larger in conditions in which the carrier of the gap signal was more complex, e.g., amplitude-modulated, or in which the acoustic background was complex, for example, when high-frequency noise was present. Mean gap thresholds were significantly longer for the older subjects in 24 experimental conditions. The robustness of the effect given the variety of signals and listening conditions was striking. The mean gap thresholds of the older subjects were about 27 and 37% larger with 1 and 6 kHz noise-burst signals, respectively, than those of the younger subjects. These results are important for several reasons. First, the differences cannot be easily attributed to differences in absolute sensitivity, as can the differences reported in previous studies. Half of the conditions used a noise-burst signal with an upper cutoff frequency of 1 kHz and encompassed frequencies for which absolute sensitivity was precisely the same in each group. Second, the magnitude of the difference in gap thresholds was similar to age-related differences that have been recently reported in our neurophysiology team's recordings from young and old mice (Walton *et al*., 1998). Third, regardless of the marked differences in method and subject selection, results from different labs point to the same mechanism (Moore *et al*., 1992; Schneider *et al*., 1994).

Background condition had little effect on mean gap thresholds for the low-passed noise-bursts with a cutoff frequency of 6 kHz. For example, the mean gap thresholds in quiet, with a noise floor, and with a noise floor and high-frequency masker were 2.8, 2.7, and 2.9 msec, respectively. Pairwise comparisons for the 6 kHz signal indicated that mean gap thresholds of neither group increased with the addition of a noise floor. Gap thresholds increased only when both a noise floor and a gated-high-frequency masker were present, and then only slightly (although significantly at $P < 0.05$). Mean gap thresholds of the young subjects in the three background conditions

were 2.3 (quiet), 2.3 (noise floor), and 2.5 msec (noise floor and gated-high-frequency masker). The mean gap thresholds of the older subjects in the corresponding background conditions were 3.2, 3.2, 3.3 msec, respectively.

The high-frequency masker conditions were used to provide a straightforward interpretation of between-group differences in the noise-floor conditions even if high-frequency absolute thresholds were not exactly matched. That is, the gap thresholds of the two groups were expected to be comparable in the quiet condition and increase in the noise-floor conditions for the older group only. If the relatively better performance in the noise-floor condition reflected the more sensitive high-frequency hearing of the young group, then addition of a high-frequency masker should have eliminated their relative advantage. As a result, group performance should have been equivalent in the noise-floor plus high-frequency masker conditions. In fact, the addition of the high-pass masker resulted in increased mean gap thresholds for the 6 kHz signal in both groups of subjects. To estimate the contribution of high-frequency hearing, gap thresholds were correlated with absolute thresholds at 8 kHz. Correlations were insignificant, ranging from 0.010 to 0.143. Correlations with 6 kHz absolute thresholds were also calculated and were similarly small. While this probably reflects, in part, the narrow range of absolute thresholds at 6 and 8 kHz, the lack of significant correlations suggests that it is unlikely that the age effect is primarily related to the very small differences in high-frequency sensitivity.

Individual data of the 40 subjects were examined in 24 scatterplots representing each of the experimental conditions. Two representative conditions are shown in Fig. 39.2. Subject age in years is plotted on the abscissa; gap thresholds in milliseconds on the ordinate. Each data point represents the mean gap threshold of one subject. There are several aspects worth noting, which have been discussed in previous studies. First, there is considerable overlap between age groups in the distributions of gap thresholds. Second, the range of gap thresholds of the older group is broader than for the younger group, although the variability is similar when examined on a log scale. Finally, several older subjects appeared to have exceptionally poor temporal resolution in each condition.

One aspect of the data that has not been previously noted is shown in both panels of Fig. 39.2. Note that gap detection by several younger subjects appears exceptionally acute even when compared to the smallest gap thresholds of the older subjects. Interestingly, small (1 to 2 msec) neural correlates of gap thresholds measured in onset and primary-like neurons in the inferior colliculus of young mice have also been reported (see below, and Walton *et al*., 1997). These scatterplots illustrate that the age-related increase in mean gap thresholds reflects not just larger gap thresholds in a few older subjects but an overall shift in the distribution of gap thresholds with age. While there is considerable overlap between the two distributions, roughly a third of the gap thresholds of the older subjects fall well outside the range of the younger subjects and the gap thresholds of a few younger subjects are considerably smaller than the smallest old gap thresholds.

While pairs of subjects had been matched for absolute sensitivity at audiometric frequencies, it is possible that age-related differences in absolute sensitivity to the wideband signals could have contributed to between-group differences

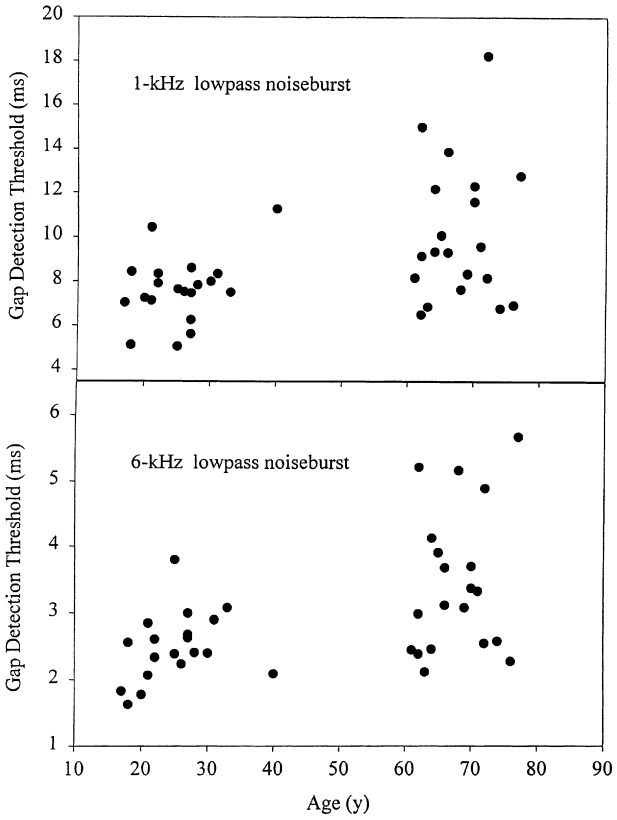

FIG. 39.2. Scatterplots of gap thresholds as a function of subject age. The top plot contains the gap thresholds obtained with a modulated noiseburst lowpassed at 1 kHz presented in a complex background. The bottom plot shows the gap thresholds obtained with a modulated noiseburst lowpassed at 6 kHz presented in a quiet background. (From Snell, 1997, with permission from the American Institute of Physics.)

in gap thresholds. To examine this possibility, individual absolute and masked thresholds obtained for sample signals in three background conditions were examined using ANOVA and pairwise comparisons. The results of these analyses indicated that the mean masked thresholds did not significantly differ between groups and therefore could not have contributed to the between-group differences in the noise-floor conditions. Also, the masked thresholds (dB SPL) for each subject were higher than the corresponding absolute thresholds, ensuring that the gap thresholds obtained in the noise-floor condition were actually masked gap thresholds. Sensation levels for the unmasked signals were slightly higher for the younger subjects but exceeded 30 dB SL for all subjects.

Our results indicate that age-related changes in temporal acuity occur across a range of stimulus characteristics and background conditions. Mean gap thresholds of older subjects were larger when compared to mean gap thresholds of younger subjects with matched audiograms for signals varying in spectra, intensity, and depth of modulation. Although the gap thresholds of younger and older subjects showed similar patterns in response to various signal manipulations, older subjects were more susceptible to the effects of background noise in most conditions. For instance, when a noise floor

was added to a low-passed noise-burst signal with a cutoff frequency of 1 kHz, the gap thresholds of the older subjects increased, whereas the gap thresholds of the younger subjects remained stable. Mean thresholds of both groups increased slightly when a high-frequency masker was gated with the signal and allowed to partially fill the gap.

C. Age-Related Changes in Temporal Processing: Auditory Brain-Stem Response

We evaluated temporal processing in young and aged adults using the auditory brain-stem response (ABR) (Walton *et al*., 1999). The ABR is a surface-recorded evoked potential that reflects activity arising from the auditory nerve and auditory brain stem (Møller, 1994). This response is ideal for primary sensory measurements as the response is only minimally affected by attention and arousal (Amadeo and Shagass, 1973; Picton and Hillyard, 1974), but is strongly dependent on numerous variables, including stimulus level, rate, and level of a continuous masking noise (Burkard and Hecox, 1983, 1987). In addition, the ABR is affected by some subject variables, including development (Hecox and Burkard, 1982). Walton *et al*. (1999) used an ABR forward masking paradigm to investigate temporal processing. In this paradigm, a primary signal, called the masker, is presented, followed by a second signal, called the probe, which elicits the ABR. Walton *et al*. (1999) used constant-level sinusoid maskers and probes, and varied the time interval between the end of the masker and the onset of the probe. This latter interval is referred to as the forward-masker interval. As with many recent auditory studies from the Rochester group, they used young and old subjects that were audiometrically normal. Specifically, they had thresholds of 20 dB HL or less for the octave frequencies from 250 to 8000 Hz, inclusive. Masker/probe frequencies included 1, 4, and 8 kHz. Probes were presented at 40 dB above perceptual threshold (40 dB sensation level), while maskers were presented at a level that just masked the ABR response when the probe was presented at masker offset. Probes were presented alone, and with forward-masker intervals of 0, 2, 4, 8, 16, 32, and 64 msec. Figure 39.3 shows responses to 4 kHz probes and maskers, for one young and one old subject, for all masker conditions. Note that wave V, indicated by the arrow heads, is the only ABR peak consistently seen in these recordings. Wave V is currently thought to arise from rostral brain-stem structures such as the lateral lemniscus (Møller, 1994), and hence any age-related differences up to and including the pons/midbrain level for auditory temporal processing should be manifested in wave V behavior.

Figure 39.4 shows a mean wave V latency shift for the 4-kHz probe/masker plotted across forward-masker interval. The latency shift is relative to the no-forward-masking condition (within subject and probe/masker frequency). Circles represent the young-adult data, while the squares represent the old subjects' data. Few subjects showed reliable responses

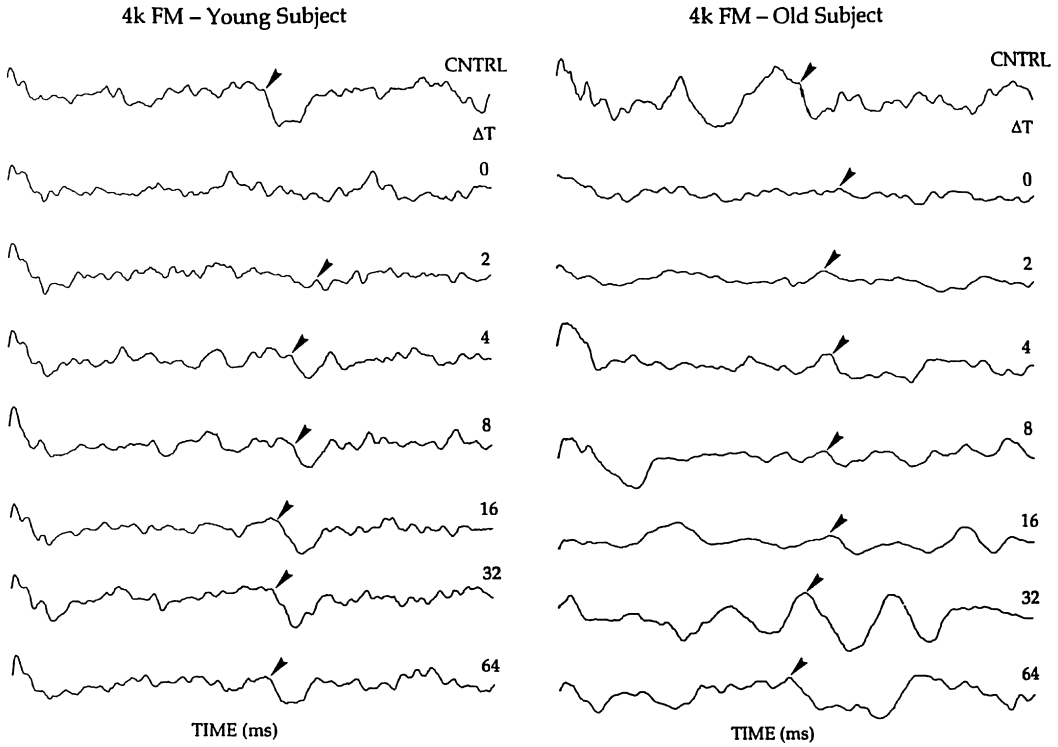

FIG. 39.3. ABRs across forward-masking interval (ΔT) for the 4 kHz masker-probe condition are shown for one young subject and one old subject. The unmasked, or control, response is shown as the top waveform for each subject, with the arrowheads denoting wave V latency. Note that for short ΔTs (2–8 msec) wave V latency in the young subject (24 years) has begun to recover to the control latency, while the wave V latency in the older subject (73 years) is still prolonged. ΔTs ranged from 0 to 64 msec and vertical calibration bar represent 0.2 nV while the horizontal bar represents 1 msec. (Reprinted from Walton *et al*., 1999, with permission from Elsevier Science.)

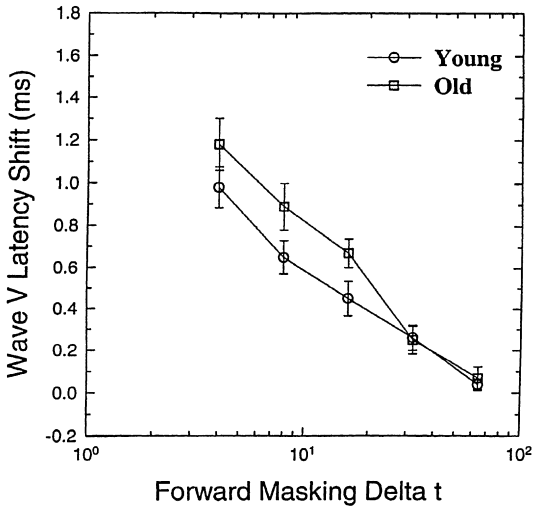

FIG. 39.4. Wave V latency shifts. The unmasked latencies are plotted across forward-masking interval for the 4 kHz probe for the young (◯) and old (□) subjects. Means are shown by symbols with standard deviation shown by vertical lines. The maximum prolongation of the mean wave V latency was approximately 0.9 msec for the young group and 1.2 msec for the old group. Again, means are based on 10 subjects. (Reprinted from Walton *et al*., 1999, with permission from Elsevier Science.)

for forward-masker intervals below 4 msec, and hence data are shown only for forward-masking intervals of 4 msec and above. Note that for young adults, wave V latency shift is less than that of the old adults, but only for forward-masking intervals of 16 msec and less. At longer intervals, at this tone-burst frequency, the two functions converge. It should be noted that a similar age effect emerged for the 8 kHz condition but that recovery functions for the young and old subjects were nearly identical for the 1 kHz condition.

Although it is difficult to explain the 1 kHz data, the 4 and 8 kHz data support the view that the old subjects showed a neurophysiological correlate of degraded temporal processing abilities, when compared to the young-adult subjects. Interestingly, this effect was most prominent at short forward-masking intervals. Specifically, at a given forward-masker interval the wave V latency shift was greater in old subjects, but both young and old groups showed complete (or near-complete) wave V recovery by 64 msec. This age-related degradation in temporal processing ability cannot be attributed to peripheral hearing loss, as all subjects had audiometric thresholds within normal limits.

D. Neuroimaging Brain Systems Underlying Speech Perception in Noise

We have begun initial hypothesis testing concerning the effects of background noise on cortical speech/language processing and how these systems are affected by age (Frisina *et al*., 1999). These studies have been made possible through the cooperation of the positron emission tomography (PET) center at Buffalo's Veterans Administration Medical Center of Western New York. Recent advances in the techniques of PET neuroimaging, coupled with more options for advanced statistical analyses of PET images, have made it possible for us to include this procedure in our study of presbycusis. Regional cerebral blood flow (rCBF) images are acquired by PET using ^{15}O-water as a tracer and indicator of brain activity (Posner *et al*., 1988). Differences in neural activity are reflected as differences in rCBF. The central thesis that underlies this strategy is the fact that the brain contains essentially no energy or metabolic reserves, and, as increments in neural activity are required to perform additional "brain work" there must be a corresponding increment in rCBF.

rCBF measurements were made as normal hearing young and old subjects listened to speech alone, speech in noise, and noise alone, i.e., tasks that were designed to activate brain functions and the corresponding neural systems that mediate the tasks. Measurements of these three conditions were compared to a resting state. Differences in rCBF associated with these listening tasks were analyzed using statistical parametric mapping. Statistical parametric mapping is a widely used statistical strategy for identifying increases in cerebral blood flow produced by stimuli presented to individuals (Friston and Frackowiak, 1991; Lockwood *et al*., 1993). We collected PET data on two groups of subjects, most of whom had completed the above-mentioned speech perception and temporal coding experiments, and thus were well characterized audiologically in terms of speech recognition and gap detection (Frisina and Frisina, 1997a,b). All young ($n=9$) and old ($n=7$) subjects had normal hearing as defined audiometrically, yet showed age-related differences in speech recognition and gap detection as reported above.

In our initial PET study, we measured the change in CBF produced by listening to context-positive sentences (Frisina *et al*., 1999). The subjects' task was to repeat aloud the last word in each sentence. Three conditions were used, with each condition being repeated for each subject to improve statistical power. The first condition consisted of listening to 30 sentences presented in quiet at a rate of one sentence every 4 sec at a level of 80 dB SPL. The second condition was identical to the first, except that the sentences were presented in the presence of their multitalker (babble) background noise. The noise was gated on/off 500 msec before and after each sentence. The noise intensity level was set individually for each subject so that each would achieve approximately 50% correct performance level (previous research with these subject groups prior to entering the PET study provided this information). The third condition consisted of presenting the noise stimuli without sentences. The subjects were instructed to give an answer to each sentence. In cases where they did not recognize the target word, they were instructed to say the word "nope" in order to help equilibrate the spoken word/motor portion of the task. The young (22–35 years of age) and elderly (60–71 years of age) normal listeners had rCBF measurements made at rest and while performing under the three conditions described above.

The PET data shown in Fig. 39.5 (see color insert) are for the young subjects only. They represent areas of activation for the speech stimuli presented in quiet, for all nine subjects combined. The background brain renderings showing lateral (top) and medial (bottom) views of the brain in MRI format are averages and do not represent any subject's specific brain of the present study. As indicated in the two top parts of the figure, rCBF maxima were found in the temporal lobes, consistent with earlier PET mapping studies of auditory cortex using speech-like stimuli in quiet. The two bottom portions of this

figure indicate that some activity also occurs in the auditory midbrain (inferior colliculus) and cerebellar portions of the brain stem involved in sound processing. Because of technical limitations that we recently surmounted, previous speech/language PET investigations have generally not been able to examine brain-stem nuclei. The effects of background noise on the brain activity occurring during this speech recognition task are shown in Fig. 39.6 (see color insert) for the young subjects. Temporal lobe activity is still present, as with the speech in quiet (top portions of Fig. 39.6). However, comparisons of the bottom portions of Fig. 39.5 and 39.6 indicate that there is a significant increase in the brain activity in the auditory midbrain and cerebellar regions when the speech was presented in background noise (Fig. 39.6). It may be that this significant increase in activity in the inferior colliculus and cerebellum is an auditory brain-stem-filtering requirement necessary for allowing perception of speech in the presence of a strong background noise. Similar results were obtained for the old subjects when comparing processing of speech in quiet and in the presence of significant background noise (Frisina *et al*., 1999; data not shown).

One representative finding concerning the effects of age on speech recognition in quiet and background noise is shown in Fig. 39.7 (see color insert) (Frisina *et al*., 1999). Here, activations of old subjects have been subtracted from young subjects for the speech-in-quiet speech recognition task. Results for the speech-in-noise task were similar (not shown). Note that the young subjects show more activity in the auditory midbrain on both sides (bottom portions of the figure). This may be a neural correlate of the young subjects' superior abilities of discriminating the speech from the background noise and thus having improved performance of speech recognition in noise. Additional increases in activity can be seen bilaterally in the visual cortex and on the left side of the brain in the anterior cingulate cortex for the young subjects. Earlier behavioral studies (Pichora-Fuller *et al*., 1995; Frisina and Frisina, 1997a,b) showed that old subjects with normal audiometric thresholds or peripheral hearing loss used context as well or better than young subjects when listening tasks were made difficult by the introduction of background noise. These behavioral comparisons suggested that increased cerebral resources of the old subjects were being used to overcome the deficit caused by the decline in auditory processing capacity in the brain-stem or inner ear hearing loss. Thus, increased rCBF to the cortical levels, as revealed in PET imaging, by old subjects with normal audiometric thresholds, would be consistent with their necessity to compensate for the brain-stem temporal resolution decline. Future studies will compare rCBF in young and old listeners with normal audiometric thresholds to rCBF in old subjects with different degrees of peripheral hearing loss. Such studies will help to elucidate further the neural bases of presbycusis.

III. Neurobiology of Temporal Processing—Animal Models

A. Neural Correlates of Acoustic Gap Detection

Initial investigations of the neural bases of auditory temporal processing were conducted in young adult CBA mice to determine whether any correspondence could be demonstrated between behavioral measures of temporal processing and single-nerve cell physiological data (Walton *et al*., 1997). The CBA mouse strain loses its hearing slowly in life, on a time frame similar to that of humans, when calibrated for the different absolute life spans of mice and men. This was one means for assessing the adequacy of the choice of the mouse as an animal model for correlation of behaviors involving hearing with underlying neurology. Our approach was to measure sensitivity to brief gaps in broadband noise using acoustic startle response paradigms. Then, utilizing the same strain of mouse, measure responses of single nerve cells in the auditory midbrain (inferior colliculus) for the same type of gap stimulus. More specifically, in this behavioral reflex modification procedure used to measure gap detection, stimuli are presented at brief intervals prior to the elicitation of a startle reflex by a noise burst. The startle response is inhibited depending upon the salience of the "warning" stimuli used. In this case, the warning sound were gaps ranging from 1 to 15 msec, placed in a continuous noise preceding the startle elicitor by 60 msec. The advantages of this method are that no prior training is required and that sensory thresholds in laboratory animals can readily be obtained in a matter of hours rather than days or months.

1. Behavioral Correlates of Acoustic Gap Detection

Temporal acuity was studied in about 200 CBA mice, ranging in age from 2 months to 29 months, using the behavioral technique of reflex modification audiometry (Young and Fechter, 1983). The mouse was placed in a small cage set on top of an accelerometer which measured the force of the acoustic startle response to a brief burst of white noise (115 dB SPL, 20 msec in duration), and this apparatus was placed in an anechoic chamber. The startle noise burst was given in the presence of a white noise background (70 dB SPL), either after 15 to 30 sec of continuous noise (since the preceding trial) or 60 msec after the occurrence of a brief silent period in the noise (a gap) that could be 1 to 15 msec in duration. The startle reflex is inhibited by gaps that briefly precede it and past research has shown that in a variety of species, including humans (Ison and Pinckney, 1983), the threshold for reflex inhibition approximates the threshold obtained by conventional psychophysical procedures. In addition to providing a behavioral measure of gap threshold, the methodology provides a measure of the effects of suprathreshold levels of stimulation, which can be assumed to be related to the general efficiency of temporal processing in the auditory system. The threshold was defined conventionally, as the first duration at which the strength of reflex inhibition was 50% of its maximum strength. This criterion avoided any measurement problem caused by the fact that the asymptotic levels of inhibition were affected by age.

The thresholds for gap detection varied with age, with the older mice being less sensitive to brief silent periods in noise: mice younger than 1 year of age ($n=109$) had a mean gap threshold value of 3.06 msec ($\pm$ 0.12, SEM); mice between 1 and 2 years of age ($n=42$) had a mean gap threshold of 3.76 ms ($\pm$ 0.40); and mice over 2 years of age ($n=67$) had a mean gap threshold of 4.02 msec ($\pm$ 0.45). These differ-

ences, while small, were significant, F (2,215) $=3.37$, $P < 0.05$, and the linear trend was also significant, $P = 0.01$. One very interesting aspect of these data is that the variance clearly increased in the older animals ($P < 0.001$), indicating that the decrement in auditory processing produced by age was far from uniform within the group. Many old mice had gap thresholds of 2 to 4 msec that were the equal of those obtained in the youngest mice. It may be noted that gap thresholds obtained in our mice were very similar to those obtained in human subjects under similar stimulus conditions (Snell, 1997): 2 msec in the youngest human listeners compared to 3 msec in the best of the oldest listeners. Again, as in the mice, this small difference was significant, and again, the variance in the old listeners was greater than that of the younger listeners.

In contrast to the small age effect on the detection thresholds for brief gaps, the behavioral effects of suprathreshold gaps were substantial. The longest gap, 15 msec in duration, produced 58% ($\pm$ 1.6%) inhibition in the youngest mice, 47% ($\pm$ 3.2%) in the middle group, and just 37% ($\pm$ 2.4%) in the oldest groups of mice. The analysis of these data showed that the age effect was highly significant, F (2,217) = 27.0, $P < 0.0001$, and in contrast to the effects of age on threshold, which accounted for but 3% of the variance, age accounted for 20% of the variance in asymptotic inhibition. In addition, while age substantially affected the variance of the threshold data, age had no effect on the variance of the inhibition data.

These data suggest that a major difference between young and old animals in their response to brief gaps in noise has to do with the behavioral effectiveness of the longer gap stimuli. As in humans, the ability to detect gaps presented at brief intervals is evidently maintained by many of the older animals, and their thresholds do not differ from those of the younger mice; in contrast, the behavioral effectiveness of suprathreshold gaps is substantially and more uniformly impaired in the older mice. These behavioral data are found to have many parallels in the neural activity of cells recorded in the auditory midbrain of a subgroup of these same mice. Together these data indicate that the time constant of the neural machinery required for tracking a rapidly changing acoustic event, characteristic of a speech signal, for example, is little affected by age, save in a small subgroup of aged listeners. In contrast, many aged listeners appear to be less successful than most young listeners in effectively responding to suprathreshold stimuli: measured either behaviorally or neurally, the aged auditory system is less able to generate a substantial response to a suprathreshold input.

2. Neurophysiological Correlates of Acoustic Gap Detection

Single unit studies were conducted on mildly tranquilized mice to determine if relations existed between the behavioral gap coding and the underlying neurology (Walton *et al*., 1997). At least 1 day prior to single neuron recording, a small threaded holding tube and indifferent electrode were attached to the skull with cyanoacrylate glue and dental acrylic under avertin anesthesia (0.02 ml/g body weight). Experiments were carried out in a heated (27–30°C) soundproofed booth. A small hole (approximately 500 mm diameter) was drilled over the surface of the inferior colliculus under methoxyflurane anesthesia. During experiments, mice were mildly tranquilized with taractan (5–12 mg/g body weight) and placed in a form-fitting plastic restraint attached to a custom-built stereotaxic frame. Metal tungsten (1–3 MΩ) or glass microelectrodes (8–12 MΩ) were advanced through the inferior colliculus using a remote-controlled micropositioner. Single units were isolated using conventional electrophysiological techniques and recording sites were verified to be in the central nucleus of the inferior colliculus using horseradish peroxidase histochemistry.

Stimulus generation and manipulation were computer-controlled using a digital signal processing platform (Tucker-Davis AP2) and custom software package. The amplified output was led to a high frequency leaf tweeter (Panasonic 100) having a frequency response ranging from 1 to 100 kHz and located at 30° contralateral azimuth. Noise was digitized from 2 to 60 kHz and normalized to within $\pm$ 2 dB by measuring the transfer function at the entrance of the external meatus (1/4″ B and K microphone). A second DAC channel synthesized continuous background noise which was attenuated independently. The noise carrier used for the gap stimulus and the background noise were ''fresh'': they were selected at random from a 7.2-sec-long normalized noise buffer at temporally different points for each of the 75 stimulus repetitions.

After a single unit was isolated, best frequency and minimum threshold were determined audiovisually. An automated gap series was then presented in quiet and in various signal-to-noise (S/N) ratios. Carrier intensity was typically 65 dB SPL with an overall duration of 150 msec and a cosine-shaped rise/fall time of 5 msec. A quiet gap of variable duration and 0.5 msec rise/fall time was inserted 100 msec into the noise carrier. The standard gap series consisted of gap durations of 1, 3, 6, 12, 24, 48, 96, and 0 (control) msec. The custom software time-stamped each spike arrival with a precision of 10 msec.

A neuron's ability to encode the gap is typically observed qualitatively as a difference in spike counts occurring either during the gap or in response to the second noise burst (correcting for neural latency). Composite histograms [summations of all the poststimulus time histograms (PSTHs)] were generated from the complete gap series in order to ''blind'' the analysis. The first composite histogram was simply the summation of all the PSTHs, and allows the offset latency to noise burst 1 to be determined. The second composite was constructed by shifting each gap file back in time by its appropriate gap duration, thus lining up the response to the second noise burst. Two time windows, quiescent and driven, were computed from the composites and the spike counts for each stimulus epoch was submitted to a Wilcoxon-signed rank test so that for each gap duration in a series a statistical comparison was made between the spike arrival times for control and gap stimuli. This analysis formed the bases for quantification of neural gap detection. The minimum gap threshold was defined as the shortest gap duration capable of producing a significant difference ($P < 0.05$) from the control, provided that the next largest gap stimulus also produced a significant effect.

In the case of startle inhibition, a decrease in the amplitude of the startle response is observed as gap duration increases. This is illustrated in Fig. 39.8 (adapted from Walton *et al*., 1997) where changes in the startle response, with increases

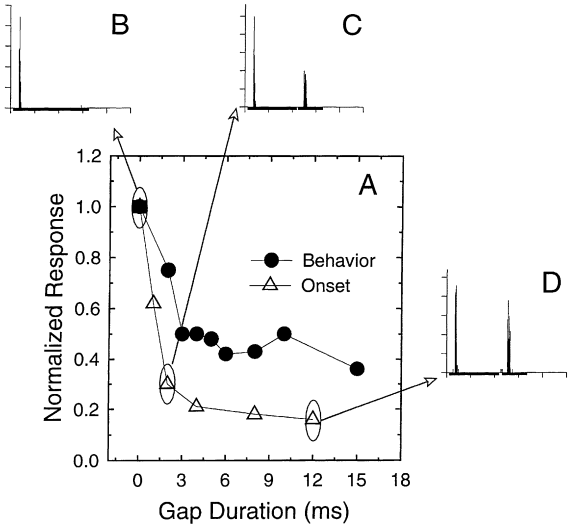

FIG. 39.8. Comparison of behavioral and neurophysiological measures of gap detection revealed the same functional relationships. (A) Mean acoustic startle results from five animals are plotted with normalized gap functions for the On ($n = 15$) units measured from the inferior colliculus in the same animals. Taking the spike counts in a control window (no response to the gap) and computing the relative change from the control value at each gap duration normalized the single unit data. (B) Single-unit PSTH showing normal onset response, with no gap. (C) PSTH showing response to a short gap (3 msec). (D) Response to a longer gap (12 msec.). (Adapted from Walton *et al*., 1997, with permission from Springer-Verlag.)

in gap duration, are plotted as filled circles (Fig. 39.8A). A normalized response of 1.0 represents the control condition, or no gap, and maximum startle amplitude. As the gap duration increases, the startle amplitude decreases and the function becomes asymptotic at about 6 msec. The neural data (open triangles) represent the mean change in discharge rate of 15 phasic type units located in the inferior colliculus. Phasic units comprise roughly 60–70% of the unit types encountered in the inferior colliculus. Phasic type neurons typically have very low background activity and discharge at the onset of each noise burst that marks the gap. The three PSTHs represent the response of a phasic unit to three different gap durations, 0 msec or the control condition (Fig. 39.8B), 3 msec (C), and 12 msec (D). To compare the startle data to the neural data, each unit's response magnitude was normalized by computing changes in spike counts relative to the control condition (Fig. 39.8B), which was represented by a value of 1.0. As the gap duration exceeded the gap threshold, phasic units exhibit rapid increases in the number of discharges evoked by the second noise burst (Figs. 39.8C and 39.8D). Although the absolute asymptote differs slightly between the behavioral and the neural data, the shape of the functions are remarkably alike. Both are characterized by a rapid change in response magnitude for gap widths up to 3 msec, and then asymptote for gaps longer than 4 msec in duration.

At the level of the inferior colliculus and auditory cortex, the majority of neurons display phasic type discharge patterns in response to noise bursts. The gap encoding ability of inferior colliculus neurons suggests that the neural code required for the perception of silent periods in ongoing sounds may be encoded by phasic type units. Considering the neural signal-to-noise ratios about acoustic signals that inferior colliculus neurons send rostrally to "central processors," phasic neurons would appear to be optimally suited for gap detection. Specifically, the targets of ON units would receive an unambiguous neural signal time locked to the second noise burst marking the gap. In addition, most ON units display rapid exponential increases in spike count as gap width increases from 1 to 10 msec (Fig. 39.8A). This results in a very high probability of discharge, which can approach >1 spike per stimulus. Correlation across many ON units could be used as a determinant of "gap detection," thus providing the neural mechanism for gap encoding. This investigation marked the first demonstration of possible neural correlates of gap detection in single neurons of the mammalian central auditory system

B. Aging Effects on Neurobiology of Temporal Processing: Animal Models

1. Neural Correlates of Acoustic Gap Detection: Single Cell Physiology

After demonstrating that nerve cells of the auditory midbrain can encode acoustic gaps in a manner similar to the behavior for the same species, investigations were undertaken to see whether this neural processing changed with age (Walton *et al*., 1998). It was hypothesized that there would be age-related degradations in the abilities of single nerve cells to encode gaps. To test this hypothesis, the same neurophysiological recording and analysis procedures were used as described in the previous section. Except here, not only were responses of nerve cells in young adult animals characterized, but also in aged animals of the CBA mouse strain. Based on extracellular recordings from 185 single nerve cells, it was discovered that the number of nerve cells capable of encoding very short duration acoustic gaps significantly declined in the old animals (Fig. 39.9) (Walton *et al*., 1998). This figure shows that about one-half of the nerve cells sampled from young animals can encode very short gaps (1 msec). Whereas only about 20% of the nerve cells of old animals can perform at this same level. In

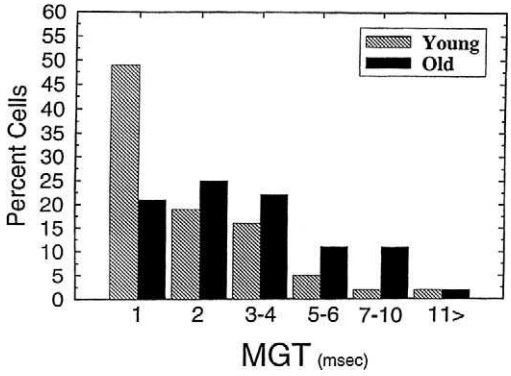

FIG. 39.9. Proportion of units having minimum gap thresholds (MGT) ranging from 1 to >11 msec for the young (hatched bars, n = 78) and old (filled bars, n = 108) mice. Note that the distribution favors considerably higher gap thresholds for the units from old animals. (From Walton *et al*., 1998, with permission from the Journal of Neuroscience.)

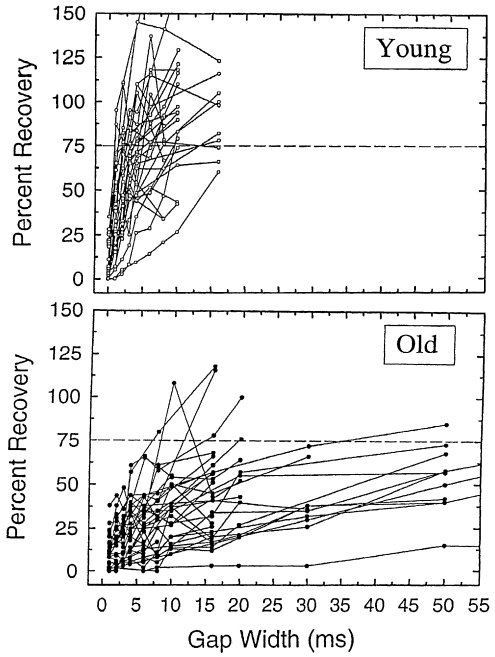

FIG. 39.10. Neural recovery functions plotted for 30 phasic units (ON and ONs types only) in young (top) and old (bottom) animals. Neural recovery was quantified by computing the number of spikes elicited by the second noiseburst (NB2) divided by the spike count to the first noiseburst (NB1) $\times$ 100. This was done for every histogram in the gap series. A recovery value of 100% would represent equal discharges to both NB1 and NB2. Dashed horizontal lines represent 75% recovery. Recovery to the 75% criterion is complete by $\leqslant$ 10–15 msec in nearly every neuron from the young animals, whereas most neurons from old animals do not reach this criterion for any of the gap durations tested. Note also that many neurons from young animals show facilitation; e. g., the response to NB2 is greater than NB1 for certain gap durations but this rarely occurred for neurons from old animals. (From Walton *et al*., 1998, with permission from the Journal of Neuroscience.)

addition, examination of this figure shows that the distribution of nerve cell gap encoding abilities shifted to longer gap durations in the old animals.

Not only was the sensitivity to gaps in sounds investigated, i.e., gap thresholds, but the strength of the neural responses to the gaps were also measured. This was done by comparing the number of neural action potentials, or "spikes," in response to the gap, relative to the response at the beginning of the noise burst that preceded the gap (Fig. 39.10) (Walton *et al*., 1998). In this figure, "Percent Recovery" is the proportion of action potentials in response to the gap, relative to the action potentials in response to the beginning of the noise burst that was presented before the gap. One hundred percent means that the response to the gap equaled that to the beginning of the stimulus. If a nerve cell showed a weaker response to the gap, the recovery would be less than 100%. If a nerve cell showed a response greater than 100%, the gap response was "facilitated." Comparing the data for the young (top) versus the old (bottom), two differences are quite striking. First, most old nerve cells did not recover to the 75% level, for even the longest gap durations tested, whereas most young nerve cells were fully recovered at relatively short gap durations (less than 15 msec). Second, many of the young nerve cells showed facilitated responses to the gap stimuli. Whereas this was virtually never seen in any of the nerve cells from old animals.

2. Neural Correlates of Acoustic Gap Detection: Nerve Cell Locations

At the conclusion of single-nerve cell recording experiments, as described in the previous two sections, injections of the marker and tracer horseradish peroxidase were made in the center of the regions from which the recordings were made. This marker/tracer performs three investigative functions. First, it marks the center of the anatomical regions from which the neurophysiological recordings were made. Because the same animals were used in the neurophysiological and histological experiments, direct comparisons were made between nerve cell sensitivity to sounds and their locations in the brain. In the present experiments on neural bases of gap coding, the region recorded from was identified to be the dorsomedial region of the auditory midbrain. This region included portions of the midbrain subdivisions known as the central nucleus, the dorsal cortex, and the commissural nucleus. Examples and details concerning these horseradish peroxidase injection sites can be found in Fig. 39.11 (Frisina *et al*., 1997). Second, the horseradish peroxidase is taken up by nerve cells that have cell bodies in the region of the injection site and is transported anterogradely down their axons to their terminal endings. For primary nerve cells that send axons to other parts of the brain, the presence of horseradish peroxidase in terminal endings indicates output regions of nerve cells from the injection site. Similarities and differences in outputs of the dorsomedial portions of the young adult CBA mouse auditory midbrain were reported as a foundation for subsequent aging experiments (Frisina *et al*., 1997). Third, horseradish peroxidase is also actively taken up by any nerve cells that send terminal endings into the effective area of the injection site. Determination of the inputs to the dorsomedial region of the auditory midbrain in young adult animals was accomplished, and their likenesses and differences with other mammals noted. Also, a point of comparison for studies in middle-aged and old CBA mice (Frisina *et al*., 1998) was charted. Major input regions were similar to other rodents, including strong inputs from the contralateral cochlear nucleus, the ipsilateral periolivary nucleus, and the ipsilateral ventral nucleus of the lateral lemniscus, as presented in Fig. 39.12 (Frisina *et al*., 1998).

3. Neural Correlates of Acoustic Gap Detection: Plasticity of Inputs

Investigations of the anatomical inputs to the region we functionally characterized as having an age-related temporal processing deficit were made by repeating the horseradish peroxidase tracing experiments, described in the previous section, in middle-aged and old CBA mice. We found that there were significant declines for some of the input regions to this portion of the auditory midbrain. For example, reductions in the number of horseradish peroxidase-labeled nerve cells were seen from all three divisions of the contralateral cochlear nucleus (Fig. 39.13) and from the ipsilateral anterolateral periolivary nucleus (Fig. 39.14). In contrast, it was discovered that there

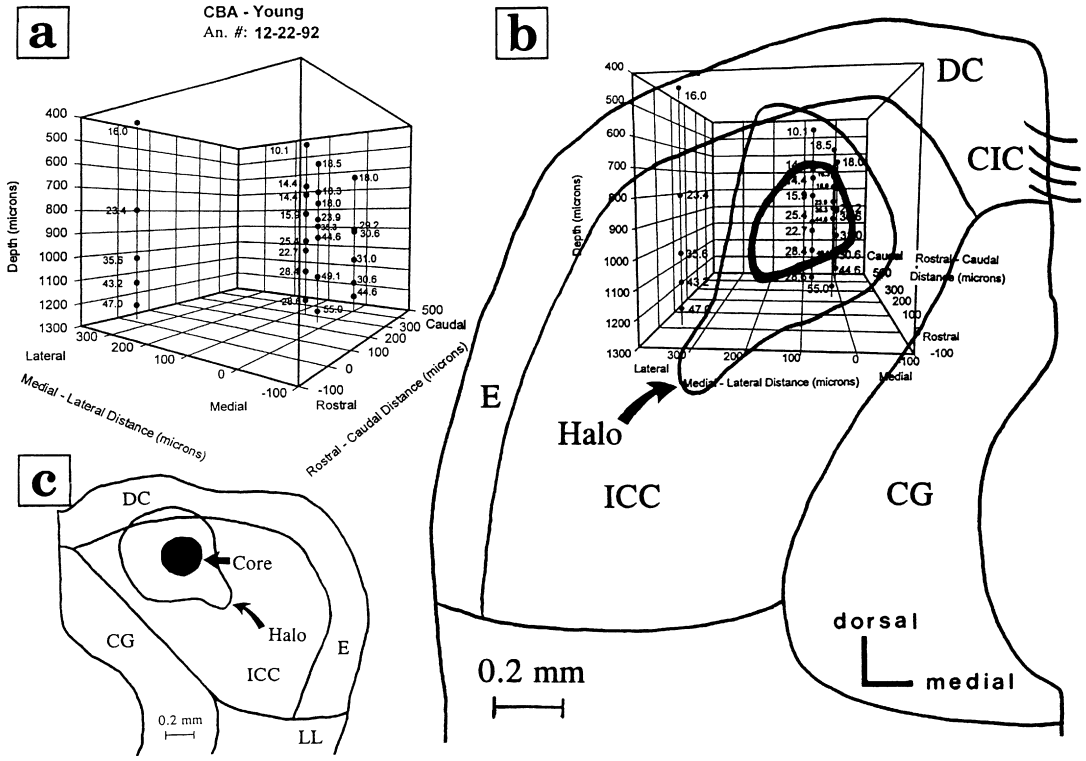

FIG. 39.11. Physiological recordings and iontophoretic injections of horseradish peroxidase were always centered in the 18 to 24 kHz region of the dorsomedial inferior colliculus, at about the halfway point rostrocaudally. Portions of the injection site halo and some of the recordings extended outside of this region as shown here. Boundaries between divisions within the inferior colliculus are based upon Willard and Ryugo (1983). (a) Example of a physiological map from one of the animals represented in a 3D graphical format. The best frequency of each single unit or multiunit cluster is given in kHz. The graph is rotated so as to provide a mediorostral vantage point. All axes are in arbitrary μm units. As expected, the best frequencies increase as one moves deeper in the inferior colliculus. An.; animal. (b) Correspondence of the physiological best frequency map (rotated to a paracoronal plane) and the neuroanatomical cytoarchitectonics. The dense core of the injection site has a bold border, and the halo a thin border (arrow). Injection sites were placed in dorsomedial central nucleus of the inferior colliculus (ICC) and halos sometimes extended into the dorsal cortex (DC). The 3D physiological data (a) are calibrated to the coronal, anatomical section at the 300 μm rostrocaudal plane, i.e., at the injection site center, both anatomically and physiologically. CG, central gray; CIC, commissure of inferior colliculus; E, external nucleus of inferior colliculus. (c) Camera lucida drawing of the dense core and halo of the center of the injection site in dorsomedial inferior colliculus from another animal (An. 12). Boundaries between ICC, DC, and E should be considered approximate since they are based upon Nissl-stained material (not Golgi). (Adapted from Frisina *et al*., 1997, with permission from the American Institute of Physics.)

was an age-related stability of inputs from the other regions of the auditory brain stem such as the rest of the superior olivary complex (Fig. 39.14) and nuclei of the lateral lemniscus (Fig. 39.15). It was noteworthy that behavioral measures of auditory temporal processing also started showing signs of age-related decline in middle-aged animals, correlated with the middle-aged declines in the inputs revealed here, despite the fact that middle-aged CBA mice have minimal changes in sensitivity to sounds (cochlear thresholds) (Frisina *et al*., 2000).

4. Neural Correlates of Acoustic Gap Detection: Immunocytochemistry Studies

The presence of calcium-binding proteins, involved in the intracellular regulation of calcium stores, was next examined in the same region of the auditory midbrain (dorsomedial inferior colliculus) that showed functional temporal processing declines with age as well as the reductions in neural inputs described in the previous section. Indicators of calcium regulation were examined since intracellular calcium imbalances are so intimately involved in cell function and death. Labeling with antibodies to calbindin and calretinin in young and old CBA mice were examined qualitatively and quantitatively. Quantitative analyses, including blind counts of immunostained cells, revealed a change in the presence of these calcium binding proteins with age (Zettel *et al*., 1997). As shown in Fig. 39.16 (Zettel *et al*., 1997), significant declines in the number of calbindin-immunoreactive nerve cells declined with age in the inferior colliculus region exhibiting the declines in auditory temporal processing. This reduction in the presence of calbindin appeared not to be related to the residual hearing of the CBA strain, because it also took place in the C57 strain that is profoundly deaf in old age. Age-related declines in calbindin immunoreactivity had previously been observed in other brain systems, so the reduction observed here was not unexpected.

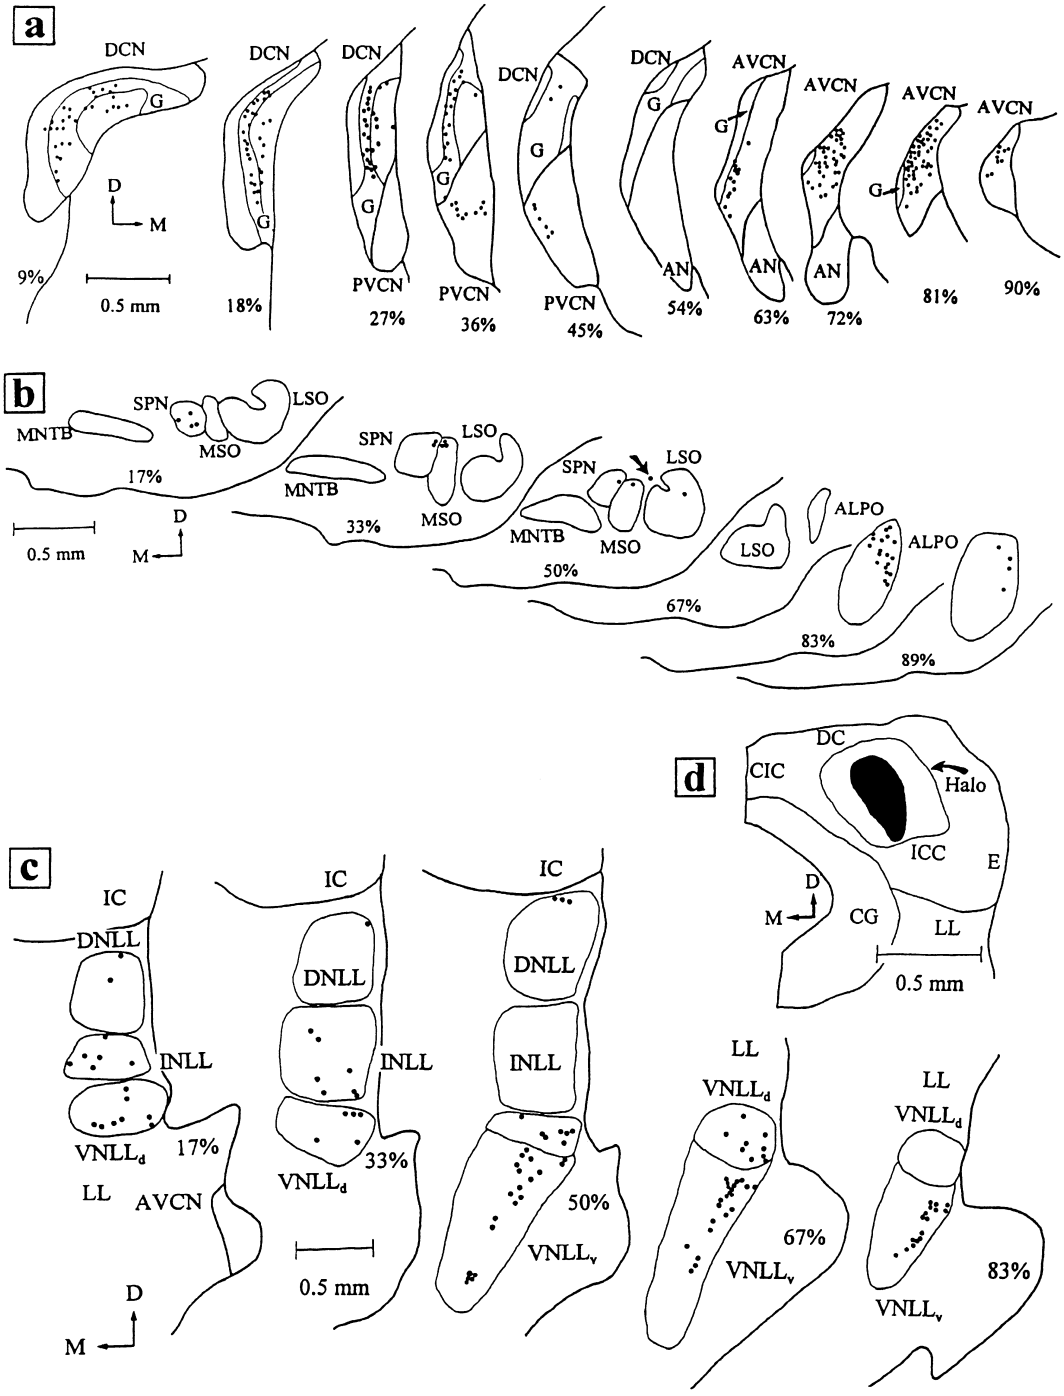

FIG. 39.12. Distribution of labeled neurons in serial coronal sections of contralateral cochlear nucleus (CN), ipsilateral superior olivary complex, and ipsilateral nucleus of the lateral lemniscus (NLL) from representative animals. (a) Camera lucida drawings showing spatial distribution of retrogradely labeled neurons in dorsal CN (DCN), posterior ventral CN (PVCN), and anterior ventral CN (AVCN). Percentages indicate distance from the caudal boundary of the CN. (b) Camera lucida drawings showing spatial distribution of retrogradely labeled neurons in the superior olivary complex. Arrow designates a labeled neuron in dorsolateral periolivary nucleus (DLPO). DNLL, dorsal nucleus of lateral lemniscus; ALPO, anterolateral periolivary nucleus; LSO, lateral superior olivary nucleus; MNTB, medial nucleus of the trapezoid body; MSO, medial superior olivary nucleus. Percentages indicate distance from the caudal boundary of the superior olivary complex. (c) Camera lucida drawings showing spatial distribution of retrogradely labeled neurons in the NLL. DNLL, dorsal nucleus of lateral lemniscus; INLL, intermediate nucleus of lateral lemniscus; VNLLd, ventral nucleus of lateral lemniscus, dorsal division; VNLLv, ventral nucleus of lateral lemniscus, ventral division. Percentages indicate distance from the caudal boundary of the NLL. (d) Camera lucida drawings showing spatial extent of the injection site in the dorsomedial inferior colliculus, centered in the 18 to 24 kHz physiological region. (D), dorsal; M, medial; CG, central gray; CIC: commissure of the inferior colliculus; DC, dorsal cortex of IC; E, external nucleus of inferior colliculus; ICC, central nucleus of inferior colliculus; LL, lateral lemniscus. (Reprinted from Frisina *et al.*, 1998, with permission from Elsevier Science.)

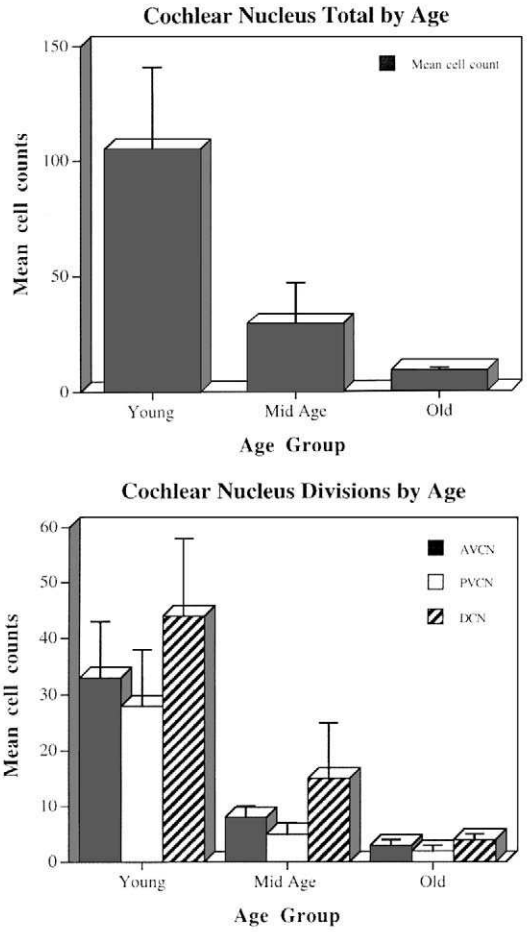

FIG. 39.13. Significant declines occurred for the inputs from the contralateral cochlear nucleus in the middle-aged and old animals relative to the young animals. (top) Large declines occurred for the total number of labeled neurons from all three divisions of the cochlear nucleus. The most dramatic decline was from the young to the middle-aged group. (bottom) Breakdown of mean cell counts for each division of the contralateral cochlear nucleus. As with the total number of cells (top), the most noticeable decline occurred in middle age. The relative declines were similar for all three divisions; i.e., the DCN always had the most labeled neurons, and the PVCN, the least. AVCN, anteroventral cochlear nucleus; DCN, dorsal cochlear nucleus; PVCN, posteroventral cochlear nucleus.

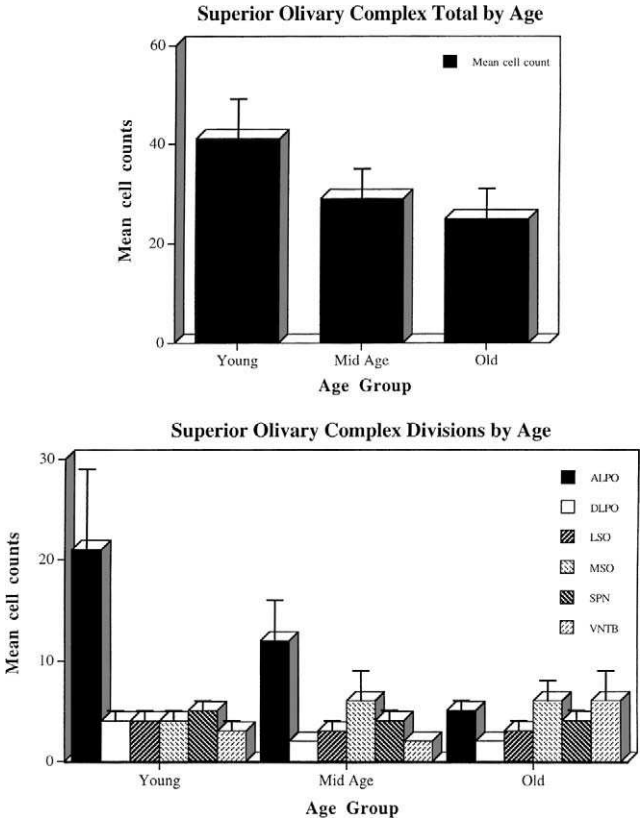

FIG. 39.14. Significant declines occurred for the inputs from the ipsilateral superior olivary complex in the middle-aged and old animals relative to the young animals. (top) Large declines occurred for the total number of labeled neurons summed over all the divisions of the olivary complex. (bottom) However, examination of the superior olivary complex nuclei that contained horseradish peroxidase-labeled neurons indicates that only in ALPO, which contains most stained cells in young animals, is there a significant age-related decline. ALPO, anterolateral periolivary nucleus; DLPO, dorsolateral periolivary nucleus; LSO, lateral superior olivary nucleus; MSO, medial superior olivary nucleus; SPN, superior paraolivary nucleus; VNTB, ventral nucleus of the trapezoid body.

What was surprising was that an upregulation of the presence of calretinin was discovered in this same region of the auditory midbrain for the CBA mouse strain. It may be that this increase was required for, or was in response to, the functional activity of these nerve cells in the old mice who could still hear, but who had reductions in their abilities to resolve timing aspects of sound. No age-related change in calretinin was observed in the C57 strain that is profoundly deaf in old age.

IV. Summary and Future Directions

In general, hearing loss in the aged has been attributed to ''presbycusis.'' However, to appreciate the specific problem that we addressed, it is necessary to understand the subtle but real distinction between ''hearing loss in the elderly'' and ''hearing loss due to biological aging.'' The former may result from a variety of acoustic insults that accumulate with time. For example, long-term exposure to noise and ototoxic substances, dietary factors, and circulatory deficiencies have been shown to exert deleterious effects on hearing due to hypoxia or glucose deprivation. It may be that the aging auditory system is more fragile and thus shows a greater effect of acoustic trauma. However, these insults are not inevitable and may be prevented in aging, for example, by appropriate changes in the noise condition of one's work and recreation, dietary habits, or early medical treatment. Alternatively it could be that physiological function is compromised and anatomical structure is degraded in the aged central and peripheral nervous systems even in the absence of explicit acoustic or metabolic threats. In order to make such distinctions our overall strategy was based upon two assumptions that could be tested in principle. The first assumption was that acoustic insults such as those described above have a specific affinity

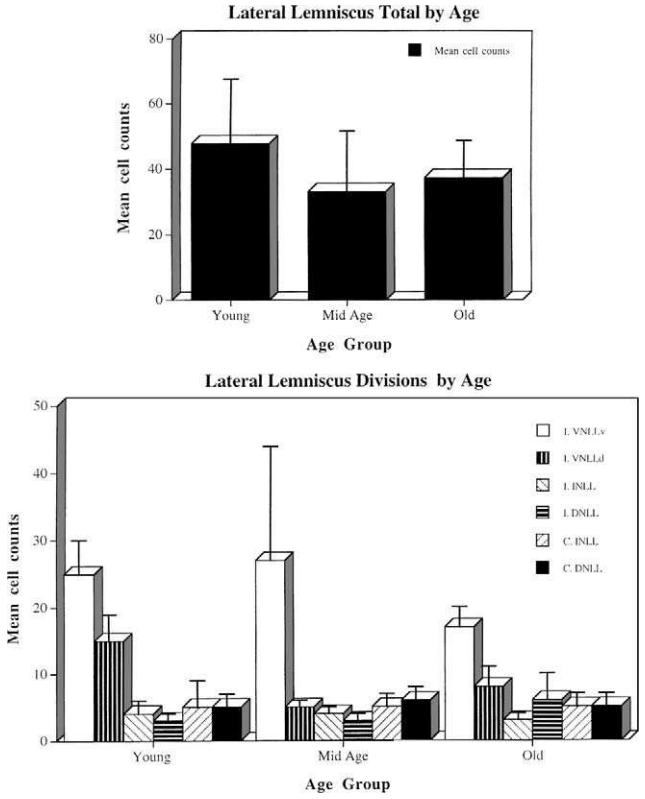

FIG. 39.15. In contrast to the cochlear nucleus and superior olivary complex, only modest declines (not statistically significant) were observed from the ipsilateral nuclei of the lateral lemniscus (NLL). (top) Overall declines in labeled neurons from NLL were small. (bottom) Ipsilateral VNLLv had the most labeled cells, and showed a small decline in the old animals. Ipsilateral VNLLd showed a modest decline in the middle-aged mice. The rest of the nuclei had low numbers of stained neurons that showed no age trends. C, contralateral; DNLL, dorsal nucleus of LL; I, ipsilateral; INLL, intermediate nucleus LL; LL, lateral lemniscus; VNLLd, ventral nucleus of LL, dorsal division; VNLLv, ventral nucleus of LL, ventral division.

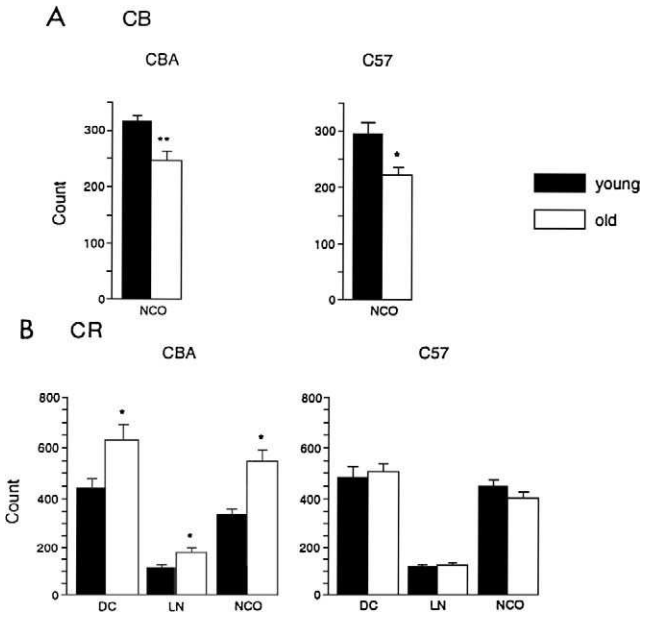

FIG. 39.16. (A) The average number of calbindin-immuneactive cells in the nucleus of the commisure (NCO) of the inferior colliculus (IC) of young (filled bars) vs old (unfilled bars) CBA and C57 mice. Error bars denote standard error of the mean. Calbinin-containing cells declined significantly in old mice of both strains. (B), The average number of calretinin-immuneactive cells in dorsal cortex (DC), lateral nucleus (LN), and NCO of young vs old CBA and C57 mice. Calretinin-containing cells increased significantly in all three areas in old CBA mice, but there were no significant differences between young and old C57 mice. ($^{*}P < 0.005$;$^{**}P < 0.01$). DC, dorsal cortex of inferior colliculus; LN, lateral nucleus of inferior colliculus; NCO, nucleus of the commisure of inferior colliculus. for peripheral locations within the auditory system, and thus persons with no apparent peripheral hearing loss may be assumed to be essentially free from traumatic insult. The second assumption was that animal models of presbycusis were available that captured the essential features of human presbycusis and would therefore allow us to differentiate central and peripheral neural effects on hearing in the aged.

Parallel human and animal multidisciplinary experiments on temporal processing were carried out to test these assumptions. Results from system-level experiments in humans suggested that reduced speech perception in background noise, characteristic of presbycusis, is likely caused by functional declines in the brain's temporal processing capacity. Further, manifestations of this decline were seen at the single-cell level in the auditory brain stem of experimental animals. In turn, associated structural and chemical changes in the same animals were found that could account for these functional declines. Future advances aimed at arresting, reversing, or preventing presbycusis are likely to rely upon pharmacological agents (medication or diet) and new developments in gene therapy.

Neurophysiological Manifestations of Aging in the Peripheral and Central Auditory Nervous System

I. Introduction

The auditory system undergoes both age-related peripheral and central pathology. The former is obseved as a decline of sensitivity, while the latter is observed as alterations in neural processing in specific brain regions. Neurons can be selectively lost in a given brain region, and their interconnections reduced or severed. For example, large cortical neurons are lost and neuronal debris, plaques, and neurofibrillary tangles begin to appear. Synaptic connections, which provide the communication between neurons, are also degraded. These age-related structural changes certainly must affect the neural encoding of biologically relevant signals, including those involved in perception. In fact, one of the most devastating sensory deficits that accompany the aging process is the deterioration of auditory perception of biologically relevant sounds, clinically referred to as presbycusis.

Presbycusis is not only the most common communication problem among the elderly, it is also the most common auditory disorder in the entire population (Schoeborn and Marano, 1988). A common misconception is the belief that presbycusis solely involves dysfunction of the peripheral auditory system. Behavioral, neurophysiological and neuropharmacological evidence from human subjects and animal models of presbycusis indicate that there are age-related alterations in the central auditory system as well. This chapter explores the neurophysiological manifestations of aging in the peripheral and central auditory system at a microscopic and macroscopic level. Studies involving the recording from single brain neurons will provide the microscopic view, while auditory evoked potential (AEP) studies, which measure neural activity from populations of neurons, will provide macroscopic insight.

II. Animal Models of Presbycusis

One advantage of using AEPs to measure auditory function is that it enables investigators to compare data from animal models to data from human subjects using similar stimulus paradigms. In contrast, in order to investigate aging at the single neuron level one needs to incorporate animal models of presbycusis. Animal models are required because of the invasive nature of single nerve-cell electrophysiology. In addition, animal models offer several practical advantages to the study of age-related changes in the peripheral and central auditory systems, including short life spans and the ability to control extraneous variables that might alter auditory function, including noise exposure and susceptibility to middle-ear disease.

Not surprisingly, humans are not alone in suffering from age-related hearing impairment. All of the common small laboratory rodents, including rats (Krauter *et al*., 1981), mice (Henry and Chole, 1980; Henry, 1982), gerbils (Schmiedt *et al*., 1990), guinea pigs (Altman and Dittmer, 1972), and chinchillas (McFadden *et al*., 1999), show evidence of peripheral auditory dysfunction with age. The chinchilla and gerbil offer audiograms which are grossly similar to that of the human; however, both are outbred strains that exhibit wide variability in hearing loss and cochlear pathology as they age. In addition, the long life span of the chinchilla (12–20 years) makes it impractical for most age-related research (McFadden *et al*., 1999). Al-though the mouse has an audiogram that is displaced several octaves higher in frequency than the human, its lifespan of 2–3 years is optimal for aging research. Furthermore, where genetic control is required, more research devoted to the auditory system has been done on two strains of laboratory mouse, the CBA and C57Bl/6, than any other species. These two strains differ in the time course, severity, and cause of their age-related peripheral hearing loss (Willott, 1984, 1986; Willott *et al*., 1988).

The hearing of the CBA strain remains stable throughout much of its life and then gradually declines to a very mild loss by 24 months of age. The C57Bl/6 strain offers a unique control to the CBA strain in that it develops a rapid, genetically induced, progressive sensorineural hearing loss over the first 12 months of its life (Henry and Chole, 1980; Willott, 1986; Li and Borg, 1992). As is true for humans, the progressive

loss of sensitivity for high frequency tones in the middle-aged hearing-impaired C57BL/6 mouse can be ascribed to degeneration in the peripheral receptive end organ (Mikaelian, 1979). It is interesting that the severe high-frequency hearing loss seen in the middle-aged C57BL/6 mouse is accompanied by a reorganization of central afferent connectivity at the level of the auditory midbrain and cortex, as has been shown in a series of impressive studies (Willott, 1986; Willott *et al*., 1993). At present there is no evidence to suggest that a similar reorganization follows peripheral degeneration in the brain of old CBA mice (Willott *et al*., 1988; Walton *et al*., 1998).

In this chapter, we will first review what is known about age-related changes in the auditory system from single-unit studies. This, of course, will be limited to nonhuman animal models and it is also limited by the auditory areas studied. Specifically, the effects of age on single-unit processing have yet to be investigated in the cochlear nucleus, medial superior olive, all trapezoid body nuclei, medial geniculate body and auditory cortex. This will be followed by a review of aging effects on AEPs, which will include both human and animal studies.

III. Single Neuron Studies

A. Aging and Auditory Nerve Activity

Sound is converted from mechanical energy into neural impulses within the cochlea via a complex hydromechanical transduction mechanism. The central auditory system has available to it the spike discharge patterns of the entire population of auditory nerve fibers and sound features are encoded in the trains of auditory nerve fiber action potentials generated within the cochlea. An extensive body of work has shown that the entire population of auditory nerve fibers encode stimulus properties, both by variation in discharge rate and action potential timing. Therefore, any type of dysfunction in the normal cochlear transduction process will lead to changes in auditory nerve activity. For example, in the case of a cochlea that has a high frequency noise-induced sensorineural hearing loss, a region of the cochlear base is damaged and behavioral thresholds are elevated in the frequencies corresponding to the damaged area. When recording from single auditory nerve fibers that innervate this region, one finds that their thresholds at best frequency (BF; frequency at which a unit responds at the lowest intensity) are also elevated.

Nearly all of the work on the effects of aging on peripheral auditory function has been done by a group at the Medical University of South Carolina using the Mongolian gerbil as the animal model. To avoid problems with noise exposure from ambient environmental sources, animals were raised in a special noise abatement facility which limited the amount of external noise present in their cages. The South Carolina group's first studies with ''quiet-raised'' gerbils focused on the effects of age on intensity coding of auditory nerve fibers. Auditory nerve fibers encode the intensity of simple acoustic stimuli by systematically varying their discharge rate. Typically the change in discharge rate is plotted as a function of intensity to form a rate-level function. The slope of a rate-level function represents the degree of change in neural responsiveness that results from increases in stimulus intensity. Nearly all auditory nerve fiber rate-level functions asymptote at moderate to high sound intensities. Thus, a steep function indicates that a neuron is able to encode small changes in intensity very effectively. Hellström and Schmiedt (1991) collected auditory nerve fiber rate-level functions and whole-nerve cochlear action potential amplitude-level functions from young and old gerbils. The whole-nerve evoked response represents the population response of many auditory nerve fibers. They reported that the slopes of the functions of the whole-nerve amplitude versus stimulus intensity were shallower in aged gerbils. However, no age effect was found when they compared the slopes of auditory nerve fiber rate-level functions from young and old animals, with slopes ranging from 2 to 25 discharges/dB, regardless of an animal age or a fiber's BF.

Hellström and Schmiedt (1996) also found that minimal age-related changes occurred in the filtering properties of auditory nerve fibers recorded in quiet-aged gerbils. They compared the slopes and suppression areas of tuning curves from auditory nerve fibers in young and old gerbils and found that only the tip-to-tail ratios were smaller and that high-frequency selectivity decreases in units from aged animals. This is directly related to the high frequency loss being greater than the low frequency loss, resulting in a slight elevation in the tip of the tuning curve. No differences were found in the slopes of the tuning curves or in the shape or size of the suppression areas.

Auditory nerve fibers have relatively high spontaneous activity compared with other neurons in the central auditory system. A fiber's spontaneous rate (SR) is the discharge rate observed in the absence of external stimulation. A classification scheme used in many studies separates the auditory nerve fiber population into two classes: low (<18 spikes/sec) and high ($\geq$18 spikes/sec) SR fibers. Low and high SR fibers also differ in other important characteristics. High SR fibers tend to have low acoustic thresholds, steep slopes of rate-level functions, and saturating rate-level functions. Low SR fibers have higher thresholds, shallower rate-level slopes, and, most importantly, low SR fibers tend to encode amplitude modulation, or the rapid fluctuation in stimulus intensity, very well (Winter *et al*., 1990; Joris *et al*., 1994; Frisina *et al*., 1996). Therefore, it is thought that low SR fibers could play an important role in recovery from masking to high intensity maskers because of their expanded dynamic range and exquisite temporal processing abilities. Schmiedt *et al*. (1996) found an age-related decline in the proportion of auditory nerve fibers which had low spontaneous activity. Figure 40.1 shows the effects of age on the distribution of SRs in young and old gerbil auditory nerve fibers for two different best frequency regions, above and below 6 kHz. In young gerbils, more low SR fibers (dashed bars) have BFs above 6 kHz than below 6 kHz. In contrast, a similar proportion of high spontaneous rate auditory nerve fibers have BFs above and below 6 kHz, regardless of age. However, in old gerbils the proportion of low SR fibers with BFs above 6 kHz decreased by about 30%, which was significantly different when compared to that seen in young animals.

The South Carolina group's research findings concerning age-related changes in driven activity of auditory nerve fibers can be summarized as follows: (1) auditory nerve fiber responses in aged gerbils generally reflect changes in cochlear thresholds, (2) auditory nerve intensity and frequency coding are affected, but only mildly, and (3) there appears to be an

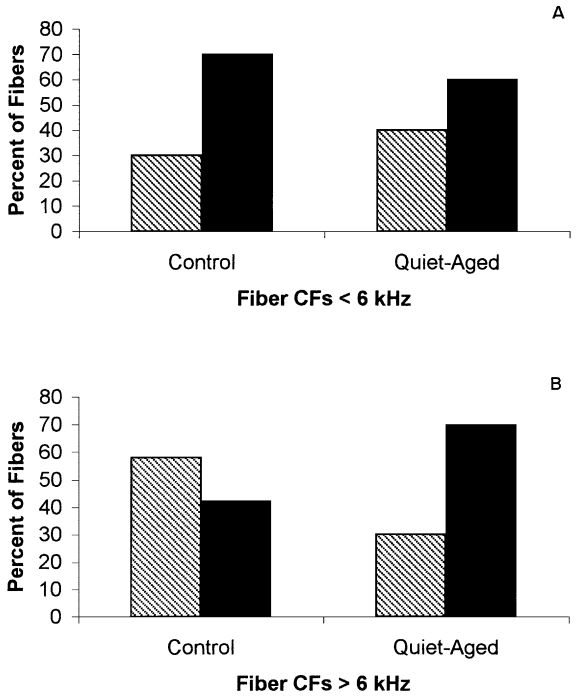

FIG. 40.1. Effects of age on spontaneous discharge rates (SRs) of auditory nerve fibers. The proportion of auditory nerve fibers encountered with low (<18 spikes/sec) and high (>18 spikes/sec) SRs for fibers with characteristic frequencies (CFs) below 6 kHz are shown in (A), while those with CFs above 6 kHz are shown in (B). Low SR fibers are indicated by the hatched bars and high SR fibers are indicated by the dark bars. For fibers with CFs less than 6 kHz the proportion of low and high SR fibers is similar. However, for fibers with CFs above 6 kHz the proportion of low SR fibers decreases and the number of high SR fibers increases in the aged animals. Adapted from Schmiedt *et al*. (1996), with permission of the author and publisher.

age-related decline in the number of auditory nerve fibers that have high thresholds and low spontaneous rates. An age-related factor in the maintenance of the endocochlear potential appears to be the underlying source of the deficits reported by the Schmiedt and coworkers. The endocochlear potential is a positive steady state potential which is generated in stria vascularis and provides the necessary driving potential for the transduction process. Numerous studies have shown that normal hearing depends on a normal endocochlear potential. Concurrently with the auditory nerve studies, Schulte and Schmiedt (1992) reported a reduction in the amplitude of the endocochlear potential with age and that the reduction is secondary to a decline in the ion transporting enzyme Na,K-ATPase located in stria vascularis (Gratton *et al*., 1995, 1996). Their data suggest that the drop in the endocochlear potential is directly related to decreased levels of Na,K-ATPase activity. They concluded that all of the findings related to auditory nerve activity could be explained by a systematic decrease in the endocochlear potential with age (Gratton *et al*., 1997).

B. Aging and the Superior Olivary Complex

The superior olivary complex is the first major convergence point for binaural information in the central auditory system. The major superior olivary complex nuclei involved in processing ascending information are the lateral superior olive (LSO), medial superior olive (MSO), and medial nucleus of the trapezoid body. Neurons in the LSO and MSO receive, and compare inputs from both ears following processing by the cochlear nuclei. In the LSO, when a sound arises from the ipsilateral ear the neural input is excitatory, and when the sound arises from the contralateral ear the input is inhibitory. Only one study has investigated age-related changes in single unit responses to binaural stimuli in the LSO (Finlayson and Caspary, 1993). Previous neurochemical studies had reported age-related alterations in inhibitory neurotransmitters in brain stem nuclei involved in binaural processing (Caspary *et al*., 1990, 1995; Milbrandt *et al*., 1994). Finlayson and Caspary (1993) hypothesized that this should lead to deficits in the ability of neurons to encode binaural signals, since neural processing of binaural inputs in the LSO is shaped by the interplay of excitatory and inhibitory circuits arising from each ear. To test this hypothesis, they recorded from single neurons in the LSO from young and old Fisher 344 rats and found that other than the characteristic age-related threshold shift nearly all other parameters studied remained stable with age. Although differences between young and old rats did not reach statistical significance, a greater proportion of neurons from old rats exhibited lower inhibitory drive when the contralateral ear was stimulated. This trend is supportive of the idea that a decline in inhibition may reduce the contrast in binaural signals, resulting in the perceptual deficits observed in elderly listeners.

C. Aging and the Auditory Midbrain

The auditory midbrain, or inferior colliculus, represents the first major convergence of both binaural and monaural neural information in the auditory system. The cytoarchitectonics of the central nucleus of the inferior colliculus (ICc) is remarkable, in that neurons form laminar sheets analogous to the layers of an onion. Each sheet is formed by the perikarya and processes of principal, or disc-shaped neurons whose dendrites extend outward in a circular fashion. A second type of ICc neuron is a stellate cell with dendrites that extend across the laminar sheets, an arrangement that is thought to allow for parallel processing within and across laminae. The tonotopic organization of the ICc is formed by the individual laminae, with each lamina representing a narrow range of frequencies. If an electrode is passed through the middle of the inferior colliculus and BFs are sampled, low frequencies are represented dorsally and high frequencies ventrally.

Sophisticated neural processing occurs within each lamina. For example, Langner and Schreiner (1988) found that amplitude modulation was mapped in a systematic fashion onto individual laminae. A similar systematic map is also found for sound intensity, where the most sensitive neurons (lowest thresholds) are located near the center of an isofrequency lamina and neurons with increasingly higher thresholds fall on concentric isointensity contours around the center (Stiebler and Ehret, 1985). Thus, the characteristics of the neuronal architecture within each lamina could provide a basis for parallel processing of complex acoustic signals, so that multiple sound features (e.g., frequency, intensity, amplitude modulation, etc.) could be analyzed simultaneously.

Willott was the first to examine age-related changes in basic response properties of inferior colliculus neurons in the CBA mouse model of presbycusis (Willott *et al*., 1988). Willott observed only minor age-related changes in responses properties of 2-year-old CBA/J mice. Multiple-unit recordings revealed a slight reduction in sensitivity across all frequencies, and a maintenance of the ICc's tonotopic organization and of the Q_{10}s (sharpness of threshold tuning curves) in 22-month-old mice. In old mice, although single units in the ICc showed no alterations in their temporal response patterns to tonal stimuli and were generally responsive to suprathreshold sounds, there were several signs of more subtle aging dysfunction. There was an increase in the number of so-called "sluggish" units, or neurons which responded with fewer than 50 action potentials for the entire recording period, regardless of sound intensity. Sluggish neurons were found to increase with age, comprising 3% of the neuronal population in the young inferior colliculus, but increasing to 22% in the old inferior colliculus.

Willott and colleagues also discovered the connection between altered neural processing in aged inferior colliculus neurons and their topographic location. Specifically, while no age-related change was noted in spontaneous activity across the whole inferior colliculus, when the dorsal (low frequency) and ventral (high frequency) regions of the inferior colliculus were analyzed separately, an age-related difference emerged. In the dorsal inferior colliculus the proportion of neurons which were spontaneously active decreased with age, while in the ventral inferior colliculus the number of units increased with age. Several parameters of single-unit response areas were measured, including BF, upper and lower frequencies to which a unit was responsive at 80 dB SPL and BF for rate (the frequency to which the unit exhibited the greatest number of spikes). Figure 40.2 summarizes these results and shows that there was a decrease in the upper frequency to which units from old mice would respond. This implies that the frequency selectivity of these units had been altered without affecting threshold or rate BF.

With respect to binaural processing in the inferior colliculus, the initial combination of signal processing by the two ears occurs at the level of the SOC, and further processing takes place in the nuclei of the lateral lemniscus (NLL). The targets of SOC and NLL neurons project to inferior colliculus neurons with similar BFs. Palombi and Caspary (1996a) measured binaural response properties for inferior colliculus neurons in young and old rats. Because binaural responses are shaped by the summation of excitatory and inhibitory inputs, Palombi and Caspary hypothesized that if there were an age-related alteration in inhibitory neurotransmitters, binaural processing would be affected. Surprisingly, they found no statistically significant differences in any of the binaural responses properties, for units from young and old rats. The authors did report a trend toward encountering fewer E/I units in the aged rat inferior colliculus than in the young rat inferior colliculus.

These same authors published a follow-up study that investigated the effects of age on monaural response properties to simple sinusoidal stimuli in the Fisher 344 rat (Palombi and Caspary, 1996b). The temporal response patterns of neurons located in the central nucleus and external nucleus of the inferior colliculus were classified into four groups: onset, pause, sustained, and inhibitory (Fig. 40.3). In the central nucleus

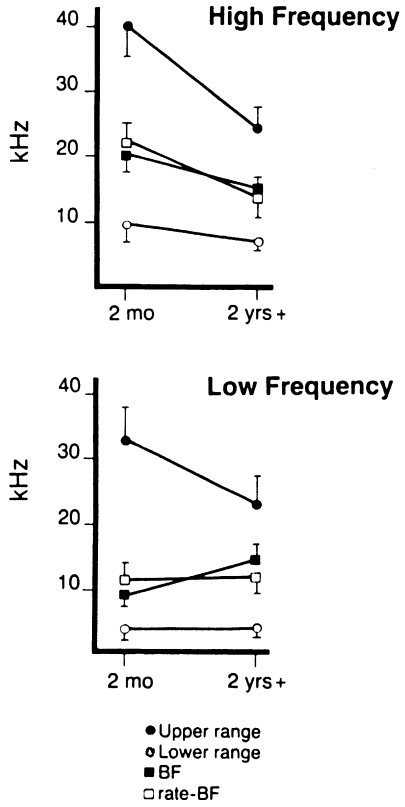

FIG. 40.2. Characteristics of excitatory tone response areas in young (2-month-old) and old (>24-month-old) CBA mice for neurons encountered in the dorsal (low-frequency) and ventral (high-frequency) regions of the central nucleus of the inferior colliculus. The upper (•) and lower boundaries (○) represent the edges of the low- and high-frequency sides of the response area. The best frequency, (BF, ■) represents the frequency–intensity combination at threshold. The rate-BF (□) is the frequency at which the strongest response occurred. Note that in both the high- and the low-frequency regions of the inferior colliculus the upper boundary of the excitatory response area significantly decreases in the aged animal. Error bars represent standard error of the mean. From Willott *et al*. (1988), with permission of the author and publisher.

there was a decline in the proportion of units with onset type patterns with advancing age, and this appeared to be compensated for by a slight increase in pause and sustained patterns. Overall, aging did not appear to affect the proportion of the different types of temporal response patterns encountered in the external nucleus. They also found no effect of age on the spontaneous rates and no change in the mean absolute first spike latency of inferior colliculus neurons from old rats when compared to young rats. Aged neurons did appear to be affected in the manner in which stimulus intensity was encoded. Specifically, there was a decline in the percentage of units displaying nonmonotonic rate-level functions. The mean maximum discharge was significantly lower in aged neurons, decreasing over 11%. The authors conclude that these age-related changes reflect a subtle, but real, deficit in the dynamic range of many neurons recorded from old rats. They postulate that the alteration in dynamic range might be due to a loss of inhibition, especially at higher intensities.

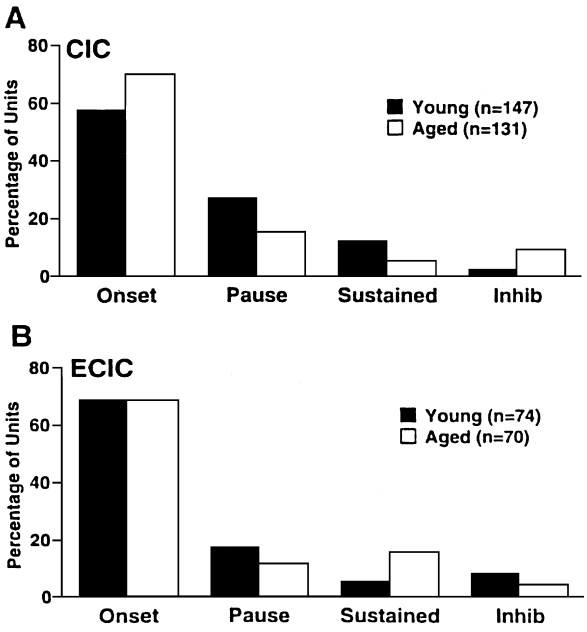

FIG. 40.3. Proportion of inferior colliculus neurons which were classified into the four response patterns: onset, pause, sustained, and inhibitory, in young and old Fisher 344 rats. The data are derived from the central (top) and external (bottom) nuclei of the inferior colliculus. The number of units from young and old rats are shown in each panel. There was a slight increase in proportion of onset units in the aged rat, which was offset by a slight decrease in pausers and sustained units. From Palombi and Caspary (1996b), with permission of the author and publisher.

D. Age-Related Deficits in Neurophysiological Correlates of Temporal Processing

Birren and Fisher (1995) characterized aging as a generalized slowing in the speed of behavior. The speed at which the auditory system processes incoming acoustic signals can be measured by several temporal processing tasks, one of which is gap detection. Gap detection requires the listener to detect brief silent intervals in an ongoing sound, usually a wideband noise (Plomp, 1964; Green and Forrest, 1989). Since one of the key factors contributing to poor speech recognition in elderly listeners is a deficit in temporal resolution, neurophysiological correlates of gap detection may provide evidence of a central auditory temporal processing component (Schneider *et al*., 1994; Fitzgibbons and Gordon-Salant, 1996; Snell, 1997). Walton *et al*. (1997) explored the relation between behavioral gap detection and neural correlates of gap detection in IC neurons recorded from the same young-adult mice, as a preface to investigating temporal processing in aged mice. This study addressed a common question in research which aims to compare behavioral and neurophysiological data: That is, can the neurophysiological representation of a given stimulus underlie the behavioral response?

In the Walton *et al*. (1997) study, behavioral gap detection was measured using the startle inhibition paradigm (see Chapter 39). This was followed by single-neuron recordings in the inferior colliculus using a similar gap detection paradigm. Behaviorally, increasing the gap duration results in an increase in the strength of startle inhibition, i.e., the perceptual salience of the gap increases. This is illustrated by the filled circles in Fig. 40.4, which represent the magnitude of startle inhibition plotted as a function of gap duration. A value of 1.0 represents the startle amplitude when there is no gap preceding the startle stimulus. As the gap duration increases, reflex inhibition increases and the startle amplitude decreases, with the function reaching an asymptote at about 6 msec. In order to compare the neural data to the behavioral data, two types of units which differ in their temporal response pattern were analyzed: onset and primary-like. Onset type neurons are characterized by their robust response to the onset of a stimulus, after which they either cease responding or show only a slight response for the duration of the stimulus. In contrast, primary-like units respond strongly to the onset and continue to respond vigorously throughout the remainder of the stimulus. Onset units encode gaps in ongoing stimuli by their onset response to the second noise burst, while primary-like units encode gaps by a complete cessation of activity during the gap. The neural data were normalized by computing the change in response strength evoked by the gap to the response of a control stimulus (no gap). The mean change in normalized discharge rate to

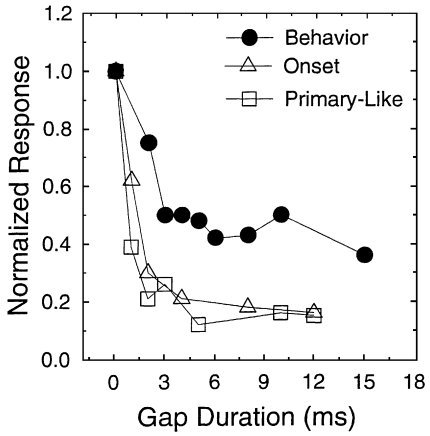

FIG. 40.4. Data comparing behavioral gap detection and neural encoding of gaps by inferior colliculus neurons in young CBA mice. Behavioral gap detection was measured using the startle inhibition paradigm. A value of 1.0 for the normalized response represents the control condition, or no gap, and maximum startle amplitude. As the gap duration increases the startle amplitude decreases and the function becomes asymptotic at about 6 msec. Neural encoding of gaps is shown for two different unit types, onset and primary-like. Phasic type neurons typically have very low background activity and discharge at the onset of each noise burst that marks the gap, while primary-like units discharge continuously to both noise bursts which mark the gap and stop discharging during the gap. In order to compare the startle data to the neural data, each unit's response magnitude was normalized by computing changes in spike counts elicited in a control condition, which is represented by a value of 1.0. As the gap duration exceeds the gap threshold, phasic units exhibit rapid increases in the number of discharges evoked by the second noise burst. Although the absolute asymptotes differ slightly between the behavioral and neural data, the time course of the behavioral and neural response are remarkably similar. All are characterized by a rapid change in response magnitude for gap widths up to 3 msec, and then asymptote for gaps longer than 4 msec in duration. From Walton *et al.* (1996), with permission of the author and publisher.

gaps at various durations is shown for onset units (triangles) and primary-like units (squares) for gap durations of up to 15 msec. Although the absolute asymptote differs slightly for the behavioral and neural data, the shapes of all three functions are remarkably alike. All three functions are characterized by a rapid change in response magnitude for gap widths up to 3 msec, and then asymptote for gaps longer than about 4 msec in duration.

The major difference in terms of gap encoding between onset and primary-like neurons is the background signal-to-noise level from which they operate in order to signal the presence of the gap. Onset neurons typically have very low spontaneous or ongoing activity and discharge at the onset of each noise burst marks the gap. In contrast, primary-like units respond vigorously before and after the gap. It is important to note that at the level of the inferior colliculus and auditory cortex the majority of neurons display onset discharge patterns in response to noise bursts (Irvine, 1986). Onset neurons, with their low spontaneous and sustained discharge rates, appear to be optimally suited for gap detection. The central targets of onset units would receive an unambiguous neural signal, time locked to the onset of the second noise burst marking the gap. In addition, most onset units display a rapid exponential increase in spikes as gap width increases from 1 to 10 msec (Fig. 40.4). This results in a very high probability of discharge, which can approach >1 spike per stimulus. If correlation across many onset units could be used for gap detection, then this would provide one central neuronal population mechanism for gap encoding. In summary, neurophysiological correlates of an auditory temporal processing task (gap detection), which appears to be related to presbycusic deficits, are present in the discharge patterns of the majority of inferior colliculus neurons in the CBA mouse.

Walton *et al*. (1998) systematically compared response properties and neural gap detection ability in inferior colliculus neurons of young and old CBA mice. Two questions concerning age-related changes in temporal acuity were asked. First, is the ability of the auditory midbrain to encode temporal features of sound (e.g., gaps) affected by age? Second, are there concomitant age-related changes in other single-unit response properties that could underlie behavioral gap detection? Neurons were studied using stimuli that were 20 dB or more above the specific units' threshold, and no correlation was found between threshold to tone or noise and gap threshold. The data in answer to the first question are shown in Fig. 40.5, indicating that aging does have an affect on neural gap detection. The frequency distributions shown in Fig. 40.5 represent single unit minimal gap thresholds of neurons from young and old CBA mice. Although short gap thresholds of 1 msec were observed in units from both young and old animals, the frequency of occurrence of thresholds of 1 msec was much lower in old CBA mice. More specifically, roughly 50% fewer neurons had gap thresholds of 2 msec or less in the inferior colliculus of old CBA mice relative to units from young mice. This magnitude of neuronal decline in temporal acuity parallels the behavioral deficit observed in gap detection studies in old mice (see Chapter 39).

Walton *et al*. (1998) also noted a second, more striking age-related difference, which is illustrated in the gap recovery functions of Fig. 40.6. They found that the majority of neurons

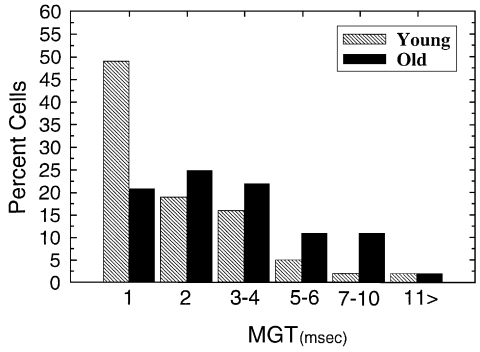

FIG. 40.5. Comparison of neural gap thresholds from IC units in young ($n = 78$) and old ($n = 108$) CBA mice. The proportion of units with the shortest gap thresholds decreases by about 50% in the old mice. This is offset by an increase in the number of units having longer gap thresholds of 2 msec or more in the old animals. From Walton *et al*. (1998), with permission of the author and publisher.

with onset response patterns displayed a deficit in neural recovery. Neural recovery can be quantified by comparing the spike counts to the first and second stimuli in the gap-detection paradigm. In Fig. 40.6 (top), gap recovery functions from young mice display rapid recovery, that is, the majority of units increase their spike counts to near control values (1.0) for gaps of about 10 msec. In contrast, in many neurons from old animals, the responses typically failed to recover to 75% of control values by 10 msec. It is also worthwhile to note that many units from young mice show enhancement or facilitation, where the response to the second stimulus exceeds the control response (response greater than 100%). This rarely occurred in neurons from old mice.

Another metric of neural temporal resolution is the mean first-spike latency, or the time it takes to elicit the first spike for each stimulus presentation. In the young CBA mouse inferior colliculus, the distribution of first-spike latencies is rather broad, spanning from several milliseconds to over 50 msec. The latency gradient runs along the tonotopic axis, with neurons having long first-spike latencies lying dorsally and those units with the shortest latencies located ventrally. Therefore units with low BFs should have long first-spike latencies and high BF units should have short first-spike latencies (Stiebler and Ehret, 1985; Willott, 1986; Walton *et al*., 1998). Mean first-spike latency was computed for the control stimulus for both young and old mice and is plotted as a function of BF in Fig. 40.7. As expected, response latency for units from young mice (top) declines with increases in BF. In contrast, for neurons from aged mice (bottom) the dependence of mean first-spike latency on BF is much less apparent, even though the distributions of first-spike latencies are similar (two-sample t test, $P > 0.05$). Furthermore, note that the gradient of shortest response latencies across BF is readily apparent in units from young mice (top, dotted line). That is, the shortest latencies are associated with the highest BFs. This gradient appears to be absent in the first-spike distribution for the old mice. Neurons with short first-spike latencies occur for both low (<10 kHz) and high BF units. This does not appear to be due to the lengthening of latencies in high-frequency units as one might expect, but rather to the shortening of laten-

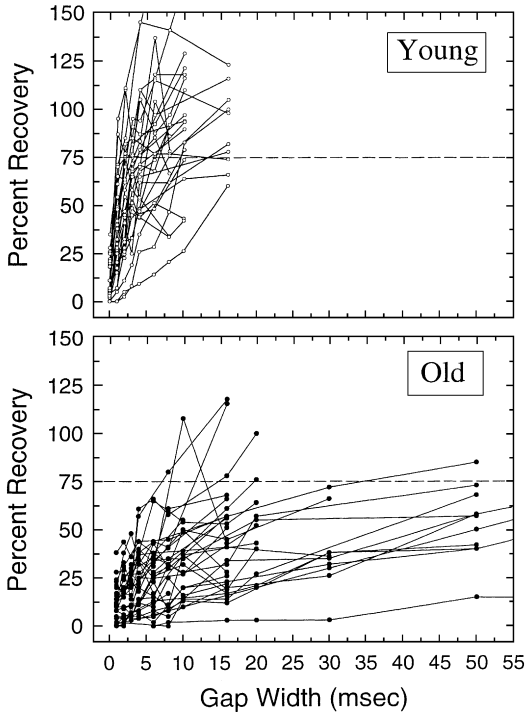

FIG. 40.6. Neural recovery functions derived from the response to gaps of various durations plotted for 30 onset units in young (top) and old (bottom) CBA mice. Neural recovery was quantified by computing the number of spikes elicited by the second noise burst marking the gap and then dividing that number by the number of spikes elicited by the first noise burst $\times 100$. Therefore, a recovery value of 100% would represent equal discharges to both the first and the second noise-burst markers. This calculation was completed for every histogram in the gap series. The dashed horizontal lines represent 75% recovery. Note that recovery to the 75% criterion is complete for gaps of 10–15 msec or shorter in nearly every neuron from the young animals, whereas most neurons from old animals do not reach this criterion even for gap durations longer than 20 msec. Also, facilitation (gap response is greater than control response) was discovered for units in young animals, but was rarely observed in units from old animals. From Walton *et al.* (1998), with permission of the author and publisher.

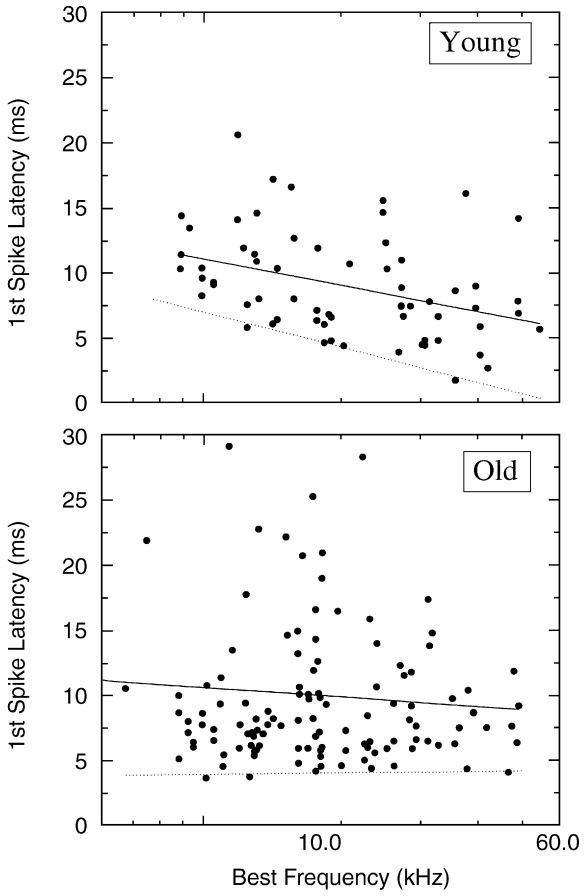

FIG. 40.7. Comparison of the mean first spike latency distributions and regression analyses plotted as a function of BF for young (top) and old (bottom) units. Response latency measures were derived from the control gap condition, a noise burst presented at 65 dB SPL. In order to measure only spikes evoked by the signal, the analysis period was restricted to the first 25 msec following response onset for onset units. The measurement window was increased to 50 msec for sustained and primary-like units. Response latencies ranged from 3 to 22 msec in the young distribution and 3.3 to 28 msec in the old distribution. The results of the linear regression analysis are shown by the solid lines, whereas the dotted lines (fit by eye) highlights the gradient of shortest first spike latencies in both young and old distributions. See text for additional discussion. From Walton *et al.* (1998), with permission of the author and publisher.

cies in low frequency units. The spread of latencies among neurons with similar BFs either remained unchanged (high BFs) or slightly expanded with age (low BFs). Shorter first-spike latencies in neurons from old CBA mice is consistent with reduced inhibition in old CBA mice.

The finding that aging differentially affects the representation of first-spike latencies (presumably) along the tonotopic axis, but not the spread of latencies within isofrequency slabs, suggests that there are at least two mechanisms influencing latency in the inferior colliculus. One mechanism establishes a latency gradient for determining the shortest latencies along the tonotopic axis, and it is this factor that is affected by age. The second factor establishes a latency spread within each isofrequency sheet, and this representation of response latency appears to be preserved with age, at least for high BF units. One other metric of response latency, the variance of the first-spike latency, was analyzed and remained stable with age. Previous reports indicate that variance in first-spike latency from inferior colliculus units should increase with the mean first-spike latency (Langner and Schreiner, 1988). Walton *et al.* also found that this relationship holds true for units from both young ($r^2 = 0.35$), $P < 0.001$) and old ($r^2 = 0.52$), $P < 0.001$) animals.

To summarize results from auditory midbrain studies, key findings from single cell recordings across multiple laboratories suggest that both intensity and temporal processing are disrupted in the inferior colliculus of the old rodent. Although Caspary's group found no significant decline in inferior colliculus binaural response properties with age, they did find subtle changes in other response measures, such as spontaneous activity and changes in the ratio of monotonicity. Walton's group has demonstrated the occurrence of an upward shift in the distribution of gap thresholds with age, increased recov-

ery from prior stimulation, as evidenced in increased recovery times in neurons from old mice, and alterations in the normal topographic map of first-spike latency in old mice. What are the implications of these findings? First, it must be reiterated that the temporal coding deficits noted above are not associated with global changes in all inferior colliculus neurons in aged animals; i.e., some neurons are spared. Whatever mechanisms are responsible for the alteration in temporal coding, they are acting on specific neurons. Second, the magnitude of the age-related deficits by single units using the gap detection paradigm are on the order of those reported in human listeners. Schneider *et al.* (1994), for example, found that mean gap thresholds were 1 to 1.5 msec greater in older subjects, with near-normal audiometric thresholds when compared to that seen in the young adult control group. Finally, many of the neurophysiological observations fit within the framework of the loss of inhibition model. Previous work has shown that both inferior colliculus single-unit recovery functions and topographic latency gradient present in the inferior colliculus can be modified by blocking GABAergic and glycinergic circuits (Park and Pollak, 1993a,b). Age-related alterations in single neuron recovery and the map of latency in single neuron recordings could be a reflection of an age-related imbalance in excitation and inhibition required for normal cellular function.

E. Summary of Single-Unit Studies

The challenge of exploring the effects of aging on auditory neural processing is made difficult because of the auditory system's enormous complexity. For the most part, the mechanisms which alter neural processing in the majority of nuclei of the central auditory nervous system remain unknown. Yet we believe that both degradations in the central nervous system and the sensorineural hearing loss that accompanies the aging process are responsible for the decrements in speech perception of the elderly listener in quiet and background noise. If therapeutic interventions are to be developed, we must continue to investigate how auditory processing at the cellular level is affected by age. The results presented in this portion of the chapter indicate that many age-related alterations in auditory processing are present in neurophysiological measures. In future studies, neurophysiological investigations must be complemented by neuroanatomical, pharmacological, and molecular approaches in order to elucidate the cellular machinery responsible for the behavioral deficits related to presbycusis.

IV. Effects of Aging on Auditory Evoked Potentials

A. Introduction

Unlike the single-unit electrophysiology measures summarized earlier in this chapter, auditory evoked potentials (AEPs) can be recorded noninvasively and thus can be recorded in both humans and in nonhuman mammals. The advantage of human studies concerning the physiological manifestations of aging is that the results are directly relevant to human aging. Furthermore, they provide a physiologic measure of auditory function that can be compared to perceptual measures of auditory function, ranging from tonal thresholds to the processing of speech in a noise background. The study of human AEPs, in isolation, does have several disadvantages. First, it is not typically possible to perform parallel physiologic and anatomical studies. Thus, we cannot verify, for example, hair cell loss at the time that the physiologic measures were obtained. Second, humans can live upward of 100 years, and hence longitudinal studies of aging are generally impractical, and cross-sectional studies are required. For these cross-sectional studies, we need to match for myriad factors, the most important of which are gender and hearing loss. Third, humans do not exist in a controlled environment, and hence many uncontrollable factors influence the effects of aging on the auditory system (e.g., noise exposure, administration of ototoxic agents, diet). The study of animal AEPs allows combined physiologic and anatomic study. In addition, many species of rodents have life spans of about 3–5 years, thus allowing longitudinal studies if these are deemed optimal for a specific experiment. The use of animals allows much greater control of both genetic and environmental factors than is possible in human studies. Finally, one can use animal models for physiologic studies using both invasive (e.g., single unit measures) and noninvasive (e.g., AEP measures). Once the relationships, between AEP and single-unit changes in the aging animal model are understood, it becomes possible to study human AEP in aging. If the animal and human AEP changes with aging are similar, then we can generalize the results of the invasive animal measures to the human aging auditory system.

In the present review of aging and AEPs, we will present both human and nonhuman work, as these parallel bodies of work are complementary. When the human and animal studies show similar changes with aging, we can conclude that the particular animal species is a good animal model for the aging human auditory system. Where possible, we will present the hearing status of the animals, as audiometric threshold in young adults can influence AEPs, and we would like to separate the effects of sensorineural hearing loss from age-related changes, per se. This process is difficult for several reasons. First, the hearing status of humans/animals in these studies is investigated or reported with varying degrees of rigor. Some studies simply report that they have ''normal hearing'' or reported ''no hearing difficulties.'' Others closely match the hearing thresholds of young and old subjects. The latter approach may seem optimal, but it appears that substantial inner hair cell loss can occur in the presence of normal hearing thresholds (Trautwein *et al.*, 1996; Qiu *et al.*, 2000). In addition, distortion product otoacoustic emissions (DPOAEs) are not only within the normal range, but may actually be larger than normal in ears with inner hair cell lesions (Jock *et al.*, 1998). Although normal threshold does not guarantee a completely normal auditory periphery, threshold does remain the primary clinical measurement of hearing.

B. Overview of Auditory Evoked Responses

Following presentation of an acoustic stimulus, a group of potentials can be recorded that reflect excitation from cochlear hair cells, auditory nerve fibers, and the nuclei and tracts of the auditory nervous system. If one places an electrode in or near the cochlea of the inner ear, one can record a series of poten-

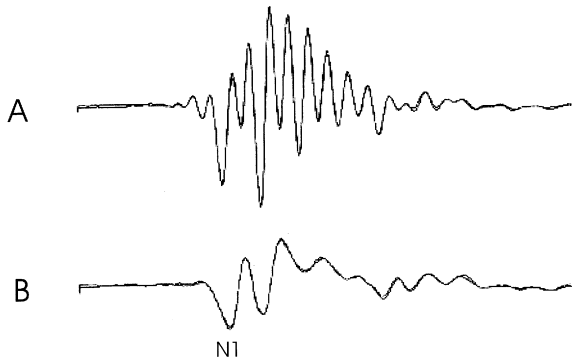

FIG. 40.8. Responses recorded with a round window electrode in the chinchilla. (A) An 80 dB pSPL fixed-phase 2 kHz tone burst is the stimulus, and the cochlear microphonic (CM) is seen as a series of potentials following the stimulus microstructure. (B) An 80 dB pSPL alternating-phase tone burst is the stimulus, and the CM has been cancelled, leaving the compound action potential. In each waveform, the time base is 12.8 msec. Tone-burst envelope is 2 msec rise time, (cosine^2), 1 msec plateau, presented at 21 Hz. Each response is the average of 100 stimulus presentations, and two waveforms are superimposed for each condition.

tials that are generated by the hair cells and auditory nerve fibers. One such recording, obtained from a round window electrode of a chinchilla, is shown in Fig. 40.8. Three potentials can be recorded. One is called the cochlear microphonic (CM), which is thought to primarily reflect outer hair cell function (Trautwein *et al*., 1996). The CM has the same frequency as the activating stimulus (in the case of Fig. 40.8A, this frequency is 2000 Hz). The summating potential (SP) is a DC potential that follows the envelope of the stimulus and appears to represent both inner and outer hair cell activity (Durrant *et al*., 1998). Otoacoustic emissions (OAEs) are also responses that appear to come predominantly from outer hair cells (Trautwein *et al*., 1996) and are recorded noninvasively from the ear canal with a sensitive microphone. Finally, the eighth nerve response, as recorded from the round window, can be seen as a series of one or more negative deflections and is called either the compound action potential (CAP) or the whole-nerve action potential (WNAP). The first negative peak of the CAP or WNAP is typically labeled N_1, as shown in Fig. 40.8B. Using scalp electrodes, a series of up to perhaps seven peaks can be measured within 10 or so msec following the onset of a moderate to high level click stimulus. This response is called (among other names) the ABR. As the name indicates, the generators of this response are (mostly) located in the auditory brain stem. The vertex-positive peaks are typically labeled with capital Roman numerals. An example of a human ABR is shown in Fig. 40.9, with several of the more prominent peaks appropriately labeled.

Middle latency responses (MLRs) are a series of potentials whose latencies extend out to approximately 70–80 msec. The peaks are labeled by a P or an N (indicating whether they are vertex positive or vertex negative), subscripted by a, b, or c (although several authors have reported a positive wave occurring before P_a, and label it P_0). An example of MLRs obtained from a human subject is shown in Fig. 40.10. A series of potentials with latencies extending up to 500 msec or more are referred to as event-related potentials (ERPs). These potentials

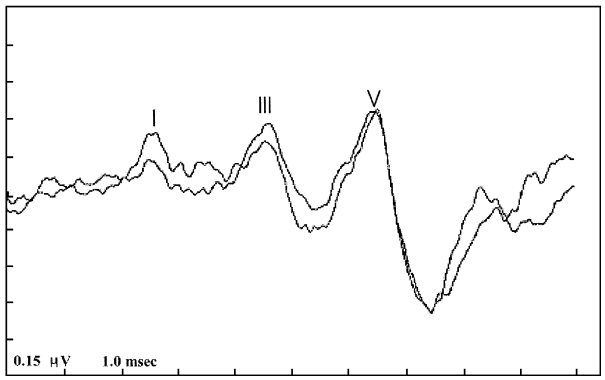

FIG. 40.9. The auditory brain-stem response (ABR) from one human subject is shown. Each response is the averaged response to 2000 presentations of an 80 dB nHL alternating-polarity click stimulus presented at a rate of 21 Hz. The time base is 10 msec and two responses are superimposed.

as a group are dependent on both the stimuli used (e.g., frequency, level, rate) and on subject state (e.g., attention and arousal). The slow vertex potential (SVP) is a series of peaks that can be recorded to a simple transient stimulus, and consists of a series of positive and negative peaks (labeled by "P" or "N"), and subscripted with either increasing peak number (e.g., N_2) or by the average latency of the peak (e.g., N_{200}). An example of the SVP is shown in Fig. 40.11A. Other peaks (such as the P_3 or the mismatch negativity, MMN) must be obtained by more complex stimulus paradigms, such as the oddball paradigm. In the oddball paradigm, a frequent or standard stimulus is presented most of the time (say, 85%), while a rare or deviant target stimulus is randomly presented occasionally (e.g., 15%). The responses to the frequent and rare stimuli are averaged separately. In the example shown in Fig. 40.11, the subject was asked to count the rare stimuli, and a response is seen in the "rare" condition (Fig. 40.11B) that is not seen in the "frequent" condition (Fig. 40.11A) which is labeled the P_3. In the sections that follow, we will review age-related changes in OAEs, CAPs, ABR, MLRs, and ERPs.

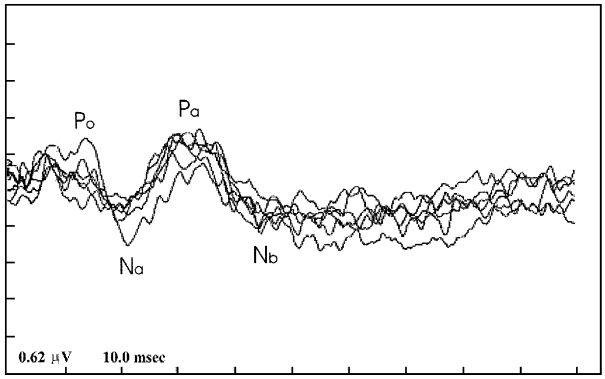

FIG. 40.10. The middle-latency response (MLR) from one human subject is shown. Each response is the averaged response to 1000 presentations of an 80 dB nHL, alternating-phase click stimulus presented at a rate of 9.1 Hz. The time base is 100 msec.

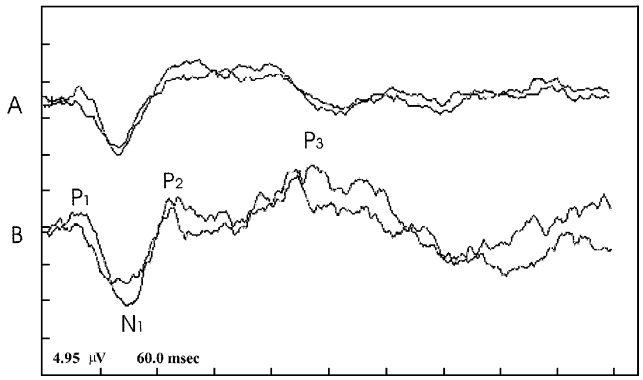

FIG. 40.11. The event-related potential (ERP) obtained using the oddball paradigm. Frequent stimuli were 2 kHz tone bursts, and rare stimuli were 1 kHz tone bursts. Rare stimuli were presented 20% of the time. The time base is 600 msec, and each set of responses (frequent plus rare) was to 200 stimulus presentations. Two responses are superimposed for each condition. Responses to frequent stimuli are shown in (A), while responses to rare stimuli are shown in (B).

C. Otoacoustic Emissions

Bonfils *et al*. (1988) investigated click-evoked OAEs (COAEs) across age in 151 ears of human subjects whose age ranged from 2 to 88 years. Mean audiometric thresholds increased with increasing age. In addition, COAE threshold increased with increasing age. The increase in COAE threshold paralleled the increase in perceptual click threshold with increasing age. Stover and Norton (1993) evaluated COAEs, tone-burst evoked transient OAEs (TBOAEs), spontaneous OAEs (SOAEs), stimulus frequency OAEs (SFOAEs), and distortion product OAEs (DPOAEs) in normal hearing subjects ranging in age from 20 to 80 years. With increasing age, there was an increase in mean audiometric threshold. Fewer SOAEs were observed in the older age groups. The older age groups showed smaller amplitude COAEs and TBOAEs than did the younger groups. SFOAEs were present in all subjects in the younger age groups, but present in only half of the subjects in their 60s and 70s. No clear patterns of DPOAE changes with aging emerged. Despite the observed changes in OAEs with age, statistical analyses revealed that these age-related changes were not independent of hearing thresholds; i.e., age-related changes in OAEs are confounded by changes in audiometric threshold across groups. Karzon *et al*. (1994) investigated DPOAEs in elderly subjects. Elderly subjects, on average, had higher audiometric thresholds than did the young adults. Mean DPOAE amplitudes (to 75 dB SPL primary tones) were reduced in the older subjects. When they compared the normal hearing young adult ears to the subset of elderly ears with normal hearing (20 dB HL or less from 250 to 8000 Hz), the mean DPOAE amplitude of the elderly ears was lower than that of the young ears, with the largest differences below 2 kHz and above 4 kHz. Kimberley *et al*. (1994) evaluated DPOAEs across age and hearing loss. DPOAE amplitude decreased with increasing (worsening) threshold. In the subset of ears with normal threshold, there was a systematic decrease in DPOAE amplitude with increasing age. It appears that normal hearing elderly ears have reduced DPOAE amplitudes, suggesting that OHCs may not be functioning normally in the aged ear with normal audiometric thresholds.

Parham (1997) investigated C57BL/6 mice across age. C57 BL/6s exhibit an adult-onset, progressive hearing loss, starting in the high frequencies. He found progressive elevation of ABR thresholds with increasing age, starting in the high frequencies, and progressing towards lower frequencies. Evaluating high frequency DPOAEs, using f2 frequencies between 8 and 16 kHz, he found a progressive decrease in response amplitude with aging. It appears that progressive hair cell damage results in elevation of ABR threshold and decreases of DPOAE amplitude.

D. Electrocochleography

Nozawa *et al*. (1996) found a gradual elevation in guinea pig click-evoked CAP threshold with advancing age. Hellström and Schmiedt (1990) evaluated CM and CAP input/output functions in young-adult (4- to 7-month) and old (35- to 37-month) gerbils. Mean CAP thresholds were higher in the older gerbils, and there was much greater variability in thresholds in the old gerbils, as compared to young-adult gerbils. The maximum CAP amplitude at each frequency in each animal was determined, and a mean ''maximum'' amplitude was compared across age groups. On average, there was a substantial (roughly 50%) decrease in maximum CAP amplitude with advanced age. Maximum CM amplitudes, evaluated in a similar manner, were smaller in the old gerbils at 500 Hz, similar in young and old gerbils at 1 kHz, and actually somewhat larger in older gerbils at 2 and 4 kHz. The reduction in amplitude of the auditory nerve response (i.e., decrease in CAP amplitude) does not appear to be entirely the result of threshold elevation; otherwise CM amplitude decrement (reflecting outer hair cell function) would parallel CAP changes.

E. Aging Effects on the Auditory Brain-Stem Response

1. Effects on Peak Latencies and Interwave Intervals

In humans, there is much controversy over the effects of aging on the ABR peak latencies across age. Jerger and Johnson (1988) evaluated the latency of ABR wave V to high-level click stimuli across gender, age, and hearing loss. There was an increase in wave V latency with increasing high-frequency hearing loss. When separated by age (those less than 50 years, those greater than 50 years) and grouped according to their 4 kHz threshold, the young females had shorter wave V latency than young males, and older females had shorter wave V latencies than older males. When compared across age (and within gender), older females had longer wave V latencies than younger females, but there was little effect of age on wave V latency for the males. These data reveal complex interaction of gender, age, and hearing loss on wave V latency. Elberling and Parbo (1987) evaluated the ABR interwave intervals across gender, age, and high-frequency hearing loss using multiple-regression analysis. The I–III and I–V intervals were smaller in females than in males. In addition, these interwave intervals were found to decrease with increasing age and increase with increasing hearing loss. Costa *et al*. (1990) found increasing wave I latency and decreasing wave III and V latency with

increasing age in normal hearing subjects. Thus, they found a decrease in the I–V interval (''central conduction time'') with aging. Rowe (1978) evaluated young and old subjects with no history of hearing loss. He found an increase in ABR peak latencies and an increase in the I–III interval but not the III–V interval with increasing age. Chu (1985) investigated normal-hearing young and old subjects, and found an increase in ABR peak latencies with increasing age. There was little change in the I–III interval across age, but a small increase in the III–V and I–V intervals with age. Even when older subjects were limited to those with ''normal hearing,'' there is little consensus as to the effects of aging on ABR peak latencies and interwave intervals. The sparse description of audiometric data in some of these studies suggests that one cause of the across-study variability regarding aging and ABR peak latency shifts could be the varied criteria for ''normal hearing.''

A number of animal studies have investigated the effects of aging on ABR peak latencies. Backoff and Caspary (1994) investigated ABR peak latencies in young-adult (3- to 6-month) and old (20 to 23 months) rats. To click stimuli, ABR thresholds were increased for the older rats. In addition, ABR peak latencies and interwave intervals were increased in the older rats. Nowaza *et al*. (1996) investigated guinea pig ABR peak latencies and interwave intervals to click stimuli. CAP and ABR thresholds increased with advancing age (and hence serve as a confounding factor in this study). ABR peak latencies increased with increasing age, but there was no change in interpeak intervals with increasing age. Ingham *et al*. (1998) evaluated ABR changes in guinea pigs to click stimuli, and found an increase in ABR threshold with advancing age and a trend toward increasing ABR peak latencies with advancing age that failed to reach significance. In addition, there was no change in interwave intervals with advancing age. Hunter and Willott (1987) investigated ABR changes with aging in C57BL/6J and CBA/J mice. To click stimuli, there is an increase in latency of the ABR peaks in C57 BL/6 mice, but only when threshold elevation is substantial. CBA mice ABR peak latencies did not show any systematic changes with aging. Cooper *et al*. (1990) investigated changes in ABRs in young and aged rats to tone-burst frequencies of 3, 8, and 40 kHz. Thresholds increased with increasing age, which was most pronounced for the higher frequencies. ABR peak latencies increased with increasing age, with the smallest age-related latency shifts seen at 8 kHz. In addition, there were increases in the interwave intervals with increasing age.

Perhaps the most systematic series of aging studies of the ABR has been performed by Mills and his colleagues. Mills *et al*. (1990) evaluated ABR threshold with advancing age in gerbils, and found that the tone-burst thresholds of 6- to 8-month-old gerbils increased on average by roughly 10 dB when compared to young animals and by 36 months increased by roughly 20–35 dB. The gerbil is a somewhat unique animal model of presbycusis, in light of the fact that age-related hair cell loss is comparatively modest, and age-related changes in the stria vascularis are quite pronounced (Schulte and Schmiedt, 1992). Boettcher *et al*. (1993b) compared ABR peak latencies in young adult and aged gerbils. They grouped aged gerbils by audiometric threshold. Aged gerbils with near-normal thresholds showed similar or somewhat shorter latencies than young adult gerbils. Aged gerbils with mild threshold elevation (compared to young adult gerbils) showed increased peak latencies at low tone-burst levels, with normal latencies at higher tone-burst intensities. In aged gerbils with greater threshold elevation (compared to young adults), ABR peak latencies were typically increased at all tone-burst levels. These data appear to support the view that threshold elevation is a confounding variable when evaluating ABR peak latency shifts with advanced age.

2. Effects on Peak Amplitudes

ABR peak amplitudes have been reported to decrease with increasing age in humans (Costa *et al*., 1990; Psatta and Matei, 1988). Psatta and Matei (1988) reported an increase in the V/I amplitude ratio with advancing age, which suggests a greater age-related change in wave I amplitude than wave V amplitude. Rowe (1978) found little change in wave V amplitude across age for 60 dB nHL clicks presented at 30 Hz. Mean wave V amplitude was slightly greater for the old subjects to 60 dB nHL clicks presented at 10 Hz, while wave V amplitude was substantially less in old adults than young adults to 30 dB nHL clicks presented at 30 Hz. Thus, amplitude changes with aging may depend, in part, on the acoustic stimuli used. Although not universal, generally speaking it appears that human ABR peak amplitudes decrease with increasing age.

In animal studies, ABR peak amplitudes also appear to decrease with advancing age. In Fischer 344 rats, Backoff and Caspary (1994) found a general decrease in ABR peak amplitudes to click stimuli in old (20 to 23 months) rats as compared to young adult (3 to 6 months) rats. Hunter and Willott (1987) found that in aging C57 BL/6 and CBA mice, ABR peak amplitudes decreased with increasing age. Ingham *et al*. (1998) found a decrease in guinea pig ABR peak amplitudes to click stimuli with advancing age. Boettcher *et al*. (1993a) evaluated ABR peak amplitudes to tone-burst stimuli in young (6 to 10 months) and aged (36 months) gerbils. Even for aged animals with near normal thresholds, ABR peak amplitudes were reduced, compared to young adult gerbils. This age-related amplitude decrease was particularly evident at higher tone-burst levels. This age-related decrease in ABR peak amplitude tended to increase with increasing hearing loss to high frequency tone-bursts for ABR wave III, and for all tone-burst frequencies except 16 kHz for ABR wave IV. In general, animal studies tend to show a reduction in ABR peak amplitudes with advancing age.

3. Temporal Processing and Masking in the ABR across Age

A number of AEP studies have investigated temporal processing and masking effects across age in humans and other mammals. Walton *et al*. (1999) investigated temporal processing in normal hearing young and old adults using a forward masking paradigm, where a tone-burst masker was presented prior to the presentation of a same frequency tone-burst stimulus. The time between masker offset and stimulus onset was varied. For high-frequency toneburst stimuli (but not low frequency tone-bursts), there was a substantial increase in wave V latency shift (compared to no masker control condition) in the

normal hearing older subjects. These data suggest a degradation in temporal processing in older subjects.

McFadden *et al*. (1997a,b) also demonstrated age-related changes in several suprathreshold auditory measures in the aged chinchilla. Consistent with the observations in gerbils and other rodents, they reported a 20 to 30 dB decline in peripheral sensitivity in old chinchillas. In addition, they recorded near field evoked responses from the inferior colliculus using a variety of masking paradigms. McFadden and colleagues found that old chinchillas displayed abnormal peripheral masking patterns, in that tone-on-tone masking produced greater threshold shifts in old chinchillas relative to young animals. Aging effects on temporal resolution were not observed, as forward masking recovery functions were comparable across age. They concluded that the cochlea of the aged chinchilla displays many of the functional deficits found in aged humans and that aging of the brain, in and of itself, may be the major factor in the perceptual deficits related to presbycusis.

Backoff and Caspary (1994) investigated ABR peak latencies and interwave intervals across click rate and age (3 to 6 months, and 20 to 23 months) in Fischer 344 rats. An evaluation of ABR peak latency shifts when increasing rate from 10 to 40 Hz showed greater latency shifts of waves 4 and 5 in the older rats (compared to young adult rats). Boettcher *et al*. (1996) investigated gap detection by CAP and ABR in gerbils. They found reduced CAP and ABR amplitudes with increasing age, essentially replicating earlier findings from their lab (Hellström and Schmiedt, 1990; Mills *et al*., 1990; Boettcher *et al*., 1993). At brief noise gaps, there was a substantial prolongation of ABR wave IV latency (but not CAP latency) in the aged animals. These data support the notion of a central component to age-related auditory changes in temporal processing. In one study of masking effects across subject age, Boettcher *et al*. (1995) investigated masked ABR thresholds in young and old gerbils using a 1 kHz low-pass and an 8 kHz high-pass masker. They found higher thresholds in the old gerbils to the low-pass noise for 2 and 4 kHz tone bursts, but not to the high-pass masker. These data are best interpreted as excess upward spread of masking in the aged animals, and hence the result of reduced peripheral frequency specificity, rather than the result of any central change.

F. Middle Latency Responses and Aging

Woods and Clayworth (1986) investigated MLR peak latencies and amplitudes to click stimuli in young and old adults. The older subjects showed higher audiometric thresholds than the young adults, with mean differences of 12.3 dB at 500 Hz, increasing to a mean difference of 49.6 dB at 8 kHz. In elderly subjects, Pa was prolonged as compared to that seen in young adults. Peak-to-peak amplitudes that included Pa were larger in the elderly subjects than in the young adults. Amenado and Diaz (1998a) evaluated MLR peak latencies and amplitudes in adults ranging in age from 20 to 86 years. Binaural clicks were presented at 60 dB above threshold. As perceptual thresholds to click stimuli increased with increasing age, click level was higher in the older subjects in this study. MLR peak latencies showed no consistent change across age group, but MLR peak amplitudes typically increased with advancing age. Kelly-Ballweber and Dobie (1984) investigated binaural interaction in the ABR and MLR of young and older males. They matched average audiograms for both age groups, such that both groups showed normal low-frequency sensitivity, and a moderate high-frequency hearing loss. Clicks were presented monaurally or binaurally at 99 dB peSPL. Evaluating mean data to binaural stimulation, ABR wave V and MLR waves Pa and Pb were prolonged in the older subjects. Most interestingly, mean peak amplitudes to binaural stimulation were larger for wave V, Na–Pa, and Pa–Nb. Lenzi *et al*. (1989) investigated MLRs in normal hearing (thresholds of 20 dB HL or less from 250 to 2000 Hz) young and aged adults. ABR peak latencies increased with advancing age in response to 50-dB SL clicks. There was a general increase in the latency of MLR peaks Na, Pa, and Nb with increasing age, to both clicks and 1 kHz tone burst stimuli. Although they did not show any data, the authors also reported a general decrease in MLR amplitude in the elderly subjects.

G. Event-Related Potentials and Aging

Spink *et al*. (1979) investigated ERPs to 1 kHz tone bursts in young (all 22 years old) and older (61–64 years old) adults. Tone-burst level was varied and ERPs collected in response to 64 tone-burst presentations at each level. For both age groups, N1/P2 amplitude increased with increasing amplitude up to 45 dB HL, with no change in amplitude for higher stimulus levels. They report no difference in ''relative amplitude'' across age group. For both age groups, ERP peak latencies decrease with increasing tone-burst level. There were no significant differences across age in the latencies of P1 or N1. In contrast, P2 latency was significantly shorter in older subjects for high-level tone bursts, and similar to young adults at lower tone-burst levels. Goodin *et al*. (1978) evaluated ERPs in young and old subjects whose hearing status was unspecified, using the oddball paradigm. After age 20, there is an increase in the latency of N1, P2, N2, and P3 with increasing age. This latency shift (by linear regression) was 0.1, 0.7, 0.8, and 1.8 msec/year for N1, P2, N2, and P3, respectively. They also reported a decrease in N1–P2 and N2–P3 amplitude with increasing age. Smith *et al*. (1980) investigated the effects of subject age on ERPs, again using the oddball paradigm. All subjects were women (young, 18–33 years old; aged, 65–80 years old), and half of the subjects in each age group were instructed to ignore the tones while reading, while the other half were instructed to count the tones. Three recording channels were utilized, with the noninverting leads located at Fz, Cz, and Pz. In comparison to young adult subjects, old subjects showed significantly greater P1 amplitude, significantly smaller P2 amplitude and statistically identical N1 amplitude. Young adult subjects showed larger P3 amplitudes than the older subjects, for both the reading and the counting tasks. Amenado and Diaz (1998b) evaluated ERPs to an oddball paradigm in subjects ranging in age from 20 to 86 years. In these subjects, three age groups were constructed: young adults (20–39 years old), middle-aged adults (40–59 years old), and older adults (60–86 years old). Stimuli were presented at 90 dB SPL. Target stimuli were 2 kHz tone bursts, while nontarget stimuli were 1 kHz tone bursts. Audiometric data were not reported. N1 and P2 latencies did not differ significantly across age groups. To nontarget stimuli, P2 ampli-

tude at Fz increased with increasing age. P3 amplitude decreased with increasing age, but only in males. Amenedo and Diaz (1998c) evaluated N2b and the MMN in young (23 to 29 years old), middle-aged (41 to 59 years old), and older (63 to 77 years old) adults to 90 dB SPL 1 kHz (standard tones) and 1500 Hz (deviant tones) presented dichotically. The audiometric thresholds of these subjects were not specified. N2b latency was longer in the middle-aged and older adults than in the young adults. N2b amplitude did not vary significantly across age group. MMN latency and amplitude did not vary across age group.

Puce *et al*. (1989) evaluated P3 as recorded from both the scalp and the intracranial electrodes in patients being investigated for focal seizures. Using the oddball paradigm, the scalp-recorded P3 latency increased and its amplitude decreased with increasing age in a group of control subjects. In the patient population, both intracranial and surface P3 recording showed increasing P3 latency with increasing age. In contrast to the control subjects, in the patients with seizures, there was no systematic change in either intracranial- or surface-recorded P3 amplitude across age. Pfefferbaum *et al*. (1980a,b) evaluated auditory ERPs in young adult (mean age, 22.5 years old) and elderly (mean age, 78.6 years old) women using an oddball paradigm composed of frequent stimuli (1 kHz tone bursts), and two infrequent stimuli (500 and 2000 Hz). The subjects were instructed to press a key to one of two infrequent stimuli (called the target) and performed no motor task for the other infrequent stimulus (the nontarget infrequent stimulus). Responses to both infrequent stimuli were analyzed off-line, both by averaging and by using single-response analysis procedures. Young and old subjects did not differ in terms of correct responses, false alarms, or reaction time. N1 latency did not differ across age groups, while P2 latency was significantly prolonged in older subjects. N1/P2 amplitude was significantly larger in the older subjects. Evaluating N1 and P2 amplitudes (relative to baseline), both showed mean amplitudes that were greater in the older subjects, but only P2 amplitude differences reached significance. P2 amplitude distribution across the scalp varied with age, with P2 amplitude largest at Cz in the younger subjects, but equally large at Fz and Cz in the older adults. To both target and nontarget infrequent stimuli, P3 latency was prolonged in the older subjects. P3 amplitude distribution differed across age, with the young adults showing larger P3 amplitudes in more frontal electrode locations. In contrast, older subjects showed similar P3 amplitudes for all electrode leads. Finally, slow wave activity (a negativity following P3 at more frontal electrodes) was decreased in the older subjects. In an evaluation of both visual and auditory P3, Pfefferbaum *et al*. (1984) found increasing P3 latency with increasing age to both auditory and visual stimuli. For both modalities, age-related P3 amplitude changes appeared as a change in scalp topography: Young adult subjects showed P3 amplitudes that were largest posteriorly (e.g., as Pz), while older subjects showed a more uniform distribution (i.e., amplitudes were similar at Fz, Cz, and Pz).

Swartz *et al*. (1994) investigated P3 latency and amplitude to a variety of auditory discrimination tasks using musical stimuli, in both young (18–37 years old) and older (65–85 years old) adults. Audiometric data were not obtained, but subjects reported that they could follow conversation without the use of a hearing aid. Although mean P3 amplitude was smaller in the older subjects for several of the discrimination tasks, this effect failed to reach statistical significance. In contrast, P3 latency was significantly longer in a subset of these discrimination tasks. Bellis *et al*. (2000) investigated ERP amplitudes to an oddball paradigm in a group of children (8–11 years old), young adults (20–25 years old), and older adults (greater than 55 years old). Hearing thresholds were less than 25 dB HL for the octave frequencies ranging from 500 to 8000 Hz. Deviant stimuli were synthetic /da/ syllables, and standard stimuli were synthesized /ga/ syllables. All stimuli were presented to the right ear, and responses recorded over the left and right temporal lobes were compared. P1–N1 amplitude was larger in children than in the adults, but there was no difference in P1–N1 amplitude for the young and older adults groups. In the children and young adults, responses recorded over the left (contralateral) hemisphere were significantly larger than those recorded over the right (ipsilateral) hemisphere. This asymmetry was not observed in the older adults. In contrast, the MMN did not significantly differ over the right and left temporal lobes in any age group.

H. Summary of AEP Studies

The most consistently reported age-related change in evoked responses is a reduction in response amplitude from responses emanating from the auditory periphery and brain stem. This has been reported for all time epoch of responses, including OAEs, CAP, and ABR. Less consistently, there are reports of age-related changes in AEP peak latencies and interwave intervals. Most interestingly, there have been several reports showing response enhancement of MLRs. Paradigms involving temporal processing (forward masking or gap detection) show greater ABR peak latency shifts at short forward-masking intervals or brief gaps in aged subjects. AEP studies that stress the temporal processing capabilities of the auditory system appear to be promising paradigms for the study of the aging auditory system. A recurring theme throughout this literature review is that even mild threshold elevations across age groups appears to confound the interpretation of age-related changes. This highlights the importance of careful documentation or control of audiometric thresholds when evaluating AEP changes across age.

V. Conclusions

Aging is frequently accompanied by a decline in sensory perception, clinically referred to as presbycusis. Until recently, the underlying neural mechanisms responsible for the perceptual decline in the aged auditory system remained poorly understood largely due to the lack of research. This chapter has presented a review of peripheral and central auditory processing from single cells and from populations of cells using auditory evoked potentials as it relates to neural presbycusis. Studies which have investigated neural processing to simple stimuli found no evidence which suggests an age-related deterioration in neural function. However, when more complex stimuli or masking paradigms are used age-related alteration in neural processing begin to emerge. A complete understand-

ing of the neurological bases of presbycusis will be unraveled only by using acoustic signals which model the types of listening situations where elderly listeners have difficulty. The final objective is to correlate age-related deficits in neural processing to biological changes in auditory neurons so that potential therapies can be formulated which could slow or alleviate presbycusis.

Genetics and Age-Related Hearing Loss

One of the important challenges confronting modern molecular genetics is identifying the genes responsible for presbycusis, or age-related hearing loss. The genetic causes of presbycusis and other nonsyndromic types of hearing impairment are largely unexplored. However, clues about presbycusis genes are available from studies of animals (particularly inbred and transgenic strains of mice), humans with other forms of progressive, late-onset hearing loss, and mitochondrial diseases. This chapter provides an overview of basic genetic concepts as a background for understanding advances in the rapidly changing field of molecular genetics of hearing loss and age-related diseases. In addition, it offers insight into the possible genetic basis of presbycusis, with a focus on the potential contributions of mitochondrial dysfunction.

I. Introduction

Age-related hearing loss (AHL), or presbycusis, affects 30–35% of the population ages 65–75 years and 40% of the population over 75 years of age. Most of the changes in auditory perception that occur with age can be attributed to pathological changes in the cochlea, particularly the loss of sensory hair cells and degeneration of the stria vascularis. The causes of AHL are unknown, but several factors are likely to play a role. As summarized in Fig. 41.1, etiological agents may include environmental factors such as noise, ototoxic drugs, and environmental toxins and genetic defects, both inherited and acquired. A substantial proportion of AHL cases are likely to arise from interactions between genetic and environmental factors. Individuals with certain genetic predispositions may be more sensitive to environmental insults that produce hearing loss over time. In addition, disease states and the genetic background of an individual can exacerbate the effects of deafness-causing genes.

Even though the field of molecular genetics is advancing rapidly, it is still in its infancy with respect to identifying genes causing various forms of hearing loss in humans, including presbycusis. The purpose of this chapter is twofold. The first aim is to provide the reader with an overview of basic genetic concepts, to help establish the background necessary for keeping abreast of developments in the rapidly expanding field of molecular genetics. The second aim is to present some thoughts about potential genetic mechanisms that could contribute to human presbycusis. It is important to note that genes for presbycusis in humans have not yet been identified. Nevertheless, we have several clues about potential genes from studies of mice and other animals, humans with other forms of genetic late-onset hearing loss, and mitochondrial diseases.

II. Genetic Mutations and Disease

Currently there are about 4000 known human genetic diseases, and more than 10% of these include hearing loss as a component. Some genetic conditions are caused by changes in the normal number of chromosomes, as in Down syndrome. Mutations in chromosome number are relatively frequent, occurring in approximately 20% of human conceptions. However, they are usually lethal early in development, and are therefore seen in fewer than 1% of human births. The more common type of mutation in surviving individuals involves a single gene or a single pair of genes. Genetic hearing loss arising from mutations of nuclear and mitochondrial genes will be the primary focus of this chapter.

III. Classification of Genetic Hearing Impairment

Hearing impairment can be acquired (e.g., the result of acoustic trauma, disease, or ototoxicity), inherited, or due to unknown causes. As shown in Fig. 41.2, heredity accounts for the largest proportion (20–60%) of hearing impairment in humans.

In classical genetics, it is important to know how a genetic condition is transmitted from one generation to the next (if at all) and whether the genetic condition has single or multiple effects. This leads to a classification of hereditary hearing impairment into two categories based on physical manifestations (phenotypes) and four categories based on inheritance (see Fig. 41.2). When hearing loss is accompanied by other clinical manifestations, it is said to be syndromic. When it occurs alone, as in presbycusis, it is nonsyndromic.

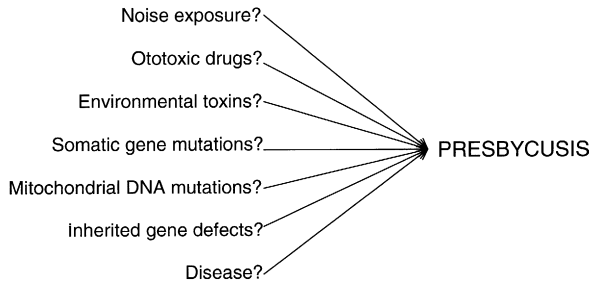

FIG. 41.1. Potential etiological factors for presbycusis. Etiological factors include environmental agents, spontaneous and inherited genetic mutations, and interactions between environmental agents and the individual's genetic background.

There are more than 200 forms of syndromic hereditary hearing impairment. However, the largest proportion (70–95%) of hereditary deafness is nonsyndromic. It is estimated that autosomal recessive defects account for about 80% of cases of nonsyndromic hearing impairment, autosomal dominant forms for about 15%, and X-linked forms for 1–3%. There is currently no way to estimate the proportion of cases of genetic hearing impairment due to mitochondrial and polygenic inheritance. However, evidence for the role of mitochondrial inheritance and mitochondrial mutations in causing hearing loss directly or indirectly (e.g., by increasing susceptibility to environmental agents) is growing.

A second way of classifying genetic hearing impairments is according to their underlying pathology. Steel and her colleagues (e.g., Steel *et al*., 1983; Steel and Brown, 1994) classify gene mutations into three categories: (1) *morphogenetic* abnormalities, arising from mutations affecting development of the auditory placode; (2) *cochleosaccular* defects, arising from disturbances in the stria vascularis and typically associated with pigmentation defects; and (3) *neuroepithelial* defects, which involve primary abnormalities of the organ of Corti in the cochlea, the maculae of the sacculus and utricule and the cristae of the semicircular canals. Neuroepithelial defects are associated with nonsyndromal hearing loss and are often recessive. They appear to be the most common type of cochlear pathology in humans. The recent mapping and cloning (sequencing) of genes responsible for neuroepithelial defects represent major steps toward solving the genetic puzzle of presbycusis.

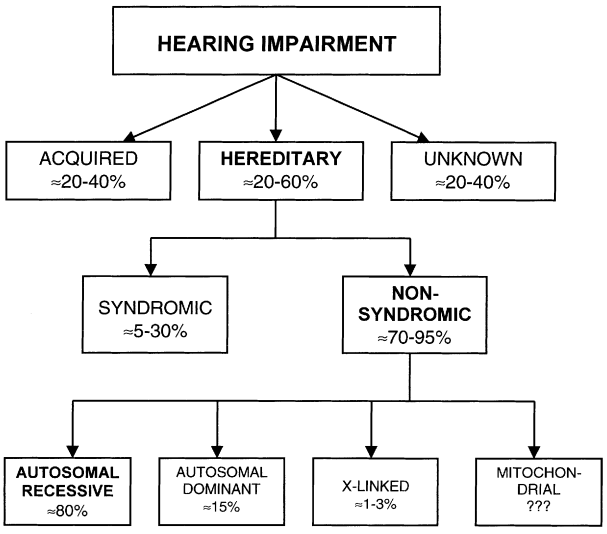

FIG. 41.2. Classification of genetic hearing impairment based on clinical manifestations and mode of inheritance.

IV. Mapping and Sequencing Genes

Mapping a gene refers to the process of localizing the gene to a particular section (locus) of DNA on a specific chromosome. This provides clues as to the gene identity and function. Sequencing a gene refers to the process of identifying the order of bases on the gene that direct the coding of a protein. The entire human genome contains approximately three billion bases. It has been estimated that the information from sequencing the entire human genome will fill the equivalent of 14 sets of the Encyclopedia Britannica, or 200 volumes the size of a Manhattan phone book. Sequencing the entire human genome is the goal of a program supported by the Department of Energy and the National Institutes of Health called the Human Genome Project.

As of this writing, the Hereditary Hearing Loss Home Page (Van Camp and Smith, 1999) lists 31 autosomal dominant deafness loci (DFNA1–31), 28 autosomal recessive deafness loci (DFNB1–28), 6 X-linked deafness loci (DFN1–4; DFN 6; DFN8), and 2 mitochondrial gene mutations. More than 50 genes causing nonsyndromic hearing impairment have been localized to specific chromosomes, and in 19 cases, the gene has been sequenced or cloned. Cloned genes now include 10 autosomal dominant genes, 6 autosomal recessive genes, 1 X-linked gene, and 2 mitochondrial genes. Most of these genes are associated with neuroepithelial defects. The identification of so many loci for deafness (DFN) genes illustrates that many genes control hearing function and that hearing impairment is heterogeneous. All of the known DFN genes produce sensori-neural hearing loss, and most forms of DFNA and DFNB deafness are progressive. These genes may therefore provide clues about genes responsible for presbycusis. A brief overview of basic genetic concepts is provided in the Appendix at the end of this volume.

V. Clues for Presbycusis Genes

Although a genetic basis for some forms of AHL has been suspected for many years (e.g., Schuknecht, 1974), nothing is known about the mode of inheritance of AHL, the number of genes that might be involved, or how the genes might act. One of the challenges for molecular genetics in the 21st century is to map and sequence the genes responsible for AHL. This is a daunting proposition for several reasons. First, there is no single clinical phenotype that defines presbycusis. The classic symptoms associated with AHL are a bilaterally symmetrical elevation of high-frequency thresholds, and decreased ability to understand speech, especially in the presence of background noise. However, other phenotypes are frequently observed, and there is controversy over the predominant cochlear pathology

in presbycusis. Is the loss of sensory hair cells the most common form of histopathology, or is strial dysfunction more prevalent? The diversity of AHL phenotypes will complicate the search for underlying genes. Second, the various phenotypes of genetic AHL are likely to be due to the actions of many genes, each with allelic variants, or alternate forms, and both direct and indirect effects. Third, the fact that different genetic conditions can result in identical clinical findings will make it difficult to use gene linkage to identify AHL genes.

Before concluding that these difficulties will make it impossible to uncover genes for presbycusis, one should consider other recent successes that seemed impossible only a decade ago. Until recently, mapping genes responsible for any autosomal recessive hearing loss was considered too difficult because of the extreme genetic heterogeneity and the wide range of audiometric patterns which affected individuals exhibit. Now, several DFN genes have actually been cloned or sequenced. The identification of genes for human presbycusis may not be far behind.

Many of the clues for presbycusis genes come from genetic studies of animals, particularly mice. Presbycusis is one of a number of conditions that occur in both mouse and human in which hearing loss develops as an inconsistent and late-onset feature. Of the thousands of gene loci that have been mapped in mice and humans, more than 400 are homologous between the two species. Fortunately, there is a strong tendency for gene loci order and groupings to be conserved between humans and mice. Thus, when genes for hearing loss are mapped in the mouse, reasonable predictions can be made regarding the location of homologous genes in the human. Human homologs and mutations can be sought in conserved areas of the human genome.

A. Clues from Genes Causing Neuroepithelial Defects in Mice and Humans

1. Genes for Unconventional Myosins

The *myo7a* gene codes for myosin VIIA, an unconventional myosin expressed in hair cells of the inner ear. A mutation of *myo7a* was found to be responsible for the *sh1* mutation in the shaker-1 mouse (Gibson *et al*., 1995). The *sh1* mutation was first reported in 1929 by Lord and Gates (see Ruben, 1991) and has since served as a valuable model for progressive hearing loss. Shaker-1 mice have profound hearing loss associated with degeneration of the organ of Corti, along with the shaker–waltzer type behavior that is typical of mice with vestibular defects.

Since 1995, mutations in the homologous human gene, *MYO7A*, have been shown to cause three distinct forms of hearing loss. One mutation produces Usher's syndrome type 1b, a recessively inherited syndromic disease characterized by congenital deafness, vestibular dysfunction, and retinitis pigmentosa (Weil *et al*., 1995). Another mutation, corresponding to the *sh-1* mutation in mice, gives rise to DFNB2 (Liu *et al*., 1997; Weil *et al*., 1997), and a third mutation has been found to cause DFNA11 (Liu *et al*., 1997).

Discovery of *myo7a* was an extremely important event in molecular genetics for three reasons. *Myo7a* was the first gene found that affects the sensory hair cells directly. The discovery of *myo7a* in the mouse led to identification of the gene causing Usher's syndrome type 1b in the human. Importantly, this is the first gene found where mutations cause both dominant and recessive, and syndromic and nonsyndromic forms of hearing loss.

A second myosin gene mutation causing a neuroepithelial defect was found shortly after *myo7a*. This mutation was found in the gene coding for myosin VI, responsible for the Snell's waltzer mouse mutation (Avraham *et al*., 1995). In shaker-1 and Snell's waltzer mice, the earliest gross abnormalities involve the actin-rich stereocilia of the sensory hair cells. Shaker-1 mice show disorganization of the stereocilia bundle, and Snell's waltzer mice have stereocilia that are fused.

Myosin VI and VII are two members of a class of unconventional (non-muscle-like) myosins. The precise roles of the unconventional myosins in the cochlea are unknown, but two functions are likely (Steel and Brown, 1994). One function of the unconventional myosins may be in adjusting the tension of the tip links that connect adjacent stereocilia. The tip links are involved in opening and closing the hair cell transduction channels, thereby increasing or decreasing the flow of potassium ions through the apical surface of the hair cell, and mutations may interfere with this process. A second role of the unconventional myosins is in the movement of vesicles and other elements around the hair cell, using actin as a substrate. Interestingly, a mutation that affects another protein that may be involved in the trafficking of membrane vesicles has been shown to cause DFNB9. This protein, called otoferlin, is coded by a gene (*OTOF*) that is expressed in the inner hair cells of the organ of Corti and in vestibular type I sensory cells.

A third myosin gene mutation is responsible for DFNB3 in the human and the *sh-2* mutation in the mouse. This gene codes for myosin XV, a unique myosin protein that appears to be necessary for actin organization in hair cells. The hair cells of shaker-2 mice have very short stereocilia, and a long actin-containing bundle protrudes from the basal end.

Mutations affecting myosin VII, myosin VI, myosin XV, and otoferlin point to the importance of vesicle trafficking, regulation of current flow, and actin organization in normal hair cell function. Each of the mutations produces a different nonsyndromic recessive hearing impairment.

2. Genes for Connexin

GJB2 is the gene that codes for the beta-2 gap junction protein, connexin 26 (CX26). CX26 is one of six connexin protein subunits that form gap junctions–plasma membrane channels that allow small molecules to pass from one cell to another. In the cochlea, CX26 is found in the epithelial supporting cells surrounding the sensory hair cells and in fibrocytes lining the cochlear duct. Gap junctions between the supporting cells and fibrocytes provide a route whereby potassium ions that pass through the base of the hair cell can be returned to the endolymph above the hair cell.

The *GJB2* gene is small, and the entire protein-coding sequence is located in a single exon. This makes the gene relatively easy to screen for mutations. More than 20 different mutations of *GJB2* have been found in families with autosomal recessive nonsyndromic hearing loss. The most common mutation, called the 30delG or 35delG mutation because it arises

from a deletion of one base in a sequence of 6 guanine residues at position 30–35 in the CX26 DNA sequence, causes DFNB1. The 30delG mutation appears to have arisen several times independently in many human populations and may be carried by nearly 1 in every 30 people, making it one of the most common disease-causing mutations identified so far. Interestingly, individuals who are homozygous for the 30delG mutation show wide phenotypic variation, with hearing impairment ranging from mild to profound. Two carriers of *GJB2* mutations, one for the 30delG mutation and the other for another *GJB2* mutation causing hearing loss, 167delT (deletion of a thymine residue starting at position 167), have moderate hearing impairment themselves. It is intriguing to speculate that some cases of AHL could be associated with carrier status for a *GJB2* mutation (Steel, 1998).

Identification of genes causing neuroepithelial pathology and nonsyndromic recessive deafness in mice and humans is an important advance. Mutations involving myosins and connexin point to vulnerable elements in the cochlea and show how small changes in channel function can profoundly disrupt normal hair cell function. Could the cochlear pathology leading to presbycusis involve similar genes?

B. Clues from Genetic Studies with Gerbils

Next to the mouse, the gerbil is the most frequently used animal model of human presbycusis. The primary age-related pathological change in the gerbil inner ear is degeneration of the stria vascularis, resulting in ''metabolic'' presbycusis, characterized by a relatively flat loss of sensitivity across frequencies. Researchers at the Medical University of South Carolina are using a molecular biology technique known as mRNA differential display–polymerase chain reaction (DD-PCR) to investigate age-related changes in cochlear gene expression (LaMarche *et al*., 1999). Eleven differentially expressed PCR products have been cloned and sequenced. Five of them match known genes. In aged gerbils, upregulation was seen in the partial transcripts for the mitochondrial genes cytochrome C oxidase and 16S rRNA and a gene coding for an actin monomer binding protein that is a cell suicide protein. Downregulation was observed in partial transcripts for a gene coding for a transporter protein involved in assembly and turnover of cell membranes and extracellular matrix constituents, and the gene that codes for the receptor for activated C-kinase. These findings are significant, because they are the first to show evidence of altered gene expression in aged animals with hearing loss. Ultimately, studies will localize the differentially expressed transcripts to specific cell types through *in situ* hybridization or immunocytochemistry.

C. Clues from Genes Producing Dominant Progressive Hearing Loss in Humans

Dominant progressive hearing loss (DPHL) in humans resembles presbycusis in several ways. It is a nonsyndromic form of progressive sensori-neural hearing loss. Some individuals lose the ability to hear high tones or frequencies first, while others may lose the ability to hear the low or middle frequencies first. The biggest difference between DPHL and AHL is in age of onset. In some families, DPHL is first detected in early childhood. In other families, hearing loss may not be evident until early or middle adulthood. However, all known forms of DPHL have onset prior to the third decade of life.

The onset, rate of progression, initial frequencies involved, and ultimate severity of hearing loss vary among families, but are fairly consistent within families. The variability of phenotypic expression suggests that more than one gene can cause DPHL. Indeed, several genes have now been identified. Given the phenotypic similarities between DPHL and AHL, it is likely that an understanding of how the DPHL genes act will provide insights into the mechanisms leading to presbycusis.

D. Clues from Studies of AHL in Mice

A series of studies using inbred, F1 hybrid, and BXD recombinant inbred strains of mice (Erway *et al*., 1993; Johnson *et al*., 1997; Willott and Erway, 1998) has implicated three separate genes for AHL. One gene, responsible for the AHL trait in C57BL/6J mice, has been mapped through linkage analysis to a region of chromosome 10 (Johnson *et al*., 1997). Classical genetic analyses have shown that *Ahl* is inherited as a recessive trait (Erway *et al*., 1993). The phenotype produced by *Ahl* resembles human presbycusis in several ways. It is progressive, primarily involves the sensory hair cells and spiral ganglion cells of the cochlea, and produces a hearing loss that is initially high frequency in nature.

The location of the *Ahl* gene on chromosome 10 is depicted in Fig. 41.3. It is interesting that many other genes for hearing loss map to the same region on the mouse chromosome or to homologous regions of human chromosomes. In mice, waltzer (*v*), Jackson circler (*jc*), Ames waltzer (*av*), and deaf waddler (*mdfw*) mutations map to the same region. It is possible that the AHL trait in C57 mice is a less severe, allelic form of one of these four genes. The *Ahl* locus also has positional homology with human DFN genes DFNA10, DFNB8, and DFNB12, and the Usher syndrome type ID gene, USH1D. Each of these genes is a candidate for *Ahl*. Other candidates for *Ahl* based on positional homology are *Gja,* which codes for an alpha-1 gap junction protein similar to CX26, and various collagen genes. Three defective human collagen genes are responsible for syndromes with late-onset hearing loss, and other atypical collagens have been shown to influence structural integrity of the inner ear matrix (Slepecky *et al*., 1992).

E. Could Mitochondrial Dysfunction Be the Key to AHL?

It is easy to speculate that mtDNA mutations could play a role in presbycusis. MtDNA has a high mutation rate, and somatic mtDNA defects tend to accumulate with age, particularly in tissues with high metabolic rate and low mitotic activity (Lestienne and Bataille, 1994; Sherratt *et al*., 1997; Suomalainen, 1997). Many studies have documented decreased oxidative phosphorylation activity in senescent and degenerative tissues, particularly in tissues with high metabolic rates. It has been postulated that the progressive decline in oxidative phosphorylation and the accumulation of mtDNA mutations results from damage by ROS (Sherratt *et al*., 1997; Suomalainen, 1997). All of these observations suggest that the metabolically active cells of the inner ear, particularly cells of the stria

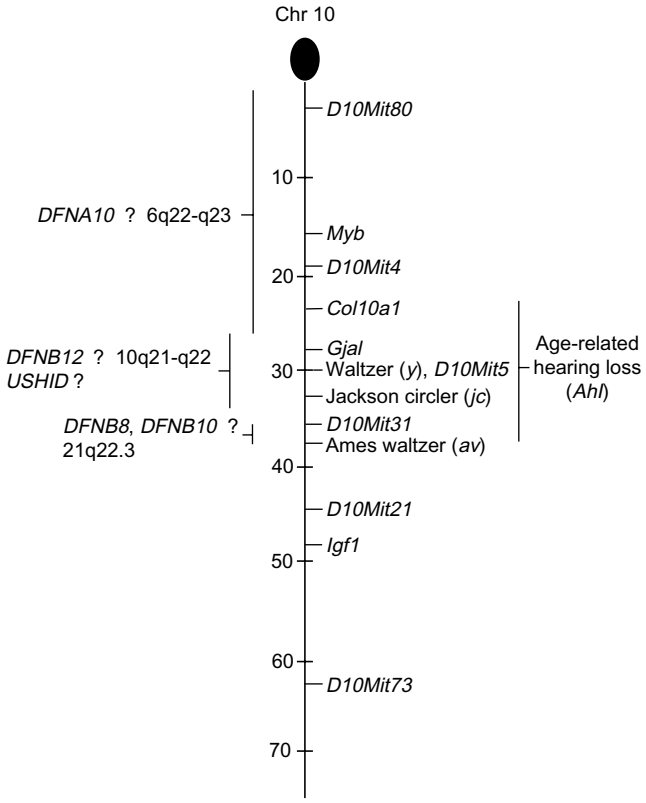

FIG. 41.3. Location of *Ahl* on mouse chromosome 10. There are possible homologies with human chromosomal regions containing nonsyndromal deafness genes and the Usher syndrome type ID gene. (From Johnson *et al*., 1997, with permission from Elsevier.)

vascularis and postmitotic hair cells, would be prime targets for mitochondrial dysfunction.

Investigations of the auditory system in aged animal models have uncovered mtDNA deletions (Seidman *et al*., 1997; Ueda *et al*., 1997) and evidence of impaired energy metabolism (Ding *et al*., 1999). Recent studies with C57BL/6J mice (Ueda *et al*., 1997) and human patients with presbycusis (Fischel-Ghodsian *et al*., 1997) support a relationship between acquired mtDNA defects and presbycusis. Mitochondrial mutations in the peripheral auditory system increase with age in both C57BL/6J mice and humans with presbycusis.

One mutation of mitochondrial rRNA associated with nonsyndromic hearing loss (not presbycusis) has been identified. This is a point mutation (A to G transition) of the 12S rRNA gene at nucleotide 1555 (1555A > G), associated with maternally inherited nonsyndromic deafness (Prezant *et al*., 1993). In some families with this mutation, deafness occurs only after use of aminoglycosides. This is because aminoglycosides affect translational fidelity by binding to the mRNA decoding region and stabilizing mismatched tRNAs (Lestienne and Bataille, 1994). This is an instance where the mtDNA mutation is not pathogenic itself, but causes maternally inherited sensitivity to specific environmental factors.

Because cells usually contain mitochondria in excess of basal needs, clinical features of mtDNA mutations may appear only if a large proportion of the mitochondria is affected or if the energy demands of the cell are extreme. The number of mitochondria found in a particular cell tends to reflect the cell's energy requirements. Hepatocytes may contain several thousand mitochondria, whereas resting lymphocytes may have only a few, and mature erythrocytes have no mitochondria at all (Sherratt *et al*., 1997). Mitochondria are constantly changing shape and positions within a cell, and they tend to accumulate in regions of the cell where energy requirements are high. In the normal inner ear, mitochondria numbers are highest in the cells of the stria vascularis and the spiral ganglion neurons. These cells also express the greatest amounts of Na,K-ATPase, an enzyme whose function depends on the ATP produced by mitochondria. The large numbers of mitochondria and the high energy requirements of the stria vascularis cells and spiral ganglion neurons leads to the hypothesis that these cells might be particularly vulnerable to degeneration during aging.

Recently, Seidman *et al*. (1997) examined tissue samples from brain, auditory nerve and stria vascularis of Fischer rats for evidence of a common mtDNA deletion involving 4834 base pairs. The 4834-base-pair deletion was absent from cochleas of young rats but present in 50% of the stria vascularis samples and in 29% of the auditory nerve samples from animals over 18 months of age.

The region of human mtDNA that is equivalent to the 4834-base-pair deletion in rat mtDNA corresponds to a 4977-base-pair deletion in humans. Bai *et al*. (1997) looked for 4977-base-pair deletions in mtDNA obtained from archived temporal bones. They found the common deletion in 14 of 17 samples from individuals who had presbycusis when they died. However, 8 of 17 aged individuals with no hearing loss also showed the deletion. In another study, Fischel-Ghodsian *et al*. (1997) found a high frequency of mtDNA mutations in temporal bones of aged individuals, but there was no apparent relationship between the amount of hearing loss and the number of sequence changes in mtDNA samples. Thus, while these studies show a strong positive correlation between aging and the common 4977-mtDNA deletion, the link between hearing loss and this particular deletion is weak. However, there are many reasons to continue the search for a link between other mtDNA mutations and presbycusis.

VI. Interactions between Genetic Background and Environment

Environmental agents can cause hearing loss only when the exposed individual is genetically susceptible. Differences in the degree of susceptibility among individuals may also have genetic causes (see Spillman, 1994). An example of this is seen with SOD1 mice created at Cephalon, Inc. Knockout mice of the strain have targeted deletions of *sod1*, the gene that codes for copper–zinc superoxide dismutase (Cu/Zn SOD). Cu/Zn SOD is an antioxidant enzyme found in the cytoplasm of cells. Its role is to convert the superoxide radical to a less reactive molecule. Wild type and knockout SOD1 mice show progressive high-frequency hearing loss and basal cochlear pathology as they age. However, knockout mice lacking Cu/Zn SOD show far greater hearing loss and cochlear pathology than normal. The effects of partial (50%—heterozygous knockout mice) and total (100%—homozygous knockout mice) elimination

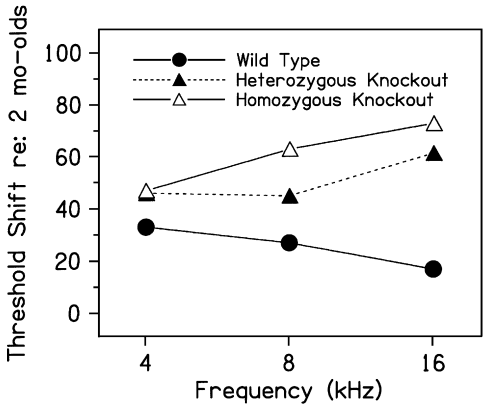

FIG. 41.4. Age-related threshold shifts of SOD1 mice at 13 months of age. Threshold shifts were estimated by comparing auditory brain-stem response thresholds of 13-month-old mice to 2-month-old mice. Wild type mice with normal levels of Cu/Zn SOD had less hearing loss than mice that partially or totally lacked Cu/Zn SOD (heterozygous knockout and homozygous knockout mice, respectively).

of Cu/Zn SOD on age-related hearing loss in SOD1 mice are shown in Fig. 41.4. Compared to young (2-month-old) SOD1 mice, aged (13-month-old) SOD1 mice of all three genotypes had substantial threshold shifts at all frequencies. However, threshold shifts were greatest in the aged mice lacking Cu/Zn SOD, particularly at high frequencies. It is clear that the *sod1* gene does not cause AHL. However, absence of its normal gene product, Cu/Zn SOD, exacerbates genetic AHL (McFadden *et al*., 1999a,b).

VII. Looking to the Future

The information coming from molecular genetics research is likely to influence the field of presbycusis research in two distinct ways. First, molecular techniques may soon aid in the diagnosis of presbycusis. Second, individuals identified as being at risk for presbycusis may one day have the option of choosing gene therapy to prevent hearing loss. Conceivably, gene therapy could involve replacing the defective gene with a functional copy, using carrier vectors such as adenoviruses and herpes simplex I viruses. Alternatively, genes could be inserted that would encode therapeutic agents such as neurotrophins and growth factors to reverse damage in early stages. The cochlea is a good candidate for gene transfer therapies, because of its large fluid spaces and its immunological isolation.

VIII. Conclusions

The role of genetic factors in the etiology of AHL is not known. However, rapid progress in the field of molecular genetics and the availability of appropriate animal models of presbycusis hold promise for unraveling the genetics of AHL in the early part of the 21st century. Clues for human presbycusis genes come from studies with animals, particularly inbred strains of mice, humans with other forms of nonsyndromic hearing loss, and mitochondrial disorders. These studies suggest that it may be most fruitful to concentrate initial research efforts on genes that influence myosin, connexin, actin, and collagen in the inner ear and on mitochondrial mutations.

Animal Models of Presbycusis and the Aging Auditory System

A variety of animal models are available for the study of presbycusis and the aging auditory system. Most widely used are mice, gerbils, rats, chinchillas, and guinea pigs. The rate and severity of presbycusis ranges from mild to severe in various animals, paralleling the range observed in humans.

I. Introduction

One of the most important ways that animal models contribute to presbycusis research is by showing what types of processes and events can and do occur in the aging mammalian ear. All of these may not be shared by humans, and one should never assume that they necessarily are. Nevertheless, the information obtained from animal research can be used to formulate credible, testable hypotheses about mechanisms underlying presbycusis or to suggest new clinical approaches to the human condition. The study of animals also speaks to the ubiquity of certain changes—their generality within the mammalian family. Understanding the properties of presbycusis in various animal species contributes to understanding presbycusis in humans.

The major advantage of using animal models, of course, is the ability to overcome the ethical and practical limitations inherent in the use of human subjects. These limitations include the following: (1) With respect to histological studies, it is usually impossible to obtain rapid and thorough fixation of postmortem neural and cochlear tissue in humans, increasing the likelihood of autolytic artifacts while decreasing the quality and validity of histological specimens. (2) Notwithstanding the rapid evolution of modern imaging technology, it is still the case that most modern *in vivo* methods, required to reveal the anatomical and physiological details of neurons, cannot be used with human subjects. (3) Most elderly people exhibit some degree sensorineural cochlear pathology which can cause secondary morphological and physiological changes in the central auditory system. This would result in a confounding of the influences of peripheral impairment and biological aging, as discussed below. (4) Environmental and genetic influences may interact with age-related biological events to affect the auditory system of older individuals in unknown ways, making it difficult to determine the role of each. The cochlea is especially vulnerable to noise-induced damage, and it is likely that many—if not most—individuals who spend decades of their life in industrialized settings have some degree of noise-induced hearing loss. These problems limit the usefulness of much data obtained from human subjects. The use of animal models can mitigate at least some of the problems, particularly those of a technical nature.

II. Research Considerations in Choosing Animal Models

A. Peripheral Hearing Loss

Perhaps the most important consideration in choosing a particular animal model for gerontological auditory research is the rate and magnitude of age-related hearing loss. Individual humans exhibit very large differences in this regard, with some fortunate people maintaining near-normal hearing well into old age, whereas others begin to experience high-frequency loss during young middle age or earlier. Thus, animal models are needed to represent a range of severity of presbycusis. Hearing loss can be manipulated experimentally in animals using intense noise exposure, cochlear surgery, ototoxic drugs, or other means. However, these procedures can be problematic in gerontological contexts because they typically produce sudden cochlear damage, whereas presbycusis develops gradually over a significant segment of the life span. In addition, mechanically induced lesions tend to be anatomically well delineated, whereas age-related cochlear pathology is not likely to have a discrete "border" between damaged and healthy regions, and drug and noise effects tend to exhibit a good deal of variability across individual animals, even when conditions are tightly controlled. Fortunately, various animal models exhibit age-related hearing loss ranging from minimal to profound, without the necessity of experimental manipulation. These are discussed below.

B. Aging and the Central Auditory System

Hearing is accomplished by the brain and its ability to take the trains of electrical impulses traversing the auditory nerve fibers and transform them into auditory sensations and perceptions. The neuroanatomical ''hardware'' required for this daunting task is incredibly complex, subtle, and, like the cochlea, subject to negative age effects. Indeed, the CAS is threatened by two concomitants of aging. First, changes in the structure or function of the CAS can occur as an aspect of biological aging, as is the case for many other brain regions discussed throughout this book (see also Willott, 1999). With respect to the auditory system, these central effects of biological aging can occur whether or not significant cochlear pathology accompanies aging. However, the cochlear pathology typically associated with aging results in the partial removal or attenuation of neural input from the ear to the brain. The central effects of peripheral pathology can include a variety of changes in the central auditory system secondary to cochlear damage (Willott, 1991). Central effects of peripheral pathology can be superimposed upon and/or interact with central effects of biological aging and it is clear that, for a full understanding of the fate of the central auditory system and the perceptual deficits that accompany aging, both types of central effects must be addressed.

In trying to differentiate between central effects of biological aging and central effects of peripheral pathology the use of animal models becomes extremely important. The majority of older people suffer some loss of hearing and, at the same time, a number of other central age effects. Thus, central effects of biological aging and central effects of peripheral pathology tend to coexist in older humans, making it difficult to interpret the nature of their hearing deficits, particularly those involving the perception of speech and other suprathreshold sounds. In animal models, however, it may be possible to differentiate central effects of biological aging and central effects of peripheral pathology to some extent. This is particularly true with inbred mice, as discussed later.

III. Methods for Evaluating the Functioning Auditory System in Animals

Numerous neurobiological and other methods can be used to study the aging nervous system of animal models, as indicated throughout this book. In order to understand the significance of such changes in the auditory system it is useful to know whether an aging animal exhibits presbycusis; and if so, how severe are the hearing deficits? One of the obvious limitations of animal models is the inability of subjects to indicate directly whether, how well, and what they hear. Thresholds and suprathreshold perception must be inferred from physiological measures and/or behavioral performance. Fortunately, an adequate arsenal of techniques is available.

A. Physiological Approaches

The logic of physiological measures of auditory function is straightforward: use acoustic stimuli to evoke responses in the auditory system and then vary the stimuli while observing changes in the responses. Whereas evoked responses of various types can be obtained easily from animals, there are some gerontological issues that must be addressed. To use these methods with animals usually requires anesthesia or tranquilization. If dose–response curves and/or tolerance of the drug were to differ in old animals (as is often the case), evaluation of auditory function could be confounded. Also, it is important to maintain body temperature in anesthetized animals because hypothermia can alter neural activity. Size, body fat, and temperature regulation mechanisms might be different in old animals, so care should be taken to maintain body temperature with a heating pad or appropriate device. Another issue is the ''endurance'' of old animals in experiments that require long periods of time, such as single-unit recordings.

One method that can deal with these sorts of concerns is the averaged auditory brain-stem response (ABR), perhaps the most widely used measure of auditory sensitivity in animal models. The ABR is easily obtained using commercially available hardware and software and is capable of determining thresholds as well as some suprathreshold parameters (e.g., response latency and amplitude). ABR thresholds are not strongly influenced by anesthesia, the procedure is relatively brief, and body temperature can be maintained by placing the animal on a heating pad or blanket. ABRs can also be used in masking paradigms to provide additional information about auditory functioning. For example, Walton *et al.* (1995) showed that, in mice with age-related hearing impairment, forward masking was evident in the auditory brain stem—more so than in the cochlea. Other event-related potentials, such as middle-latency responses and other cortical responses have been used less frequently with aging animals, but have promise for evaluation of suprathreshold auditory function.

Otoacoustic emissions (OAEs) are finding increasing use in gerontological studies. The OAEs reflect outer hair cell function, and outer hair cell are usually the most vulnerable of cochlear cells with respect to age-related degeneration. An example of the use of OAEs in chimpanzees is shown later.

The use of single- and multiple-unit recordings to obtain more sophisticated information about auditory processing has resulted in some important findings. Issues of anesthetic effects and experiment duration are more cogent for this type of work, especially when recordings are obtained from cortex. However, despite these potential problems a number of important findings have emerged. Some examples are mentioned later in this chapter, such as the discovery of central reorganization of frequency maps, sluggish neurons, deficits in gap detection responses, and indications of diminished inhibition in older animals.

B. Behavioral Approaches

While we can describe the physiological changes in animals' auditory systems, it is difficult to fully appreciate their significance without the use of behavioral and psychophysical methods. Whereas auditory behavioral studies are presently part of the gerontological research landscape, a great deal more effort is need in future research.

Auditory sensation and perception are inferred from behavioral performance (e.g., the animal is trained to respond to a sound). Because both learning ability and performance

may be affected by age-related factors (Willott, 1999; other chapters in this book), great care must be taken not to misinterpret a behavioral deficit as being due to hearing loss, rather than more general learning/performance changes. The best way to do so is by demonstrating that the old animals are capable of performing the behavioral task using nonauditory stimuli and/or using some auditory stimuli that can still be heard well. For example, if an animal fails to respond to a high-frequency tone but still responds well to a low-frequency tone, one can assume a high-frequency hearing deficit, rather than general performance failure.

A variety of auditory behaviors are amenable to gerontological studies in animals. These include the following.

1. The Acoustic Startle Response

The acoustic startle response is reliably elicited by bursts of noise or tones having sound pressure levels (SPLs; re 20 μPa) of 80–90 dB and greater. The jerk-like motor reflex is easily measured by commercially available movement-sensitive (startle) devices, and acoustic startle response latency, amplitude, and threshold are readily obtained. Inability or difficulty in evoking acoustic startle response is diagnostic of either severe hearing loss (Parham and Willott, 1988) or a brain-stem neurological deficit. Figure 42.1 shows an example of how the amplitude of acoustic startle response evoked by 100 dB SPL tones changes with age in two strains of mice differing in severity of presbycusis. As C57 mice lose high-frequency sensitivity with age, acoustic startle response can no longer be obtained with 16-kHz tones, whereas amplitudes decline moderately with 4-kHz stimuli. By comparison, acoustic startle response amplitudes remain large as CBA mice age.

2. Prepulse Inhibition

Prepulse inhibition is a behavioral method that utilizes the startle response as a behavioral "probe" to determine the effectiveness or salience of sounds that modulate the startle. Prepulse inhibition is highly reliable, requires no training, and is readily observable in rodents and humans (Hoffman and Ison, 1980). Prepulse inhibition occurs when a moderately intense (nonreflexogenic) tone "prepulse" (S1) is presented

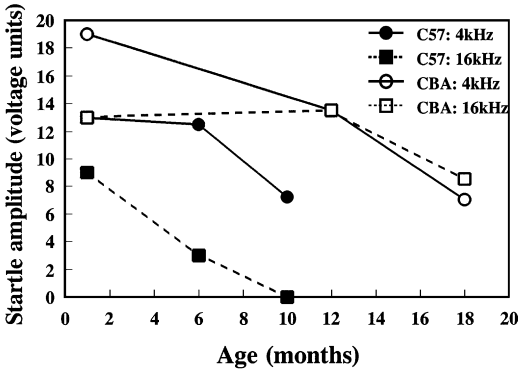

FIG. 42.1. Acoustic startle amplitude in C57 and CBA mice as a function of age. Amplitudes decline rapidly in C57 mice, particularly for 16 kHz tones. CBA mice maintain good acoustic startle response amplitudes as they age. Data were obtained from Parham and Willott (1988).

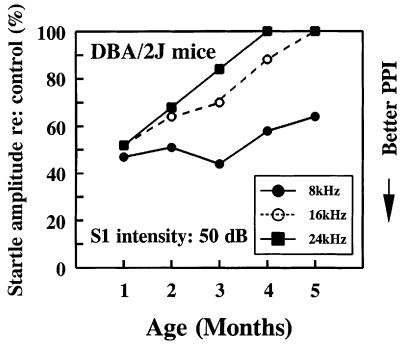

FIG. 42.2. Prepulse inhibition used to show age-related hearing loss. As DBA mice lose high-frequency cochlear sensitivity, prepulse inhibition is no longer produced by 24 kHz tone prepulses. However, lower frequency prepulses maintain their ability to produce prepulse inhibition. Data were obtained from Willott *et al.* (1994b).

10–200 msec before a startle-evoking stimulus (S2), and the response to the startle probe is inhibited. The ratio of startle amplitudes for paired S1–S2 trials divided by S2-only trials defines prepulse inhibition. The S1 activates inhibitory circuits that reduce the response to the probe, so the degree of prepulse inhibition is a measure of the salience of the S1 prepulse. Obviously, if an S1 tone cannot be heard, it will not produce prepulse inhibition; thus measurement of prepulse inhibition while varying the SPL of an S1 can be used to identify animals with hearing impairments (Willott *et al.*, 1994b). Figure 42.2 shows how prepulse inhibition can be used to demonstrate high-frequency hearing loss in DBA mice, an inbred strain that exhibits very rapid, early-onset progressive hearing loss (see below).

3. The Use of Aversive Events

Mild shock is used in several behavioral paradigms that can be used to indicate the salience or potency of auditory stimuli. They have not been widely applied to presbycusis research, but have promise in this regard. Fear-potentiated startle is widely used to investigate the neurobiological basis of anxiety (Davis *et al.*, 1993) and because fear-potentiated startle utilizes Pavlovian conditioning procedures, it is also used to investigate the neurobiological basis of learning and memory. If an auditory stimulus is used as a conditioned stimulus (CS), fear-potentiated startle can be used as a test for auditory behavior. In fear-potentiated startle, a mild shock is paired with the auditory CS for several trials, so that the CS elicits fear. When an animal is then startled in the presence of the CS, startle is potentiated. Thus, the effectiveness of an auditory CS can be measured as a function of age and/or presbycusis. In our experience, old mice (Willott, 1999) and mice with early presbycusis (Falls *et al.*, 1997) continue to exhibit fear-potentiated startle, providing a test of the behavioral salience of sounds in a learning context.

Avoidance conditioning utilizes the shock as a negative reinforcer—an animal will learn to make a behavioral response when an auditory stimulus is presented; this response prevents it from being shocked. Avoidance conditioning is rapid and can be used to test auditory discrimination and other abilities. In the lick suppression paradigm, the subject learns to associate

a mild shock to a drinking spout with the acoustic condition, and presentation of the stimulus causes the subject to stop licking. For example, Heffner and Donnal (1993) used lick suppression to compare spatial localization in young and middle-aged C57 mice with presbycusis; they learned that the shock depended on whether sounds came from one versus two locations. When young, the mice had a mean left/right localization threshold of 33° for broadband noise, but this dropped to 46° 5 months later. Both the loss of high-frequency sensitivity and altered central neural responses (cf. McFadden and Willott, 1994a,b) probably contributed to the localization deficit.

4. Appetitive Conditioning

A potential problem with aversive stimuli in aging research is that old animals that cannot perform well on the task might be subject to shocks that they cannot prevent. The use of positive reinforcers (food or water rewards) precludes such problems. Whereas appetitive tasks often take longer to learn, this is usually not a problem with aging research. Several studies can serve as examples for the use of positive reinforcement to evaluate age-related auditory changes. Harrison (1981) employed a cross-sectional design to evaluate the ability of aging Sprague–Dawley rats to localize sounds. Stimuli were 300-msec noise pulses at 70 dB SPL emitted from one of two loudspeakers. The rats, ages 12 and 30 months, were trained to press a lever (for food reward) close to the speaker emitting sound during a trial. Both old and young rats acquired the learned response quickly, but the percentage of correct responses reached an asymptotic level which was lower (i.e., fewer correct responses) for the older rats. In another study, Brown (1984) used a longitudinal design with Sprague–Dawley rats, training them to press one bar (on the left side of the testing apparatus) if a pink noise was presented from the left side and to press a bar on the right when the sound was presented on that side. By 21 months of age, accuracy of localization had declined from greater than 90% to less than 69% correct. Both studies indicate that aging is accompanied by decreased directional hearing ability in Sprague–Dawley rats. In another example, Sinnott *et al*. (1997) used food reinforcement in a go/nogo detection paradigm to demonstrate age-related changes in responses to of gerbils to human vowel sounds.

In summary, it is clear that a number of behavioral methodologies can be applied to the study of presbycusis in animals. Those mentioned here are applicable to a range of animals from rodents to humans and other primates. Additional techniques are available that may be less broadly applicable, such as more difficult or complex tasks that can be used with chimpanzees.

IV. The Animal Models

A. Mice

Mice have been used increasingly in the past two decades as subjects for auditory research (Willott, 1991; Henry and McGinn, 1992). For gerontological research, mice are unparalleled as experimental subjects with regard to the range of time courses and severity of age-related hearing loss, the various types of cochlear pathology that occur, availability of mutants for immunological and other disorders affecting hearing in adults, genetically engineered mice, and the advanced state of mouse genetics (Willott, 1996b). These factors, combined with the general practical and economic advantages of mice as gerontological research subjects, point to an exciting future in presbycusis research.

The auditory system of *Mus musculus* is functionally mature by age 1 to 1½ months (Shnerson and Pujol, 1983). Thus, in strains or mutants that hear well at this age it can be assumed that the auditory system has developed ''normally.'' That is, early-onset cochlear hearing loss and associated dramatic effects on auditory development have not occurred. Thus, age effects are not confounded by developmental ones. Subsequent changes related to gradual adult-onset hearing loss and/or biological aging can then be interpreted within the gerontological context. Strains vary from those which maintain rather good hearing throughout most of their life (e.g., CBA, C3H, many F1 strains) to those which exhibit very early progressive loss of hearing (e.g., the DBA/2J strain). In the latter regard, there are few if any members of other species that reliably exhibit progressive hearing loss before old age. Table 42.1 summarizes the literature showing properties of age-related hearing loss for a number of mouse strains and mutants. Especially noteworthy are the following.

TABLE 42.1. Age-Related Hearing Loss in Various Mouse Strains and Mutants

Mouse	Reference[a]	Description of hearing loss
Inbred strains		
CBA	1	Little age-related loss through 18 months to 2 years
CBA/J,	2,3,4	
CBA/H-T6J	5	
CBA/CaJ	6,7	
C3H/HeJ	8,9	Maintains good hearing for 18 months or more
C3H/HeSnJ	10	
SJL/J	11,12	Little loss of hearing at 200 days
BALB/c	5,13	Hearing loss appears during first year of life
	14,15	
WB	5,13	Hearing loss appears during first year
A/J	11,12	Relatively high AP thresholds at 50 days but little further loss at 200 days
AU/SsJ	11,12	AP threshold elevations from 4 to 64 kHz by 200 days
AKR/J	11,12	AP threshold elevations (especially high frequencies) by 200 days

TABLE 42.1. (Continued)

Mouse	Reference[a]	Description of hearing loss
C57BL/6	3,12,3	Progressive high frequency loss after 2 months, severe by 1 year, profound by 2 years
C57BL/6J	4,6	
C57b/16	16	
C57BR/cdJ	11,12	Similar to C57BL/6 but at an accelerated rate, losses already evident at 50 days
C3H/*lpr*	9	Elevation of thresholds by 10 months in conjunction with autoimmune disease
SAM-P/1	17	High and low frequency losses by 6 months, profound by 12 months
SAM-R/1	17	Similar to SAM-P/1 but slower progression, profound loss by 20 months
LP/J	18	Relatively high AP thresholds at 50 days, profound loss by 200 days
DBA/2J	5,14	Rapid age-related loss, beginning by 1 month, profound by 3–5 months
	19	
CD/1	20	Hearing loss probably too early, rapid for aging research
BXD strains	21	All 25 BXD strains exhibit hearing loss ranging from worse than DBA to C57-like
129/J	22	These strains exhibited elevated ABR thresholds before the age of 3 months; some might be useful as models of early-onset presbycusis; most are presumably not good candidates for studies wishing to use relatively old mice that can hear
129/ReJ		
129/SvJ		
ALR/LtJ		
ALS/LtJ		
BUB/BnJ		
C57BLKS/J		
C57BR/cdJ		The same study also identified more than 60 other inbred strains that had good hearing at 3 months; some of these may have potential as later onset or normal-hearing aging models
C57L/J		
I/LnJ		
MA/MyJ		
NOD/LtJ		
NOR/LtJ		
SKH2/J		
Outbred Strain		
NMRI	23	Gradual behavioral threshold elevations through 18 months, 20–30 dB for 60–80 kHz, <20 dB for 15–40 kHz
F1 hybrids		
CBA/BALB	5	Normal hearing to 2+ years
CBA/WB		
CBA/C57		
CBA/DBA		
DBA/BALB	5	Severe hearing loss during first year of life
DBA/WB		
DBA/C57		
C57/WB	5	Moderate hearing loss by 2 years but better than parental inbred strains
C57/BALB		
BALB/WB		
CBA/CaJ/ AU/SsJ	24	Excellent hearing to at least 1 year of age
"BD"	25	Moderate hearing loss during first year of life, profound by 18 months
Mutants		
Dancer	26	Progressive hearing loss between 1 and 13 months (but much variability among individuals)
Shaker-1	27,28	Some hearing, but early, rapid degeneration; deaf by 3–7 weeks of age
Waltzer		
Pirouette		
New	8	Profound hearing loss from birth, but cochlear pathology progressed through 18 months
Light (Blt)	29	Reduced endocochlear potentials during the first year of life
Hypophosphatemia	30	Abnormal phosphate metabolism; late-onset hearing loss
Trembler	31	PMP-22 homozygote; progressive hearing loss
Mov-13 transgenic	31	COL1A1 heterozygote heterozygotes; progressive hearing loss

[a] 1, Wenngren and Anniko, 1988a; 2, Henry and Chole, 1980; 3, Hunter and Willott, 1987; 4, Willott, 1986; 5, Erway *et al*., 1993; 6, Li and Borg, 1991; 7, Henry, 1982; 8, Kitamura *et al*., 1991; 9, Trune *et al*., 1989; 10, Trune *et al*., 1996; 11, Shone *et al*., 1991a; 12, Henry, 1983; 13, Jimenez *et al*., 2000; 15, Willott *et al*., 1998; 16, Mikaelian, 1979; 17, Saitoh *et al*., 1994, 1995; 18, Chole and Henry 1983a,b; 19, Willott *et al*., 1984; 20, Shone *et al*., 1991b; 21, Willott and Erway, 1998; 22, Zheng *et al*., 1999; 23, Ehret, 1974; 24, Henry *et al*., 1992; 25, Church and Shucard, 1986; 26, Wenngren and Anniko, 1988b; 27, Deol, 1956; 28, Steel *et al*., 1983; 29, Cable *et al*., 1993; 30, Steel *et al*., 1989; 31, Steel, 1995.

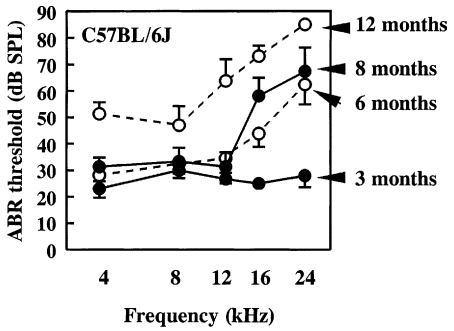

FIG. 42.3. ABR thresholds from C57 mice as they age. These thresholds were obtained longitudinally from the same set of mice. Earliest and most severe losses are at high frequencies. Data are from routine testing in our laboratory.

C57BL/6J mice (C57; also called B6) have been the most extensively studied animal model of age-related hearing loss. Peripheral function develops in an apparently normal fashion, being optimum between 1 and 2 months of age. Sometime during the following few months, however, high frequency sensitivity begins to decline. By 6 months of age loss of high frequency sensitivity (e.g., >20 kHz) is significant; by 1 year, losses are severe and have begun to encompass lower frequencies; after about 15 months of age, thresholds for all frequencies are typically in excess of 80 dB SPL (Mikaelian, 1979; Henry, 1983; Willott, 1986; Li and Borg, 1991). The advantage here is that the onset of hearing loss in most humans suffering from presbycusis likewise occurs after maturation has progressed beyond sensitive developmental periods; like C57 mice, most people begin their adult life with good hearing. Figure 42.3 shows ABR thresholds revealing age-related hearing loss in C57 mice.

It is now known that a recessive gene is responsible for the progressive hearing loss in C57 mice (Erway *et al*., 1993; Willott *et al*., 1995; Johnson *et al.*, 1997). The *Ahl* gene (for *a*ge-related *h*earing *l*oss) is found on chromosome 10 and results in damage to the cochlea, characterized by a consistent pattern of histopathology (Mikaelian, 1979; Henry and Chole, 1980; Cohen and Grasso, 1987; Willott and Bross, 1990; Li and Borg, 1991; Mizuta *et al*., 1993; Spongr *et al*., 1997). Prior to 2–3 months of age, little cochlear pathology is evident in C57 mice. By 6 months, degenerative changes of the organ of Corti (e.g., distortion, clumping, and loss of outer hair cells) have begun and are most pronounced in the basal turn. The loss of outer hair cells is more severe than, and precedes the loss of inner hair cells, and this is reflected by changes in otoacoustic emissions (Parham, 1997; Jimenez *et al*., 2000). Supporting cells also show degenerative changes. By 2 years of age the basal region of the C57 organ of Corti is virtually devoid of recognizable structures. A pronounced loss of spiral ganglion cells occurs in aging C57 mice, with nearly complete loss in the basal cochlea during the second year of life. Some atrophy of the stria vascularis is observed in aging C57 mice, but the most striking strial changes is an increase in pigment. Histopathological changes are shown in Fig. 42.4.

Vascular dysfunction occurs as well. Brown *et al*. (1995) evaluated vascular changes in the aging inner ear of C57 mice. Microvascular reactivity was monitored by laser Doppler flowmetry and assessed by the change in cochlear vascular conductance in response to the application of sodium nitrorusside (a vasodilating agent) to the round window. In C57 mice vascular conductance increased less than that of young mice and age-matched CBA mice, which continued to hear well (see Table 42.1). There were also differences in the duration of the vascular conductance change. The findings suggest that cochlear blood flow may be altered in hearing-impaired C57 mice.

DBA/2J mice (DBA; also called D2) exhibit optimal hearing before 25 days of age, but sensitivity rapidly deteriorates thereafter (Ralls, 1967; Willott, 1981; Willott *et al*., 1984). By 5 months of age, hearing loss is severe, and anatomical signs of degeneration seen in the outer hair cells, inner hair cells, and spiral garglion cells. DBA mice also possess the *ahl* gene, but also appear to have one or two additional genes with deleterious effects on hearing.

BALB/c mice have a time course and pattern of hearing loss somewhat like that of C57 mice, although different substrains may progress faster (Willott *et al*., 1998) or slower (Jimenez *et al*., 2000) than C57. BALB/c mice also possess a recessive gene but it is probably not *Ahl* (Erway *et al*., 1993). Like the other strains, BALB/c exhibits a progressive loss of hair cells and spiral ganglion cells that is most severe in the cochlear base and least severe in the middle turns; however, BALB/c mice have relatively more spiral ganglion cells loss in the apex.

BXD recombinant inbred strains of mice have been widely used in genetic studies using quantitative trait loci analysis and other methods. Numerous genetic markers have been identified for the BXD strains, thus providing a powerful method of examining correlations between phenotypes (e.g., hearing loss) and genotype. The BXD strains were derived by successive brother–sister matings from original F1 hybrids of C57 and DBA strains. As indicated above, both of the parental strains are homozygous for the *Ahl* gene, so all BXD strains possess the gene (and some are also homozygous for the other one or two hearing-loss genes of DBA). Whereas all 25 BXD strains exhibit progressive hearing loss (Willott and Erway, 1998), the severity ranges from worse-than-DBA to C57-like in time course and severity. This suggests that the number of hearing-loss genes (one, two, or three) and/or genetic background contribute to the severity of hearing loss. Ultimately, selected BXD strains can be used to ''vary'' the time course of hearing loss and elucidate the genetics of age-related hearing loss.

129-Related inbred strains are the source of most embryonic stem cells used to create targeted mutations. 129 Strains exhibit moderate hearing impairment at 7 months (Zheng *et al*., 1999). Because 129 and C57 mice are commonly used in genetic engineering, caution is warranted in the use of genetically altered mice in presbycusis research.

Mice with genetic mutations often have severe congenital or early-onset ear pathology (Steel *et al*., 1983; Steel, 1995). However, some of these mutants may be useful in aging research. For instance, the Dancer mutant succumbs to progressive hearing loss during the first year of life (Wenngren and Anniko, 1988b), making it a potential model for studying the genetics of presbycusis.

Mice that retain good hearing until relatively late in life include outbred NMRI mice, CBA strains, C3H strains, and

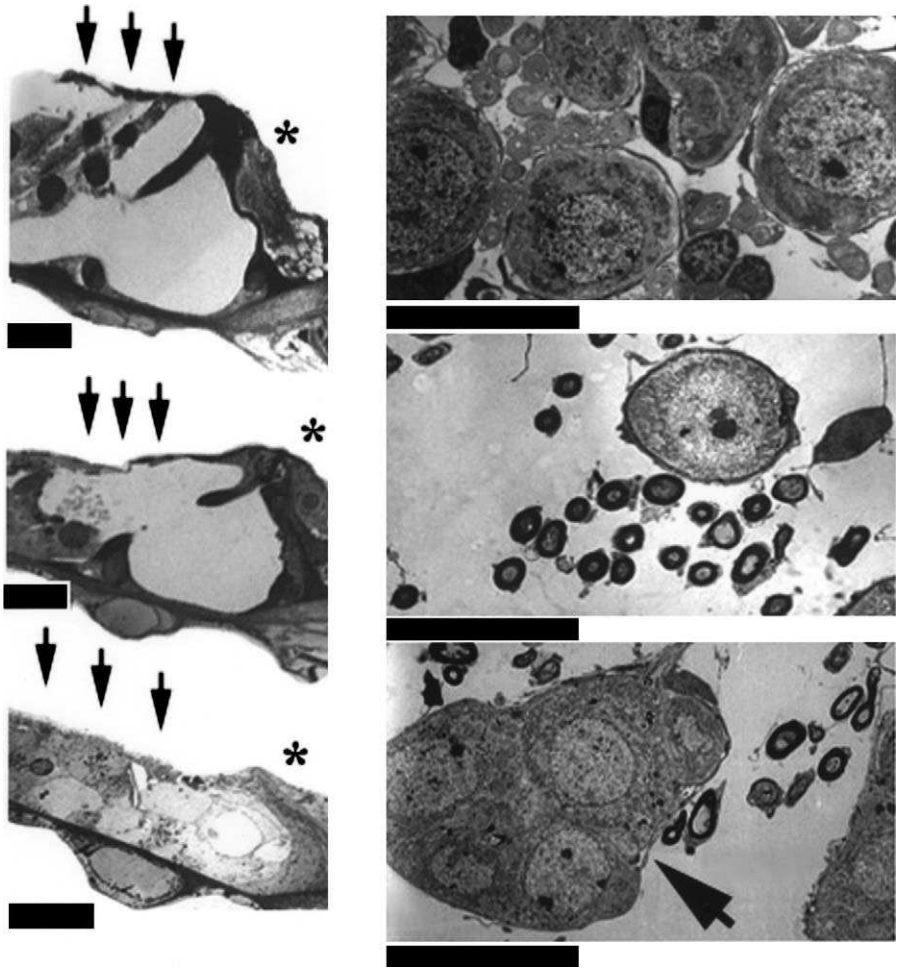

FIG. 42.4. Some age-related histopathological changes in the C57 mouse cochlea. Scale bars, 10 μm. The left column shows changes seen in the basal region of the organ of Corti. The arrows point to the location of the three rows of outer hair cells; the asterisks are above the inner hair cells. The top micrograph (a semithin section) shows the earliest histopathological changes, degeneration of outer hair cells in the outer row; such changes can be seen as early as 2–3 months of age in the extreme cochlear base. Progressive degeneration gradually occurs, as all outer hair cells in the basal cochlea disappear (middle micrograph); most inner hair cells remain intact. At the bottom is an electron micrograph showing complete loss of organ of Corti structures that occur during the second year of life. The organ of Corti, including the IHCs, is replaced by a nonfunctional sheet of cells. The right column shows electron micrographs of spiral ganglion cells. In young, normal-hearing mice, spiral ganglion cells are packed tightly within the cochlea (Rosenthal's canal). Compare this with the middle micrograph obtained from an older mouse, containing only a few somata and cross sections of myelinated axons. The bottom micrograph shows clumping of spiral ganglion cells (large arrow) that occurs in the spical region of the cochlea—another type of pathology that is typical of aging C57 mice.

a number of F1 hybrids. CBA mice in particular have been used extensively in research on aging and the auditory system, when a model of mild presbycusis is desired. They do not exhibit age-related hearing loss until relatively late in life (Henry, 1983; Willott, 1986; Wenngren and Anniko, 1988a; Willott *et al*., 1988a). CBA mice show virtually no loss of hair cells at 16 months of age; at 2 years of age a few inner hair cells have been lost, and there is a small loss of outer hair cells with a total loss only at the extreme cochlear base (Henry and Chole, 1980). Also, virtually no loss of spiral ganglion cells is observed during the first year of life of CBA mice, and only a minimal decrease throughout the cochlea is seen by 2 years. There are age-related changes in CBA mice, however. Suzuki *et al*. (1998) obtained evidence that ears of aging of CBA mice (21 months) had reduced capacity to maintain stable blood flow. They measured cochlear blood flow with laser Doppler flowmetry during intermittent occlusion of the anterior inferior cerebellar artery, which alters cochlear perfusion pressure and causes a decrease in blood flow. The compensatory dilatory response was reduced in the old mice. In another study, Ding *et al*. (1999) measured dehydrogenase and glycogen levels in the CBA cochlea and found evidence for altered energy metabolism in aging mice.

Another model for minimal presbycusis is the B6.CAST–$^{+ahl}$/+ congenic strain. These mice were produced from back crosses of C57 with CAST/Ei with marker assisted selection to produce a congenic line of B6 mice that lacks the *ahl* gene and, therefore, has normal hearing (Johnson *et al*., 1997). Because they are genetically very similar to C57 but hear normally, comparison of 6-month-olds of the two strains

can help to isolate the effect of hearing loss from other genetic influences on the central auditory system.

Mice with genetically determined age-related cochlear pathology prior to old age provide excellent models for central effects for peripheral pathology, while those maintaining good hearing can be used to evaluate central effects of biological aging. The most extensive and detailed life span studies on the central auditory system have been done with C57 and CBA mice, and they exemplify, respectively, aging with and without significant cochlear pathology, allowing elucidation of central effects of peripheral pathology and central effects of biological aging, respectively.

Anatomical studies of C57 mice have found that age-related sensorineural cochlear pathology is associated with changes in the neuropil volume of cochlear nucleus subdivisions and the size and number of neurons (Browner and Baruch, 1982; Willott *et al*., 1987, 1992, 1997; Briner and Willott, 1989; Willott and Bross, 1990). However, the occurrence of these effects depends upon the subdivision examined—the anterior ventral cochlear nucleus (AVCN), posterior ventral cochlear nucleus (PVCN), and dorsal cochlear nucleus (DCN). Those regions heavily innervated by the terminals of primary fibers from spiral ganglion cells (AVCN, PVCN, layer III of DCN) are relieved of much of their normal input from the impaired cochlea, and it is here that anatomical signs are most pronounced. In contrast, DCN layers I and II, which receive little direct primary fiber input, and higher-order structures such as the inferior colliculus, which receive no cochlear input, show fewer anatomical changes through the median life span age of 2 years (Willott *et al*., 1994a). Nonetheless, higher-order structures do exhibit age effects such as changes in synaptic density (Kazee *et al*., 1995), calcium binding proteins (O'Neill *et al*., 1997; Zettel *et al*., 1997; Idrizbegovic *et al*., 1999), and other neurobiological variables.

Some morphological changes in the cochlear nucleus of DBA and BALB/c mice are similar to those in C57 mice. However, because the time course of progressive cochlear pathology differs, so do the central changes. Figure 42.5 shows the relative age-related change in AVCN volume for C57, DBA, BALB/c, and normal-hearing CBA strains. Note that even though cochlear pathology and central changes are rapid and severe in DBA mice, the ultimate loss of neurons and AVCN volume reaches a stable level similar to that in C57 and BALB/c mice, with no additional changes thereafter. AVCN volume in normal-hearing CBA mice grows during year 1 before starting to decline gradually.

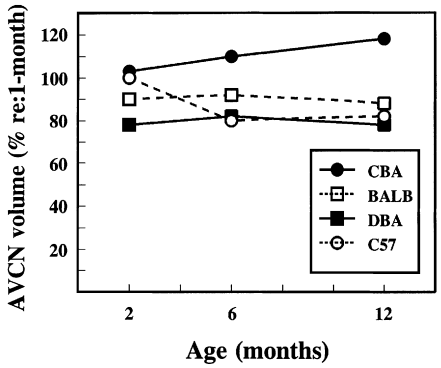

FIG. 42.5. Relative change in the volume of the anterior ventral cochlear nucleus of four inbred strains of mice. CBA mice retain good hearing as they age, and exhibit a maturational increase in AVCN volume. The other three strains exhibit early progressive hearing loss and lose AVCN volume. Data were obtained from Willott and Bross (1996) and Willott *et al*. (1987, 1998).

Neurophysiological studies have also evaluated central effects of peripheral pathology and central effects of biological aging in C57 and CBA mice. In either strain, neural coding activities that rely on populations of neurons must do so with diminished numbers due to threshold elevations and an increase in "sluggish neurons"—those that respond to sound, but do so unreliably (Willott *et al*., 1988a,b). Nonetheless, the responses of most ("nonsluggish") neurons in middle-aged C57 and very old CBA mice reveal a remarkable degree of "normalcy," at least when simple tones are used as stimuli. When more complex auditory processing is required, age effects become more prevalent, such as deficits in gap detection (Walton, *et al*., 1995, 1998; Ison *et al*., 1998).

As C57 mice lose high-frequency hearing, the way frequency is represented in the central auditory system is altered (Willott, 1986, Willott *et al*., 1988b). The inferior colliculus central nucleus is tonotopically organized: neurons in the superficial portions are sensitive to low-frequency sounds, whereas neurons in progressively deeper regions are sensitive to progressively higher frequencies (Stiebler and Ehret, 1985, Willott, 1986). In the ventral inferior colliculus, neurons respond very well to high-frequency sounds but do not respond to low or middle frequencies. As C57 mice age and lose functioning of the high frequency (basal) portion of the cochlea, neurons that were formerly (normally) sensitive only to high-frequency sounds become sensitive to lower frequencies. In this form of hearing-loss-induced plasticity there is a reorganization of frequency representation in older C57 mice [see Willott (1996a) for a detailed discussion]. The degree of reorganization of frequency representation differs considerably in different parts of the central auditory system. In the auditory cortex, hearing-loss-induced plasticity is even more pronounced than it is in the inferior colliculus as virtually the entire auditory cortex quickly becomes responsive to low and middle frequencies (Willott *et al*., 1993). By contrast in the AVCN and PVCN, the lowest-level central auditory system structures, neurons exhibit elevation of thresholds but little if any plasticity of the type seen at higher levels (Willott *et al*., 1991). Thus, the cochlear nucleus regions, which exhibited the greatest degenerative anatomical changes associated with central effects of peripheral pathology (see above), showed the least amount of physiological plasticity in the representation of frequency.

B. Gerbils

The Mongolian gerbil has an audibility curve similar to that of humans, despite its small size (small rodents typically have a higher frequency range of hearing, as demonstrated in mice). This makes gerbils an attractive animal model for auditory research. For gerontological studies, it shares the practical advantages of mice, being economical to maintain, with a life span of about 3 years. Mongolian gerbils are not explicitly inbred, which can be viewed as a plus because humans are also genetically diverse. Thus, consistent findings related to age are

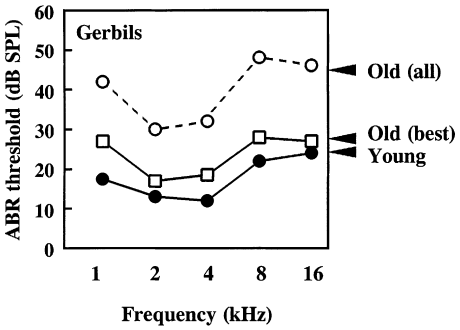

FIG. 42.6. Age-related hearing loss in gerbils. Because of the between-subject variability, ABR thresholds are shown from all old animals as well as the four best. The latter exhibit minimal loss compared to young gerbils, but overall a flat pattern of hearing loss is seen. Data were obtained from Boettcher *et al.* (1993).

presumably robust across genotypes. On the minus side, gerbils exhibit a great deal of variability in the severity and time course of presbycusis, one of the disadvantages shared by studies of humans.

As shown in Fig. 42.6, gerbils usually maintain good hearing through 16–18 months of age, then exhibit losses (Mills *et al.*, 1990). However, threshold elevations are typically not severe even by age 3 years (life expectancy), and the high-frequency losses are not substantially greater than the low-frequenciy losses (Henry *et al.*, 1980; Boettcher *et al.*, 1993a).

Scanning electron microscope material obtained by McGinn and Chole (cited in McGinn and Faddis, 1987) revealed little loss of hair cells or other cochlear pathology in gerbils as old as 30 months. Tarnowski *et al.* (1991) also found that inner hair cell loss was minimal in old gerbils, and whereas some outer hair cell losses occurred, they were quite variable between animals and correlated poorly with threshold shifts. Keithley *et al.* (1988) found a loss of spiral ganglion cells appearing first at 24–30 months of age. In the oldest animals (36–42 months) a 15–25% loss occurred. Recently, Zheng *et al.* (1998) presented evidence suggesting that the sensorineural damage that does occur involves apoptosis. The development of vacuoles was seen in the auditory nerve, but only central to the Schwann–glial border (Keithley *et al.*, 1988). The age-related development of vacuolar lesions in the gerbil cochlear nucleus appears to involve degeneration of dendrites (Faddis and McGinn, 1997), although their functional significance is not clear.

The somewhat flat pattern of hearing loss and moderate sensorineural pathology in old gerbils suggest strial pathology. This has been supported by a series of studies from the Medical University of South Carolina, which included quiet-aged gerbils. They found considerable evidence for the occurrence of progressive changes in the vasculature and integrity of the stria vascularis and associated events such as Na^+,K^+-ATPase activity and its effects on the endocochlear potential (Schulte and Schmiedt, 1992; Gratton *et al.*, 1995, 1996, 1997; Schmiedt, 1996; Adams and Schulte, 1997) and deposition of the glycoprotein laminin in strial capillaries (Sakaguchi *et al.*, 1997).

The South Carolina team also demonstrated a variety of electrophysiological changes in quiet-aged gerbils. ABRs had reduced amplitudes, altered latencies, stable responses to stimulus repetition, and abnormal response to noises separated by gaps in ABR wave IV but not wave II (Boettcher *et al.*, 1993a,b, 1995, 1996). Compound action potentials and auditory nerve fibers also showed age-related changes including altered input–output intensity functions, reduced frequency selectivity, and a change in spontaneous activity of nerve fibers (Hellström and Schmiedt, 1990, 1991, 1996, Schmiedt *et al.*, 1990, 1996).

C. Rats

Rats have some compelling advantages as an animal model for aging research. Most notably, a large gerontological database is accruing for neurogerontological research in rats, as is evident in other chapters (see also Willott, 1999). Thus, a great deal is known about the aging rat nervous system, and many neurobiological techniques are available. Moreover, rats have been the favorite subject in behavioral research, which should facilitate behavioral evaluations of auditory function in aging animals. Most of the presbycusis research on rats has used the Sprague–Dawley and Fischer 344 strains.

In Sprague–Dawley rats, Crowley and colleagues (1972a,b) found that the cochlear sensitivity for click stimuli was optimal at 12 months and then declined by about 12 dB at 24 months. Cooper *et al.* (1990) observed ABR threshold increases of about 18 dB at 3 kHz, 14 dB at 8 kHz, and 32 dB at 40 kHz in 24 to 29 month-olds. Longitudinally measured behavioral thresholds for narrow noise bands remained unchanged through 14 months but exhibited progressive elevations through 30–39 months (Turnock and Harrison, 1975; Harrison, 1981). Rats over 30 months old typically showed a hearing loss of 10–15 dB at frequencies above 32 kHz and below 1 kHz, a less pronounced age effect than that of Cooper *et al.* (1990). However, their ABR study used tone bursts whereas the behavioral work used filtered noise bands.

Keithley and Feldman (1982) observed only small degrees of hair cell degeneration beginning by 6 months of age, with greater vulnerability of outer hair cells as opposed to inner hair cells. The greatest losses of hair cells occurred at the cochlear base and apex. Keithley and Feldman (1979) found a significant reduction in the number of spiral ganglion cells by 23 months with little apparent further loss through 34 months. The losses occurred throughout the length of the cochlea, but were greatest near the base and apex. Type I ganglion cells (which synapse on inner hair cells) were lost to a greater degree than inner hair cells, suggesting that at least some type I spiral ganglion cells were degenerating for reasons other than the loss of the hair cells that they innervated. Conversely, they saw the disappearance of outer hair cells at the cochlear base, but not type II spiral ganglion cells presumed to innervate them, suggesting that outer hair cells can atrophy without involving neural cells. Hoeffding and Feldman (1988) showed that the median number of normal auditory nerve fibers was reduced by 21% at age 26.5 months and by 24% at 36 months. Old Sprague–Dawley rats also show evidence of altered basilar membrane composition with respect to fibronectin and the number of mesothelial cells (Keithley *et al.*, 1993).

Fischer 344 rats show a loss of sensitivity with aging that is probably more severe than that of Sprague–Dawley rats. By 25 months of age, there is an elevation in click thresholds of 20

dB (Simpson *et al*., 1985), whereas thresholds to tone pips (3, 8, and 40 kHz) were on the order of 30 dB or more (Cooper *et al*., 1986). Recent work indicates that older Fischer 344 rats exhibit decreased cochlear vascular function (Seidman *et al*., 1996). There is also evidence that deletions of mitochondrial DNA may contribute to presbycusis in these rats (Seidman *et al*., 1997).

A good deal of gerontological research has focused on the rat central auditory system. A series of studies on the medial nucleus of the trapezoid body of Sprague–Dawley rats revealed a number of age effects (Casey and Feldman, 1982, 1985a,b, 1988). These included a loss of neurons, increased pigment deposits, neuronal degeneration, and vascular abnormalities. Other studies have demonstrated age-related decrease in inhibition in the lateral superior olive (Finlayson, 1995), age-related increases in glial fibrillary acid protein (a marker for gliosis) in the cochlear nucleus (Jalenques *et al*., 1997), and hearing-loss-induced plasticity in the inferior colliculus (Keithley *et al*., 1994).

The inferior colliculus makes great use of gamma-aminobutyric acid (GABA) in its neural circuits. Caspary, Milbrandt, and colleagues have provided strong evidence that inhibitory processes involving the neurotransmitter GABA become diminished in the inferior colliculus of aging Fischer 344 rats (Caspary *et al*., 1990, 1995; Milbrandt *et al*., 1994, 1996, 1997; Raza *et al*., 1994; Milbrandt and Caspary, 1995). Older rats are characterized by fewer inferior colliculus neurons containing GABA (as shown by immunocytochemistry), decreased basal concentrations of GABA, decreased release of GABA by inferior colliculus neurons, decreased activity of glutamic acid decarboxylase (an enzyme involved in making GABA), changes in GABA receptors at synapses, and a decrease in the number of presynaptic terminals using GABA. Neural responses of inferior colliculus neurons are altered as well, some of which suggest decreased inhibition (Palombi and Caspary, 1996a,b).

D. Chinchillas

Chinchillas are a popular animal model for auditory research, having a number of technical advantages, a good ability to learn discrimination tasks, and an audibility curve which is similar to that of humans (Miller, 1970). With respect to gerontological auditory research, chinchillas appear to have low susceptibility to middle ear infections and a life span of about 20 years.

Bohne *et al*., (1990) provided a detailed, quantitative description of the histopathology of the inner ear of 80 chinchillas, some as old as 19.2 years. All aging animals exhibited some degeneration of the organ of Corti, but it was generally mild. Only 5% demonstrated primary neural degeneration. Outer hair cells degenerated by about 1% per year compared to 0.35% per year for inner hair cells. Many animals had circumscribed regions of hair cell loss, and these became more prevalent with age. Total degeneration of regions of the organ of Corti was rare. Some strial degeneration and lipofuscin accumulation were also typical of old chinchillas.

McFadden *et al*. (1997a) obtained auditory evoked potential thresholds and also assessed outer hair cell function with distortion product otoacoustic emissions and histopathological evaluations. Like Bohne *et al*. (1990), they found a small but significant decline in auditory sensitivity and outer hair cell function. The losses were greatest at higher frequencies, as shown in Fig. 42.7. This, along with the slow time course of hearing loss, recommend chinchillas as a model for the study of aging when mild cochlear pathology occurs. Because the old animals continue to hear relatively well, gerontological experiments elucidating suprathreshold auditory responses can be performed. In this regard, McFadden *et al*. (1997b) obtained several measures of suprathreshold auditory function (e.g., frequency resolution, forward and remote masking) before and after exposure to noise. They observed abnormal responses, even for frequency ranges where hearing thresholds were near normal.

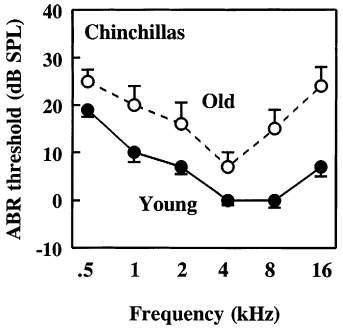

FIG. 42.7. Age-related hearing loss in chinchillas. High-frequency ABR threshold elevations are slightly greater. Data were obtained from McFadden *et al*. (1997a,b).

E. Guinea Pigs

Guinea pigs have been used widely in auditory research, and have been the subject of several aging studies. Dum *et al*. (1980) measured ABR thresholds and found them to be near normal at 15 months, but elevated by 30–40 dB at 24 months with little further change by 3 years. The threshold elevations were relatively "flat," being similar for frequencies of 500 to 15,000 Hz. Proctor *et al*. (1998) and Ingham *et al*. (1998) obtained similar found ABR threshold elevations in animals aged to 3 and 4 years, respectively. However, there appears to be considerable between-subject variability in ABR changes in aging guinea pigs (Nozawa *et al*., 1996). For example, Ingham *et al*. (1998) found no evidence for retrocochlear deficits, whereas Proctor *et al*. (1998) reported markedly reduced ABR amplitudes. In addition, Ingham *et al*. (1998) found evidence for conductive hearing loss in old animals (mean elevation for click thresholds was 32 dB), but 24% appeared to have severe sensorineural hearing loss in which ABRs could not be elicited. More than 40 years ago Pestalozza *et al*. (1957) also concluded that both middle ear conductive and cochlear sensorineural hearing loss occurred in older guinea pigs.

Covell and Rogers (1957) were the first to describe the histological features of the aging guinea pig inner ear. At 5 years of age, pathology of the stria vascularis was not consistent, but included regional atrophy and increased pigmentation. The most prominent age-related change was a decrease in the number of spiral ganglion cells near the cochlear apex and, to a

lesser extent, in the base (not the typical pattern observed in humans and other animals). Fiber degeneration proceeded in each of the bipolar directions (into the eighth nerve and toward the organ of Corti), suggesting primacy of neural degeneration. Degenerative changes in the organ of Corti were prominent only in the oldest guinea pigs and only in the regions of spiral ganglion cell loss. Recently, Ingham *et al*. (1999) reported about a 20% loss of outer hair cells restricted to the cochlear apex of 4.5-year-olds. Other studies were consistent with these in finding little hair cell degeneration, but failed to include particularly old animals (see Willott, 1991).

F. Cats

Historically, cats have been one of the most important animal models for auditory anatomical and physiological research, and much is known about the cat auditory system. However, their utility as subjects for aging research is limited by their relatively long life span and lack of availability of old research subjects, particularly ones that have been maintained under known environmental conditions.

Auditory thresholds become elevated in aging cats. Harrison and Buchwald (1982) reported that the mean thresholds for clicks presented in the free field were elevated by about 30–50 dB in cats ages 12 to 23 years. In older cats of unspecified ages, Schuknecht (1955) found atrophic changes in the organ of Corti and loss of efferent and afferent nerve fibers, especially nearer the cochlear base. However, the histopathological profiles were rather variable within the general framework of sensorineural atrophy. Behavioral audiograms differed substantially as well. Spoendlin (1970) presented electron micrographs from a 13-year-old cat "which apparently did not hear well." The supranuclear portion of the outer hair cells appeared normal but extremely large lysosomal bodies, filled with dense inclusions, were seen in the subapical area of outer hair cells. There was also a marked reduction in the efferent innervation of the organ of Corti. An age-related increase in stria vascularis pigment has been reported in old cats (Conlee *et al*., 1989).

G. Dogs

Whereas dogs are rarely employed in auditory research, they do exhibit age-related cochlear histopathology reminiscent of that observed in humans. Johnsson and Hawkins (1972, 1979) indicated that the inner ear of several dogs they examined histologically had changes that included strial atrophy, sensorineural degeneration, and vascular disturbances. Knowles *et al*. (1989) examined the middle and inner ears of dogs aged 1.5 to 17 years. The middle ear ossicles appeared normal, but the density of spiral ganglion cells was reduced, primarily in the basal turns of the cochlea. In dogs with elevated ABR thresholds, the density of spiral ganglion cells was reduced to 40% in the lower basal region. Some dogs had severe hearing loss and these had nearly complete loss of spiral ganglion cells in the basal turn. Recently, Shimada *et al*. (1998) supported these findings, showing similar cochlear changes in old dogs. All in all, dogs may be a good model for post mortem studies of cochlear histopathology and aging.

H. Nonhuman Primates

Monkeys and chimpanzees have the advantage of being relatively closely related to humans. Of course, this also results in their primary disadvantages—a rather long life span, great expense, and ethical/political issues that complicate their use in research. Consequently, only a few studies of presbycusis in nonhuman primates have been performed.

Bennett *et al*. (1983) used psychophysical techniques to show that old rhesus monkeys exhibited presbycusis, especially showing losses at high frequencies. Hawkins *et al*. (1985) presented histopathological data on 15 rhesus monkeys, ages 4 to 31 years. Missing hair cells were seen in aging monkeys, particularly in the extreme cochlear base and apex. Their three 31-year-olds had a complete loss of inner and outer hair cells and nerve fibers in the first 2–5 mm of the basal turn. Loss of nerve fibers was seen in the same regions as hair cell loss and was interpreted as being secondary. A partial loss of spiral ganglion cells in the basal turn was characteristic of older animals. There were few consistent changes in the stria vascularis, spiral ligament, and Reissner's membrane (except for an increased number of lipofuscin granules in the oldest group). Taken together, the authors saw the changes as similar, albeit of lesser magnitude, to those typical of sensorineural presbycusis in humans.

Johnsson and Hawkins (1972) examined the temporal bone of a 39-year-old chimpanzee. The animal exhibited relatively mild outer hair cell loss, mainly in the basal turn, and diffuse strial atrophy throughout the cochlea. More recently, Cone-Wesson *et al*. (1995) obtained distortion product otoacoustic emissions and ABR thresholds from three chimpanzees ages 5, 14, and 38. Compared to the younger chimps, the 38-year-old, Susie, had elevated ABR thresholds and reduced distortion product otoacoustic emission amplitudes, indicative of hearing loss similar to that observed in humans. Distortion product otoacoustic emission amplitudes are shown in Fig. 42.8.

I. Other Species

Little work on presbycusis has been done on other species of research animals. Bhattacharyya and Dayal (1985) evaluated surface preparations of cochleas from 4-year-old rabbits. While this is not an extremely old age for rabbits, which

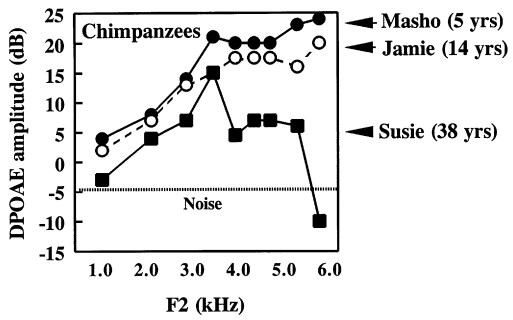

FIG. 42.8. Distortion product otoacoustic emissions from three chimpanzees. The responsiveness of the outer hair cells to low frequencies (indicated by the amplitude of the distortion product otoacoustic emission) is relatively normal in the old chimpanzee, Susie, but high frequency amplitudes are clearly reduced. Data were obtained from Cone-Wesson *et al.* (1995).

may live 6–10 years, mild damage to the organ of Corti was observed in both base and apex. In quail, Ryals and Westbrook (1988) found that age-related hair cell loss was minimal, amounting to less than 10% in the oldest birds. By contrast, 20–60% of spiral ganglion cells were lost in the old group, with the greatest losses occurring in the middle section of the papilla. Accumulation of lipofuscin was also seen in aged spiral ganglion cells. Despite the paucity of research, there is evidence of some age-related hearing loss, even in these species.

V. Some Topics Best Studied with Animal Models

As indicated earlier, ethical and practical issues often dictate the use of animal models. Three types of research requiring animal models are presented here as relevant examples.

A. Effects of Dietary Restriction

It is well established that restriction of caloric intake can have beneficial effects on the health and longevity of rodents (e.g., Ausman and Russell, 1990; Bronson and Lipman, 1996). Of course, controlled dietary restriction studies require the use of animal models. Several studies have evaluated age-related hearing loss in this respect. Feldman (1984) examined the cochleas of Sprague–Dawley rats whose lives were extended to 45–48 months by dietary restriction. The cochleas of the extremely old rats exhibited degenerative changes more severe than those of normally aged rats. While the extended life (restricted diet) animals showed substantially more severe pathology, there was no difference in severity between normal reared and restricted diet rats at age 26 months. Therefore, the time spectrum of age-related change was not reshaped. Rather, the additional passage of time resulted in a continuation of degenerative change that is normally terminated by the end of life. The story is not this simple, however. Willott *et al.* (1995) evaluated the effects of a calorically restricted diet on age-related hearing loss in five inbred strains (C57, CBA, DBA, BALB/c, WB), and their 10 possible F1 hybrid strains. Both ABR thresholds and postmortem cochlear histology indicated that genotype interacted with diet with regard to age-related hearing loss and cochlear pathology. The low calorie diet was associated with amelioration, exacerbation, or no effect depending on strain (see also Henry, 1986; Sweet *et al.*, 1988; Park *et al.*, 1990). Only in four strains was evidence obtained to indicate that the low calorie diet ameliorated age-related hearing loss.

B. Vulnerability to Noise-Induced Hearing Loss

An important question is whether the older ear is more or less susceptible to hearing loss from exposure to very intense noise. This is another area of research in which ethical and practical issues favor the use of animal models, especially given the variability in noise-induced hearing loss among humans (e.g., Mills *et al.*, 1996, 1997). Animal studies have begun to address the question, but it is a complex one. It appears that when the noise exposure is moderately intense and the threshold shift is temporary, there may be little or no age differences (Sun *et al.*, 1994; McFadden *et al.*, 1998). However, when very high levels of noise are involved, age may be associated with greater vulnerability (McFadden *et al.*, 1998). Studies on mice indicate that genetic influences may play a role as well. Specifically, mice possessing the *ahl* gene, such as C57, are more vulnerable to noise-induced hearing loss (Shone *et al.*, 1991a; Li and Borg *et al.*, 1993; Erway and Willott *et al.* 1996).

C. The Effects of the Acoustic Environment

At this time, little if anything can be done to effectively slow or ameliorate the progression of sensorineural presbycusis. We have been investigating a simple yet intriguing phenomenon that holds promise as a means of altering the severity and time course of progressive sensorineural hearing loss: exposure to augmented levels of controlled acoustic stimulation, what we have termed an augmented acoustic environment (Turner and Willott, 1998). With an appropriate augmented acoustic environment, the auditory system of hearing-impaired individuals can continue to be stimulated despite threshold elevations. In C57, DBA, BALB/c, and other strains of mice with progressive sensorineural hearing loss, exposure to a 70 dB SPL broad band noise augmented acoustic environment has been shown to alter age-related hearing loss. As seen in Fig. 42.9 ABR thresholds of BALB/c mice become elevated between ages 3 and 12 months (filled circles). However, in mice maintained with the augmented acoustic environment from age 25 days (open circles), hearing loss is minimal. Effects have thus far been demonstrated with ABR thresholds, spiral ganglion cells and hair cell counts, and behaviorally by increased amplitude of the acoustic startle response and improved prepulse inhibition (Turner and Willott, 1998; Willott and Turner, 1999).

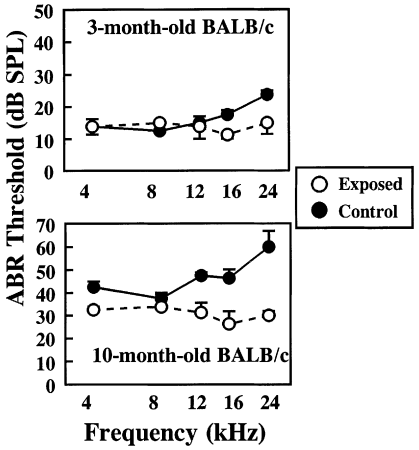

FIG. 42.9. The effect of exposure to an augmented acoustic environment on ABR thresholds. Exposed mice received a 70-dB SPL broad band augmented acoustic environment nightly from age 25 days. At age 3 months, control BALB/c mice have good thresholds, with only slight elevations at higher frequencies; exposed mice have better high frequency thresholds. By 10 months of age, BALB/c mice had significant hearing loss, but this was ameliorated in the exposed mice, particularly at high frequencies. In other words, the augmented acoustic environment slowed age-related hearing loss. Data are from Turner *et al.* (1999).

The augmented acoustic environment work is another example of auditory gerontological research requiring the use of animal models. Because the augmented acoustic environment has no effect on normal hearing mice, one must have subjects where the occurrence and time course of sensorineural hearing loss can be reliably predicted. Only then can augmented acoustic environment-exposed and nonexposed animals be compared to determine the specific effects of the augmented acoustic environment. This can be done most readily using inbred mice, such as C57 and DBA, as we have done.

VI. Evaluation of the Animal Models and Relationship to Humans

The animal model data demonstrate several important points (see also Willott *et al*., 1991).

- The various categories of presbycusis-related cochlear pathology seen in humans (Schuknecht, *et al*. 1974; Willott, *et al*. 1991) can all be seen in nonhuman animals. These include sensory, sensorineural, neural, vascular, cochlear–mechanical, and strial (metabolic) varieties.
- Because animals reared in institutional or commercial animal facilities are not usually exposed to excessive noise or ototoxic drugs, presbycusis appears to occur in mammals despite minimal ''contamination'' by industrial or urban environmental conditions.
- The differences in age-related pathology among different strains of mice demonstrate the role of genotype in certain forms of presbycusis. Genetic effects are also seen in the central auditory system. For instance, a loss of AVCN neurons was observed during the second year of life in CBA mice, but not in C57 mice (Willott *et al*., 1987), and the degree of cell loss in the modens of the trapezoid body differed for Sprague–Dawley and Fischer 344 rats (Casey and Feldman, 1982; Casey, 1990).
- At least some degree of sensorineural pathology appears to be a ubiquitous concomitant of aging across species.
- The cochlear base and, to a lesser extent, the apex are particularly vulnerable to age-related change in many species.
- Outer hair cells are more vulnerable than inner hair cells.
- The work on animal models demonstrates the complexity of age-related histopathological change in the central auditory system. Age-related changes differ among neuron types (e.g., bushy, multipolar, and octopus cells of the mouse cochlear nucleus). Within an individual, considerable variance in age-related histopathology occurs among neurons. The condition of octopus cells in aging mice ranged from normal to severely degenerated. In another example, Feldman and Vaughan (1979) noted that intermingled with neurons exhibiting signs of pathology or degeneration were many auditory cortical neurons of old rats which appeared to be free of pathology.
- The presence of high frequency hearing loss is likely to cause marked disruption of central frequency representation and other aspects of auditory processing (central effects of peripheral pathology). However, even in the absence of serious hearing loss, age-related changes can occur (central effects of biological aging).
- Very old individuals are likely to have a reduced number of central auditory system neurons. However, the losses are typically modest, even in the cochlear nucleus. The volume of central auditory system structures tends to be smaller in old individuals, with loss of neuropil contributing significantly to the reduced volume.
- There is considerable variability among individuals in the severity of presbycusis, the number of neurons surviving to old age, and many other age effects. Material from mice suggests that genetics plays a strong role in this regard. However, even in inbred mice, variance is substantial.
- While many similarities exist among humans and other species, the magnitude of age-related pathology is typically not severe in the animal models (with exceptions such as certain mouse strains). Whereas many humans are fortunate to retain relatively good hearing as they age, many others experience hearing loss that is more severe than most of the animal models. This may be due to a number of factors including the length of the life span and effects of environmental insults, diet, drugs, and genotype. While the involvement of these variables is far from being fully understood, research on animal models, with its ability to systematically control genetic and environmental variables, provides our best hope of future progress in elucidating their relevance to presbycusis.

The Development of Animal Models for the Study of Presbycusis: Building a Behavioral Link between Perception and Physiology

Elderly listeners often complain that they cannot understand what people are saying to them, a problem that may result in part from their inability to hear critical frequencies in the speech signal and in part by a failure in auditory processing that results in speech that is heard only in a distorted and near incomprehensible form. Behaviorally based psychophysical studies in laboratory animals have shown that the sensory attenuation that accompanies aging occurs in species other than humans and have served to validate other types of animal models, most often using evoked potentials, that have provided considerable insight into the physiological bases of attenuation. These animal models now have great potential as testing platforms for potential therapies intended to maintain or recover physiological function and, thus, sensory ability. In comparison, the nature of the processing deficits that may yield perceptual distortion is less well understood even in aged humans, let alone in laboratory animals. This chapter briefly reviews the development of animal models that demonstrate age-related sensory attenuation of simple auditory signals and then describes our behavioral study of a potential source of perceptual distortion in age-related changes in temporal acuity in mice. Our findings are similar to those of our colleagues who study neural temporal acuity in the aged central auditory nervous system of mice, and similar also to the data of our colleagues who study sensory temporal acuity in aged humans. This behavioral link between neurophysiology and sensation and perception supports the hypothesis that a diminished reactivity to threshold and suprathreshold gaps in noise in particular types of cells in the human auditory midbrain is responsible for distorting the perceptual representation of speech.

I. The Need for Animal Models of the Presbycusic Listener

The intent of the present work is to describe briefly the possible sensory and perceptual bases of age-related hearing loss, and the continuing search for ways of capturing these psychological attributes in animal models that may aid in the better understanding of their physiological bases and, potentially, in the development of strategies for prevention and remediation. Many aged human listeners have two complaints about their diminished hearing abilities. One is that they can no longer hear certain familiar, pleasant, and important sounds, such as the telephone or the door bell, or birds singing and children playing. This is a sensory phenomenon of diminished sensitivity. The other is that while they may certainly hear people talking and saying something, they may then find it impossible to make out what it being said. This aspect of their hearing loss that affects speech perception is a very serious matter because it undermines human communication in a great variety of contexts, and besides presenting obvious practical problems, it may lead also to social isolation from colleagues, family, and friends (Working Group, CHABA, 1988).

A question of fundamental interest is the degree to which these two have the same cause or, instead, result from separable malfunctions in basically different types of sensory/perceptual and physiological mechanisms that will require different therapeutic strategies for their remediation. The search for animal models that capture the critical elements of these two complaints and would support an analysis of their underlying causes is a challenging task: particularly challenging is the development of models that focus on the perception of complex acoustic signals, and yet it is this pursuit that seems especially important because it is here that age-related changes in brain structure and brain function are likely to play a decisive role in producing the perceptual deficits of the aging human listener.

II. Evidence for Attenuation and Distortion as Sensory Bases of Presbycusis

Plomp (1978) has described two very general categories of hearing loss in human listeners, one that he called "class A" (for attenuation) and the other "class D" (for distortion). He argued that a class A loss may be remedied by amplification, while class D is not. Drawn in broad strokes, the recent studies of these concepts of attenuation and distortion have been allied with different experimental and theoretical approaches to the understanding of presbycusis in aged humans, each suggesting a different type of underlying sensory or perceptual deficit and having a different physiological basis and a different anatomical location.

For the first of these approaches, by far the more familiar, the fact that once normally heard signals are no longer audible is understood as being a simple reflection of the clinical observation that the sensory threshold for significant spectral frequencies of acoustic stimulation is elevated in the elderly listener. Age-related changes in the audiogram are readily detected in the clinic, and there is considerable epidemiological evidence showing that a majority of aged humans exhibit a progressive loss of sensitivity for simple tonal stimuli, an attenuation effect that begins with the high frequencies and then becomes increasingly apparent at lower and lower frequencies with advancing age (for example, Pearson *et al*., 1995; and Fig. 43.1). The change in absolute thresholds that is seen in the clinic must certainly correlate with the loss of audibility of certain sounds in the real world. As this loss of audibility must ultimately encroach on critical speech frequencies, it is plausible to hypothesize that it is responsible for the changes in speech understanding of "more-or-less audible" speech. For example, the identifying hallmarks of speech presence might be readily heard, such as its overall amplitude envelope or its relatively low-frequency vowel structure, while the especially informative high-frequency spectral cues for consonants fall below the detection threshold; thus "speech" would be heard, but not comprehended.

The evidence for the class D loss in hearing that causes specific sorts of difficulties for complex acoustic stimuli over and above those due to the class A deficit seems persuasive to many investigators, but the supporting data are by no means as pervasive as those for the class A deficit, and there are no large-scale epidemiological studies that identify and then describe the incidence of a class D hearing loss. Then further, it is possible that the complete independence of these forms of hearing loss may be quite rare, that is, the presence of distortion may largely occur following attenuation of the auditory signal, but attenuation may not inevitably yield distortion.

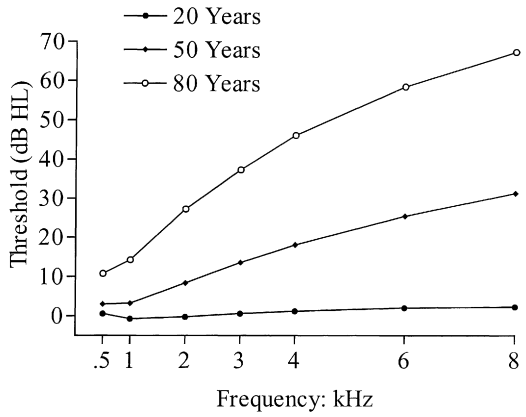

FIG. 43.1. Changes in hearing thresholds as a function of signal frequency in men of different ages. Adapted with permission from Pearson *et al*. (1995, Table III, p. 1199).

Independence is perhaps best encountered as a characteristic of a neurological disorder called "word deafness," which is seen in some patients who, in contrast to patients with classic aphasia, have normal reading and writing abilities and even normal speech, but share a total inability to understand the spoken word (e.g., Buchtel and Stewart, 1989). Word deafness appears to result as a consequence of bilateral damage to the auditory cortex and thus does not provide an apt model for most presbycusic listeners. However, these case histories are important because they provide evidence of great theoretical significance in their demonstration of the complexity of the processing mechanisms that are necessary for maintaining the clarity of the speech signal. They show also, first, that speech may be uninterpretable even though its entire spectral content is perfectly audible (the audiograms of these patients are typically normal), and second, at least some of these case histories provide evidence that the deficit in speech understanding is associated with a deficit in a very simple sensory dimension, namely, temporal acuity. For this reason the tragic neurological accident that leads to word deafness has had important implications for the search for animal models of presbycusis. It is relatively easy to measure temporal acuity in laboratory animals, and though it should not yet be argued that the aged presbycusic listener has subtle neurological problems at the level of the auditory cortex, it certainly seems reasonable to hypothesize that changes in temporal acuity may be in part responsible for a class D hearing loss.

In further support of the idea that distortion and attenuation may be at least in part independent, there is a larger class of apparently neurologically intact human listeners who also have normal or near-normal audiograms, but share a very similar and isolated problem in understanding speech. They differ in one respect from the neurological patients, which is, namely, that their problem is manifest only in the presence of masking noise and not in quiet, as the word-deaf patient cannot understand speech presented in either noise or quiet. Middelweerd *et al*. (1990) studied a relatively large group of patients of this sort, who, with their mean age of just 36 years, would not be classified as being "aged listeners," but nonetheless express this particular presbycusic-like complaint. Middelweerd *et al*. (1990) found a small and inconsequential difference between this patient group and a control group of listeners both in the audiogram and in speech perception measures obtained in quiet, but reported that there were large and clinically significant differences between the two groups when speech was presented in noise. It is not known if this group of patients had a deficit in their temporal acuity or even if they would have problems in processing simple signals in noise, which is a deficit in sensory processing that could be readily investigated in the psychoacoustics laboratory: but clearly, they have problems in understanding speech in noise in the absence of any apparent deficit in their absolute thresholds.

The third source of data pointing to the importance of distortion as a distinct species of hearing loss that is set apart from changes in audibility is presented often incidentally in the reports of experiments that have attempted to characterize aged and hearing-impaired listeners as a group. Thus, for example, Glasberg and Moore (1989) report a correlation matrix for hearing impaired and mostly aged listeners (mean age 61 years) which provided measures of the relationships between speech reception thresholds in quiet and in noise with a variety of psychoacoustic measures. They showed that the correlation between an absolute threshold measure and speech reception threshold in quiet was extremely strong, essentially accounting for all of the variance in the speech thresholds ($r=0.96$). However, this correlation between the speech reception threshold and absolute thresholds was reduced in size when the speech reception threshold was obtained in noise, and in this noise condition the speech reception threshold was instead correlated with measures of acuity and resolution in the temporal and spectral domains (gap detection thresholds and frequency discrimination). Similarly, Ison *et al.* (1998) compared speech reception threshold in quiet and masking noise in a group of aged listeners with but modest hearing loss ($n=21$; mean age, 68 years) with a second group of normal young listeners ($n=19$; mean age, 22) (Fig. 43.2). The speech reception threshold measured in quiet was correlated with absolute threshold measures to the same extent in both young and old subjects, and, indeed, this difference in the class A deficit accounted for all of the apparent age difference between the groups in their speech thresholds. This consequence of the deficit in audibility occurred only in the quiet condition, and, in striking contrast, the correlations between speech reception thresholds obtained in noise and their absolute detection thresholds were close to zero. These data indicated that the age difference in speech perception in noise was not determined by their small class A deficits apparent in the audiogram and provides additional evidence for the independence of the class D hearing loss. It is also of interest that in psychoacoustic work using a largely overlapping group of subjects, these elderly listeners also showed a deficit in temporal acuity.

There are other scattered observations indicating that the hearing abilities of aged listeners may be quite heterogeneous in their composition, and that although decrements in audibility may fully account for speech perception losses in many listeners, in other listeners decrements in temporal or spectral resolution may prove to be more important. For example, Lutman and Clark (1986) measured speech identification thresholds in noise for 23 mostly aged listeners (mean, 60 years old; range, 44–72), all having substantial hearing loss and all wearing hearing aids. Their speech measures were related to audiometric thresholds obtained at 2 kHz, but also they were related independently to gap detection and frequency resolution thresholds: these data are certainly consistent with the suggestion that changes in audibility (class A deficits) and changes in frequency and temporal acuity (which are presumably two important bases of class D deficits) make independent contributions to speech perception. However, the authors also noted that their correlation could be attributed in large part to the presence of a small group of subjects with very high gap thresholds who also required very high signal/noise ratios to correctly identify the speech signals: this observation agrees with the outcome of most aging research in its showing that the aged form a heterogeneous group of persons having diverse capabilities and, perhaps, diverse causative factors lying behind the differences of their performance from that of the young.

III. The Development of Animal Models to Study Attenuation

The reports above, and others like them, suggest that indeed changes in both the audibility and in the perceived clarity of

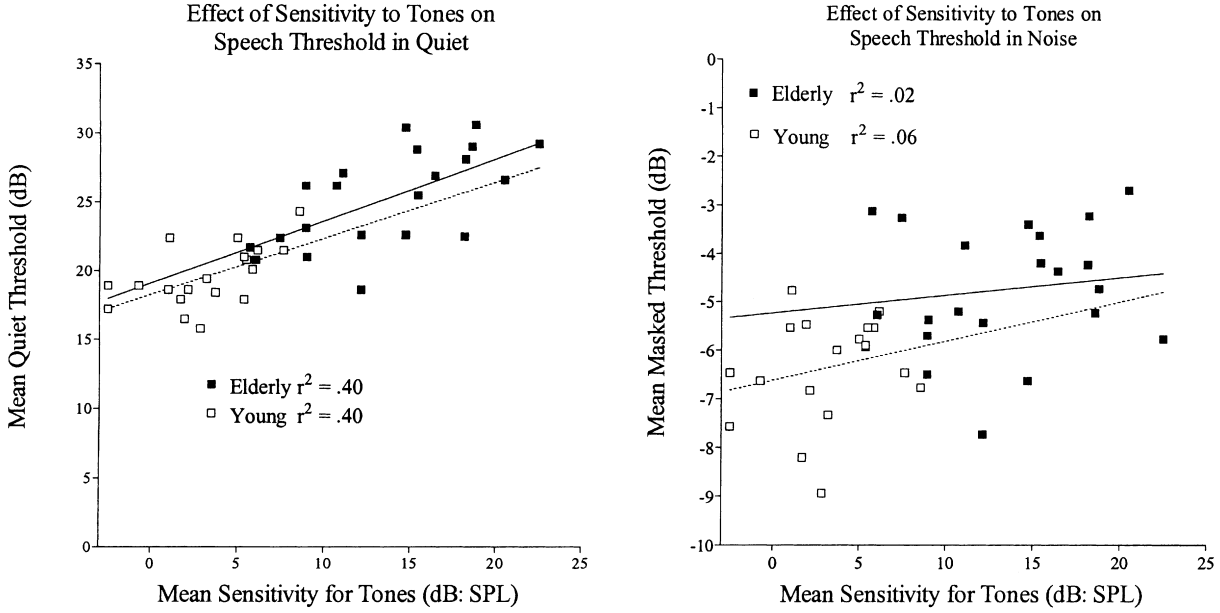

FIG. 43.2. Regression of speech reception thresholds in quiet (left) and noise (right) on the group mean audiogram, in groups differing in age (solid lines and symbols are the aged group, dotted lines and open symbols the young group). From Ison *et al.* (1998).

acoustic signals may provide two partially dissociable consequences of age that make it difficult for many aged listeners to understand speech, especially in noisy and reverberant conditions. The question then is whether it is possible to design animal models that might capture these two sensory effects in the laboratory, models that will help to understand the physiological bases of age-related hearing loss, and afford an animal testing platform for proposed therapeutic strategies prior to their clinical application.

In humans, changes in audibility are readily obtained in clinical audiograms, using a simple procedure in which the critical question asked of the listener is whether or not he or she heard the test tone. Long (1994) has persuasively argued that similar psychophysical tests based in the behavior of animals are critical to illuminating the problem of how neurophysiological events are expressed in sensation and perception. She presented the basic principles common to these tests, their difficulties in implementation, and many of their findings for the standard psychoacoustic dimensions of threshold determination, frequency processing, temporal acuity, and so forth. Comparative hearing researchers have been concerned with the limits of animal perception at least since the time of Yerkes (1905), and behavioral audiograms are available for many species of animals (see, for example, Fay, 1988). Unfortunately, there are some serious obstacles in the design and in the application of most standard psychophysical tests in animals, some of which may especially detract from their use with aged populations. This is not to say that laboratory procedures to measure sensory events in animals have not been exceedingly powerful and useful, for at best they have both of these attributes. However, many of these procedures require the use of sophisticated training procedures that are extraordinarily time intensive, and this alone severely limits the numbers of subjects that can be run in any one experiment. As a result, it is not unusual for the published and paradigmatic classical audiograms characteristic of different species to have been obtained for just two or three young animals of that species.

The results of psychophysical tests in animals are typically reliable and readily replicated in young normal animals. Thus, comparing the audiograms obtained in the hooded rat by Heffner *et al*. (1994), with those obtained in just 3 albino rats by Kelly and Masterton (1977), reveals the stability of outcomes that can be obtained in the best of these experiments. However, the restrictive use of only small numbers is a very serious impediment to aging research, especially if the degree of variability among old animals should approach that of aging human listeners. In addition, most psychophysical behavioral tests require animals who are well motivated and cooperative and are able to perform learned responses under stimulus control, and this sometimes under conditions of time pressure: aged animals in these tests may be affected by age-related deficiencies in a great variety of necessary perceptual–motor and integrative talents, and thus their performance must always be interpreted with great care.

Stimulus-controlled performance of learned behavior is undoubtedly the ''gold standard'' of behavioral psychophysics. Other tests have been developed that do not depend on the animal's having learned a discriminative reaction to the presence of a stimulus, often using the elicitation or the modification of simple reflex behavior. These tests are more readily applied to large numbers of subjects and do not require the use of highly motivated and well trained cooperative subjects, but to say that they represent sensory and perceptual events in the same way that human detection experiments can be thought to represent sensory events demands some strong assumptions and, often, arguments from analogy. Nevertheless, there are tradeoffs and compromises in animal testing that must be considered carefully. At best, a study of presbycusis in an animal model should not depend alone on one sort of experimental procedure, but has been embedded into an empirical and theoretical context that borrows from different research domains an achieve a coherent picture of hearing in the aging animal.

There are very few published behavioral audiograms in any aged animal that approach the level of completeness typical of the human audiogram, but one most impressive set of behavioral audiograms in the animal literature was reported by Bennett *et al*. (1983). They studied three groups of rhesus monkeys, an old group ($n=3$, 31 years of age), a middle-aged group ($n=2$, 24 years of age), and a young group (9 years of age). Thresholds for frequencies between 125 Hz and 32 kHz were assessed in an operant conditioning procedure in which the monkey learned to move its head toward the drinking tube on hearing or failing to hear a tone that normally would be presented at a particular time. The experiment required 3 years for its completion. The authors used an adaptive tracking procedure to follow detection thresholds, each examination period consisting of three 2-month-long tests given 1 year apart. The data provided by Bennett *et al*. are presented in Fig. 43.3. Like older human listeners, the middle-aged monkeys showed a loss of high frequency hearing but little change in the low frequencies compared to that seen in the youngest group. The oldest group of monkeys showed a general loss of sensitivity across the spectrum that was exaggerated for the highest frequencies, this too being consistent with the audiograms of very old human listeners. Bennett *et al*. reported also that the three oldest subjects were quite different from each other despite their long common environmental history. This is interesting: old human listeners can be very different from each other in their hearing abilities and so, apparently, are monkeys.

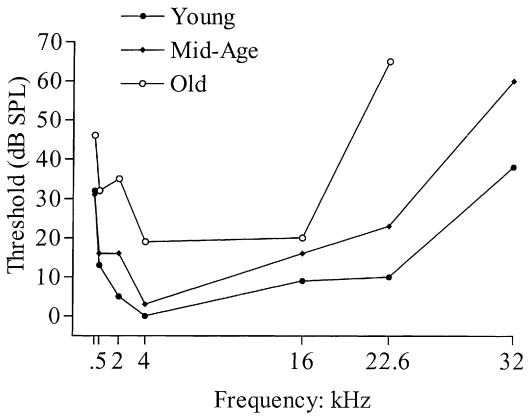

FIG. 43.3. Changes in hearing thresholds with age in monkeys, *Macaca mulatta,* as a function of age, from 9 to 31 years. Data adapted with permission from Bennett *et al*. (1983), copyright © 1983 American Psychological Association.

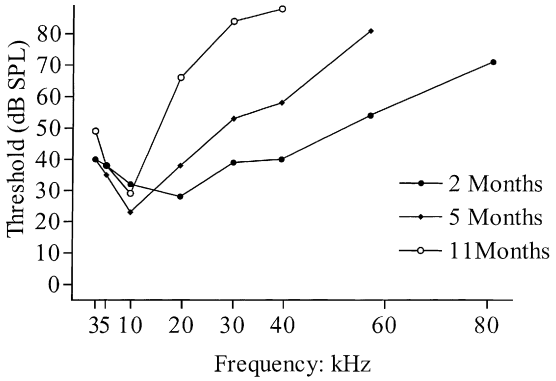

FIG. 43.4. Age related changes in threshold across frequency in three groups of aging mice. The data were adapted from Mikaelian *et al*. (1974), with permission.

Another impressive behavioral analysis of age-related changes in hearing was published for the C57/B16 mouse by Mikaelian *et al*. (1974). This was a seminal paper in its introduction of a mouse model of human presbycusis that has subsequently led to an active exploration of the genetic bases of hearing loss, its peripheral basis in the organ of Corti, and its central consequences for both structure and function. These authors trained groups of water-deprived mice to press a lever for a water reinforcement on the presentation of a tone, and then followed their thresholds for various periods of time as the mice (17 in total) aged variously from about 2 to 21 months. Figure 43.4 is a graph of data selected from their more extensive set of groups, showing thresholds at 2, 5, and 11 months. The pattern of loss is very similar to that exhibited in both humans and monkeys, in its becoming evident first at high frequencies and then progressing in its severity with age. Mikaelian *et al*. also examined the organ of Corti under the light microscope in some of these mice. They observed a loss of hair cells and supporting cells in the basal high-frequency region beginning as early as 3 months of age in this mouse, even as it entered early adulthood. This structural deterioration then progressed toward the apex and was accompanied by losses in the spiral ganglion cells, these anatomical changes roughly in concert with the loss of sensitivity.

At about the same time, Ehret (1974) published an extensive series of behavioral audiograms in a different strain of mouse that did not suffer from a relatively early onset and genetically based hearing impairment. He had developed a Pavlovian conditioning procedure in mice in which tone presentation was followed by a brief shock, so that as the mouse came to anticipate the shock it was possible to observe a facial grimace or eye blink on the presentation of the tone. Following this initial training a series of different frequencies and levels of tonal stimulation were presented in order to determine the threshold levels of stimulation that yielded responses. Ehret reported thresholds for 32 house mice ranging between 2 months and 18 months of age. The youngest mice were the most sensitive, and while subtle age differences were present variously across the tested frequency spectrum, the most systematic age-related changes were at the higher frequencies: here the performance of older mice diverged from that of younger mice at progressively lower frequencies with advancing age, an outcome very similar to that described above for humans, monkeys, and the younger mouse with the early onset age-related hearing loss.

These procedures were then replicated and extended in an interesting and provocative report by Henry and Chole (1980) who used the same behavioral procedure in two strains of mice, one, the C57BL/6 related to the strain studied by Mikaelian *et al*., which suffers from a rapid onset age-related hearing loss, and the other the CBA/J strain that, like the house mouse studied by Ehret, maintains its hearing for 18 months or more. These authors also measured auditory evoked potentials in many of the same mice, and in some of these mice they dissected out the organ of Corti in order to count the numbers of inner and outer hair cells present across the basilar membrane under the light microscope. The stimuli ranged across the spectrum between 5 and 80 kHz, and the mice ranged from 45 to 760 days in age, with sample sizes of seven or eight at the younger ages and just two or three at the oldest ages. This study thus provided a very useful comparative analysis of the correspondence between behavioral and electrophysiological functional measures and an important component of its physiological substrate, between different strains and age groups of mice.

The behavioral and the electrophysiological audiograms obtained in the youngest CBA mice were quite similar to each other, though neither showed the same sharpness of the V-shaped tuning curve that is apparent in the data of Mikaelian *et al*. The behavioral thresholds also were more variable than the electrophysiological measures, but the group means suggested a high frequency loss occurring between 200 and 470 days of age and then a large spectrumwide loss in the oldest animals. The authors noted that this audiometric pattern in the very old CBA mice resembled that of a conductive loss, and indeed, they found middle ear blockage on postmortem examination. Behavioral thresholds for the C57BL mouse were more in line with those of Mikaelian at least qualitatively, for they showed a substantial specific high frequency loss between 65 and 100 days of age, and then a complete flattening of the audiogram near the limits of the sound production equipment at 200 days and beyond. However, while electrophysiological and behavioral measures were roughly equivalent in the CBA mouse, for the C57BL mice the young electrophysiological thresholds were very much lower than their behavioral estimates, by 40 to 50 dB. Henry and Chole ascribe the poor behavioral results in the C57BL mouse to its hyperactivity and greater emotionality in the testing situation. The contrast between these behavioral results and those described by Mikaelian *et al*. reveals the importance of fitting the behavioral testing paradigm to the needs of the particular laboratory animal, with a suggestion that the Pavlovian conditioning used by Ehret and by Henry and Chole was not appropriate for the C57 strain. The appearance of discrepant observations such as this points to the need for a unifying conceptual approach to understand the apparently different outcomes of multidisciplinary paradigms.

Henry and Chole found that there were no changes in either inner or outer hair cell counts in the CBA mouse up through 470 days of age. In the C57BL mouse there were no losses in hair cell counts at 100 days of age, but a substantial loss

in thresholds of 20 to 30 dB for the higher frequencies compared to the thresholds obtained at 45 days of age. Although this might be thought of as indicating a serious disparity between structure and function in this mouse, it is now apparent that the counts of hair cells available to the methods of light microscopy are not the most sensitive measures of receptor structure, compared to the examination of stereocilia under electron microscopy. At 200 days and beyond changes in hair cell counts were more in line with changes in the audiogram.

This small list of behavioral audiograms in aged animals can be considered to be the primary justification for the belief that the sensory impact of simple sounds presented at near threshold values is diminished by age in laboratory animals just as it is in human listeners; they are also the primary justification for asserting that class A hearing losses can be modeled in the behavior of the laboratory animal. However, this short list is very far from the sum total of experimental studies of age-related changes in sensitivity in animals, but most of the studies of hearing loss in animals use not behavioral techniques but study instead some type of auditory evoked potential, often the brain-stem response.

A considerable body of research with both human listeners and animals makes it quite reasonable to argue that a physiologically based study of neural sensitivity to acoustic stimulation can serve as an able proxy for a behavioral measure of its sensory consequence. Indeed, most direct comparisons of behavioral thresholds and thresholds of auditory nerve fibers show a very strong and convincing relationship (see, for example, Pickles, 1988, p. 84). Moreover, measures of frequency-specific brain stem auditory evoked responses are routinely used in the clinic for estimating sensory thresholds in infants and difficult-to-test populations (Schwartz and Schwartz, 1991). It happens that these evoked potential estimates of sensory thresholds can be obtained as quickly and as conveniently in animals as they can in humans, which is often a welcome contrast with behavioral procedures. Further, their ready acceptance as a surrogate for psychophysically obtained audibility measures in the clinical examination of difficult-to-test humans and their overall correlation with behaviorally obtained audiograms in humans argue that they already serve audiology very well at a practical level: thus, it has seems eminently reasonable to use evoked potential measures rather than behavioral measures to study class A deficits in laboratory animals. Figure 43.5 describes brain stem auditory-evoked responses measures of threshold (the ''ABR'') obtained in our laboratory for C57BL/6J mice ranging from 6 weeks to 5 months of age. The qualitative appearance of these data is exactly that described by Mikaelian in his behavioral assessment of audibility thresholds in a closely related strain of mice, though in our observations the onset of severe hearing loss was much earlier than in his. Our 6-week-old and 3-month-old mice gave approximately the same thresholds as obtained by Mikaelian *et al*. at 2 months of age, but our 5-month-old mice had a much greater loss at the high frequencies. Given the similar values obtained in the younger mice this difference in the older mice seems unlikely to result from the difference in methodologies, but rather from real individual differences that might be anticipated in small groups of old mice (Li and Borg, 1991). More to the point, the overall similarity of these two sets of data attests to the validity of the use of an electrophysiological measure of detection thresholds as a reasonable surrogate for behavioral measures of audibility.

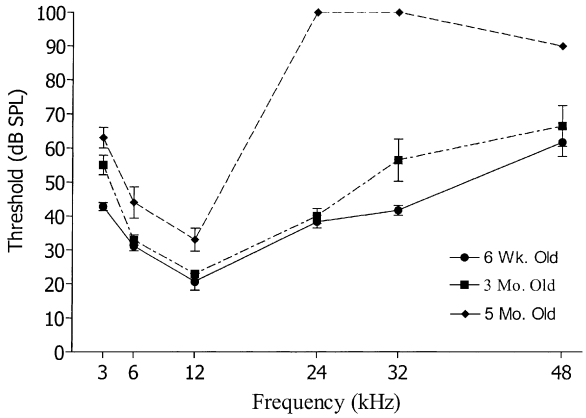

FIG. 43.5. Absolute thresholds in C57BL/6J mice obtained at three different ages, 6 weeks ($n=9$), 3 months ($n=7$), and 5 months ($n=5$). Group means $\pm$ SEM.

From a practical standpoint, the electrophysiological methods have much to recommend them, for the ABR thresholds can be obtained in less than 1 h, while the behavioral thresholds may take many days, even weeks, of training and testing. As a result of this, there are many more examples of the use of evoked potentials for assessing age-related changes in detection thresholds in animals, compared to the use of behavioral thresholds. The list of aged animals that have been tested includes almost all of the laboratory animals common to auditory research, such as mice, rats, guinea pigs, chinchillas, cats, marmosets, and so forth. As a result of this large body of work, there can be little doubt that age-related loss in electrophysiologically defined threshold measures of stimulus detection is a universal phenomenon across mammalian species.

One may object that these measures of neural thresholds, most of them obtained under anesthesia, do not really assess sensory or perceptual experience. However, the general overall correspondence of the data so obtained with the data characteristic of more direct measures of sensation seems sufficient justification for their use. Besides, a philosopher with an even stricter interpretation of the nature of scientific constructs might point out that neither learned behaviors nor psychophysical judgments allow direct inspection of sensory experience in either laboratory animals or human listeners. Of course, all of the conclusions we draw from all of these experiments, regardless of their indicator response, are simply inferences about the sensory and perceptual experiences of our subjects, and their validity lies very simply in their ability to generate coherent and interesting ideas and data. Most certainly, the use of various sorts of evoked potentials in animal models of age-related hearing loss has generated an enormous understanding of the changes in the organ of Corti that underlie the decrements in sensitivity that accompany aging. Most recently these methods, together with some simple behavioral methods of reflex modification, are being used in research that is attempting to prevent early-onset age-related changes in hearing (Sundin and Willott, 1999; Willott *et al*., 2000).

IV. An Animal Model for Studying Distortion

As described earlier, some human listeners who have normal or near normal audiograms have trouble perceiving speech, sometimes when they are in relatively quiet surroundings but particularly when people are speaking in an unfavorable acoustic environment in which competing noises and reverberation mask the speech signal: it is these data that suggest the importance of distortion in limiting the listening abilities of the aged. If it were true that the phenomenon of distortion is specific to language processing and human speech then it would of course be impossible to develop an animal model that would allow us to study its neural basis. However, the working hypothesis that the concept of ''distortion'' describes a set of related phenomena resulting from deficits in processing complex acoustic stimuli along perceptual dimensions other than audibility seems quite reasonable and is likely to be productive. For example, it may be that distortion results because of changes in mechanisms that aid in the processing of signals presented in noise; or spatial location, frequency analysis, or the analysis of signals that rapidly change in time; or mechanisms that maintain the integrity of a complex stimulus on the basis of the common fate of its components.

The loss of audibility of simple acoustic stimuli presented at near-threshold levels almost certainly results in large part or perhaps entirely from age-related degenerative changes in the cochlea. However, while the loss of clarity in a complex acoustic signal might result from changes in the ear, in principle it might well accompany all sorts of functional changes at any level of the nervous system where age-related degenerative processes result in the loss of neurons, perturb neuronal connectivity, or reduce transmitter release or receptor sensitivity. Not surprisingly, our understanding of the perceptual processing deficits that result in the distorted representation of acoustic events in animal models of aging and their physiological bases is much behind our understanding of attenuation. This state of affairs results in part because of a degree of uncertainty in our knowledge of the important dimensions of perceptual processing that are necessary for a faithful representation of an acoustic event even in young human listeners, as well as the difficulties in measuring such subtle effects in laboratory animals. Behavioral studies of auditory thresholds in aging animals have provided the crucial information leading to the subsequent development of the physiological bases of class A hearing loss, and it seems reasonable to suppose that comparable studies of perceptual processing deficits in aging animals will serve the same important purpose for understanding class D hearing loss.

There are several potential perceptual bases of distortion, but the following discussion focuses on temporal acuity for gaps in noise as this is the area in which our laboratories have made the most progress in collecting interdisciplinary data showing parallels between mouse behavior and both human sensory performance and animal physiology. Then further, we think that deficits in temporal acuity are likely to be present in the aged listener and are likely to have a disturbing effect of the clarity of a complex acoustic signal. There are both *a priori* and data-driven reasons for supposing that temporal acuity must be important for speech perception in the human listener. The speech signal can be thought of as a complex array of sinusoidal acoustical signals that vary over time in composition and amplitude. Kewley-Port (1983) reported that certain phonemes differ only in temporal profiles of their frequency spectra on a 5-msec time scale. Our ability to identify these phonemes must depend not only on our detecting their spectral components but also on our encoding their rapidly changing temporal pattern.

Shannon *et al*. (1995) used the temporal envelope of a speech signal to modulate a wideband noise signal and then added onto this envelope an increasing number of narrow spectral bands filtered out from the speech signal. These authors reported that speech understanding was excellent even for a severely degraded signal in the spectral domain, as long as its overall dynamic pattern was maintained. Rosen (1992) has reviewed a set of these experiments that all point to the importance of the temporal cues of the speech envelope for speech understanding. These examples indicate that the ability to track rapidly changing signals must be critically important for accurate speech perception. A further interesting footnote to these ideas was provided by Turner *et al*. (1995), who showed that the ability to recognize the speech signal in amplitude modulated noise was not diminished in hearing-impaired listeners when allowances were made for their class A deficit: they argued that this supported the hypothesis that deficits in temporal acuity seen in some listeners are not limited by their peripheral hearing loss, but results from independent changes in central auditory processing mechanisms.

One of the most dramatic examples of the importance of central processing for the temporal analysis of acoustic signals is presented in the description by Buchtel and Stewart (1989) of the diminished psychoacoustic abilities of their patient with word deafness who was introduced briefly above. In addition to his near total inability to understand the spoken language, this patient suffered a major deficit in his ability to distinguish between the presentation of one versus two tone pips. He required not the usual interval between the pips of about 15 msec to make the correct discrimination, but, remarkably, he required the pips to be separated by about 300 msec. That this was an auditory rather than a cognitive deficit was shown by his normal ability to discriminate between one and two light flashes at various separations.

Some further suggestive evidence for the hypothesis that deficits in temporal acuity are the basis of the problems in speech perception seen in some aged listeners is provided in a classic report by Tyler *et al*. (1982). These authors showed that in a group of listeners differing in age and in degree of hearing loss, temporal processing as assessed by gap detection was strongly correlated with a measure of speech perception in noise. This correlation was primarily due to differences in gap detection in an older subgroup of subjects, older than the median of 58 years of age: in this subgroup the percentage of the variance accounted for by differences in gap detection approached 70%.

There are many experimental reports showing that temporal acuity as measured by gap detection thresholds does decline with age and also with high frequency hearing (for example, Buus and Florentine, 1985). Other data have shown that high frequency components of a wideband carrier make significant contributions to gap detection in human listeners (for example, Buus and Florentine, 1985; Snell *et al*., 1994) and in mice

(Allen *et al*., 2000): thus it might be anticipated that age-related attenuation of the high-frequency components of a gap carrier would result in a decrease in gap sensitivity. The question is, then, whether age by itself might have an independent effect on temporal acuity. Here a report by Snell (1997) is important in its showing longer gap thresholds in elderly listeners compared to those of younger listeners, even though the aged listeners were a select group with near normal hearing. The mean differences between the groups were not large, on the order of 1 to 2 msec across the various conditions, but about one-third of the elderly subjects were outside of the range of the younger subjects, and several elderly listeners had particularly poor temporal acuity. In interpreting these results, it is important to note that the correlations between temporal acuity and measures of high frequency hearing were negligible and accounted essentially for none of the variance in temporal acuity. Of course, this does not mean that in general high frequency hearing ability would not correlate with temporal acuity among a group of listeners who differed considerably in their degree of hearing impairment, but it does mean that in these groups in which aged differences were considerable (26 versus 70 years of age) and differences in thresholds were minimal, the effect of age on temporal acuity was indeed independent of changes in audibility.

Our behavioral data on gap detection obtained in mice are reasonably comparable to those obtained by Snell in the values obtained for thresholds in the mouse compared to the human listener, and in the mean differences in threshold between young and old mice. We are studying gap detection in the CBA mouse, the same mouse strain used by Henry and Chole (1980) as a model of hearing loss that occurs very late in its life span, beyond about 18 months of age. The behavioral method that we use is called ''reflex modification audiometry'' (Young and Fechter, 1983). The method has been used to measure sensory processing in a variety of species (see Ison and Hoffman, 1983; Hoffman and Ison, 1991), including humans. In its present application, the mouse sits in a small cage mounted on top of an accelerometer, and occasionally hears a brief noise burst that produces a flinch-like startle reaction, which is detected by the accelerometer. It is possible to use this startle reflex itself as a measure of suprathreshold hearing (Parham and Willott, 1988, for example), but for reflex modification the basic observations of interest are provided by presenting small threshold and near-threshold stimuli just prior to the startle stimulus. When presented at lead times of about 100 msec, the weak prestimulus inhibits the reflex response to the louder stimulus, and the presence of inhibition is used as objective evidence for prestimulus detection. Similar work with humans (Ison and Pinckney, 1983) has shown that gap thresholds obtained with this procedure approximate those obtained by conventional psychophysical methods. Besides its sensitivity to near-threshold stimulus levels, the great advantage of this methodology is that it does not require that the animal be trained at the task. It has also been shown that reflex inhibition for suprathreshold noise pulses presented in quiet does not vary as a function of age in mice, indicating that the inhibitory mechanisms themselves do not appear to change with age, even though reflex expression to the startle eliciting stimulus is considerably reduced in old mice (Ison *et al*., 1997).

Over 200 mice were run in our experiment on gap thresholds in mice of different ages (reported in Barsz *et al*., 2000), 109 below 1 year of age (range of 2 to 8 months); 42 over 1 year but less than 2 years (range 13 to 20 months); and 67 over the age of 2 years (age 24 to 29 months). The fact that many animals can be tested quite efficiently in little time is one of the great advantages of the method, compared to those methods that require the use of training, but the thresholds we obtain are about the same as those obtained with these other methods (Wagner *et al*., 2000). It is also important that the method can be used to indicate the salience of suprathreshold stimuli, which we now believe may be more important than the simple assessment of threshold values for aging research.

The prestimulus was a gap that ranged in duration from 0 to 15 msec, that was presented 60 msec before the startle eliciting stimulus. Fig. 43.6 shows the type of data characteristic of experiments of this sort. The size of the response in each gap condition was ''normalized'' with respect to the baseline size of the uninhibited control condition which had no gap presented. It can be seen in all age groups that as the gap duration increased the relative size of the startle reflex diminished, rapidly when the gap increased over the range of 2 to 6 msec and more slowly afterward. The majority of mice showed an abrupt inhibitory effect for gaps between 2 and 4 msec in duration, with stragglers accounting for most of the drop in the response at the longer intervals.

It is very clear in these data that the asymptotic inhibitory effect of the gaps declined with age, this indicating that the longer gaps were less salient in the older mice. The individual data of each mouse were further analyzed in order to determine a gap threshold, this defined as the smallest gap duration that provided at least one-half of the asymptotic level of inhibition, thus providing threshold values that were independent of the asymptotic peak of inhibition. Fig. 43.7 shows the mean gap thresholds for these mice when again ranked in 1-year categories, the youngest group showing the smallest thresholds and the older group showing the largest thresholds.

These age effects for both asymptotic relative response values and for the mean gap thresholds were highly significant in the analysis of variance. These mean differences between

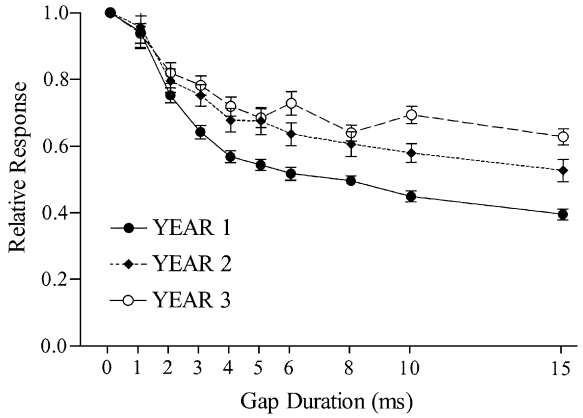

FIG. 43.6. Amplitude of the startle response (relative to the baseline control value) as a function of gap duration, in mice less than 1 year old ($n = 109$), between 1 and 2 years of age ($n = 67$), and more than 2 years old ($n = 67$).

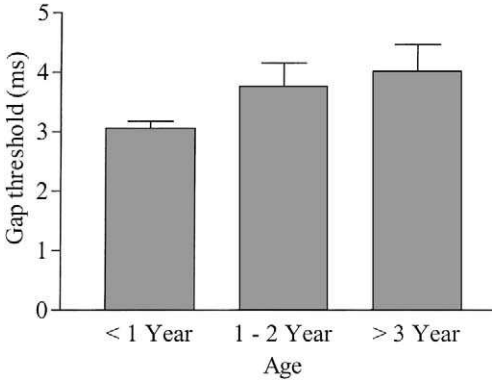

FIG. 43.7. Mean gap thresholds in mice of different ages.

the three groups in their threshold values are not extraordinarily large, but in fact they are about equivalent to the mean differences obtained in young versus old human listeners, as was shown in the data of Karen Snell. Then further, the variance in the scores within the oldest group of mice was significantly larger than that obtained in the youngest mice, and although many of the oldest mice had normal thresholds of 2 and 3 msec, about 10% had thresholds beyond the range of the younger mice.

How might these effects be explained? Our mouse experiment was different in design from that of Snell's human experiment because the mice were not preselected for their having particularly good absolute thresholds. Thus, like an unselected group of human listeners, it might be expected that, for the aged groups as a whole, measures of absolute sensitivity would be reduced in comparison to young mice. In fact, this was the case. We were able to measure thresholds in about one-third of these mice using the ABR, 37 of the youngest group, 17 of the middle-aged group, and 14 of the oldest group. These threshold data are given in Fig. 43.8. There were significant differences in sensitivity with age, with the groups being somewhat different throughout the spectrum, but different especially beyond about 20 to 24 kHz. At these higher levels, and depending on the frequency, the youngest mice had thresholds about 5 to 10 dB below those of the middle-aged group and 10 to 20 dB below those of the oldest group of mice.

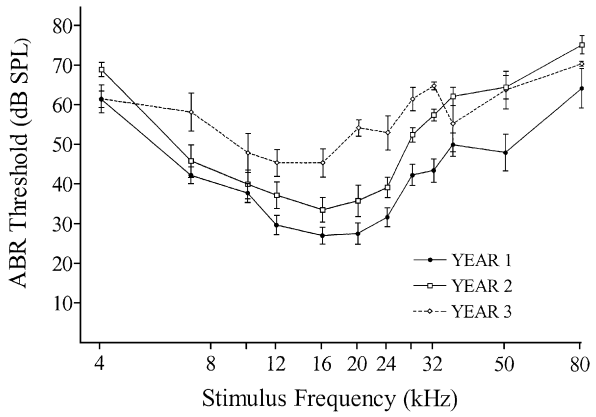

FIG. 43.8. Mean ABR thresholds (± SEM) in CBA mice of difference ages, within the first year (mean, 5 months), second year (mean, 16 months), or third year (mean, 25 months) of life.

Although there was no correlation between age in months and ABR thresholds within the first year of life (the range was just 3 to 8 months) there were substantial individual differences in threshold sensitivity, with the interquartile range within this group being about 20 dB. The presence of these individual differences in sensitivity to simple tone pips as given in the ABR data made it possible to determine whether differences in gap threshold would be affected by a class A hearing loss in mice. A correlation analysis of these data showed that sensitivity to moderately high frequency stimuli (the average of the thresholds taken from 28 to 50 kHz) was significantly correlated with gap detection thresholds, with the differences in threshold accounting for about 20% of variance in gap levels ($r = +0.46$). This correlation could perhaps have been anticipated because in other work we have found that in mice, as in humans, gap detection is better if the carrier for the gap has these high frequency components (Allen *et al.*, 2000), but it is an interesting confirmation of human data. It might then also be anticipated that the older mice would be less sensitive to the gaps simply because of their relatively poor sensitivity to high frequency stimuli. Indeed this may have contributed to an overall effect of age on gap detection, but in fact, we were not able to find a significant correlation between gap detection thresholds and ABR thresholds. However, we did find that in the two older groups of mice small gap thresholds could be found both in mice with poor threshold sensitivity for high frequency stimulation and in mice with good sensitivity to high frequency stimuli, but very large gap thresholds were found only in older mice that showed poor sensitivity to high frequencies in the ABR measures. The data suggest that a class A deficit may have been necessary but not sufficient to produce a deficit in gap detection thresholds.

In contrast to the small effect of age on gap detection thresholds, shown in Fig. 43.7, there was a relatively large effect of age on the asymptotic levels of inhibition, as can be seen in Fig. 43.6. A correlation analysis showed that differences in sensitivity to relatively high frequency stimuli was also correlated with the relative size of the response at the longest gap durations, the least sensitive mice showing also the least inhibitory effect of gaps at these suprathreshold gap durations ($r = 0.37$, $P < 0.01$). However, in addition, there was an equally strong effect of age alone on the level of asymptotic inhibition, there being a significant correlation between age at the time of the behavioral test and the residual inhibition values after regressing inhibition on sensitivity ($r = 0.38$, $P < 0.01$).

How might increased age contribute to a decline in the salience of suprathreshold gaps, beyond its effect on measures of sensitivity to high frequency stimuli? We believe the answer to this lies in the central nervous system, because this behavioral effect has a parallel in the neurophysiological data for suprathreshold gap durations obtained in Joe Walton's laboratory. In the young mouse both the behavioral gap threshold and the overall time course of the growth of reflex inhibition with an increase in gap duration are very similar to the neural threshold and neural responsivity in phasic neurons in the inferior colliculus (Walton *et al.*, 1997). A later study of these types of cells in both young and old CBA mice (reported in Walton *et al.*, 1998) found two neural effects that resemble the behavioral effects shown here in Figs. 43.6 and 43.7. The first finding

was that the mean thresholds for the phasic cells were slightly elevated in the older mice, overall by about 1 to 3 msec depending on the type of cell. Many neurons in the old mouse had the same very sharp sensitivity as those of the young mouse, but there were proportionately fewer such cells in old compared to young mice. The second finding was that the recovery function to noise onset at the end of the gap was substantially prolonged in the older mice, with most young cells having fully recovered for gap durations between 5 and 10 msec in duration, whereas most cells in the older mice were not fully recovered even at gap durations of 20 to 30 msec. These age-related differences in neural responsivity to the end of a suprathreshold gap were obviously substantial, and, in contrast to the effects of age on gap thresholds, there was very little overlap between the young and the old neurons on this measure.

Thus in both sets of data, behavioral and neurophysiological, the major effects of age were seen in the diminished response to suprathreshold gaps, rather than in the gap detection threshold. This parallel outcome supports the thesis that the neural substrate for behavioral gap detection is in these phasic cells of the inferior colliculus and that the most apparent effect of age is to diminish the salience of suprathreshold events.

Our behavioral data point to two discrete and separable effects of age that diminish the perceptual significance of brief gaps in noise in the mouse, just as others have shown that two effects of age may be responsible for the changes in gap detection in human listeners. One effect is attenuation, which reduces the audibility of the high-frequency components of the carrier for the gap. In the conceptual scheme provided by Plomp, this is clearly a class A hearing loss. The other is manifest in the mouse both at the level of the neural processing in the central auditory neural system and in its behavior, and may be thought of most easily as a diminished neural responsivity to gaps which at a sensory level is represented by diminished salience, and in behavior as reduced inhibition. The ability to detect gaps has been shown to be strongly correlated to differences in speech perception among aged listeners, and the temporal attributes of the spoken language have been shown to contain an abundance of discriminative cues essential to its understanding. Thus we suspect that a diminished sensitivity to the dynamic acoustic structure of speech must result in a type of presbycusic hearing loss that may reasonably be thought of as distortion.

V. Conclusions and Thoughts for the Future

We think that in these data we have shown the importance of studying both threshold and suprathreshold effects in aged animals, and have found evidence for both class A and class D hearing loss in the acoustically guided behavior of old animals. Old mice, like old human listeners, show diminished threshold sensitivity to gaps, and, perhaps more important, show a diminished responsiveness to gaps presented at suprathreshold values. Evidence for the partial independence of class A and class D deficits in our data seems particularly interesting from the standpoint of trying to understand where class D deficits might arise. It has seemed reasonable to attribute class A deficits to deficits at the level of the organ of Corti and class D deficits to deficits in brain function. This distinction is not completely well founded, for it has been shown that changes in sensitivity for particular frequencies might have effects other than simple attenuation at those frequencies. Thus, at the level of the auditory nerve Woolf *et al*. (1981) found that the loss of outer hair cells reduced the threshold sensitivity of high frequency fibers to high frequency stimulation but also reduced their ability to phase lock to lower frequency stimuli presented at above-threshold values. Given the importance of phase locking to certain forms of temporal processing (in particular, sound localization) it may be expected that in this case the class A hearing loss would be accompanied by a suprathreshold class D loss. In line with this reasoning, in the present experiment the class A loss was clearly correlated with a diminished suprathreshold inhibitory effect of gaps and so may be presumed to contribute to the class D hearing loss: but the separate correlation of age with inhibition is evidence that there is an additional class D loss independent of changes at the periphery.

The strong correspondence between the behavioral data and the findings from electrophysiology provided in Walton's laboratory provides a persuasive argument for the basis of this class D loss in the reduced neural response of the aged inferior colliculus at the end of the suprathreshold gap. Together these data suggest that the amelioration of the two problems of presbycusis must have two goals, one to solve the problems of the periphery, the other to solve the problems of the aged central auditory nervous system. We can imagine that this might involve neuropharmacological treatment that would boost the function of the aged neuron, perhaps by enhancing its reactivity to important acoustic events, such as gaps in noise. Then further, given recent demonstrations of neuroplasticity within the auditory system that results from exposure to certain stimulus conditions, such as the augmented acoustic environment studied by Willott *et al*. (2000), it may be possible to find other means for enriching the auditory environment in a way that will maintain auditory function with age.

The focus in the present chapter is on the contributions that an animal model of age-related changes in temporal processing might make to our understanding of presbycusis in human listeners. Obviously the distortion of complex acoustic signals may result from other sorts of deficits, such as changes in the abilities to extract signals from noise, locate sound objects in space, attend to particular signals and properly ignore others, or maintain the coherence of a complex sound object by synchronizing the processing of its component elements, for example. It seems likely that these problems too will have their bases in a combination of both peripheral and central neural mechanisms. The search for their neural bases must certainly profit from the continued development of animal models that provide the link between the physiological and the sensory–perceptual bases of behavior and offer a laboratory method for studying therapeutic effectiveness.

Rehabilitation for Presbycusis

Current and promising future treatments for presbycusis are reviewed. Proceeding from the evidence that compensatory functional reorganization of the brain takes place with aging, rehabilitation efforts should include appropriate treatment of the peripheral and central components of age-related hearing handicaps. Treatment may include addressing age-related declines in neurochemistry, but also may include behavioral training in compensatory communication strategies following the establishment of successful hearing aid use. This chapter has one section that summarizes animal experiments which may lead to human biochemical, bioelectric, or other interventions to reduce or reverse the effects of aging in the auditory system; the second section summarizes current and potentially fruitful future approaches to audiologic rehabilitation. In this chapter, we provide the reader with cross-discipline vantage points in order to facilitate collaborative, applied research. © 2001 Academic Press.

I. Introduction

One of the challenges of research based on the scientific method is that you must hold constant, manipulate, or make random all sources of variability in an experiment so causality can be clearly shown. Usually this sort of experimental control is best achieved in animal research. The price paid for this approach is that we can never be sure that these experimental results can be applied to humans. Scientists will, therefore, always be challenged to find an application of their work that is relevant to the human condition, while clinicians will always be challenged by scientists to be more scientific in their approach to human research. This chapter represents an attempt by an audiologist and a hearing scientist to ''mingle'' their views of hearing and hearing loss and thus enable the reader to see current and future aural rehabilitation strategies from both a clinical and a scientific perspective. In this way, the scientist can review current practice and research of the clinical audiologist's art in order to be alert to areas of application. In addition, the audiologist can view the scientific horizon for clinical treatments and participate in the evaluation of the efficacy of emerging medical interventions. As a reader of a book on neurophysiology of auditory aging, it would be easy to bypass the ''soft'' science of applied, aural rehabilitation. It would be similarly easy for the audiologist to dismiss the hard science of neurophysiology as not applied enough to be useful. We urge the reader to take a few minutes to complete this review of aural rehabilitation from both perspectives. If amelioration of hearing impairments in the aged is the ultimate goal of work in this area, then we have a responsibility to be appraised of the full spectrum of treatments currently available for the elderly patient with a hearing problem, as well as to consider what the future might hold in terms of aural rehabilitation for this population.

II. Aural Rehabilitation in the (Near?) Future

The hearing health care professional working with an elderly patient currently has a limited number of rehabilitative options open to them. They can provide a technical solution to hearing impairment in the form of assistive listening devices, hearing aids, or cochlear implants. They can educate their clients so that they can optimally control their communicative situation or use multimodality strategies to enhance their speech understanding. Despite the benefits of amplification and aural rehabilitation, the combination of hearing impairment and advanced age still, unfortunately, results in social withdrawal and a feeling of isolation in many elderly patients. This section of the chapter will offer a conceptual model of age-related hearing decrements and a discussion of possible treatments for presbycusis that might become reality during the reader's lifetime. Ponce de Leon failed in his quest to find the fountain of youth. While Florida may never reveal the secrets of immortality, it seems likely that recent scientific studies may provide the basis for the prevention or treatment of age-related hearing loss.

What is presbycusis? Many people live well into the eighth or ninth decade of life and show remarkably normal hearing, while others show a steady decrement in their audiometric thresholds starting in early adulthood. While it is comforting to know that hearing loss is not an inevitable consequence of aging, the reasons underlying this remarkable variability in age-related hearing loss are largely unknown. Schuknecht

(1974) identified four different types of age-related hearing loss, relating patterns of audiometric findings to underlying anatomical changes. Whereas this is helpful as a classification scheme of presbycusis, this still does not explain the underlying causes of presbycusis, or its variable expression. It seems likely that the development of effective prevention or treatment of age-related hearing loss will follow an improved understanding of the underlying causes of presbycusis.

A. Is Presbycusis Purely Peripheral?

In the following paragraphs, we will review evidence that the central auditory system undergoes a functional reorganization in response to damage to the peripheral auditory system. We will argue that the constellation of symptoms known to comprise presbycusis is not solely the result of peripheral damage, but also the consequence of the functional reorganization of the central auditory nervous system following peripheral damage.

1. Evidence of Functional Reorganization Following Hearing Loss

A large body of evidence demonstrates that the adult brain is capable of substantial functional changes, both as a result of the normal learning process, or in response to injury. Let us review evidence that the central auditory nervous system is capable of functional reorganization in adults. The most direct evidence is available from studies of nonhuman mammals, and we will briefly review some of this literature and assume that these findings can be generalized to humans.

There is evidence that learning can produce changes in the cortical representation of sound. Bakin and Weinberger (1990) used classical conditioning to investigate changes in cortical receptive fields in guinea pigs. They implanted an electrode array in the auditory cortex. Following recovery from surgery, responses from these electrodes were recorded in the awake guinea pig to determine the receptive field of the near-field responses from the various electrodes in the electrode array. Animals were exposed to a classical conditioning paradigm, where a tone stimulus was followed in some trials by a mild electrical shock. Other animals received the tonal stimulus or the shock, in random order, but unpaired. For the animals exposed to the conditioning procedure, there was an increase in the neural response magnitude to the conditioning acoustic stimulus, and a reduction in response magnitude at other frequencies. In some instances, this actually led to a change in response best frequency to the conditioning frequency. Sensitized animals showed an overall increase in response across the receptive field, but did not show a change in tuning. Bakin and Weinberger (1990) found that the effects of conditioning lasted up to 24 hr (the longest time interval they studied). Weinberger *et al*. (1993) found evidence that these receptive field modifications could last as long as 8 weeks following training. Moreover, they found these changes in animals that were anesthetized for the cortical recording session (but not the conditioning session). Recanzone *et al*. (1993) trained monkeys to perform a specific frequency discrimination task. The monkeys improved in this task as a result of training. These trained animals were then studied physiologically by recording multiple-unit responses from primary auditory cortex. When compared to control animals, the trained animals showed an expanded frequency representation, sharper tuning, and increased response latencies for the frequency region used for the frequency discrimination task. These differences were not observed for other frequency regions. These studies demonstrate clear changes in the processing of acoustic stimuli in the auditory cortex that appear to be the result of learning.

There is also evidence of functional reorganization in adult animals following cochlear damage. One line of evidence shows changes in the tonotopic map. Kaltenbach *et al*. (1992) exposed hamsters to a damaging high level, high frequency tone, and investigated changes in the tonotopic map of the dorsal cochlear nucleus. In the nonexposed animals, there was a systematic increase in best frequency as the electrode moved in the lateral to median direction through the dorsal cochlear nucleus. Responses of the tone-exposed animals showed a gap in best frequency near the exposure frequency, or an expanded representation of the frequencies bordering the exposure frequency. Thus, the tonotopic map can be modified in response to peripheral hearing loss. However, Kaltenbach *et al*. (1992) noted that thresholds were often elevated in the region of expanded representation and suggested that these changes were in all probability the result of peripheral changes (i.e., the best frequency was shifted to a different frequency because the low threshold tip had been substantially elevated due to tone exposure). Robertson and Irvine (1989) produced cochlear lesions of limited extent in guinea pigs, and studied changes in the tonotopic organization of the auditory cortex. At long survival times (more than 1 month), the tonotopic map changes revealed an expansion in representation of tonal frequencies adjacent to the region of cochlear damage. In addition, thresholds in this expanded frequency region were very similar to normal thresholds at these frequencies. In a second experiment, Robertson and Irvine (1989) studied cortical tonotopic organization within several hours of exposure to the damaging tone. It was found that responses were shifted in best frequency in frequency regions adjacent to the damaged region, but in this case thresholds were substantially elevated compared to control values. These data suggest that changes in the map immediately following cochlear damage are likely the direct result of peripheral damage, with units in the cortical region whose best frequencies were previously in the region of greatest cochlear damage showing responses to frequencies remote from best frequency. However, the emergence of normal thresholds in these ''reorganized'' regions appears to be the result of functional reorganization. Willott *et al*. (1993) found expanded frequency representation of the midfrequency region of primary auditory cortex in aging C57 mice, as their high frequency thresholds increased due to progressive, adult-onset hearing loss. Thresholds in the expanded midfrequency region were low (near normal). These studies suggest that following traumatic or progressive hearing loss that the auditory cortex is capable of a functional reorganization of frequency representation across the auditory cortex.

A second line of evidence that the auditory system is capable of reorganization is based on evoked potential amplitude changes following cochlear injury. Salvi *et al*. (1990) exposed chinchillas to a high intensity tone that produced a substantial threshold shift for mid and high frequency tone bursts. Despite

the threshold elevation, responses as measured from the inferior colliculus often showed larger than normal responses to high level tone-burst stimuli. Popelar *et al*. (1987) investigated responses from the auditory nerve, inferior colliculus, and auditory cortex in awake guinea pigs before and after they were exposed to white noise (120 dB SPL, 1 hr). Evoked potential thresholds at 1 hr following exposure were elevated, and threshold changes were similar at all three levels of the auditory system, and recovered to near baseline values by 1 week postexposure. At 1 hr postexposure, auditory nerve and inferior colliculus response amplitudes were reduced for all tone-burst levels. In contrast, auditory cortex response amplitude was increased at 1 hr postexposure. Response amplitudes progressively moved toward baseline values (i.e., auditory nerve and inferior colliculus responses increased, auditory cortex responses decreased) and approximated baseline values by 1–2 weeks postexposure. It is interesting to note that when guinea pigs were anesthetized with urethane, all three responses (auditory nerve, inferior colliculus, auditory cortex) showed amplitude reduction following noise exposure. Thus, not only can responses from the cortex show response enhancement following hearing loss, despite smaller response amplitudes from more caudal auditory regions, but this cortical response enhancement is sensitive to anesthesia. Robert Harrison and colleagues (Wake *et al*., 1993, 1994; Takeno *et al*., 1994a,b) found that carboplatin, an antineoplastic agent, can selectively damage inner hair cells in the chinchilla. Trautwein *et al*. (1996) investigated the effects of carboplatin on the compound action potential of the auditory nerve. They found a decrease in the amplitude of the compound action potential, with little or no compound action potential threshold change until a near total loss of inner hair cells was observed. Burkard *et al*. (1997) reported a substantial decrease in the amplitude of the inferior cortex potential following inner hair cell loss, but little change in threshold. Qiu *et al*. (2000) evaluated the effects of inner hair cell loss while recording the auditory nerve, inferior colliculus, and auditory cortex potential in unanesthetized chinchillas. Threshold changes were minimal at all electrode locations, even when inner hair cell loss was quite substantial. Auditory nerve response amplitude decreased in proportion to inner hair cell loss. Inferior colliculus response amplitude also tended to decrease with increasing inner hair cell loss, but this decrease was less than that seen for the auditory nerve response. Finally, and most importantly, auditory cortex response amplitudes in many cases increased following inner hair cell loss. In some chinchillas, amplitude enhancement was most prominent at 2 weeks after carboplatin, and then reduced to near baseline values at 5 weeks after carboplatin. Others showed an increase in auditory cortex response amplitude that was similar at 2 and 5 weeks after carboplatin. We believe that cortical amplitude enhancement following inner hair cell loss is the result of auditory plasticity in response to the reduced peripheral input. These observations are of fundamental importance in the present context, because they demonstrate that substantial inner hair cell loss produces little threshold shift, and hence a normal audiogram does not guarantee a normal complement of hair cells and that, following inner hair cell loss, and the subsequent reduction in neural input to the central auditory system, cortical activity can actually be enhanced. Perhaps some of the age-related changes in auditory abilities are not directly a consequence of age-related hearing loss itself, but rather the result of the subsequent functional reorganization.

The preceding paragraphs demonstrate that the auditory nervous system is capable of functional reorganization as not only part of the normal learning process, but also in response to cochlear damage. This suggests that the social and clinical manifestations of hearing loss are not only the result of the peripheral hearing loss per se, but also possibly the result of compensatory functional reorganization. It appears that normal hearing (i.e., normal hearing thresholds) does not guarantee that the cochlea is normal, as substantial inner hair cell loss often results in only small threshold shifts (Qiu *et al*., 2000). Furthermore, functional reorganization may appear as cortical response enhancement, suggesting that such reorganization is not strictly the result of threshold shift. In terms of our discussion of the aging auditory system, it appears that we cannot conclude that the auditory system of older human subjects is ''normal'' based on thresholds alone. Furthermore, functional reorganization is possible, despite ''normal'' thresholds. These considerations suggest that elderly patients could exhibit decrements in auditory performance, despite a normal audiogram, and that these decrements could be the result of peripheral damage or compensatory functional reorganization. Thus, aural rehabilitation in the future needs to focus on a reduction of peripheral hearing loss (cochlear damage in its broadest sense) and on developing the ability to modify functional reorganization in response to cochlear damage.

B. Preventing Cochlear Hearing Loss

Let us accept the notion that peripheral hearing loss in the elderly is responsible for many of their communicative problems, regardless of whether it is the hearing loss itself or the resulting functional reorganization. Thus, the problem of presbycusis might best be solved by an ounce of prevention rather than a pound of cure. Age-related hearing loss appears to have multiple causes. For example, Schuknecht (1974) lists four distinct forms of presbycusis based on clinical manifestations and anatomical changes: cochlear, strial, neural, and cochlear–conductive. Whether age-related hearing loss is the accumulation of ototoxicity over a lifetime, the result of an adult-onset genetically based hearing loss, or simply an inevitable consequence of getting old, prevention of cochlear hearing loss with aging would presumably improve an elderly patient's quality of life. There is currently an emerging body of evidence that sensorineural hearing loss can be reduced by appropriate treatment prior to exposure to ototoxic agents.

Hu *et al*. (1997) investigated the effects of *R*-phenylisopropyladenosine on noise-induced hearing loss. *R*-phenylisopropyladenosine has been found to upregulate antioxidant enzyme activity, and in this study was topically delivered through the round window of one ear of each chinchilla, while normal saline was delivered to the opposite ear. Within several hours of *R*-phenylisopropyladenosine or saline application, each chinchilla was exposed to an octave band of noise centered at 4 kHz (105 dB SPL, 4 hr). Distortion product otoacoustic emission input/output functions and inferior colliculus evoked potential thresholds were determined at various postexposure times (15 min to 20 days), and hair cell counts

were made (20 days postexposure). Distortion product otoacoustic emissions were somewhat larger in the *R*-phenylisopropyladenosine-treated ears than the saline-treated ear. In addition, average thresholds were lower (better) in the *R*-phenylisopropyladenosine-treated ears than in the saline-treated ears. Finally, outer hair cell loss was reduced in the *R*-phenylisopropyladenosine-treated ears as compared to that seen in the saline-treated ears, while inner hair cell loss was similar for both ears. It appears that *R*-phenylisopropyladenosine can be effective in reducing noise-induced hearing loss. Hight *et al*. (1999) investigated the effects of glutathione monoethyl ester on hearing loss to high level impulse noise. Glutathione monoethyl ester was applied to one round window approximately 40 min prior to exposure to 50 pairs of 150 dB peak SPL impulses. There was a nonsignificant trend for permanent threshold shift to be less in the glutathione monoethyl ester-treated ears. There was significantly less outer hair cell loss in the glutathione monoethyl ester-treated ears than in the control ears. Wang *et al*. (1999) infused leupeptin (a calpain inhibitor) into one cochlea in a group of chinchillas using an osmotic pump. Leupeptin reduced noise-induced hair cell loss. Leupeptin had little influence on inner hair cell loss and actually increased outer hair cell loss due to carboplatin.

Canlon *et al*. (1988) investigated the effects of exposure to a low level ''conditioning'' noise prior to exposure to a higher level exposure that is potentially damaging to the auditory system. They found a reduction in threshold shift in those animals receiving the ''conditioning'' exposure, as compared to those who received only the ''damaging'' exposure. It appears that prior exposure to a nondamaging sound can reduce the damage to a ''damaging'' sound. This phenomenon has been popularly referred to as toughening. Jacono *et al*. (1998) provides a possible explanation for toughening. They investigated antioxidant activity in the cochleae of animals exposed to a variety of sounds. They found increases in glutathione reductase, γ-glutamyl cysteine synthetase, and catalase activity that were more prominent in the stria than in the organ of Corti. These data suggest that toughening may reduce noise-induced hearing loss by upregulation of free radical scavengers. When the damaging exposure occurs, the upregulated ability to scavenge reactive oxygen species provides protection above and beyond that available in the non toughened animals.

One might ask what toughening and noise-induced hearing loss have to do with prevention of age-related hearing loss. This rhetorical question is answered by Willott and Turner (1999), who studied age-related hearing loss in two strains of mice (C57BL/6J and DBA/2J) who develop a progressive, adult-onset hearing loss. Beginning at 25 days of age, mice were exposed to a 70 dB SPL broadband noise for 12 hr each evening. When compared to control animals, the mice exposed to the conditioning noise showed improved auditory performance, including lower (better) auditory brain stem response thresholds. The noise conditioning did not eliminate threshold decrement with aging, but did appear to reduce its magnitude, for measurement ages of 3–14 months in C57BL/6J mice and 2–9 months in DBA/2J mice. Both of these strains of mice exhibit an adult-onset genetically caused sensorineural hearing loss, and thus this study cannot be viewed as evidence that toughening can reduce ''normal'' age-related hearing loss. It does, however, suggest that progressive (and thus age-dependent) hearing loss can be reduced by toughening. Furthermore, if we combine the results of Jacono *et al*. (1998) and Willott and Turner (1999), then it seems likely that at least some forms of age-related hearing loss can be influenced by upregulating the free-radical scavenging abilities of the cochlea.

C. Age-Related Changes in the Central Auditory System: Age-Related Changes in GABA

GABA is an inhibitory neurotransmitter in the central nervous system, GABAergic neurons are prevalent in the neocortex of all mammals, and their characteristics in primates has been well studied (Jones, 1993). We suggest that a downregulation of GABA-A receptors is one possible mechanism leading to the cortical enhancement observed following inner hair cell loss. Furthermore, an age-related decline in GABA-A receptors may represent a compensatory mechanism for overcoming a reduction in peripheral input from the aging auditory system.

Caspary *et al*. (1990) evaluated age-related changes in GABA in neurons from the central nucleus of the inferior colliculus. They counted the number of inferior colliculus neurons that were immunolabeled for GABA and found a 36% reduction in GABA-containing neurons in the ventrolateral inferior colliculus of old as compared to young adult rats. Caspary *et al*. (1995) reviewed the work of his own group and others, and reported that not only was there a decrease in the number of immunoreactive GABA neurons in the inferior colliculus with advancing age, but that there were reduced concentrations of GABA, and decreased GABA-B receptor binding, as well as other evidence of reduced GABA activity in the inferior colliculus of the aged animal. Taken together, this work provides evidence of reduced GABA activity in the central auditory system of aged animals.

D. Age-Related Changes in Antioxidant Enzymes

Mei *et al*. (1999) studied age-related changes in antioxidant enzymes in 3-, 18-, and 28-month-old rat inferior colliculus. They found age-dependent reductions in both total superoxide dismutase and catalase. This reduction in inferior colliculus antioxidant enzymes with advancing age suggest that age-related changes in the central auditory system might be the result of a decrease in free radical scavenging ability of the aging nervous system. Thus, upregulation of free radical scavengers in the central nervous system might represent one approach to a reduction in central manifestations of age-related hearing loss.

E. Can Responses of the Central Auditory System Be Modified?

Let us accept the idea that some manifestations of hearing loss are the result of functional reorganization of the auditory nervous system following hearing loss. Is there any evidence that these changes can be experimentally influenced? Halonen *et al*. (1991) found that intraperitoneal administration of vigabatrin increased the level of GABA in cortical and subcortical regions. In addition, at some doses, there was a decrease in the concentration of several excitatory amino acids (glutamate,

aspartate, and glutamine) in cortical and subcortical structures. Should it become desirable to reverse the age-dependent decline in GABA reported by Caspary and colleagues, then drugs like vigabatrin can be used to upregulate GABA. Kilgard and Merzenich (1998) have recently shown that pairing a specific auditory stimulus with electrical stimulation of the nucleus basalis of the basal forebrain produces dramatic cortical reorganization in the rat auditory cortex. This demonstrates that functional reorganization can be experimentally induced, should this be deemed desirable. Although preliminary in nature, it appears that electrical stimulation or systemic introduction of specific drugs offer therapeutic possibilities for either promoting functional reorganization or reversing such reorganization.

Fujiyoshi *et al*. (1994) investigated the shiverer mouse, which shows central nervous system abnormalities due to an autosomal-recessive deletion of a gene for myelin basic protein. These mice show abnormalities in central myelin, but normal peripheral myelin. Shiverer mice showed greatly reduced central myelin in the auditory nerve, as compared to control animals. In addition, there was prolongation of the interwave intervals in the auditory brain stem responses of shiverer mice, compared to the controls. Transgenic shiverer mice were created by inserting the myelin basic protein gene into the fertilized eggs of shiverer mice. These transgenic shiverer mice showed levels of myelin basic protein that were less than those seen in the control mice, but greater than those seen in the shiverer mice. Similarly, the central myelin on the auditory nerve of transgenic shiverer mice was less than that seen in control mice, but more than that seen in the shiverer mice. Finally, auditory brain stem response interwave intervals were greatest in the shiverer mice, intermediate for transgenic shiverer mice, and smallest for the control mice. It appears from this study that genetically based changes to the central auditory nervous system can be partially reversed by gene therapy.

F. Summary

Presbycusis can be viewed as a combination of peripheral hearing loss and the resulting functional reorganization. In response to cochlear damage, functional reorganization can take the form of a modification of the tonotopic map the central auditory nervous system, in particular the auditory cortex. In addition, functional reorganization can take the form of amplitude enhancement in the central auditory system. Enhancement of responses from the central nervous system following peripheral hearing loss may be the result of a downregulation of GABA. If we view presbycusis as a combination of peripheral changes and the resulting functional reorganization, then treatment of presbycusis can possibly take the form of either reducing the magnitude of peripheral hearing loss with aging, or modulating the functional reorganization that occurs in response to the peripheral hearing loss. Importantly, conditioning noise and several drugs (glutathione monoethyl-ester, *R*-phenylisopropyl-adenosine, calpain) are effective in reducing hair cell loss as well as threshold changes if administered prior to noise exposure. In addition, Willott and Turner (1999) have found that long-term conditioning with a moderate level broadband noise can reduce the magnitude of adult-onset hearing loss in several strains of mice. Thus, both noise-induced and genetic (age)-induced hearing loss can be reduced by exposure to a conditioning stimulus, and noise-induced hearing loss can be reduced by either systemic application or direct application to the cochlea of free-radical scavengers or calpain inhibitors. Centrally, there appears to be a reduction in GABA-mediated inhibition with aging, but Halonen *et al*. (1991) have demonstrated an upregulation of GABA by systemic administration of vigabatrin. In addition, recent experimental studies have demonstrated functional reorganization in auditory cortex by electrical stimulation of the nucleus basalis of Meynert (Kilgard and Merzenich, 1998). These studies suggest that one can promote or reverse functional reorganization of the auditory nervous system. As we improve our differentiation of age-related hearing loss into peripheral and central changes, we should also work to differentiate those central changes that are the consequence of aging itself from those that are the result of functional reorganization in response to peripheral changes. It seems likely than in some instances, functional reorganization actually improves auditory function, while in others it produces a decrement in function. Thus, the ability to promote or reverse functional reorganization could prove to be effective ways of reducing age-related decrements in auditory function. Finally, Fujiyoshi *et al*. (1994) has shown that severe abnormalities of auditory brain stem responses in shiverer mice can be improved by gene transfer. Thus, age-related hearing loss may not be inevitable, but rather in many is likely to be the result of adult-onset genetically based hearing loss. Once these hearing loss genes are identified, then approaches to prevention of hearing loss by gene transfer will be feasible.

We have discussed future approaches to aural rehabilitation in the elderly that focus on reversal/prevention of adult-onset hearing loss and the promotion/reversal of functional reorganization. These suggested approaches are based on very preliminary studies that simply offer hope that age-related hearing loss can be reduced.

III. Audiologic Rehabilitation: The Need

An elderly person put his hearing aid in his denture-cleaning solution overnight, another person removed his canal-type hearing aid while eating a bowl of pretzel nuggets and suddenly realized that he had just pulverized their hearing aid in one vigorous bite. An 80-year-old, ex-farmer purchased two expensive hearing aids, only to find that he could not manipulate the tiny volume controls because of his massive, callused hands. We all have probably had contact with an older person who bought the hearing aid reluctantly after many complaints by spouse and family, used it for a few weeks and then put it in the dresser drawer, never to be used again.

All of these incidents illustrate that fitting a hearing aid does not necessarily solve the problems of older adults with hearing loss. Specifically, elderly patients may have a constellation of problems associated with senescence, which need to be considered. It is, therefore, important for older persons with hearing loss to have access to a full scope of quality medical as well as other professional services such as aural rehabilitation. This section of the chapter will describe current approaches to the rehabilitative treatment of age-related hearing loss (presbycusis).

A. Why Audiological Interventions?

Audiologists are trained to assist not only in the quantification and diagnosis of the hearing loss, but in the rehabilitation of persons with hearing impairments. Their aural rehabilitation training provides advanced knowledge and skills regarding the fitting of hearing aids and the use of assistive listening devices. Further, they can provide auditory training, lip-reading training, and personal counseling that aids in their adjustment to the use of amplification and improved communication strategies. Each of these areas will be reviewed briefly so that the reader will understand the necessity and the scope of services that are available.

B. Aging and Hearing Loss (Presbycusis) Defined

1. Characteristic Hearing Thresholds

Initially, presbycusis results in a gradual change in hearing sensitivity, but can eventually end with a communication impairment of sufficient magnitude to result in an isolated, frustrated, and sometimes angry person with a severely reduced quality of life. Typically, hearing loss begins by the fourth or fifth decade of life in the higher frequencies, and has little consequence for communication or enjoyment of life in its early stages. The hearing loss gradually increases in the higher frequencies and spreads to the mid frequencies over the next 10–30 years (Gates *et al*., 1990). Initially, the aging person adapts to the gradually changing hearing thresholds without conscious effort or knowledge of the hearing loss. However, as the degree of hearing loss worsens the person may begin to experience communication difficulties that are severe enough for them to seek professional help. For this magnitude of hearing loss, patients probably obtain sufficient benefit from a hearing aid to continue its use. However, the level of communicative demands of individual lifestyles, occupations, and other factors often dictate whether they seek professional help. One person with a 40-dB HL hearing loss may not seek help or need to use a hearing aid if he/she is not socially or occupationally active and is not motivated to be so. However, another person with a 30-dB HL hearing loss, who is highly active, may be a full-time hearing aid user because missing a word or two could be critical to success on the job. Thus, disability (i.e., the communication dysfunction) and handicap (i.e., the psychosocial manifestations) cannot be predicted from hearing test results. Therefore, management of hearing-impaired clients is not based on the audiometric hearing loss alone (Erdman and Demorest, 1998).

C. Audiological and Otological Assessment

Gates *et al*. (1990) lists the causes of presbycusis as intrinsic, age-related degeneration, noise damage, biologic effects of diseases, ototoxic substances, and diet, superimposed on a genetic mechanism. This complex of etiologies warrants comprehensive medical and audiological examination so that the range of the patient's age-related hearing problems may be addressed. The otolaryngologist may need to address the age-related changes to the outer and middle ear (White and Regan, 1987), as well as age-related changes to the inner ear (Schuknecht, 1974). Older persons may also have the associated symptoms of tinnitus and/or vertigo. Some of these symptoms may respond to medical management. The audiologist's and otolaryngologist's collaboration provides the data necessary to document treatment efficacy.

Assessment of speech recognition performance in adverse listening situations is an important additional component of audiometry with the elderly because performance on standard phonetically balanced word tests (in quiet) is often normal, yet patients' complain of communication difficulties in noise. The source of these difficulties can be related to simple loss of audibility of some of the acoustic cues for speech (Souza and Turner, 1994). However, it is possible that more central structures of the auditory system may also be involved (see Gordon-Salant and Fitzgibbons, 1993). Also, Jerger (1992) presents evidence of cognitive dysfunction at cortical sites with aging. Humes *et al*. (1994) and Lesner and Kricos (1995) recommend that the audiologist sample phonemic-word, and sentence-level speech recognition in background noise in order to fully characterize speech perception deficits and thus determine the need for aural rehabilitation.

Otoacoustic emissions are basically a test of outer hair cell function. Normal otoacoustic emissions suggest normal outer hair cell function. In addition, otoacoustic emissions are influenced by stimulation of the contralateral ear. This contralateral suppression appears to be the result of activation of the cochlear efferents innervating outer hair cells. Thus, measurement of otoacoustic emissions can illuminate the condition of the efferent auditory system which may be important for sound localization and understanding speech in adverse background noise situations. Auditory evoked potentials, including the auditory brain-stem response, are powerful clinical tools for hearing screening, threshold estimation, site-of-lesion testing, and intraoperative monitoring. Future research into stimulation protocols for challenging the temporal processing capabilities of the brain stem may yield important diagnostic information (Walton *et al*., 1999; Sims and Burkard, 2000).

D. Assessment of Hearing Handicap

Garstecki and Erler (1996), Alberti *et al*. (1984), and Erdman and Demorest (1998) have described the necessity for careful determination of the broad scope of handicaps that result directly and indirectly from an individual's hearing loss. Use of hearing handicap scales enables the audiologist to detect and specify significant communication and adjustment difficulties, select from an array of rehabilitative interventions, and document treatment outcomes for consumers and third-party payers. Also, hearing handicap surveys can assist the hearing-aid fitting process by illuminating specific, troublesome listening situations. The audiologist can then program the aid with various signal processing algorithms and frequency responses to minimize the listener's difficulties. There are several standardized surveys, and each test instrument has different purposes and strengths. The few listed below are used in many clinics, but many more are available (see review by Lesner and Kricos, 1995).

1. The Hearing Handicap Inventory for the Elderly

The Hearing Handicap Inventory for the Elderly (HHIE) was designed by Ventry and Weinstein (1982) to determine

whether non-institutionalized individuals have sufficient difficulty with understanding spoken communication to warrant professional follow-up. A brief screening version (Ventry and Weinstein, 1983; Weinstein, 1986) consists of 10 questions, which can be quickly completed in the clinic waiting room. Research results have indicated that the brief version has adequate sensitivity and specificity to screen for significant hearing-related communication difficulty (American Academy of Audiology, 1991; Jupiter and DiStasio, 1998).

2. The Denver Scale

The Denver Scale of Communication Function for Senior Citizens Living in Retirement Centers, by Zarnoch and Alpiner (as cited and reproduced in Hull, 1997), has been designed specifically for the institutionalized elderly client to determine their need for aural rehabilitation.

3. Communication Profile for the Hearing Impaired

Once the hearing loss has been identified, by the HHIE or by audiometric evaluation, further assessment of the psychosocial effects of the hearing loss is required. The Communication Profile for the Hearing Impaired (CPHI) is a 145-item survey, which has been normed on large, national samples of hearing-impaired adults (Erdman and Demorest, 1998; Demorest and Erdman, 1987). This comprehensive assessment tool has several subscales: communication performance, communication importance, communication environment, communication strategies, and psychological adjustment. This instrument is useful in two ways. First, it can alert the practitioner to an individual's specific needs and monitor the outcomes of rehabilitation. Second, CPHI's normative research across diverse populations of hearing-impaired individuals may be helpful in documenting the adjustment variables that influence the success of aural rehabilitation.

E. Hearing Aids

Once the hearing loss has been documented by audiologic assessment, medical interventions have been exercised and the degree of communication handicap determined via interview and handicap surveys, the audiologist has the necessary information to determine whether a hearing aid is needed and if the client is motivated to proceed with purchase. Because a binaural hearing aid fitting costs between $1800 and $6000, hearing aids are a major commitment by the patient.

1. New Hearing Aid Techniques and Technologies

The most frequent hearing complaint of the older person is the understanding of speech in a background of noise. Unfortunately, listening in noise with a hearing aid can be extremely difficult, as background noises are amplified along with the speech. Furthermore, a person with sensorineural hearing loss frequently perceives high intensity sounds as loud, or even uncomfortably loud (i.e., recruitment or hyperacusis). Thus, when loud environmental sounds are made even louder by amplification, the hearing aid user may quickly decide that amplification is more harmful than helpful. Audiological research has focused on these problems with some success in prescription fittings for loudness control (Storey *et al*., 1998). Within the past 5 years, hearing aids have been developed that have low power, digital signal processing chips, CMOS memory, and directional, multiple microphone arrays. This technology enables even more fitting flexibility for making speech audible, while compressing this audible speech into a substantially reduced dynamic range (between threshold of audibility and threshold of discomfort). These hearing aids have client-controlled, multiple ''programs'' which are designed for various listening circumstances (e.g., crowded restaurant, one-on-one listening, music appreciation, telephone reception). Frequently, audiologists work with computer-assisted algorithms that are directly interfaced to the hearing aid so that fittings take place on the individual's ear, rather than by estimations of the required fitting prescription based on averaged data. Digital hearing aids' noise reduction algorithms have not shown significant improvements in speech recognition performance in noise, but most hearing-impaired persons subjectively ''prefer'' them when cost is not a factor (Newman and Sandridge, 1998). The use of directional microphones or multiple-microphone arrays has been shown to provide significant improvements in speech reception performance in background noise (Schuchman *et al*., 1999). Also, digital circuitry for management of acoustic feedback (hearing aid squeal) is a definite benefit for those using higher gain or open ear aid fittings. More research is needed to determine the ultimate potential of these circuits. In the near future, digital hearing aid circuits may allow reduction of periodic types of noise (e.g., engine noise) through automatic detection and adaptive filtering.

2. Hearing Aid Fitting

The audiologist can help the hearing-impaired person sort through the hearing aid options by negotiating an informed priority list and discussing hearing aid style and feature options from several instrument manufacturers. The audiologist will then fit the hearing aid to restore hearing sensitivity for the important speech frequency range, and control loudness such that comfortable use in all listening situations is assured. The ultimate purpose of any fitting, however, is improved speech recognition in the user's typical listening situations. Once a prescription is determined, it is frequently verified by the use of *in situ* acoustic measurements of the aid's performance in the user's ear and by assessment of speech recognition in quiet and background noise. The process is best accomplished over the course of several visits, and adjustments are made as the user acclimates to the hearing aid.

3. Hearing Aid Types

Choosing a hearing aid has become a complex task involving economic, health, lifestyle, and cosmetic issues. Second generation digital instruments are smaller, and can be used in completely-in-the-canal aids. However, hearing aid components such as a telecoil for use with the telephone, client-controlled volume control, and programming may need to be sacrificed with the completely-in-the-canal or in-the-ear style aids due to lack of space in an individual's ear canal. Handheld remote controls are available with some hearing aids to improve the older client's ability to manipulate controls with

these small instruments, but some patients find it inconvenient to use and easy to misplace.

Behind-the-ear hearing aids represent 15–20% of the market and are typically fitted to persons with moderate to profound hearing losses. Behind-the-ear hearing aids enable coupling with other assistive listening devices such as FM or infrared sound transmission systems. These systems are increasingly important if the level of hearing loss is moderate to profound, or if the user must hear in high background noise or in long-distance situations (see below). Generally, behind-the-ear systems are lower in cost than custom-assembled completely-in-the-canal systems, have fewer problems with acoustic feedback, and need to be repaired less often.

For those persons with severe to profound hearing loss who receive limited benefit from conventional amplification (e.g., aided speech recognition scores of less than 40% using the CID Everyday Sentences), the cochlear implant is often useful (Allum, 1996; Koch, 1996). The cochlear implant requires surgery and costs approximately of $30,000–$40,000. However, many of the implanted persons are able to use the telephone for the first time in many years. Most of the remainder of the users can use lipreading and their implant to reestablish functional receptive communication.

An intriguing alternative to the implant uses digital signal processing to transpose high frequency speech sound to lower, audible frequency ranges. Currently, this sort of frequency-transformation algorithm is being used with children with profound hearing loss, but it may also be an alternative to the cochlear implant with the elderly. With either the cochlear implant or the transposing hearing aid, extended periods of individual aural rehabilitation are required to fine-tune the fittings. The user needs intensive retraining for speech perception with these devices' representation of sound.

4. Assessment of Improvement via Hearing Aid Fitting

Survey scales have been shown to be effective for documenting the client benefit from hearing aid fitting. The APHAB (Abbreviated Profile of Hearing Aid Benefit) designed by Cox and Alexander (1995) uses 24 questions concerning self-ratings of communication performance and problems with and without a hearing aid. In addition, the client can document the results of two different hearing aids as part of the hearing aid evaluation process. The current version has a normative database for the elderly. The APHAB can be administered and scored on a personal computer in a few minutes.

The Client Orientated Scale of Improvement (COSI) (Dillon *et al*., 1997) is a quick and simple means of documenting hearing aid benefit. The specifics of the five ''most troublesome'' listening situations are documented. These are rank-ordered by the client from ''most troublesome'' to ''least troublesome'' and then scaled by the client as to frequency of occurrence or severity. When the hearing aid fitting has been completed, the client again ranks the severity and frequency of the five problem listening situations.

F. Assistive Devices

Assistive devices, a term referring to both assistive listening devices and alerting devices, are an integral component of comprehensive hearing-care services (Sandridge and Lesner, 1995). Persons with hearing impairment must listen in less than ideal situations that limit the performance of their hearing aid. With an assistive listening devices, effective listening distance can be increased, signal-to-noise ratio improved, and effects of adverse room acoustics minimized. Sandridge (1995) provides a complete review of systems that work with a hearing aid, or work independently of hearing aids. For example, there are simple hard-wired earphone extensions for the TV speaker, telephone equipment options, and sophisticated FM radio or infrared systems connected to the person's own hearing aid. Each system has its advantages and disadvantages in terms of fidelity, cost, susceptibility to interference from other sources, ease of use, maintenance, portability, and the specific communication situation for which it is designed (e.g., one-on-one conversation, in church, in a meeting, in a classroom, etc.).

Alerting devices are useful for anyone with any degree of hearing loss. Even while wearing amplification, many people will miss the telephone ring, the car blinker, the alarm clock or smoke alarm if they are some distance from the sound source. The audiologist can assist elderly persons in their selection from a wide array of alerting devices designed for these problems.

G. Psychological Adjustment

Trychin (1995), Clark and Martin (1994), and Luterman (1996) have documented the need and described counseling as a vital component in audiologic rehabilitation. Without patient counseling, daily hearing aid utilization declines for new hearing aid users. With counseling, patients report greater reductions in perceived handicap (Brooks, 1979). Even minimal amounts of counseling can significantly decrease the most commonly reported difficulties of the elderly, e.g., listening in background noise, dexterity concerns, and the belief that hearing loss is not significant enough to warrant a hearing aid (Brooks, 1989). Trychin (1995) states that a typical counseling program provides information regarding hearing loss, assistive listening devices, service providers, and resources. Participants also practice effective communication behavior that will reduce hearing problems and alter client's dysfunctional responses to communication problems when they do occur. Clients as well as their significant others (Tye-Murray and Schumm, 1994) need to develop realistic, nonjudgmental attitudes toward hearing loss.

H. Auditory and Lipreading Training

There are three traditional components within the context of aural rehabilitation: amplification, auditory training, and lipreading. Most clinicians, however, now focus on hearing aid selection and orientation, with an apparent loss of confidence in both auditory training and lipreading instruction as primary therapies (Erber, 1996). Some studies support that view (e.g., Lesner *et al*., 1987), but other studies show positive results (e.g., Walden *et al*., 1981). Recent successful auditory and lipreading training results have utilized computer-assisted instruction to enable the necessary, sustained drill and practice for auditory training and lipreading training (see Sims and Gottermeier, 2000). With a laptop computer (or Web-based dis-

tance learning), intensive auditory training and lipreading training will become more feasible. Clients will be able to obtain this training at home, with reduced treatment cost and with less need for individual therapy sessions for the entire course of auditory rehabilitation treatment.

1. Auditory Training

Auditory training is the process by which a person with impaired hearing develops perceptual skills through guided listening practice (Carhart, 1960; Cole and Gregory, 1986). During therapy sessions, an adaptive approach is used with a particular combination of stimulus and response (e.g., word identification). As therapy progresses, the clinician will present more challenging listening activities (e.g., word identification in noise). If the client experiences difficulties, remedial stimulus–response tasks that contain greater acoustic differences are presented. Recent techniques are using time-based variations in training stimuli to sequence the difficulty level. For example, Fast ForWord (Tellal *et al*., 1996) utilizes computer-processed lengthening of prerecorded phonetic stimuli. Lengthening enables the client to hear previously indistinct cues. Training progresses by gradual shortening of the acoustic speech elements to normal durations. Katz (personal communication) is using phonetic synthesis exercises with cochlear implant clients. In this technique, phonetic elements or words are presented in isolation for identification. These elements are then presented in a phoneme-by-phoneme sequence, and the listener is asked to assemble these individual sounds into words. This training challenges the auditory-memory synthesis abilities that are required to follow conversational speech.

2. Lipreading (Speechreading) Training

When amplification does not restore functional speech perception, hearing-impaired persons use vision to compensate for the missing auditory information, even when vision is impaired as well (Karp, 1988). In fact, research with normally hearing persons has repeatedly shown a robust influence of lipreading cues on speech perception when the auditory and visual cues for syllable perception are contradictory, i.e., the McGurk Effect (Massaro, 1998).

Lipreading/speechreading training methods focus on identification of mouth shapes associated with syllable, word, or phrase production. Practice may be silent, with vocal cues or in background noise. The lipreader is guided to make effective guesses during ongoing speech by attention to redundancies in the language and situational clues. DeFilippo (1990) and Montgomery *et al*. (1984) use techniques combining visual input with the minimal auditory cues available to the hearing-impaired client. Presentation of training materials via computer-assisted interactive video has been shown to be effective (Sims and Gottermeier, 2000).

3. Conversational Fluency Training

Erber (1996) has developed aural rehabilitation therapy based on the concepts of conversational fluency. Working on auditory and visual speech perception is of secondary importance. The main goals are to develop problem-solving skills for recognition of the source of communication breakdown, apply various repair strategies, request assistance from the communication partner, and judge the appropriateness of an applied strategy and evaluate its success. Clients work with their communication partner, and the therapist is an observer. In this way, the conversational role of the partner, and the complex interaction that typically occurs between people, is routinely incorporated into the rehabilitation process. Progress in conversational fluency is determined by such measures as the number of speaking turns taken by each participant, the amount of time during which each participant talked, and the amount of time consumed by conversational breakdown and repair.

I. Summary

Aural rehabilitation for elderly persons with hearing impairments can make the difference between a hearing aid in the dresser drawer and one in daily use. Because aural rehabilitation's goal is effective communication in the face of hearing loss, it can often provide the means for a higher quality of life through maintenance of rich social interactions instead of social isolation and depression. To be successful, it requires commitment from both the therapist and the client for thorough assessment of the full spectrum of hearing and hearing handicaps. Second, all relevant medical diagnosis and treatment must be completed. Finally, multisession individual or group aural rehabilitation should be completed in association with the fitting of a hearing aid, or other assistive devices.

1. Access to Aural Rehabilitation

The current reality of comprehensive aural rehabilitation services leaves much to be desired. Only 16% of audiologists in clinical practice extend aural rehabilitation services beyond routine fitting of hearing aids and a brief orientation to their use (Ross, 1997). There are three main reasons for this situation. First, there is a lack of client knowledge (and therefore, motivation) for comprehensive aural rehabilitation. Audiologists and their services are not well known even though there are over 11,000 audiologists in clinical practice. Second, many audiologists do not possess advanced skills and knowledge about aural rehabilitation, as graduate training is currently dominated by graduate coursework focusing on diagnostic audiology and hearing aids. Third, there are third-party reimbursement problems. In years past, elderly persons might be eligible for aural rehabilitation following hearing aid fitting; however, currently, when available, speech-language pathologists must be the providers working in a clinic, hospital outpatient department or physicians office. The CPT code used is the same code as for speech-language therapy. However, unlike audiologists, speech language pathologists cannot have their own provider number for Medicare, so the therapy must be billed under the physician's Medicare number as an in-office ancillary service. In other words, the physician bills for the therapy as if he/she is providing or supervising it, or it must be billed by the clinic, rehabilitation center, or hospital using the institution's billing number. The Academy of Dispensing Audiologists, The American Academy of Audiology, and The American Speech-Language and Hearing Association have met with the Health Care Finance Administration and

have requested that audiologists be permitted to provide the aural rehabilitation (and vestibular therapy) services using their own provider numbers (Lovenbruck, August 13, 1999, ASHA Forum).

The solutions to these aural rehabilitation access problems are being addressed by professionals in terms of changing the entry level of the audiological profession to the clinical doctorate (AuD). This 3 years (or more) educational experience may enable more opportunities for significant aural rehabilitation skill building. There is the Audiology Awareness Campaign which has as its goal making audiology a household word. In regard to third-party reimbursement issues, the clinician should not assume that elders do not have the ability to pay for aural rehabilitation themselves. Marketing studies have shown that older Americans have more discretionary funds than younger age groups because living expenses have been reduced and retirement income has increased. A last solution for greater utilization of comprehensive aural rehabilitation is a future combination of computer/Web-assisted home study.

Olfaction and Gustation in Normal Aging and Alzheimer's Disease

I. Introduction

The chemical senses of taste and smell are commonly ignored by neurologists, otorhinolaryngologists, and geriatricians, despite their important role in mediating the intake of all environmental nutrients and airborne chemicals required for life and in determining the flavor and palatability of foods and beverages. In addition to purveying aesthetic pleasures, these senses warn us of spoiled foods, leaking natural gas, polluted air, and smoke. Although age-related losses are present in all sensory modalities, the chemical senses—particularly olfaction—seem to be particularly influenced by aging. For example, while less than 2% of the American population is estimated to have olfactory loss (Doty *et al*., 1986; Hoffman *et al*., 1998), between the ages of 65 and 80 years approximately half of the population has major smell loss; over the age of 80 years, three-quarters of the population exhibit such loss (Doty *et al*., 1984). Such loss likely explains why a disproportionate number of elderly persons die from accidental gas poisoning (Chalke *et al*., 1958)[1] and why many elderly report that their food lacks flavor (Doty *et al*., 1984). The latter problem can lead to decreased motivation to eat and, in some cases, nutritional deficiencies.

Although decreased ''taste'' perception during chewing and swallowing reflects, to a large degree, attentuation of olfactory stimulation via the retronasal route (Burdach and Doty, 1987), decrements in true taste function (i.e., sweet, sour, bitter, and salty perception) are present in many elderly persons. Such decrements are particularly evident when small regions of the tongue are evaluated (e.g., Matsuda and Doty, 1995). Additionally, distortions of taste perception often occur in older persons that can be very debilitating and difficult to manage (Cohen and Gitman, 1959).

In this chapter I review, in detail, the age-related perceptual and structural changes known to occur in the olfactory and gustatory systems. In addition, the olfactory losses associated with the age-related disorder of Alzheimer's disease are examined. A brief overview of the anatomy and physiology of the olfactory and gustatory systems is also presented, so as to orient the reader to the design and function of these commonly overlooked sensory systems.

[1]In the United States alone, over 50 million dwellings are supplied with natural gas (Corwin *et al*., 1995).

II. Olfactory and Gustatory System Anatomy

A. Olfactory System

Odorants are detected by cilia projecting into the nasal mucus from the dendritic knobs of approximately 6 million specialized receptor cells of the olfactory neuroepithelium (Fig. 45.1) and, in some cases, by free nerve endings from the ophthalmic and maxillary divisions of the trigeminal nerve distributed throughout the nasal mucosa. Although the olfactory neuroepithelium has been classically located in the region of the cribriform plate, on the superior septum, and on the superior turbinate, recent data suggest that it may extend further anteriorly and ventrally than previously believed (Feron *et al*., 1998). Some airborne stimulants are also sensed within the pharynx and oral cavity via glossopharyngeal and vagus nerves. However, true odor sensations are mediated via the bipolar olfactory receptor cells; the sensations mediated by the other nerves are largely those of the skin senses, such as warmth/coolness, pungency, and irritation (Doty, 1995).

After collecting into bundles of $\sim$200 axons surrounded by ensheathing or Schwann cell mesoaxons, the unmyelinated axons of the olfactory receptor cells traverse the cribriform plate and synapse with dendrites of second order neurons within the glomeruli of the olfactory bulb (Fig. 45.2). Cells containing a given type of receptor project to the same glomerulus or a small set of glomeruli, making the glomeruli, in effect, functional units. The glomeruli also are a major source of convergence within the system, with many more neurons entering than leaving them. Complex interactions occur among glomeruli via periglomerular cells and centrifugal influences from higher centers (Kratskin, 1995).

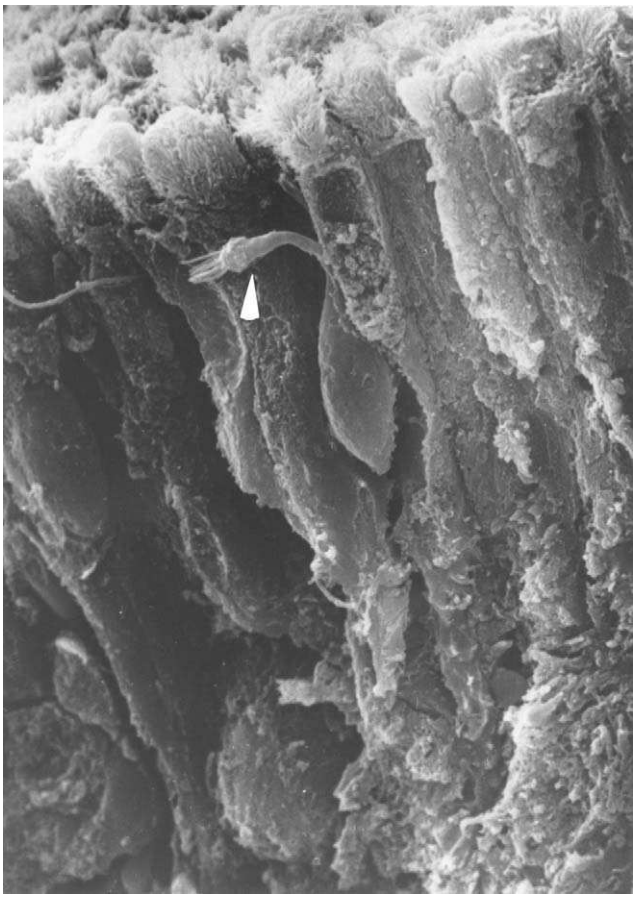

FIG. 45.1. High-magnification freeze-fracture electron photomicrograph of a cross section of the human olfactory neuroepithelium. Microvilli of supporting cells make up the bulk of the surface. Morrison, Virginia Commonwealth University—Medical College of Virginia.

Connections between the two olfactory bulbs, as well as limited contralateral bulb and cortexal projections, occur via the anterior olfactory nuclei and anterior commissure. However, the vast majority of olfactory projections from the bulb are ipsilateral. The mitral and tufted cells project directly, without thalamic synapse, to regions of the amygdala and to the more rostral elements of the primary olfactory cortex (e.g., entorhinal cortex) (Schwob and Price, 1984; Price, 1990). No clear point-to-point topography exists between the olfactory bulb regions and cortical projection sites (Price, 1990). Thus, small areas of the bulb can project to large areas of the olfactory cortex and vice versa. Reciprocal connections are present between the olfactory cortex and the orbitofrontal cortex, the mediodorsal and submedial thalamic nuclei, the lateral hypothalamus, the amygdala, and the hippocampus. A major pathway from the olfactory cortex to the orbitofrontal cortex is relayed through the mediodorsal nucleus of the thalamus. Because the complete pattern of higher order olfactory projections is beyond the scope of this chapter, the reader is referred elsewhere for details of this topic (e.g., Schwob and Price, 1984; Price, 1990; Zatorre *et al*., 1992; Carmichael *et al*., 1994; Doty *et al*., 1997).

B. Taste Anatomy

Tastants are detected by cells within taste buds—rosebud-like-looking structures found on the papillae of the tongue and on the soft palate, the uvula, the epiglottis, the rostral esophagus, and the mucous membranes covering the laryngeal cartilages (Fig. 45.3). On the tongue, the circumvallate papillae, which in aggregative are spaced in a chevron-like manner across the tongue near its base, harbor the most taste buds (up to 200); far fewer buds are present on the other types of papilla (Miller, 1995). Indeed, many fungiform papillae contain only one or two buds, and no buds are found on the filliform papillae. Hot peppers and other spicy foods produce stinging, burning, and warming sensations via the trigeminal nerve free nerve endings.

The innervation of the taste buds is shown in Fig. 45.4. The afferent fibers from the taste buds of the fungiform papillae project via the lingual nerve and the chorda tympani branch of the facial nerve and eventually synapse within the nucleus tractus solitarius of the brain stem. The nucleus tractus solitarius extends from the rosterolateral medulla caudally along the ventral border of the vestibular nuclei (Norgren, 1990). The nerves which innervate the taste buds of the foliate and circumvallate papillae travel directly to this nucleus within glossopharyngeal nerve, although the taste bud afferents on the anterior foliate papillae may do so via the facial nerve. The taste buds on the palate are supplied by fibers which travel with the greater superficial petrosal nerve, joining the facial nerve at the geniculate ganglion before reaching the nucleus tractus solitarius. Taste buds of the larynx and esophagus receive projections from the vagus nerve. In humans, the primary cortical taste area is within the parietal operculum and adjacent parainsular cortex, with the secondary cortex being in the orbito frontal lobe (for reviews, see Norgren, 1990; Pritchard, 1991; Small *et al*., 1997).

III. Age-Related Alterations in Olfactory and Gustatory Function

A. Olfaction

As noted in the first paragraph of this chapter, age-related decrements in olfactory function are, on average, quite large. To reiterate the point made earlier, approximately half of the population between the ages of 65 and 80 years have major difficulty in smelling, whereas approximately three quarters over 80 years of age cannot smell. Such losses are apparent on a wide variety of olfactory tests, including tests of odor detection, identification, discrimination, adaptation, and suprathreshold odor intensity perception (Murphy, 1983; Doty, 1989; Gilmore and Murphy, 1989). In addition, age-related declines have been noted in tests sensitive to intranasal irritation and other trigeminally mediated somatosensory sensations (Stevens and Cain, 1986). Although it is not clear whether age declines in a linear or quadratic (or some combination of both) manner over the age span, it is clear that (a) large individual differences in function are present in smell function in older individuals, (b) olfactory dysfunction is greatest after the sixth decade of life, and (c) the age-related loss begins at an earlier age for more men than for women. The age-related changes in odor identification ability, as measured by the widely used and

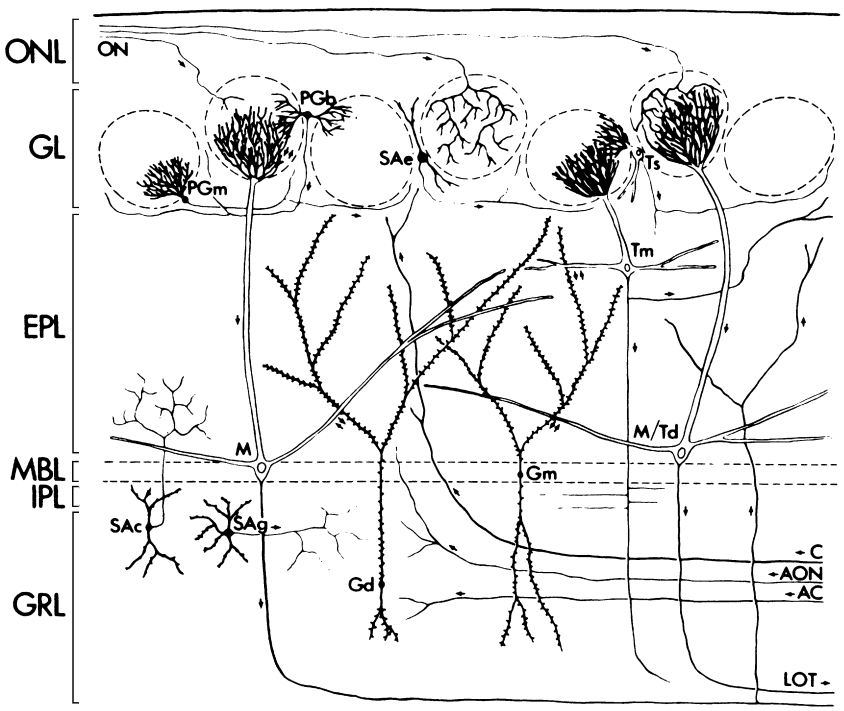

FIG. 45.2. Diagram of major layers and types of olfactory bulb neurons, as based upon Golgi stained material. Main layers are as follows: ONL, olfactory nerve layer; GL, glomerular layer; EPL, external plexiform layer; MBL, mitral body layer; IPL, internal plexiform layer; GRL, granule cell layer. ON, olfactory nerves; PGb, periglomerular cells with biglomerular dendrites; PGm, periglomerular cells with monoglomerular dendrites; M, mitral cell; M/Td, displaced mitral cell or deep tufted cell; Gm, granule cell with cell body in mitral body layer; Gd, granule cell with cell body in deep layers; SAc, short-axon cell of Cajal; SAg, short-axon cell of Golgi; C, centrifugal fibers; AON, fibers from the anterior olfactory nucleus; AC, fibers from anterior commissure; LOT, lateral olfactory tract. standardized University of Pennsylvania Smell Identification Test, are shown in Fig. 45.5 (Doty *et al*., 1984). These age-related losses are not culture specific, and are much more more pronounced than the influences of gender or smoking on smell function (Doty *et al*., 1984; Frye *et al*., 1990).

In general, decreased sensitivity occurs across a spectrum of odors, although a decline in olfactory function may occur slightly more for some odorants than others (depending upon such factors as the odorant's threshold and the nature of the function relating odorant concentration to perceived intensity). Although the tendency for threshold values of different odorants to be correlated suggests that a ''general olfactory acuity'' factor may exist (analogous to the general intelligence factor derived from items of intelligence tests) (Yoshida, 1984; Doty *et al*., 1994), it should be noted that the thresholds of a number of sensory modalities tend to be correlated with one another, as well as with several cognitive measures (e.g., verbal memory). Hence, a ''general sensory acuity/cognitive'' factor may be operative that encompasses a range of sensory and cognitive entities and subsumes intermodal correlations (Stevens *et al*., 1998).

B. Taste

Age-related decreases in gustatory detection threshold sensitivity occur for both chemical and electrical stimuli (Nilsson, 1979a,b), although, in the case of whole-mouth chemical testing (e.g., ''sip and spit'' testing), the magnitude of the age-related loss is not as marked as that seen in olfaction (Weiffenbach and Bartoshuk, 1992). Decreases in threshold sensitivity have been reported for such tastants as caffeine, citric acid, hydrochloric acid, magnesium sulfate, propylthiourea, quinine, sodium chloride, sucrose, tartaric acid, and a large number of amino acids (see Schiffman *et al*., 1979; Schiffman and Clark, 1980; Cowart, 1981, 1989; Murphy, 1983; Weiffenbach *et al*., 1986; Murphy and Gilmore, 1989; Warwick and Schiffman, 1990; Schiffman, 1997). There is some suggestion, however, that not all taste qualities exhibit the same degree of age-related loss. For example, Weiffenbach *et al*. (1982) reported that, in a study of 81 healthy adults ranging in age from 23 to 88 years (including healthy elderly participants enrolled in the National Institute on Aging's Baltimore Longitudinal Study), sensitivity to sodium chloride and quinine sulfate decreases slightly with age, whereas sensitivity to sucrose and citric acid does not. Methodological factors undoubtly determine to a large degree the extent to which age-related changes occur in any given taste quality. The marked age-related decrement to NaCl when regional assessment is performed is shown in Fig. 45.6.

Age-related changes in suprathreshold taste perception to chemicals have also been observed. For example, flatter functions relating tastant concentrations to perceived intensity have been reported in elderly relative to young adults, at least for some stimuli (e.g., Schiffman and Clark, 1980; Schiffman,

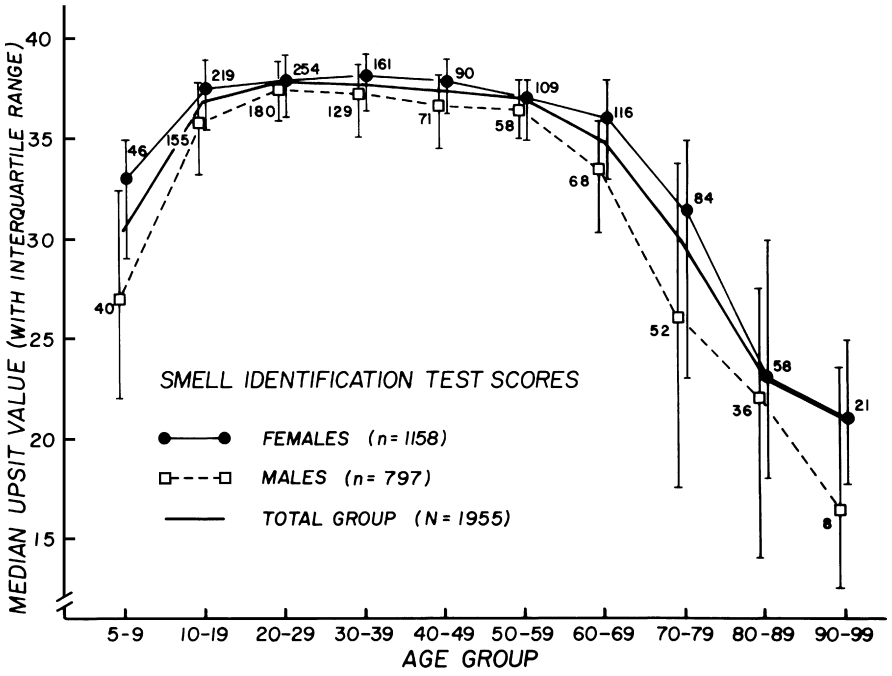

FIG. 45.5. Scores on the University of Pennsylvania Smell Identification Test as a function of age in a large heterogeneous group of subjects. Numbers by data points indicate sample sizes. 1991), although exceptions clearly exist (Chauhan and Hawrysh, 1988). It should be noted, however, that the slope of such functions can be markedly altered by changes in intensity that occur at the extemes of the stimulus continuum, and need not reflect decreased sensitivity across the entire supra-threshold stimulus range. In a manner analogous to what occurs in olfaction (see Fig. 45.5), sex differences in taste function may become more apparent in the later years (Coats, 1974; Fikentscher *et al.*, 1977; Baker *et al.*, 1983; Weisfuse *et al.*, 1986; Lassila *et al.*, 1988).

IV. Changes in Olfaction and Gustation in Alzheimer's Disease

Nearly all studies of olfactory function in patients with Alzheimer's disease report decreased test scores relative to age-matched controls (Doty, 1991; Mesholam *et al*., 1998). Such decrements are observed for tests of odor threshold, discrimination, identification, and memory (Serby *et al*., 1985; Knupfer and Spiegel, 1986; Doty *et al*., 1987; Murphy *et al*., 1990; Moberg *et al*., 1997; Mesholam *et al*., 1998). Although some authors note that olfactory test scores are inversely related to the severity of the dementia (Waldton, 1974; Knupfer and Spiegel, 1986; Murphy *et al*., 1990), such associations are weak ($r_s < 0.40$), and the possible influence of dementia on subtle aspects of nonolfactory components of the tests makes such findings somewhat enigmatic. Earlier notions that detection thresholds are not altered in Alzheimer's disease (AD) and, therefore, by inference, implying that the peripheral olfactory pathways are intact (Serby *et al*., 1991), are not viable in light of the many studies finding threshold deficits in AD (Doty *et al*., 1987; Murphy *et al*., 1990; Mesholam *et al*., 1998) and in patients with central lesions (Doty *et al*., 1997). Although AD-related olfactory dysfunction may reflect, to some degree, the aforementioned physiological changes seemingly associated with normal aging, this is not the whole story. Thus, even very early-stage AD patients with mild dementia consistently score much more poorly on olfactory tests than age-matched controls (Doty *et al*., 1987).

Whether or not patients with Alzheimer's disease similarly exhibit gustatory deficits is not clear. Waldton (1974), in a pioneering study in which apparently the subjects were simply asked after the presentation of a tastant whether or not it was sensed, reported that most of his demented patients exhibited considerable loss of taste function, although no distinction among types of dementia was made. Subsequent studies have generally failed to observe any meaningful taste-related deficits to the basic taste qualities in patients with Alzheimer's disease (Koss *et al*., 1988; Murphy *et al*., 1990). However, Schiffman *et al*. (1990) reported decreased sensitivity to glutamic acid, but not to hydrochloric acid, in AD patients, although this loss was also seen in patients with other forms of dementia as well (e.g., multi-infarct dementia). Given the small numbers of studies on this topic, additional data on this general issue are sorely needed.

V. Causes of Changes in Chemosensory Function in Aging and in Alzheimer's Disease

A. Olfaction

The most common cause of age-related alterations in the ability to smell appears to be damage to the olfactory neuroepithelium from environmental insults (e.g., from viruses, bacteria, toxins, and pollutants). The distal elements of the olfactory receptors are exposed rather directly to the external milieu, thereby being susceptible to nosogenic attack. In general, the olfactory neuroepithelium undergoes cumulative damage throughout life, exhibiting increasing numbers of islands of respiratory-like metaplasia soon after birth (Nakashima *et al*., 1984), decreased epithelial thickness, and decreased numbers of olfactory receptors (Rosli *et al*., 1999). Such damage is likely accelerated in certain environments, such as in the workplace and in some outdoor situations, where increased exposure to chemicals and other predisposing factors exist (Corwin *et al*., 1995). Furthermore, older persons may be more susceptible to epithelial damage, having a less resilient olfactory membrane due to such factors as reduced protein synthesis (as in hypothyroidism) (Beard and Mackay-Sim, 1987; Mackay-Sim and Beard, 1987), loss of neurotrophic factors (Appel, 1981), altered vascularity (Somlyo and Somlyo, 1968), decreased intramucosal blood flow (Hasegawa and Kern, 1977), increased viscosity of the nasal mucus (Koopmann, Jr., 1989), secretory gland and lymphatic atrophy (Koopmann, 1989), and, potentially, decreases in enzyme systems which deactivate xenobiotics within the olfactory mucosa (Dahl and Hadley, 1991).

Interestingly, there is now strong empirical support of Krmpotic-Nemanic's observation (1969) that the number and cross-sectional area of the foramina of the cribriform plate are decreased in the elderly as a result of appositional bone growth. Kalmey *et al*. (1998) examined the posterior regions of the cribriform plate of 57 cribriform plates from 40 skulls of known age and sex. The area of the cribriform plate foramina was determined using a computer analysis of 35 mm pictures of these regions. The mean area of the foramina was 47.3% less in men over the age of 50 years than those under the age of 50 years. The corresponding figure for women was 28.8%. Although the degree to which such occlusion of the foramina contributes to the olfactory loss observed in the elderly is not known, this phenomenon deserves primary consideration.

Even though olfactory receptor cells have the capacity to reconstitute themselves periodically (Graziadei and Graziadei, 1978), this plasticity is likely compromised, at least in some segments of the neuroepithelium, by age-related processes (Breipohl *et al*., 1986; Loo *et al*., 1996). Animal studies suggest that the ratio of dead or dying cells to the number of receptor cells increases with age, implying age-related decreases in mitotic activity. Relative to younger animals, epithelial repair is slower or nonexistent following damage to the receptors by chemical agents such as zinc sulfate or methyl-formiminomethylester (Matulionis, 1982; Breipohl *et al*., 1986), belying an altered neurogenic process.

Destruction of the olfactory receptors leads to degenerative changes within the glomeruli of the olfactory bulb. This observation was capitalized on by in a pioneering study by Smith (1942) to estimate age-related losses of human olfactory receptors. Smith counted the glomeruli within 205 olfactory bulbs of 121 cadavers, and noted that loss of olfactory nerves begins soon after birth and continues throughout life at approximately 1% per year. Smith's findings have been supported by more recent studies. Thus, Meisami *et al*. (1998) measured the number of mitral cells and glomeruli in olfactory bulbs from three young adult women, three adult women of late middle age, and three women in advanced old age. The number of mitral cells and glomeruli decreased steadily with age at an approximate rate of 10% per decade; in the 9th and 10th decades of life, less than 30% of these structures were present. Such decreases presumably explain, in part, the finding from *in vivo* quantita-

tive magnetic resonance imaging studies that human olfactory bulb and tract volumes decrease with age (Yousem *et al*., 1998).

Hinds and McNelly (1977) measured the volume of the glomerular, external plexiform, internal granular, and olfactory nerve layers in Sprague–Dawley rats at 3, 12, 24, 27, and 30 months of age. The size and number of mitral cells were also measured in both the main and accessory bulbs. The volumes of the layers decreased after 2 years, although developmental volumetric increases were noted prior to that time. The decrease in mitral cell layer volume paralleled a sharp decrease in mitral cell number, and an increase in the volume of individual mitral cell body volumes and nucleus sizes, as well as increases in the sizes of mitral cell dendritic trees.

These findings were subsequently observed in the Charles River rat strain (Hinds and McNelly, 1981), although mitral cell loss was not seen in the older animals. Importantly, this study also assessed alterations within the olfactory neuroepithelium. A comparision of regression lines for changes in number of septal olfactory receptors to that of mitral cell body sizes suggested that the decline in receptor number began several months prior to the decline in mitral cell size, implying the bulbar changes followed the epithelial changes. An apprent compensatory increase in synapse number per receptor cell was present in the surviving receptor cell population.

Unlike the epithelium and bulb, the rat piriform cortex shows little age-related change. Thus, Curcio *et al*. (1985) examined the piriform cortex cells and synapses of 3 to 33 month-old rats and found no significant changes in cortical layers Ia and Ib volumes or in the numerical and surface densities of the synaptic apposition zones in layer Ia, which are formed largely by mitral cell axons. Although age-related changes in nuclear volume, soma volume, or numerical density of layer II neurons were not found, the proportion of layer Ia occupied by dendrites and spines was modestly (18%) decreased. An increase in the proportion of glial processes, but not by an alteration in the proportion of axons and terminals, was also noted.

The basis of the olfactory loss observed in AD is poorly understood and it is not yet clear whether such loss simply represents an exaggeration of the olfactory pathology present in normal aging. Histologically, severe changes are observed in the olfactory mucosa (see Fig. 45.7). One postmortem study reported a 40% reduction in the cross-sectional area of the olfactory tracts of AD patients, as well as a 52% loss of myelinated axons in these tracts (Davies *et al*., 1993). Other studies have reported the presence of AD-related neurofibrillary tangles and neuropil treads and Parkinson's disease-related Lewy bodies in all layers of the olfactory bulb, with the exception of the olfactory nerve cell axon layer (Ohm and Braak, 1987). Interestingly, the olfactory bulbs of over 40% of nondemented persons 50 years of age and older also exhibit neurofibrillary tangles (Kishikawa *et al*., 1990).

In AD, central limbic structures that receive olfactory bulb projections preferentially exhibit relatively high numbers of neurofibrillary tangles and neuritic plaques (Hooper and Vogel, 1976; Pearson *et al*., 1985; Reyes *et al*., 1993). Such structures include the hippocampal formation, the periamygdaloid nucleus, the prepiriform cortex, and the entorhinal cortex (Ferreyra-Moyano and Barragan, 1989; Jellinger *et al*., 1991; Braak *et al*., 1996a,b). The most salient and earliest signs of traditional AD neuropathology appear within the transentorhinal cortical regions (Jellinger *et al*., 1991; Braak *et al*., 1996a,b).

Among the more interesting and controversial theories concerning the etiology of the olfactory dysfunction in AD and some other neurodegenerative disorders (e.g., Parkinson's disease), as well as the etiology of the diseases themselves, is the ''olfactory vector hypothesis.'' One form of this theory suggests that the *olfactory loss* results from an environmental toxin, microorganism (e.g., virus, bacterium, or larvae), or other agent that progresses from the nasal cavity into the brain via the olfactory fila (e.g., Roberts, 1986; Ferreyra-Moyano and Barragan, 1989; Doty, 1991, 1997). It has been known for many years that the olfactory nerve is a major route for the entry of numerous viruses (e.g., polio virus, rabies virus, and St. Louis encephalitis virus) and other agents from the external milieu into the central nervous system (Turner and Esmond, 1926; Clark, 1929; Baker, 1995). Indeed, such observations led to the discovery in the 1930s that monkeys could be protected against intranasal inoculation of poliomyelitis virus by cauterizing the olfactory mucosa with picric acid and other caustic chemcials (Schultz and Gebhardt, 1936) and the subsequent prophylactic spraying of children's noses with zinc sulfate in Toronto and other cities in the late 1930s (Schultz and Gebhardt, 1937; Tisdall *et al*., 1937). According to this form of the theory, the olfactory loss need not be ascribed to specific disease pathology (e.g., Lewy bodies, senile plaques, neurofibrillary tangles, neurotransmitter deficiences), even though such pathology may subsequently contribute to the loss, but to damage that preceeds the major development of such pathology. This perspective need not be in opposition to the direction of the development of the subsequent neuropathology within the olfactory system (e.g., central to peripheral), as selective vulnerability of brain regions could be in play as well. Since the arguments for and against various forms of the olfactory vector hypothesis are numerous, the reader is referred elsewhere for further discussion of this topic (Pearson *et al*., 1985; Ferreyra-Moyano and Barragan, 1989; Doty, 1997).

Another intriguing hypothesis, which is not necessarily mutually exclusive of the olfactory vector hypothesis, was put forward by Kurtz *et al*. (1989). The essence of Kurtz's theory is that degeneration of the olfactory system, per se, is the basis of the cognitive decline in AD, since rats who have been anosmic for a period of time have considerable difficulty in learning an active avoidance learning task, unlike rats whose anosmia is of recent origin. To my knowledge, no further assessment has been made of this theory in either animals or humans.

B. Taste

Relative to olfaction, comparatively little research has been done to explain age-related alterations in gustatory function. As with other sensory systems, a relationship between the number of functioning receptor elements and the system's sensitivity would be expected. Three lines of evidence, from young populations, support this notion: first, the perceived intensity of tastants presented to localized regions of the anterior tongue is correlated with the the number of fungiform papillae and, hence, the number of taste buds within the stimu-

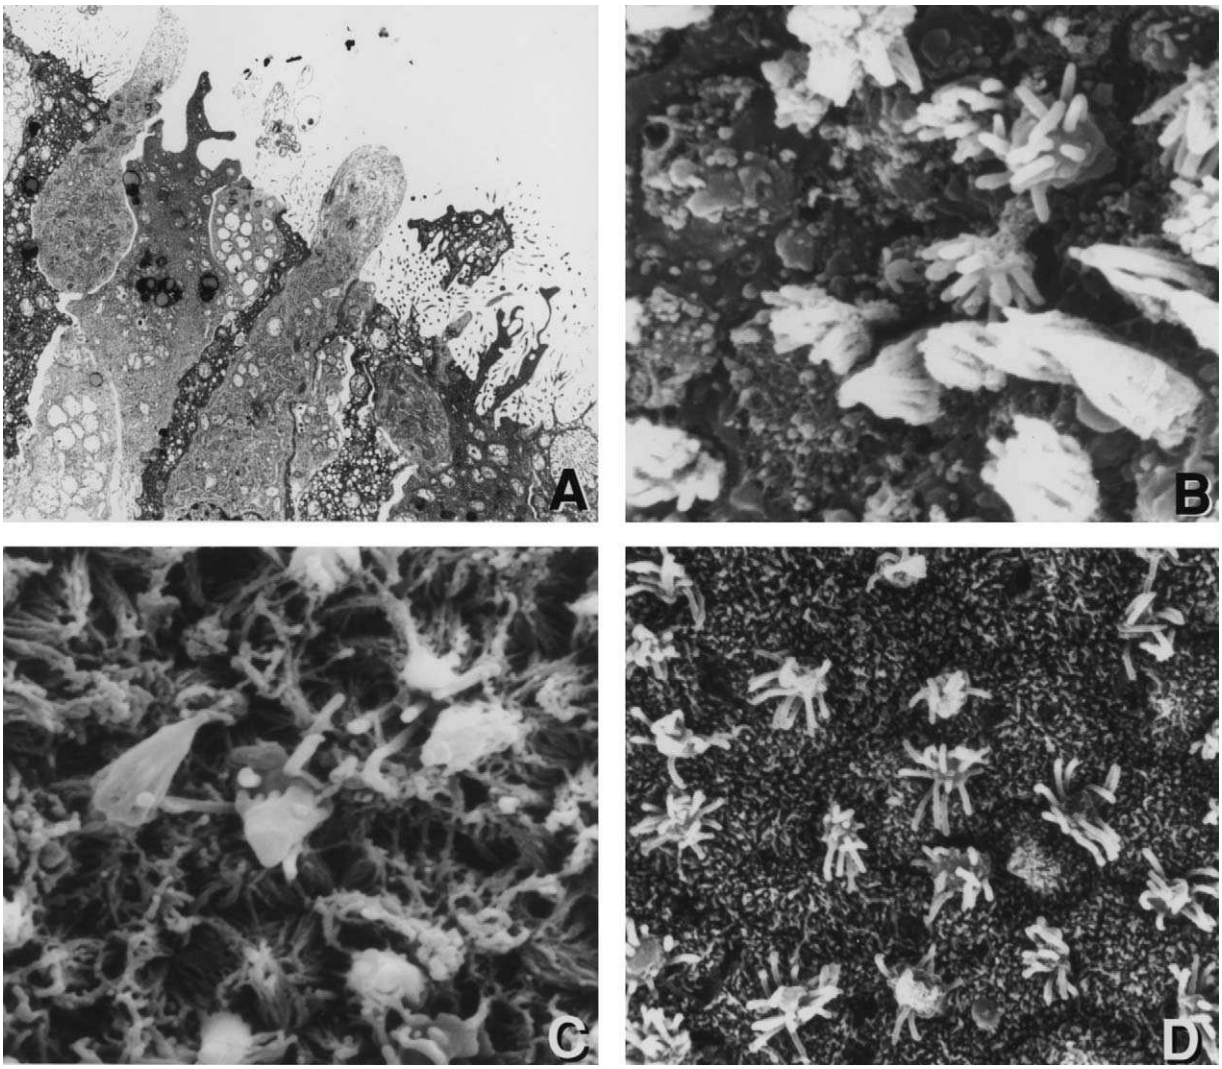

FIG. 45.7. AD-associated changes in the olfactory epithelium. (A) Severe changes in the olfactory epithelium in a 56-year-old patient with presenile dementia. The olfactory cells are highly abnormal, the olfactory knobs appear conical and frequently lack cilia, and the supporting cells are shrunken with a modified apical surface (×12,000). (B–C) Abnormal olfactory epithelium from a 60-year-old AD case (B) and a 56-year-old case with presenile dementia (C). Note the densely packed olfactory knobs, fused and short cilia, and conical transformation (both micrographs, × 11,000). (D) Well-preserved olfactory epithelium from a 66-year-old control person, with evenly distributed olfactory knobs surrounded by supporting cells (×7,000). Transmission and scanning electron micrographs were kindly provided by Drs. D. P. Perl and H. S. H. Choi, Department of Pathology, Mount Sinai School of Medicine, and Bronx VA Medical Center, New York.

lated regions (Smith, 1971); second, subjects with higher densities of taste buds and fungiform papillae (determined using videomicroscopy) rate the intensity of sucrose, NaCl, and 6-*N*-phenylthiouracil (but not citric acid and quinine HCl) higher than subjects with lower densities of taste buds (Miller and Reedy, 1990); and third, the number of stimulus sensations reported during stimulation of individual papillae is correlated with the number of taste buds present in the papillae, as determined from subsequent biopsy (Arvidson, 1979; Arvidson and Friberg, 1980). Surprisingly, however, most recent studies of rodent, monkey, and human tongues suggest that taste bud numbers in the anterior and medial regions are little influenced by age (Mistretta, 1984; Mistretta and Baum, 1984; Bradley *et al*., 1985; Miller, 1988; Miller and Reedy, 1990). For example, the average percentage of fungiform papillae-containing taste buds in Fischer 344 rats ages 4 to 6 months, 20 to 24 months, and 30 to 37 months was reported in one study to be 99.6, 99.3, and 94.7%, respectively (Mistretta and Oakley, 1986). Another study found no statistically meaningful relationship between age and taste bud densities on either the tip or the midregion of tongues from young adults (22–36 years, $n=5$), middle-aged adults (50–63 years, $n=7$), and old adults (70–90 years, $n=6$) (Miller, 1988). Marked variability in the number of taste buds on the tongue at all ages was reported to be much more apparent than any age-related alterations.

The above observations seem, at first glance, to be contradicted by study of tongue biopsies from 200 living persons (Moses *et al*., 1967). In this work, the number of dorsal lingual

fungiform papillae per square inch was found to decrease gradually from birth to 60 years of age. This finding has fallen under criticism, however, by others who make the point that a square inch of tongue surface in a child is not equivalent to a square inch of tongue surface in and adult, since the tongue continues to grow from infancy into adulthood (Mistretta, 1984).

Age-related loss of taste buds have been reported by several authors for human circumvallate papillae. Arey *et al*. (1935), in a relatively extensive study, reported the mean number of cells per circumvallate papilla as follows: from 0 to 20 years of age, 248; from 20 to 70 years, 206; and from 74 to 85 years, 88. Mochizuki (1939) reported the following figures: from 0 to 20 years, 242; from 21 to 60 years, 196; and from 61 to 90 years, 116. Although these pioneering studies have been criticized for both the number and quality of their autopsy specimens and the lack of statistical analysis of their data (Mistretta, 1984), no modern work has apparently attempted to confirm their findings using simlar procedures. A study of taste papillae and taste buds in tongues from rhesus monkeys that ranged in age from 4 to 31 years (a relatively old age for a rhesus monkey) (Bradley *et al*., 1985) reports no meaningful age-related differences in the size or number of fungiform, foliate, or circumvallate papillae, or in the number of taste buds per papilla (Bradley *et al*., 1985). Some of the older monkeys, however, were missing anterior sectors of the tongue, presumably as a result of exposure to outdoor elements or of fighting with cage mates.

Although taste bud numbers appear not to be markedly decreased in old rats (Mistretta and Baum, 1984), McBride and Mistretta (1986) discovered that the chorda tympani nerve of older rats was less responsive, electrophysiologically, to some salts, acids, and sugars. Possible explanations of this phenomena include: decreased intrinsic reactivity of taste buds to taste solutions, decreased multiple neural innervation of taste buds by some taste fibers, alterations in the general structure of the epithelium (which, for example, might impair the movement of stimulus solution into the taste bud pore), and decreased taste nerve responsiveness, per se. It is also possible that some taste buds, although anatomically present, are not fully functional because of altered turnover time or related metabolic events. Since taste buds function in a complex ionic milieu and are bathed with saliva and other secretory products, changes in such products may also undergo age-related changes. In accord with this notion is a hypothesis put forward by Bartoshuk *et al*. (1986). These investigators suggest that the heightened threshold values and flattened suprathreshold psychophysical functions observed in many elderly reflect background tastes which are noticeable at low, but not at moderate or high, stimulus concentrations. Both neural and oral environment changes (e.g., salivary constituents) could contribute to this noise. The observation that improved oral hygiene reduces taste thresholds in some older persons would appear to be congruent with this hypothesis (Langan and Yearick, 1976).

Relatively few studies have examined the structure of the gustatory system of patients with AD. An exception is a recent immunohistochemical study by Yamagishi *et al*. (1995). In this work, the innervation of the foliate and circumvallate taste buds was examined in five AD (three men, two women) and two control (both women) subjects using the following neuronal markers: antisera to protein gene product 9.5, neuron-specific enolase, tyrosine hydroxylase, dopamine beta-hydroxylase, and calcitonin gene-related peptide. Although the mean number of protein gene product 9.5-immunoreactive intragemmal nerve fibers in taste buds of the foliate and circumvallate papillae was reportedly significantly decreased in AD patients, the small number of subjects begs the question as to whether the statistical analyses were, in fact, performed on independent samples. The authors conclude that decreased innervation of the taste buds may account, in part, for decreased taste sensitivity in AD.

VI. Summary and Conclusions

It is clear from the studies reviewed in this chapter that both taste and smell function is lessened in many elderly persons. Such alterations are detected by a variety of sensory tests. Patients with AD exhibit marked declines in olfactory function, although whether they exhibit gustatory dysfunction beyond that of age-matched controls is debatable. In both taste and smell, alterations in peripheral receptive elements may well explain much of the sensory loss that is demonstrable using psychophysical tests. Nevertheless, malfunctioning within higher nervous system structures cannot, at present, be excluded from consideration and it is perhaps prudent to assume that the structural and functional bases of such changes are probably multiple, interacting, and complex.

Whatever the physical basis for altered taste and smell function in older persons, it is clear that such alterations are often profound, subjecting many such persons to risk for food and gas poisoning, and greatly limiting their appreciation of foods, beverages, and aesthetic delights. Physicians caring for the elderly should be aware of these deficiencies so as to better counsel their older patients in ways of maintaining safety and nutritional status.

Aging Effects on Muscle Properties and Human Performance

Elderly humans show large declines in functional abilities and changes in muscle properties compared to young ones. The purpose of this chapter is to relate the age-related changes in muscle to the reductions in maximum force production and in sustained power output (i.e., endurance) found in the elderly. Muscle atrophy accounts for more than half of the decline in muscle force production. The remainder of this decline can be explained by a reduction in the force per cross-sectional area of muscle fibers. Neither impaired neural recruitment of muscles nor a decrease in the proportion of fast muscle fibers appears to contribute significantly to the loss of force with age. Instead, alterations to both excitation–contraction coupling and the contractile elements are possibilities to account for the loss in force per cross-sectional area with age. Nearly equal contributions by the loss of muscle volume and changes in muscle oxidative properties are responsible for the reduction in sustained muscle power output. The reduction in oxidative capacity of elderly muscle stems from lower mitochondrial volume density and lower oxidative capacity per mitochondrial volume. Thus, loss of muscle size and changes in muscle intrinsic properties largely account for the declines in both force production and sustained power production in the elderly.

I. Introduction

Elderly humans display significant deficits in physical function as compared to the young. There is marked loss of force production by muscle starting in the sixth decade of life and continuing thereafter (Larsson *et al*., 1979). Similarly, endurance performance peaks in the second decade of life and drops with age thereafter as shown by losses in both muscle power output and oxygen uptake at the aerobic limit (Astrand and Rodahl, 1986). These changes in muscle function have important effects on physical activities of daily living in the elderly. The reduction in the capacity to generate force limits the ability of a person to rise from a chair, get in and out of a bathtub, place groceries in a cabinet, etc. Similarly, the drop in muscle endurance hinders simple tasks such as walking through a shopping mall, mowing the lawn, or vacuuming the floor. Thus, significant reductions in muscle strength and endurance compromise the ability of the elderly to lead an independent life.

There are similarities between the reductions in force production and endurance with age. In each case, the reductions reflect two main factors: the loss of muscle size and changes in intrinsic properties of the muscle cell. A number of reviews have documented changes in muscle properties with age (Brooks and Faulkner, 1994b; Larsson and Ansved, 1995; Holloszy and Kohrt, 1996). Of particular interest to the neurobiologist is Larsson's review of the effects of aging on the motor unit of the rat (Larsson and Ansved, 1995). Our goal is to identify the changes in muscle properties that are important to the decline of muscle performance in elderly humans.

II. Strength Changes with Age

A. What Determines Muscle Strength and Why Is It Reduced with Age?

The ability of human skeletal muscle to produce force declines steadily after about 60 years of age (Larsson *et al*., 1979; Vandervoort and McComas, 1986; Narici *et al*., 1991). The loss of force production in the elderly is substantial, with elderly subjects producing only about 65% of the force generated by young subjects in knee extension (Fig. 46.1) (Borges, 1989; Overend *et al*., 1992a). In one group of subjects ages 65–80 years, force production by the quadriceps muscle during isokinetic knee extension dropped an average of 10 N/year, resulting in a 39% decline in force between 65 and 80 years of age (Jubrias *et al*., 1997). A reduction of force production with age has been shown for muscles of the upper and lower extremities (Bemben *et al*., 1991; Narici *et al*., 1991), for voluntary and electrically stimulated contractions (Harridge *et al*., 1995; Vandervoort and McComas, 1986), and for isometric and shortening contractions (Davies *et al*., 1987; Frontera *et al*., 1991). Although the extent of the decline

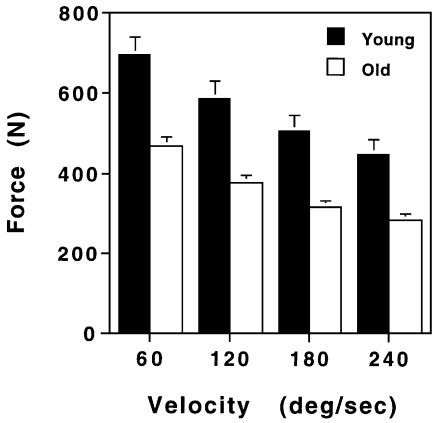

FIG. 46.1. Force production as a function of angular velocity during isokinetic knee extension in young (35 years) and old (70 years) subjects.

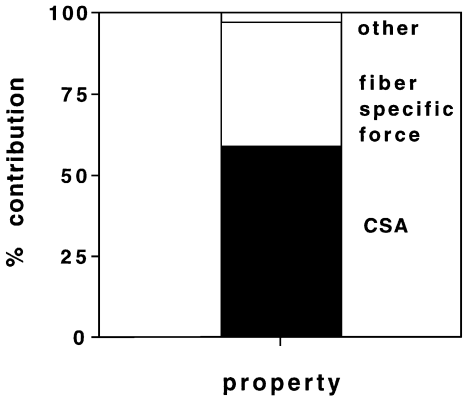

FIG. 46.3. Relative contributions of muscle cross-sectional area (CSA), muscle fiber-specific force, and nonmuscle properties (other) to the decline of force production with age by muscle *in vivo*.

appears to vary among muscles (McDonagh *et al*., 1984; Bemben *et al*., 1991), it is clear that this phenomenon represents a significant change in muscle functional capacity. A decline in muscle strength correlates with an increased risk of falls and loss of independence in daily activities (Pendergast *et al*., 1993; Sonn, 1996), so the reduction in muscle strength with age has a significant impact on both an individual's health and independence.

Muscle force production is governed by three main factors: muscle size, intrinsic properties of the muscle, and neural activation. Figure 46.2 illustrates the relationship of these factors to force production by the muscle. The combination of a muscle's size (cross-sectional area) and the specific force (force per cross-sectional area) of its fibers determines the force production capacity of that muscle. The actual force that is produced by a muscle *in vivo* results from both its capacity for force generation and its recruitment by motorneurons. Reductions in force with age must stem from changes in some or all of these factors.

Our approach in this chapter is to examine what is known about changes with age in each of these factors and from this make a reasonable estimate of the contribution each makes to the reduction of force production capacity. Figure 46.3 shows that changes in the size and intrinsic properties of the muscle largely account for the drop in force output by muscle in the elderly. Muscle cross-sectional area, which reflects the number and size of individual fibers, is the factor most responsible for declining force production with age. The specific force of muscle fibers, which is determined by such properties as contractile protein content and calcium handling and sensitivity, is lower in old age (Larsson *et al*., 1997) and accounts for the balance of the force reduction. Although a gradual loss of fast fiber content in elderly muscle is often proposed as a factor in lower force production by the elderly, we show that this is unlikely to have a significant role. The same is true for alterations in muscle recruitment. In the sections that follow, we examine the changes with age seen for each of these major factors and the mechanisms that may underlie these changes. It will be apparent that despite numerous studies describing the reduction of force with age, there are still significant gaps in our knowledge of the detailed mechanisms responsible for this decrease in muscle function.

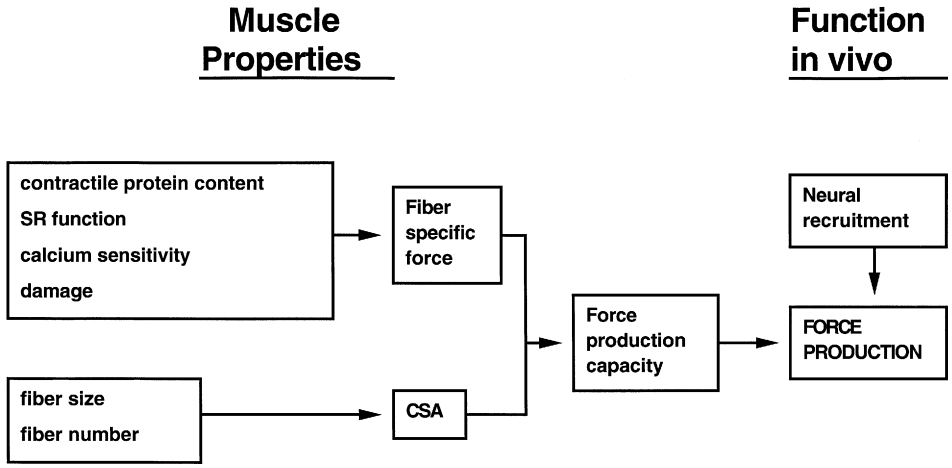

FIG. 46.2. Diagram of the relationship between muscle properties and muscle force production *in vivo*.

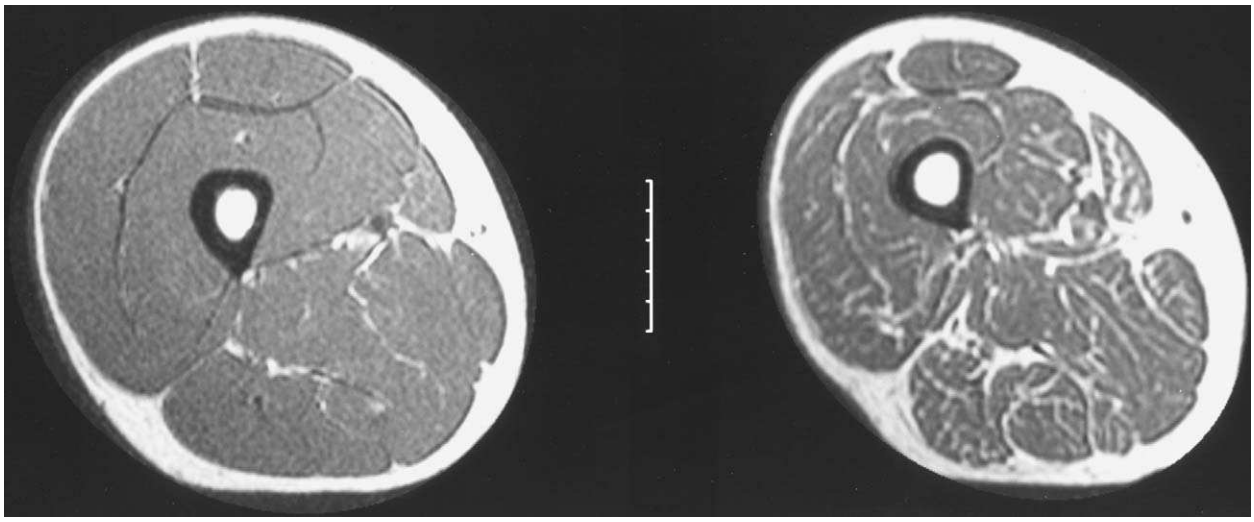

FIG. 46.4. Magnetic resonance images taken at the midthigh level in 2 subjects with similar body mass and height: left, 25-year-old male; right, 65-year-old male. Note the lesser muscle (gray) area and greater fat (white) area in the older subject.

B. Much of the Decline in Force with Age Is Explained by the Reduction of Muscle Cross-Sectional Area

1. Force versus Cross-Sectional Area

We now know that the loss of muscle mass with age is substantial and explains more than half of the reduction in force seen with aging. Magnetic resonance (MR) and computed tomography (CT) images taken *in vivo* show that elderly subjects have only about 75–80% of the quadriceps area of young subjects (Vandervoort and McComas, 1986; Overend *et al*., 1992a,b; Welle *et al*., 1996), and we found that the cross-sectional area of the quadriceps declines by about 20% between the ages of 65 and 80 years (Jubrias *et al*., 1997). Postmortem measurements show an even larger decline with age of 40% (Lexell *et al*., 1988). These numbers exceed estimates (Larsson *et al*., 1979) from anthropomorphic measurements *in vivo* that were unable to account accurately for changes in thigh composition. For example, Overend and associates (1992b) demonstrated that although the total area of the thigh was no different with age, elderly men had 26% and 18% less quadriceps and hamstring cross-sectional area, respectively, and 60% more nonmuscle tissue than did young men. Figure 46.4 shows MR images of the mid-thigh of a young and an elderly subject. This image clearly demonstrates the reduction of muscle area and increase in fat and connective tissue that accompanies aging in normal subjects. Several studies (Young *et al*., 1985; Vandervoort and McComas, 1986; Overend *et al*., 1992a) have measured both force and cross-sectional area in their subjects, and the 20–25% drop in muscle area that parallels the 35–40% drop in muscle force production suggests that the loss of muscle size can explain one-half to two-thirds of the loss of force with age.

Is this apparent connection between muscle size and force based on physical properties rather than coincidence? Figure 46.5 shows the relationship between maximum muscle force output and muscle cross-sectional area. This relationship results because the amount of force that can be generated by muscle depends in part on the number of myosin–actin cross-bridges present. Since a larger cross-sectional area contains more myofibrillar proteins, they generate more force than smaller muscles when activated similarly. Thus, the loss of muscle area with age results in lower force generation (Fig. 46.1) and accounts for up to two-thirds of the loss in force seen in aging.

2. Why Is Muscle Cross-Sectional Area Lower in the Elderly?

The number and size of individual fibers within a muscle determine the muscle's cross-sectional area, and both of these are reduced with age. In humans there is a pronounced loss of muscle fibers after about 50 years of age, but this process may begin even earlier (Lexell *et al*., 1988). These authors examined cross sections of whole human vastus lateralis muscle and found that 80-year-olds have almost 40% fewer muscle fibers in the quadriceps than do 20-year-olds. Type 1 (slow)

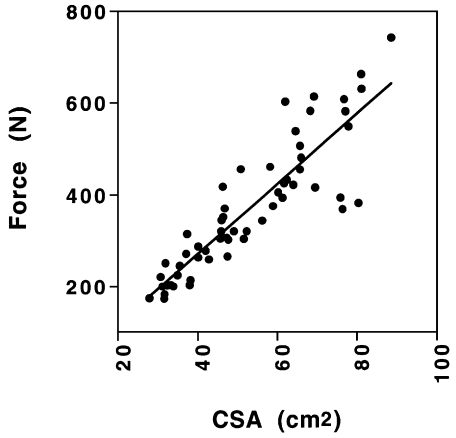

FIG. 46.5. Relationship between force output and cross-sectional area (CSA) of the quadriceps muscles, $r^2 = 0.79$.

and type 2 (fast) fibers were lost in roughly equal numbers. Muscle fiber loss is due mainly to the denervation of fibers followed by only partial reinnervation and subsequent atrophy and degeneration of the remaining denervated fibers (Larsson and Ansved, 1995; Lexell, 1995). Whole muscle cross-sectional area is also affected by a reduction of mean fiber area in the elderly. In contrast to the relatively equal loss of slow and fast fibers, fiber atrophy mainly affects fast fibers. Both biopsy (Larsson *et al*., 1979; Stalberg *et al*., 1989; Coggan *et al*., 1992) and whole cross-section (Lexell *et al*., 1988) data show a significant loss of type 2 fiber area, with the reduction ranging from 15 to 40%. This fast fiber atrophy may result from the drop in physical activity levels often seen as humans age, the denervation/reinnervation process, and lower synthetic rates of muscle proteins (Welle *et al*., 1993; Balagopal *et al*., 1997) found in older subjects. It is clear that processes both internal and external to the muscle result in the loss of muscle fiber number and area with age, leading ultimately to a decrease in the total muscle available for force production.

A comparison of the differences between the young and the old in force output and muscle cross-sectional area shows that the drop in force usually exceeds the amount of muscle atrophy (Young *et al*., 1985; Vandervoort and McComas, 1986; Overend *et al*., 1992a), with atrophy explaining about two-thirds of the force decrement. Thus, elderly muscle *in vivo* produces less force per muscle area (specific force) than does young muscle. This is also true of the continued loss of force seen after about age 60. For example, we found that between the ages of 65 and 80, muscle force production by the quadriceps decreased by about 40%, while the quadriceps's cross-sectional area dropped by only about 20% (Jubrias *et al*., 1997). Muscle atrophy is a major factor in the loss of force with age, but changes in other muscle properties or in neural input must account for the lower specific force observed *in vivo*. How can we determine which of these other factors are important in the loss of force seen in the elderly?

C. Changes in Muscle Intrinsic Factors Also Result in Lower Force Production with Age

1. Is the Specific Force of Single Muscle Fibers Reduced?

Evidence from isolated single muscle fibers strongly suggests that changes within the muscle fibers themselves are responsible for the remainder of the force deficit not explained by muscle atrophy. Studying isolated single fibers provides a way of examining the behavior of muscle without neural input or consideration of the relative fiber type proportions within the muscle, and so allows us to see whether individual fiber types of the elderly are less able to produce force than those of the young. Larsson and associates (1997) demonstrated that the specific force of fibers containing either myosin heavy chain (MHC) I or IIa isoforms is lower in elderly humans by about 10 and 25%, respectively. Although the Larsson study had a small number of subjects (4 young and 4 old), similar findings have been reported for some strains of rats and mice (Brooks and Faulkner, 1988; Degens *et al*., 1995; Li and Larsson, 1996). Since elderly human quadriceps muscle has a somewhat greater content of slow than fast muscle fibers, we can use 15% (the weighted average of 10% and 25%) as an estimate of the reduction in specific force of elderly fibers. This value is about half the size of the force deficit *in vivo* that is not explained by muscle atrophy. Thus, the combination of reduced muscle size and a lower specific force of muscle fibers in the elderly accounts for much of the observed force reduction *in vivo*.

2. What Accounts for Lower Fiber-Specific Force?

The reduced specific force of muscle fibers may result from altered calcium handling and sensitivity, a reduction in myofibrillar protein content, or lower resistance to ultrastructural damage. Unlike the ample evidence of change in muscle size and its consequences, alterations in these other muscle properties and their impact on force production are not as thoroughly researched. Thus, although it is clear that intrinsic muscle properties change, the relative contributions of these altered properties to lower fiber specific force has not been determined. Despite this, it is still possible to make an estimate of the relative importance of these factors to reduced fiber-specific force.

3. What Is the Role of Calcium in the Reduction of Specific Force?

Changes in calcium handling or the sensitivity to calcium of the contractile apparatus appear to play a significant role in the reduction of force production by elderly muscle. Calcium is important to force production since it triggers the contractile apparatus. The amount of force generated by a fiber is directly related to the concentration of calcium in the cytosol. Under normal physiological conditions in the young, enough calcium is released by the sarcoplasmic reticulum during muscle activation to saturate troponin fully and allow maximum force generation. If calcium release by the sarcoplasmic reticulum is reduced significantly the force generated by the fiber will be lower. Delbono and colleagues (1995) examined isolated human fast fibers and showed that calcium release by the sarcoplasmic reticulum is reduced by about 33% relative to young subjects. Delbono *et al*. (1997) also reported that this lower calcium release is accompanied by reduced specific force in those fibers, although the magnitude of the drop in specific force has not yet been published. However, if we use published values for the force-calcium relationship in isolated human fast fibers (Ruff, 1989), we can estimate that a decrease in calcium release as reported by Delbono *et al*. (1995) would result in about 23% less force. This approximates the 25% drop in specific force of fast fibers from the elderly reported by Larsson *et al*. (1997). The lower calcium release may be due to reduced synthesis of sarcoplasmic reticulum proteins in the elderly, which results in proteins with reduced function (Ferrington *et al*., 1998).

In addition to decrements in calcium release by the sarcoplasmic reticulum, a change in the sensitivity of the contractile apparatus to calcium would also lead to altered force production by muscle. Brooks and Faulkner (1994a) demonstrated a reduced calcium sensitivity in old vs young mice. In the old mice, saturating levels of calcium produced normal force, but lower levels of calcium produced less force than did simi-

lar levels of calcium in the young. Using the change in calcium sensitivity found in the Brooks and Faulkner paper (1994a), we calculate that a 33% drop in maximum calcium release as reported by Delbono *et al*. (1995) for older humans would result in about a 10% reduction in specific force. Thus, if the contractile apparatus of elderly humans also has a reduced calcium sensitivity, this could intensify the effect of the lower calcium release demonstrated by Delbono *et al*. (1995). Although the calcium sensitivity for elderly human fibers has not yet been reported to our knowledge, it is possible that the combination of reduced calcium release and reduced calcium sensitivity can account for the drop in fiber-specific force reported for the elderly.

4. Does a Relative Loss of Contractile Protein Contribute to Lower Specific Force?

The force generated by a muscle fiber depends on the number of actin–myosin cross-bridges formed during contraction, so a decrease in the amount of contractile protein per fiber area would also result in a lower specific force. Several papers have reported less contractile and more connective tissue in muscle fibers of old animals (Alnaqeeb *et al*., 1984; Kovanen, 1989). A drop in the contractile protein content (per volume) of fibers leading to a 40% reduction in specific force has also been demonstrated in human subjects who undergo lengthy bedrest (Larsson *et al*., 1996). It is unlikely that age alone results in the profound contractile protein loss that accompanies bed rest; however, the lower levels of physical activity commonly associated with aging might reduce the contractile protein content of elderly muscles. The importance of this mechanism to the loss of force per cross-sectional area awaits measurement of the contractile protein loss with age.

5. Is Elderly Muscle-Specific Force Lower Due to Muscle Damage?

A final intrinsic mechanism for lower force production by elderly muscle is an increased susceptibility to muscle damage coupled with a reduced capacity for regeneration. The muscle of old mice sustains more damage during eccentric contractions than does young muscle (see Brooks and Faulkner, 1994b). This also appears to be true for elderly humans as suggested by indirect measures of damage (Manfredi *et al*., 1991), but no ultrastructural studies of elderly human muscle after exercise have been reported. Elderly humans (Dedrick and Clarkson, 1990), rats (McBride *et al*., 1995), and mice (Brooks and Faulkner, 1994b) show a diminished capacity for regeneration after injury, with a prolongation of the force deficit associated with damaging contractions. An impaired ability to repair damage may stem from the lower rates of myofibrillar protein synthesis found in the elderly (Welle *et al*., 1993; Balagopal *et al*., 1997) or from reduced activation of satellite cells (Barton-Davis *et al*., 1998). The low rates of protein synthesis may also lead to a poorer quality of contractile proteins since the ability to repair routine damage from oxygen free radicals would be blunted. Barton-Davis and coworkers (1998) showed that overexpression of insulin-like growth factor in mouse muscle evoked by injection of a recombinant adeno-associated virus prevented the age-related drop in specific forces and this was apparently mediated by satellite cell activation. It is clear that muscle damage could be a factor in the lower specific force seen in the elderly, but this conclusion must await ultrastructural analysis of elderly muscle.

D. Other Proposed Mechanisms Are Unlikely to Be of Major Significance

We have shown that the reduction of force output by older subjects relative to the young can be explained by the measured reductions in muscle area and fiber-specific force. However, this explanation does not address two mechanisms that are often suggested as potential factors in the force deficit of elderly muscle: fiber type changes and altered recruitment. In this section, we examine these factors and show why neither is likely to play a significant role in the loss of force production with age.

1. Does a Decline of Fast Fiber Content Cause a Drop in Force?

Many studies report a loss of fast fiber and increase in slow fiber content with age (Larsson *et al*., 1979; Stalberg *et al*., 1989; Klitgaard *et al*., 1990). Lexell and Downham (1992) examined whole cross sections of human vastus lateralis muscle and found that the relative area of type 2 fibers is about 40% in 70-year-olds and about 50% in 30-year-olds. There are reports that muscle force production *in vivo* increases with a greater content of fast fibers (Inbar *et al*., 1981; Ivy *et al*., 1981; Young, 1984). Higher specific force for fast vs slow muscle fibers has been measured in isolated human fibers from the quadriceps, with fast fiber force per cross-sectional area about 25% higher than slow (Larsson *et al*., 1997). However, the data from single-fiber studies are conflicting, with the specific fiber preparation technique used playing a major role in determining whether a difference is seen between fast and slow fibers. We can estimate the impact of changing fiber type on force production with the figures given above. If fast fibers generate 25% more force per cross-sectional area than slow fibers and there is 10% less relative fast fiber area with age, then this drop in fast fiber content would result in a 2.5% loss of force. This reduction in force that may result from a shift from fast to slow fibers is small compared to the roughly 35% decline seen with age (Borges, 1989; Overend *et al*., 1992a). Thus, in contrast to the important influence of muscle atrophy and reduced specific force of both fast and slow types, a change in the fiber composition of elderly muscles is not a significant factor in the lower force production in this population.

2. Is Muscle Recruitment a Problem for the Elderly?

Altered neural recruitment is another potential mechanism for the decline in the force production of whole muscle with age. Neural adaptations have an important role in the strength gains seen following resistance exercise training in the young and the old (see Enoka, 1997), suggesting that neural mechanisms may also play a role in age-related losses of muscle force

production. There are two main neural mechanisms with the potential to reduce the measured force of whole human muscle: an inability to fully activate the agonist muscle and increased recruitment of antagonist muscles.

It is unlikely that an inability to recruit all motor units of a muscle at optimal contraction rates plays a major role in the loss of strength in the elderly. Studies of leg (Vandervoort and McComas, 1986; van Schaik *et al*., 1994), arm (Brown *et al*., 1990; De Serres and Enoka, 1998), and hand (Phillips *et al*., 1992) muscles indicate that older subjects are able to recruit all motor units with voluntary activation. In contrast, Kent-Braun and LeBlanc (1996) reported that four of five elderly subjects showed an additional force increment when 50 Hz electrical stimulation of the dorsiflexors was superimposed on a maximum voluntary contraction, but they did not indicate the size of the additional force. This observation was interpreted as an inability of the elderly to activate muscles at sufficient firing frequencies to achieve maximum force. In support of this, Kamen and associates (1995) have shown that elderly subjects have lower motorneuron firing rates than younger subjects. However, these authors point out that due to the increased twitch contraction time in elderly muscle, lower firing frequencies may be adequate to achieve tetanus in these muscles. De Serres and Enoka (1998) question the functional significance of the small differences in force seen with imposed high-frequency pulse trains. There is thus no compelling evidence to suggest that inadequate recruitment contributes to the reduction of force output with age.

3. Does Antagonist Muscle Coactivation Reduce Force in the Elderly?

Very little attention has been given to the role of antagonist muscle coactivation in the reduction of measured muscle force in the elderly, but this mechanism may be a contributor. Hakkinen *et al*. (1998) reported that in untrained subjects, hamstring coactivation during quadriceps contraction was greater in the elderly than in the young, during both isometric and dynamic contractions. Coactivation is in part related to training status (Osternig *et al*., 1986; Carolan and Cafarelli, 1992), and older subjects reduced the coactivation of their antagonists to levels similar to the young following training of the agonist movement (Hakkinen *et al*., 1998). The recruitment of antagonist muscles *in vivo* produces a force in opposition to that of the agonists such that the effective force output of the agonist muscle is reduced. In addition, activation of antagonist muscles reduces the neural drive to the agonists by reciprocal inhibition (Sale, 1988). Reduced coactivation of antagonists accounts for about a third of the increase in force production in the early stages of strength training in the young (Carolan and Cafarelli, 1992), so it is clear that the recruitment of antagonist muscles can have an important effect on resulting force. Taken together, these studies suggest that coactivation of antagonist muscles may contribute to the drop in force production *in vivo* seen in the elderly. We demonstrated earlier that muscle atrophy and the reduced specific force of muscle fibers are sufficient to explain the force deficit with age, but it may be that coactivation also has an important role in individuals who show very large force deficits.

III. Endurance Performance and Age

Two characteristics important to maximal force production—muscle size and intrinsic properties—are also key to endurance performance. The intrinsic properties important to strength relate primarily to the contractile elements. In contrast, the intrinsic properties important to endurance relate primarily to the supply and demand for ATP. This is apparent in the decline in endurance performance with age, which involves changes in both maximal oxygen uptake and muscle power output (Astrand and Rodahl, 1986). The goal of this section is to determine how muscle properties related to ATP supply and demand change with age, what effect these changes have on cellular energetics, and how these changes are reflected in the loss of muscle performance in the elderly.

A. Sources and Sinks for ATP in Active Muscle

Aging has an effect on each of the ATP supply and demand properties. Our goal is to evaluate the consequences of the age-related changes in the integrated energetics of the muscle cell to exercise performance at the muscle and whole-body level. To this end, let us first consider ATP supply and demand in active muscle. The integrated nature of the intracellular properties involved in the balance between energy demand and supply necessary for muscle contraction (Conley, 1994) is shown in Fig. 46.6. The primary consumers of ATP in the muscle are the ion and myosin ATPases (Rall, 1985), while the primary source of ATP for sustained contractions is the mitochondria, which use oxygen and carbon fuels in the process of oxidative phosphorylation. A secondary source of ATP—but primary source of carbon fuel—is glycolysis. This pathway is also the source of H^+ and lactate, which accumulate at high work levels and can inhibit sustained muscle contraction.

B. Balancing ATP Supply to Demand

1. Does Aging Affect ATP Supply and Demand?

We can directly measure contractile ATP demand and ATP supply using noninvasive magnetic resonance methods that characterize a whole-muscle rather than a muscle sample from a biopsy (Blei *et al*., 1993a,b; Conley *et al*., 1998, 1999b).

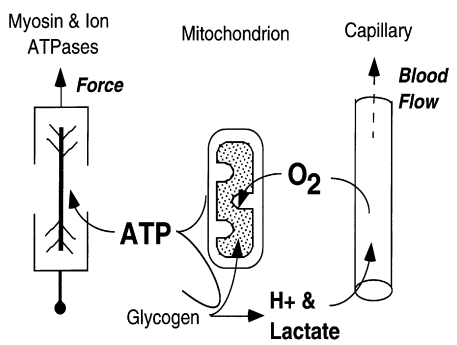

FIG. 46.6. Diagram of the mass and energy balances involved in ATP supply and demand in muscle.

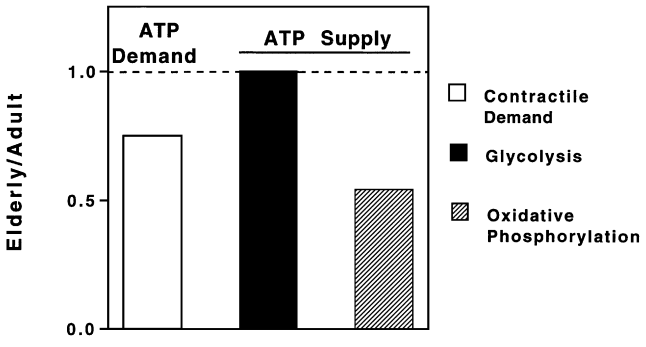

FIG. 46.7. Ratios of ATP demand and supply properties of vastus lateralis muscle in elderly (mean age, 68 years) vs adult (mean age, 38 years).

Figure 46.7 contains data from our laboratory showing that both contractile demand and oxidative capacity of elderly (mean age, 68 years) vastus lateralis are lower than in younger adults (mean age, 38 years). Contractile costs are not routinely determined on muscle, so it is unclear whether this decline between the third and the sixth decade of life is typical of aging muscle. However, the reduction in oxidative capacity has been reported in previous MR studies and supported by similar reductions in oxidative enzyme activity (Coggan *et al*., 1993; McCully *et al*., 1993). Thus elderly muscle shows reductions in both the supply and the demand for ATP compared with that seen in younger adults.

2. What Accounts for Lower ATP Demand?

Changes in contractile properties or excitation–contraction coupling could be the basis of the reduced contractile cost in elderly muscle. The basis of these changes in muscle properties may lie in an ongoing denervation and reinnervation process in elderly muscle (Larsson *et al*., 1997). Fiber type grouping and reduction in the number of functioning motor units are indicative of such a process (Doherty and Brown, 1997; Lexell, 1995). The resultant shift in myosin heavy chain to the slower type I fibers is often cited as the cause of the drop in contractile speed and ATP utilization, but there appears to be only a small fiber type change during this denervation and reinnervation process (Lexell, 1995). Thus the frequently noted change in fiber type properties with age has only a small effect on contractile costs.

An age-related change that is more important to energetics, however, is the finding of reduced contraction velocity for a given fiber type (Larsson *et al*., 1997). Several causes for this reduced velocity of contraction with age are possible. First, expression of additional, but undetected, myosin heavy chain isoforms may be responsible for the slowing of muscle with age (Larsson *et al*., 1997; Thompson and Brown, 1999). A second possibility is contractile protein changes, such as myofibrillar loss or increased spacing of myofilaments, which have also been proposed to account for the loss of specific force in elderly muscle (Larsson *et al*., 1997). A third possibility is the uncoupling of excitation from calcium release resulting in reduced calcium available for activation in elderly compared to young human muscle mentioned earlier (Delbono *et al*., 1995). Reduced calcium activation could account for the lower specific force found *in vivo* as well as the reduced cost per twitch. Lower calcium cycling itself would reduce contractile costs. Finally, the reduced regenerative capacity of elderly muscle may make it more susceptible to injury, which impairs function (Brooks and Faulkner, 1994b). An increased ''wear and tear'' as the basis of reduced function is bolstered by the Barton-Davis *et al*. (1998) finding that stimulation of muscle regeneration via activation of satellite cells by insulin-like growth factor I eliminated age-related specific force loss. The end result is a lower mechanical performance of aged human muscle fibers, which is consistent with our measurement of lower contractile ATP use.

3. What Accounts for the Lower ATP Supply?

The 50% difference in oxidative capacity per muscle mass between elderly and adult muscle shown in Fig. 46.7 is slightly larger than the 30% difference in oxidative enzyme activity reported by McCully *et al*. (1993) for groups similar in age to ours. These workers found that oxidative enzyme activity was lower in proportion to the oxidative properties measured by MR. We have found that the loss in oxidative capacity with age was due primarily to a lower mitochondrial volume but also to a reduced oxidative capacity per mitochondrial volume. Papa (1996) has shown a steady age-related decline in mitochondrial oxidative enzymes. Our finding of a 20% loss of oxidative capacity per mitochondrial volume between the fourth and seventh decade of life is similar to the loss of mitochondrial respiratory enzyme activity reported by Papa (Conley *et al*., 1999b). Both increased DNA mutations in the mitochondrial and nuclear genomes coding for mitochondrial respiratory enzymes and the direct action of oxygen free radicals appear to be the causative agents of this decline in oxidative enzyme activity (Ozawa, 1997). Thus two factors appear to contribute to this lower oxidative capacity per muscle mass in the elderly: reducedmitochondrial content and reduced activity of mitochondrial enzymes. These reductions mean a lower capacity for oxidative ATP synthesis in elderly muscle. The consequences of the lower oxidative capacity to muscle performance are discussed in section III.D.2.

4. What Age-Related Factors Account for Muscle Changes?

Nonathletic youth have lower oxidative capacity and lower muscle mass compared to endurance athletes (Proctor *et al*., 1995). Is the lower level of chronic activity with age responsible for the observed age-related changes in muscle properties? To separate those changes related to reduction in activity vs those due to aging in general, we can examine elderly subjects who have maintained a high level of activity, specifically, master athletes. These athletes show a loss of fat-free mass in general and quadriceps muscle mass in specific compared to young athletes (Coggan *et al*., 1990; Proctor and Joyner, 1997; Proctor *et al*., 1998). A reduced maximum oxygen consumption (VO_2max) per fat-free mass indicates lower oxidative capacity of the underlying muscle. The lack of difference in the activity of oxidative enzymes of these master athletes compared to young athletes suggests that histochemical determinations of single enzyme activities may not be sensitive to the age-related

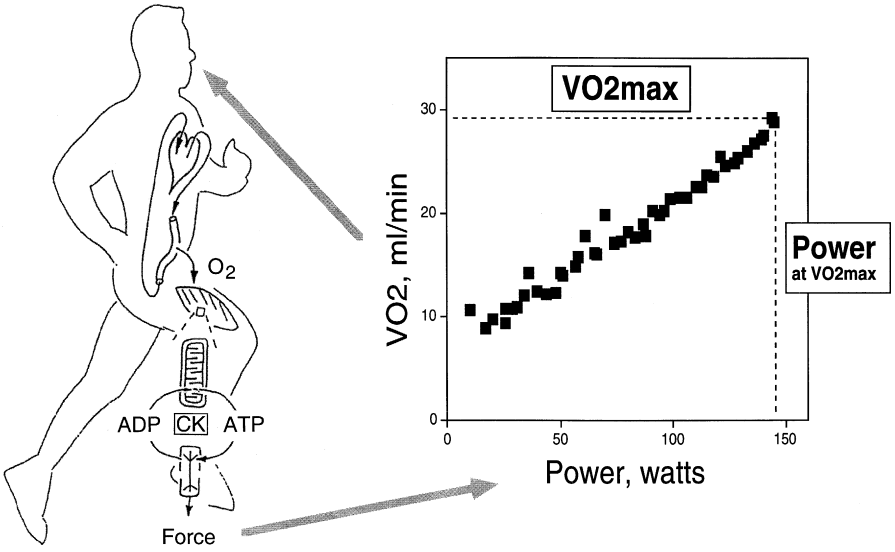

FIG. 46.8. Oxygen uptake as a function of leg power output from rest to the aerobic capacity (VO_2max) in an exercising human.

changes in the oxidative pathway. Similarly, contractile properties are slower in elderly athletes, as shown by a longer time to peak tension in a twitch (Harridge *et al*., 1997). The reduction in muscle mass, oxidative enzyme activity, and slower contractile properties in the trained master athletes indicate that these changes are an inevitable part of aging and not due to inactivity *per se*. How are the age-related changes in muscle reflected in physical performance?

C. How Human Performance Reflects the Effects of Aging on Muscle Properties

1. How Do We Measure Performance?

Typically aerobic fitness is measured as the highest oxygen consumption achieved by a subject on a treadmill or cycle ergometer. Figure 46.8 shows that O_2 uptake increases with leg power output to the limit of uptake at VO_2max. This power output by the legs represents a direct measure of aerobic exercise performance that can be related to the muscle properties governing the demand and supply of ATP. Our focus is on how these muscle properties determine aerobic leg performance; specifically, how muscles generate and use ATP in power production and how the changes in muscle properties with age affect muscle power production.

2. How Do Muscle Properties Determine Performance?

Two classes of properties are critical to muscle performance across ages: muscle mass and energetic properties. We showed previously that maximal isokinetic leg force is directly related to muscle cross-sectional area (Jubrias *et al*., 1997). The combination of muscle size and energetic properties is important to sustained muscle performance because together they determine the capacity for ATP supply and demand. This section focuses on how the intracellular properties involved in ATP supply and demand determine the ability to sustain this power output.

The key properties governing ATP flux and the role of these properties in determining muscle power output are illustrated in Fig. 46.9. This scheme is derived from a comprehensive study of the role of these properties in human endurance performance recently reviewed by Coyle (1995). Figure 46.9 connects the individual muscle properties discussed earlier to muscle power output based on the effect of these properties on ATP supply and demand. The key property in this scheme is the mitochondrial volume, which determines O_2 consumption and the majority of ATP supply. A secondary source of ATP–but a major pathway for substrate supply to the mitochondria—is glycolysis (Connett and Sahlin, 1996; Conley *et al*., 1997, 1998). This pathway may also generate H^+ during aerobic exercise, which can inhibit oxidative metabolism (as indicated by the minus sign in Fig. 46.9) and excitation–contraction coupling, thereby limiting sustained performance (Coyle, 1995). The final key muscle property is the fiber type, which is energetically important because it determines the efficiency of conversion of ATP into power output by the muscle. Muscles capable of high levels of sustained performance often have a high proportion of the more efficient slow twitch (type I) fibers, which use less ATP to generate a given power production (Coyle, 1995). To what extent can these findings help us understand the loss of performance in the elderly?

D. Maximum Aerobic ATP Supply

1. Mitochondria and O_2 Demand

The first step in understanding how the decline in muscle properties relates to the decline in muscle performance is to ask how muscle properties determine performance in young, healthy muscle. The capacity for oxidative ATP supply that underlies sustained performance depends on the mitochondrial content of the muscle. As the sites for O_2 uptake and aerobic ATP generation, mitochondria depend on the cardiovascular system for O_2 delivery to sustain ATP supply. Does this O_2 delivery ever limit the capacity of the mitochondria? Recent work indicates that there is no limitation in untrained young subjects (Cardus *et al*., 1998), but that a small cardiovascular limitation may restrict the measured VO_2 to less than the mito-

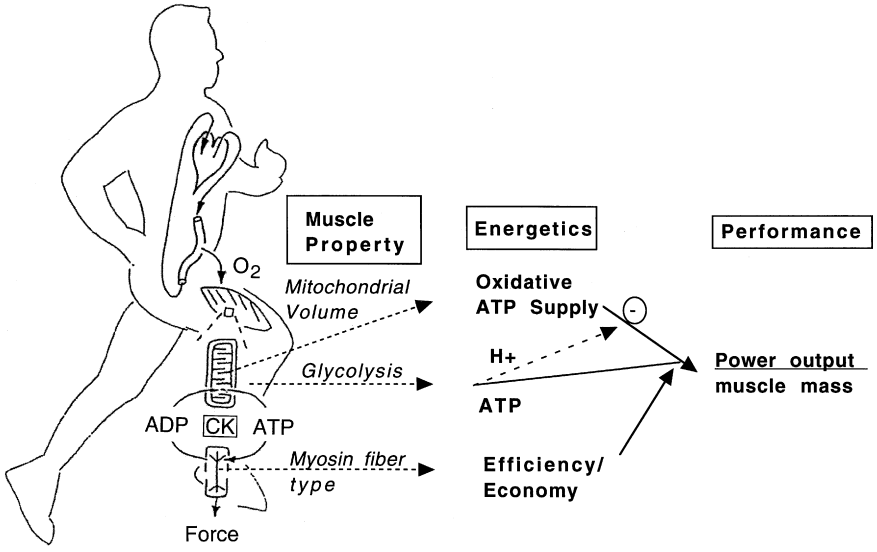

FIG. 46.9. Diagram of the links between muscle properties, energetics, and leg power output per muscle mass.

chondrial capacity in athletic individuals (Richardson *et al.*, 1999). The elderly have a greater O_2 extraction and a lower blood flow rate compared to young at the same submaximal work level (Proctor *et al.*, 1998), but there is no direct measure of an O_2 delivery limitation to sustained performance or at VO_2max in the elderly to our knowledge.

2. Muscle Oxidative Properties Are Critical to Sustained Performance

Coyle (1995) found that oxidative enzyme activity is a major determinant of leg power output and performance time of athletes. Another measure of the importance of muscle oxidative properties in determining O_2 flux is the close relation between maximum oxygen consumption per body mass and mitochondrial content of the vastus lateralis in a wide range of young subjects (Hoppeler *et al.*, 1973). A similar proportionality between VO_2max and muscle oxidative properties in elderly subjects was found by McCully *et al.* (1993). These workers found that the lower VO_2max in elderly subjects was accompanied by a lower muscle oxidative enzyme activity.

3. How Is This Reduced VO_2max Related to Power Output?

A good demonstration of the link between muscle power output and oxidative capacity was shown by Hoppeler *et al.* (1985) in young subjects. They showed that endurance training raised mitochondrial volume and leg power output. The oxygen consumption of the legs estimated from the rise in power output (estimated using a typical cycling efficiency of 25%) matched the elevation of VO_2max with training. This calculation indicated that the majority of the increase in VO_2max occurred in the leg muscles. Since the legs consume about 85% of the oxygen during cycling at VO_2max (Poole *et al.*, 1992), this correspondence between the predicted rise in VO_2 based on leg power output and the measured VO_2max makes sense. These results demonstrate that the increased VO_2 of the quadriceps generated a higher ATP flux and, in turn, supported the higher leg power output found after training.

The importance of muscle size to leg power output is evident in the comparison of elderly vs young subjects and in untrained vs trained elderly (Coggan *et al.*, 1993). The lower power output in untrained elderly reflected both a reduced muscle size as well as a lower oxidative capacity per muscle volume compared to trained elderly or the young. The difference in oxidative capacity between the untrained elderly and the trained youth resulted from primarily a lower oxidative enzyme activity but also a smaller muscle volume. These results are similar to those of Conley *et al.* (1999a) who found that the combination of lower muscle mass (65% of young adult muscle) and reduced oxidative capacity per muscle (50% of young adult muscle) accounted for the reduction of VO_2max in elderly muscle to 33% (65% $\times$ 50% = 33%) of the adult value. Thus both the size and oxidative properties of muscle need to be taken into account in understanding the oxidative capacity and power output of muscle.

4. How Does Maximal Aerobic Performance Relate to Elderly Activity?

Muscles can work to VO_2max, but this is a transient exercise that cannot be maintained. It does allow one to measure the maximal aerobic performance and determine the factors that set this aerobic limit. It is quite clear that oxidative capacity is critical to submaximal performance as well. Many endurance events occur at about 70% of VO_2max, but despite the submaximal level, performance is closely related to VO_2max (Coyle, 1995). For example, the preferred walking speed in elderly subjects elicits VO_2 well below the aerobic capacity, but speed is nonetheless related to VO_2max (Conley *et al.*, 1995; Buchner *et al.*, 1996). Similarly, Coyle (1995) reported that performance in a number of athletic events elicits submaximal sustained activity that is proportional to VO_2max. Thus, exercise for young and old alike may never reach levels that elicit VO_2max, but this aerobic capacity affects the levels of

exercise that can be sustained. How is sustained performance related to VO_2max?

E. Setting the Limit to Sustained ATP Supply

1. Glycolysis and Sustained Performance

The highest sustainable level of performance in muscles working alone and in whole-body performance is associated with accumulation of glycolytic byproducts. Glycolysis provides the majority of the substrate supply for oxidative phosphorylation during exercise. However, pyruvate production may exceed oxidation even under sustained exercise conditions, causing inhibitory byproducts, such as H^+ and lactate, to accumulate (Conley *et al*., 1997). Muscles can sustain work until H^+ begins to accumulate and intracellular pH drops; at higher work levels force production declines and work cannot be maintained. Chilibeck *et al*. (1998) found that this pH threshold occurred at a lower percentage of peak aerobic power during ankle plantar flexion in elderly (60%) vs young subjects (70%).

2. Are the Muscle and Whole-Body Thresholds for Sustained Activity Related?

The work rate at which lactate accumulates in the blood is termed the lactate threshold and typically occurs at the limit to sustained whole body activity (Coyle, 1995). Syström *et al*. (1990) found that the muscle intracellular pH decline corresponded with the threshold for lactate accumulation in the blood. Since muscle generates lactate under fully aerobic conditions (Conley *et al*., 1998) and whole-body VO_2 can increase well above the lactate threshold, the pH decline in the muscle and lactate accumulation in the blood does not represent an oxygen limitation to respiration. Instead, it reflects a glycolytic flux that exceeds the capacity to oxidize pyruvate (see Connett and Sahlin, 1996). This correspondence of the drop in muscle pH and blood lactate accumulation suggests a link between muscle fatigue and the limit to sustained performance. For the elderly, lactate accumulation in the blood is reported to occur at a lower percentage of VO_2max in sedentary compared with highly trained cyclists but is similar among well-trained athletes regardless of age (Masse-Biron *et al*., 1992). Thus, the percentage of the oxidative capacity at which the limit to sustained performance occurs may not be a strict function of age, but rather may be more related to the training state of the individual.

3. Can the Limit to Sustained Activity Be Increased?

Endurance exercise training in the elderly has been shown to raise the limit to sustained activity in two ways (Marsh *et al*., 1993). First, exercise training increases the VO_2max and thereby the capacity for ATP synthesis. Second, the lactate threshold occurs at a higher fraction of VO_2max. This elevated threshold could result from both a reduction in glycolytic flux and a higher oxidation of this flux during exercise. Thus endurance training in the elderly can increase not only the ATP supply capacity of the muscle but also the fraction of this capacity that can be sustained to support aerobic work. The resultant elevated lactate threshold and increased oxidative capacity means a higher limit to sustained ATP supply and greater sustained muscle power output.

4. Sustained Performance: Interaction of Glycolysis, Oxidative Phosphorylation, and Contractile Properties

The limit to sustained performance is a good example of the integrative nature of muscle energetics. As shown in Fig. 46.9, oxidative phosphorylation may set the limit to aerobic ATP supply, but the extent of glycolytic H^+ and lactate production will determine the fraction of the aerobic limit that can be sustained for more than a few minutes. Further, the nature of the muscle fiber type determines the efficiency of the conversion of ATP into force production. Thus there is a clear interaction between glycolysis, oxidative phosphorylation, and contractile properties in setting the limit to sustained performance. Endurance training has the potential to vary not only the aerobic limit but also the fraction of that limit that can be sustained and the muscle fiber type. Typical training studies focus on the small change achieved in VO_2max (usually <15%), which is not the only factor determining elderly performance. Perhaps it is now time to evaluate the effect of training on activities that are relevant to the functioning of the elderly in everyday life, such as sustained performance in vacuuming or carrying groceries (Conley *et al*., 1995). These sustained activities may well depend on the limit to sustained performance—and the interaction of glycolysis, oxidative phosphorylation and contractile properties—rather than on the aerobic capacity alone.

IV. Conclusions

A great deal of progress has been made in cataloging the gross changes in muscle properties and function that occur with age. It is now clear that we can account for a significant fraction of the loss of physical performance in the elderly based on the age-related changes in muscle properties. Loss of muscle size is responsible for more than half the drop in force production and sustained power output with age. This smaller muscle size reduces the cross-sectional area for force production and the volume for sustained power output. The balance of the reduction in muscle performance is primarily due to the intrinsic properties of muscle. Elderly muscle has a lower force per cross-sectional area and a smaller mitochondrial volume density for sustained ATP supply. The end result is a drop in the ability to generate and sustain force production in the elderly that greatly exceeds the loss expected from muscle mass alone. Some of this functional loss can be regained through the use of strength and endurance exercise training programs. However, studies of master athletes show that the loss of muscle mass is an inevitable part of the aging process. A focus on the mechanisms underlying the loss of muscle mass and change in properties may lead to therapies that can either reverse or avoid these apparently inevitable changes in muscle properties and the loss of physical performance with age.

Parkinson's Disease: Symptoms and Age Dependency

I. Epidemiology of Parkinson's Disease

Parkinson's disease is one of the most frequent neurodegenerative diseases, which mainly affects the elderly. To estimate incidence and prevalence of Parkinson's disease, however, some problems need to be mentioned. There exists no antemortem diagnostic test for Parkinson's disease and the most reliable diagnostic method is expert neurologic examination at regular time intervals. In autopsy studies, the diagnosis of Parkinson's disease before death has been found to be incorrect in about 24% of cases (Hughes *et al*., 1993). Essential tremor may account for 10–40% of the false-positive diagnoses of Parkinson's disease. In contrast, Parkinson's disease may be misdiagnosed as depression or, in the very elderly, ''normal'' aging. Other neurodegenerative disorders, like progressive nuclear palsy or multiple system atrophy, may not be distinguished easily from Parkinson's disease early in the course of the disease. Many ''atypical'' parkinsonian syndromes were recognized only in the past several decades and probably have been classified as Parkinson's disease in early reports.

A. Incidence and Prevalence of Parkinson's Disease

Several studies have been performed to estimate the frequency of Parkinson's disease. The overall incidence is estimated to be 20/100,000 per year, and raises to about 1% of persons over 50 years of age (Gilmore, 1984; Schapira, 1999), and even higher in older populations (Conley and Kirchner, 1999). Prevalence of Parkinson's disease varies from 10 to 405 per 100,000 population. This variation may be due to differences in case-finding procedures, in diagnostic criteria, in accessibility of medical services, and in the age distribution of populations. Most frequently, prevalence is about 100–187 per 100,000 (Mayeux *et al*., 1992). As for incidence, prevalence rises almost exponentially after age 50. By the eighth decade, prevalence in Europe and North America is estimated to be between 1000 and 3000 per 100,000 persons (Tanner and Ben Shlomo, 1999). This is confirmed by the Rotterdam Study: prevalence figures were 0.3% for those ages 55 to 64 years, 1.0% for those ages 65 to 74 years, 3.1% for those ages 75 to 84 years, and 4.3% for those ages 85 to 94 years. Among women ages 95 to 99 years, prevalence was 5.0% (de Rijk *et al*., 1995). In some studies an apparent decrease in late life is seen. This is probably due to ascertainment and diagnosis difficulties in this population, rather than an actual decline in disease frequency. In fact the only unequivocal risk factor for Parkinson's disease is increasing age.

B. Mortality

In the Hoehn and Yahr series, mortality ratio in patients with primary parkinsonism was 2.9 times that expected in the age-matched population (Hoehn and Yahr, 1967). In a recent study of parkinsonian patients, the overall risk for death, adjusted for age and sex, was 2.0 times that of persons without parkinsonism (Bennett *et al*., 1996). Since the introduction of more effective antiparkinsonian medication, especially levodopa, mortality has decreased in younger parkinsonian patients. However, in older parkinsonian patients an increase during the past few decades in mortality is found. In the United States between 1962 and 1984, mortality decreased for persons younger than age 70, but increased for persons of 75 years and older (Kurtzke and Goldberg, 1988). This is confirmed by Morens *et al*. (1996), who found that after age 60, Parkinson's disease associated mortality rates appeared to increase logarithmically. This increase in mortality rate was not attributable to age alone. Increased age-related Parkinson's disease mortality was associated with both absolute age and duration of illness longer than 10 years. Between 70 and 89 years of age, parkinsonian patients had a two- to threefold increase in the risk of dying, corresponding to a mortality ratio of 2.5 (Morens *et al*., 1996). In a recent study of Louis, Marder, and Côté risk of mortality was higher in parkinsonian patients (rate ratio = 2.7) after adjusting for baseline age, years of education, sex, ethnicity, and smoking status. It was even higher when Parkinson's disease was combined with dementia (rate

ratio = 4.9). In fact, dementia is a significant predictor of death in Parkinson's disease (Marder *et al*., 1991). A high base-line score of extrapyramidal signs was most associated with increased risk of mortality among the patients with Parkinson's disease. After subanalysis of the different extrapyramidal signs, severe bradykinesia was the motor manifestation that most highly correlated with increased mortality (Louis *et al*., 1997). The Sydney multicenter study found increased mortality risk among parkinsonian men, whereas this was not significantly different for women, compared to the general Australian population. Predictors of mortality, according to this study, are age at onset and prestudy progression rate. Several studies have shown that the effects of levodopa on mortality are apparent in the early years of the disease. In contrast, despite levodopa therapy, mortality is rising in a later stage of the disease (Curtis *et al*., 1980; Diamond *et al*., 1987). Data from the DATATOP cohort suggests that carefully selected patients with early Parkinson's disease without comorbidity have normal life expectancy when adequately treated and frequently seen by consulting physicians (Anonymous, 1998). This is confirmed by Tanner and Ben-Shlomo (1999). For persons with Parkinson's disease diagnosed before the age of 60 they found a relative survival similar to that of the general population, in contrast to people with an older age at diagnosis, who showed a lower relative survival (Tanner and Ben Shlomo, 1999).

Pneumonia is the most common cause of death, probably due to immobility and increased risk of aspiration (Anonymous, 1998). Death from cerebrovascular disease is increased as well (Gorell *et al*., 1994). Some studies have suggested a reduced risk of death from cancer in parkinsonian patients (Jansson and Jankovic, 1985; Gorell *et al*., 1994), but other studies did not confirm this (Wermuth *et al*., 1995).

C. Regional and Racial Variation

Estimates of prevalence vary widely depending on geographical location. A northwest to southeast gradient is suggested (Kurtzke and Goldberg, 1988) and Parkinson's disease prevalence appears to be highest in Europe and North America, whereas rates in Japan, China, and Africa are markedly lower. In the United States Parkinson's disease prevalence is much lower among African-Americans. Already in 1972, Kessler (1972a,b) found a higher frequency of Parkinson's disease for Caucasians then for African-Americans. In a survey of Parkinson's disease in New York, age-adjusted prevalence rates were lower for African-Americans than for Caucasians and Hispanics. Surprisingly, however, incidence rates were highest among African-American men, but these incidence rates were otherwise comparable across sex and ethnic groups. By ethnic group, the cumulative incidence was higher for African-Americans than for Caucasians and Hispanics, but more deaths occurred among incident African-American patients. These findings could result from a delay in diagnosis due to limited access to appropriate health services among these people (Mayeux *et al*., 1995). Some studies, however, show similar rates for African-American, Asian-American, and European-American subjects (Morens *et al*., 1996). In a study among a cohort of American men of Japanese or Okinawan ancestry, epidemiological data are in general in accord with those from Europe and the United States. Incidence data are 5- to 10-fold higher at each age stratum than age-specific incidence figures from China. These findings most likely cannot be explained by methodological differences between Chinese and Western studies alone. However, this possibility cannot be ruled out, as the Chinese data have not been verified yet by other studies. Similar findings have been observed in a study in Mississippi, where African-American men and women have Parkinson's disease prevalence rates more comparable to Caucasian men and women than African men and women in Nigeria (Schoenberg *et al*., 1985, 1988; Osuntokun *et al*., 1987). These data suggest that risk of developing Parkinson's disease is more a function of environmental factors than racial ones. So different distributions of Parkinson's disease causing factors across populations may contribute to geographic differences in epidemiological findings. These factors could be differences in exposure to causative and protective influences, but also genetic differences in susceptibility to disease. It could be that an environmental agent might only act in genetically susceptible people.

D. Gender Differences

Males tend to have a modestly increased age-adjusted Parkinson's disease prevalence (Diamond *et al*., 1990). Male-to-female ratio range from 0.86 (in Japan) to 3.7 (Chinese studies). In a study in New York, age-adjusted prevalence was lower for women compared with men across all ethnic groups. However, in another study, age-adjusted incidence did not differ between men and women in all ethnic groups (Mayeux *et al*., 1995). This is confirmed by the Rotterdam Study in which no significant gender differences in prevalence were found (de Rijk *et al*., 1995). Gender-specific differences show more variability worldwide than association with increasing age.

II. SYMPTOMS

A. Motor Symptoms

The classic triad of symptoms of Parkinson's disease consists of tremor, rigidity, and hypokinesia. Postural impairment has been called the fourth major symptom of Parkinson's disease. The disease is a slowly progressive disorder and signs and symptoms develop usually over several years. In the early stages of the disease the signs and symptoms may be vague and nonspecific in such a way that a reliable diagnosis cannot yet be made.

The typical parkinsonian tremor is a 3 to 6 Hz distal resting tremor. It consists of alternate contractions of agonist and antagonist muscles, including flexors, extensors, pronators and supinators of the wrists and arms during rest. This may result in the ''pill rolling'' movement of the hand. Often the typical parkinsonian resting tremor starts on one side of the body. In most patients the signs will develop in due course on both sides, but asymmetry will usually persist throughout the disease. The legs or lower jaw may also be involved. The tremor tends to disappear with action. Resting tremor is found in 79–90% of patients with Parkinson's disease in clinical studies and in 76–100% in autopsy-proven studies. Some patients have little or no resting tremor but a predominate action or postural tremor. Resting tremor can be found in other diseases as

well, like multiple system atrophy or progressive nuclear palsy. Tremor at rest may also be induced by neuroleptic agents.

Rigidity can be present in all four limbs and in the trunk, but mainly affects the arms and is often of the cogwheel type. The increase in tone is fairly equal in flexors and extensors, but slightly more in flexors. It can be diagnosed in 89–99% of parkinsonian patients.

Bradykinesia means slowness of movements, whereas hypokinesia stands for poverty of movement. Hypokinetic features include facial hypomimia, reduced eye blinking, hypophonic speech, and micrographia. There is difficulty in initiating movements, resulting in start hesitation. Rapid repetitive movements are impaired. Bradykinesia is present in 77 to 98% of patients with Parkinson's disease, but it is not unique to Parkinson's disease. It can also occur as a result of other extrapyramidal disorders, such as progressive nuclear palsy, multiple system atrophy, corticobasal degeneration, and normal aging.

Symptoms can be gravitated by contralateral activation or concentration on mental or physical tasks. Each one of these features can be present for a long time, before others develop. Symptoms usually begin unilaterally or asymmetrically. Later they are bilateral or generalized.

Gait is impaired in patients with Parkinson's disease as well. The patients walk slowly with small shuffling steps. Parkinsonian patients move in a rigid manner and turn en bloc. Their posture is stooped, because of flexion of the shoulders, neck, and trunk. In Parkinson's disease the center of gravity is shifted forward. Walking can be hampered by stutter steps, resulting in start and turn hesitation, and sudden ''freezing.'' This phenomenon refers to the patient's feet stuck to the ground while walking, rendering the patient unable to move with the lower body. It especially happens on turns and in elevators or doorways. Freezing and related phenomena are called motor blocks. It occurs in 32% of parkinsonian patients (Giladi *et al*., 1992). Retropulsion refers to the phenomenon that the standing patient, if pushed backward, is able to regain his balance slowly by small and slow steps or even fails to do so and falls. When walking, patients may have problems stopping and legs are preceded by the flexed trunk, resulting in frequent little short steps or propulsive gait. This pattern is characteristic of advanced Parkinson's disease. In the beginning of the disease symptoms are unilateral, affecting only one side. Patients appear to drag a leg when walking and arm swing is decreased at the affected side. In a later stage, when the opposite side is affected as well, steps are short and the feet barely clear the floor. Usually symptoms stay asymmetrical, in contrast to normal aging. At later stages parkinsonian patients may experience problems of autonomic dysfunction such as constipation, incontinence, hypotension, and impotence. If this occurs in an early stage of Parkinson's disease, the diagnosis should be questioned (Gelb *et al*., 1999).

Not only motor symptoms in PD occur. An olfactory disorder is sometimes also present and manifested as an increase of the olfactory detection threshold (Potagas *et al*., 1998), which is probably due to the presence of Lewy bodies in the olfactory bulb and neuronal loss in the anterior olfactory nucleus (Daniel and Hawkes, 1992; Pearce *et al*., 1995). Other features include increased saliva production and increased sweating.

None of the three major symptoms has enough sensitivity or specificity to diagnose Parkinson's disease. For this reason a scheme has been developed for diagnostic classification: The UK Parkinson's Disease Society Brain Bank clinical diagnostic criteria (see list below; Daniel and Lees, 1993).

Step 1: Diagnosis of parkinsonian syndrome:
- Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions)
- At least one of the following:
  - 4- to 6-Hz rest tremor
  - Rigidity
  - Postural instability not caused by primary visual, vestibular, cerebellar, or proprioceptive dysfunction

Step 2: Exclusion criteria for Parkinson's disease:
- History of repeated strokes with stepwise progression of parkinsonian features
- History of repeated head injury
- History of definite encephalitis
- Oculogyric crises
- Neuroleptic treatment at onset of symptoms
- More than one affected relative
- Sustained remission
- strictly unilateral features after 3 years
- Supranuclear gaze palsy
- Cerebellar signs
- Early severe autonomic involvement
- Early severe dementia with disturbances of memory, language, and praxis
- Babinski sign
- Presence of cerebral tumor or communicating hydrocephalus on CT scan
- Negative response to large doses of levodopa (if malabsorption is excluded)
- MPTP exposure

Step 3: Supportive prospective positive criteria for Parkinson's disease (three or more required for diagnosis of definite Parkinson's disease):
- Unilateral onset
- Rest tremor present
- Progressive disorder
- Persistent asymmetry affecting side of onset most
- Excellent response (70–100%) to levodopa
- Severe levodopa-induced chorea
- Levodopa response for 5 years or more
- Clinical course of 10 years or more

B. Nonmotor Symptoms

Several other nonmotor clinical features occur in Parkinson's disease, such as dementia, depression, and psychotic features. In 20 to 40% of patients with Parkinson's disease, cognitive impairment develops and the risk of dementia in nondemented Parkinson's disease patients is almost twice that of age-matched nondemented elderly controls. Prevalence of dementia in Parkinson's disease is estimated to be 10.9% (Mayeux *et al*., 1988). Parkinson's disease patients with dementia have a shorter life expectancy. Dementia in Parkinson's disease is characterized by a severe dysexecutive syndrome without instrumental disorders like aphasia, apraxia, or agnosia. In several studies, the influence of age at onset on the presentation and course of Parkinson's disease has

been demonstrated. Young onset patients have little cognitive impairment even after a disease duration of over 20 years (Quinn *et al*., 1987). Dementia mainly develops in patients with late onset, after 70 years. In this cohort of patients, the prevalence of dementia is more than twice that of younger patients (Mayeux *et al*., 1988). Usually it develops after several years of disease progression. This in contrast to diffuse Lewy body disease, where cognitive deficits occur very early (less than 2 years) or even precede motor symptoms (Dubois and Pillon, 1999). Other risk factors for developing dementia in Parkinson's disease are lack of education and severe motor deficits (UPDRS motor scores above 24) (Marder *et al*., 1990). Cognitive deficits, however, are usually less prominent than motor symptoms.

Depression is estimated to occur in 30–60% of patients with Parkinson's disease at some point during the disease. It has been suggested that there is a natural tendency for chronic, disabling diseases to induce depression. However, it appears that the prevalence of depression in patients with Parkinson's disease is higher than in other chronic disorders. In addition, the depression is unrelated to the severity of motor symptoms and depression can continue despite improvement in motor symptoms after L-dopa therapy. It is possible that depression precedes the motor symptoms of Parkinson's disease. There are some similarities between clinical and biochemical changes in Parkinson's disease and depression. Clinical similarities include akinesia and psychomotor retardation, while biochemical similarities include dysfunction of the dopaminergic, noradrenergic and serotonergic systems. Reduced serotonergic function is associated with psychomotor retardation, reduced noradrenergic function with bradyphrenia and reduced dopaminergic function with extrapyramidal symptoms, cognitive slowing, and more severe symptoms of depression (Leonard, 1999).

Psychotic symptoms may either be a manifestation of the disease itself, or it may be the result of therapy with dopaminergic agents (Douglas *et al*., 1999). Psychosis may also occur as a reaction to the disease and functional impairment (''reactive psychosis''), although this is probably a rare condition. About 30% of parkinsonian patients, treated with levodopa, have experienced psychotic symptoms and the lifetime prevalence may approach 50%. Visual hallucinations are most common and the images are usually full formed human or animal figures. Usually insight is preserved (Aarsland and Larsen, 1999).

III. Pathologic Findings

The most prominent lesion in Parkinson's disease is the degeneration of neuromelanin-containing neurons in the pars compacta of the substantia nigra, which at postmortem inspection is visibly pale. Also selected monoaminergic brain-stem nuclei (catecholaminergic and serotoninergic), the cholinergic nucleus basalis of Meynert, hypothalamic neurons, small cortical neurons (particularly in the cingulate gyrus and entorhinal cortex), olfactory bulb, sympathetic ganglia, and parasympathetic neurons may be involved in the progressive degenerative process of Parkinson's disease.

Not all dopaminergic neurons are equally susceptible. Within the substantia nigra pars compacta, neuronal loss appears to be most severe in the ventrolateral part, followed by the medial part and the dorsal part (Fearnley and Lees, 1991; Damier *et al*., 1999). It results in a regional loss of striatal dopamine (Lang and Lozano, 1998). The nigrostriatal dopaminergic neurons which project to the putamen are more affected than those which project to the caudate nucleus and nucleus accumbens and whose dysfunction is believed to be responsible for akinesia and rigidity. This pattern of cell loss seems to be unique to Parkinson's disease and is different of the pattern seen in normal aging. Neuronal loss of the medial nigral cells, with enhanced involvement of projections to the caudate nucleus, could result in more cognitive symptoms. Another possible clinicopathological correlation may be based on degenerative changes of the olfactory bulb, causing anosmia. Autonomic dysfunction may be the result of lesions in the sympathetic and parasympathetic ganglia or degeneration in the intermediolateral columns of the spinal cord (Rajput and Rozdilsky, 1976). Some believe that dementia in Parkinson's disease may be the result of cell loss in the nucleus basalis of Meynert (Rogers *et al*., 1985).

The surviving, but dying, catecholaminergic neurons may contain Lewy bodies, an important pathological feature. Lewy bodies are spherical, eosinophilic cytoplasmic inclusions with a dense core and peripheral halo, found in pigmented cells. In Parkinson's disease the most important anatomical sites where these bodies are located are the substantia nigra and locus coeruleus. They are not specific to Parkinson's disease. They are also present in other neurodegenerative disorders, in particular in Alzheimer's disease (AD). AD, however, is associated with cortical Lewy bodies, particularly in frontal, temporal, anterior cingulate, and insular regions, whereas Parkinson's disease is associated with subcortical Lewy bodies, mainly in the substantia nigra. Lewy bodies are also seen as an incidental finding in about 10% of people older than 60 years. Gibb and Lees discovered that the age-specific prevalence of Lewy bodies in the brains of persons without clinical Parkinson's disease increased from 3.8 to 12.8% between the sixth and ninth decade of life. It has been suggested that the presence of incidental Lewy bodies actually constitutes a presymptomatic stage of Parkinson's disease (Gibb and Lees, 1988a). McKeith, (1999) however, suggests a relationship between this ''incidental'' pathology and dementia with Lewy bodies.

The mechanisms of cell death in Parkinson's disease are still unknown. Several factors have been mentioned to play a role in neuronal degeneration in Parkinson's disease, such as mitochondrial dysfunction, oxidative stress and excitotoxity, and free radical production. It is believed that the neuronal death in the pars compacta of the substantia nigra in apoptotic (Burke, 1998; Burke and Kholodilov, 1998), but this is not universally accepted and necrosis has been suggested as well.

A. Number of Melanized Neurons in Substantia Nigra Pars Compacta

As described above, incidence and prevalence is highest among Caucasian people. The prevalence of Parkinson's disease probably is lowest in India, according to the results of several

studies. Prevalence ranges from 14 (Razdan *et al*., 1994) to 27 (Gourie-Devi *et al*., 1996) per 100,000 persons, whereas the prevalence in Western countries usually is above 100 per 100,000. The question arises which factors could play a role in the pathogenesis of Parkinson's disease. The pathological diagnosis of Parkinson's disease is based on the demonstration of loss melanized dopaminergic neurons in the pars compacta of the substantia nigra. In studies performed on Western populations, the amount of melanized neurons decreases with advancing age and losses of 30% (McGeer *et al*., 1977) and 48% (Fearnley and Lees, 1991) have been reported. These findings supported the role of age in the pathogenesis of Parkinson's disease. However, Muthane *et al*., (1998) found in normal Indian brains, in comparison with age-matched brain from Western populations, a significantly lower number of melanized nigral neurons, with differences up to 40%. Moreover, with advancing age, there was no significant loss of melanized neurons in the pars compacta of the substantia nigra. This finding is supported by a few studies of Caucasian people, which found no increased loss of melanized neurons with advancing age (Pakkenberg *et al*., 1991). However, in India, as elsewhere in the world, the prevalence of Parkinson's disease raises with increasing age. So probably age by itself may not be the factor responsible for the loss of nigral neurons in Parkinson's disease. Perhaps protective factors responsible for slowing or stopping Parkinson's disease are less sufficient with advancing age, thereby resulting in an increase in the prevalence among elderly individuals (Muthane *et al*., 1998).

IV. Other Movement Disorders in Elderly Patients

Aging is the only unequivocal risk factor for Parkinson's disease (Tanner and Goldman, 1996). It is also a major risk factor for several other movement disorders and neurodegenerative diseases. There are several causes of movement or gait disorders in the elderly, of which some can be easily mistaken for Parkinson's disease. The many characteristics and patterns of gait disorders may appear difficult to evaluate and require special expertise, but simple observation of the patients and their gait yield valuable information. The patient history may reveal stepwise progression, suggesting vascular disease. Pain with walking usually excludes a neurological cause of the gait disorder. Magnetic resonance imaging (MRI) may be used for screening for hydrocephalus or multiple infarcts. Positron emission tomography (PET) scans of the brain may help for diagnosing Parkinson's disease, multiple system atrophy and progressive nuclear palsy. Gait disorders in the elderly, irrespective their underlying pathology, contribute to the risk of falling and fractures (Tinetti *et al*., 1986). The higher risk of falling limits elders in their mobility and independence, also because of the fear of falling itself. Imms and Edholm surveyed in 1981 a group of older people (mean age, 78 years) and found that half of them reduced their activity because of their concerns about falling.

Many signs of gait disorders, slowing down and stiffening, are accepted as being part of aging. However, most of these signs may signal an underlying disease. Critchley (1931) warned that "an abnormal gait in the aged is frequently the result of disease outside the nervous system." In many cases gait disorders are of orthopedic (osteoarthrosis, osteomalacia, unsuspected fractures), endocrinological (hypothyroidism), psychological (depressive state, fear of falling), or general (general muscle weakness) origin (Cunha, 1998). Circulatory or respiratory systems may play a role as well in determining gait velocity because of the need to minimize energy expenditure (Elble, 1997). The incidence of subtle extrapyramidal signs on neurological examination of elderly persons with no known neurologic or psychiatric disorder is high. Bennett *et al*. (1996) showed that 35% of people over 65 years old had these subtle changes, while around 3% in similarly aged persons had Parkinson's disease. In a community study in North Carolina, 15% of adults over 60 years of age had some degree of difficulty with ambulation (Newman *et al*., 1960). In Western Europe 20–25% of people ages 80 or older, use mechanical aids for walking (Lundgren-Lindquist *et al*., 1983). A review of the variety of conditions, which can cause gait disorders or may be confused with Parkinson's disease, will be given here.

A. Essential Tremor

One of the most common causes of misdiagnosis of Parkinson's disease is essential tremor also known as senile tremor, which is a misnomer. It is inherited as an autosomal dominant disorder with incomplete penetrance. A familiar incidence is common in about one-third to one-half of cases. In the elderly, however, it is often sporadic (Gilmore, 1984). The incidence of essential tremor increases with climbing age. Considering prevalence, the Rautakorpi's *et al*. study (1982) reported a prevalence of 12.5% in his population. In a study of a population ages 65 and older, Louis *et al*. (1995) found a prevalence of 4%. A higher prevalence of 23% in a population of people older than 70 years has been observed by Elble (1998).

Essential tremor is an action with a frequency of 8 to 12 Hz (the resting tremor in Parkinson's disease is 4 to 6 Hz). It may sometimes be present at rest as well, but generally increases with activity. The amplitude increases with age. According to Marttila and Rinne (1976), essential tremor accounted for 26% of cases of presumed Parkinson's disease. This misdiagnosing can occur because of many reasons. Both conditions frequently occur in the elderly. Parkinsonian patients sometimes suffer from a postural action tremor of the hands, as seen in essential tremor. Patients with essential tremor may have some bradykinesia and rigidity, which could be normal in the elderly. Furthermore, some hallmarks of Parkinson's disease, such as asymmetric manifestation and a resting component of the tremor, can also be found in cases of essential tremor (Tolosa and Balaguer, 1989). There are, however, some striking differences between these two disorders. Essential tremor frequently involves the head in contrast to tremor in Parkinson's disease. Conversely, a resting tremor of the leg or slow vertical jaw tremor is often seen in Parkinson's disease but rarely in essential tremor. Secondary cogwheeling may be present in essential tremor, but no lead pipe rigidity and no akinesia are seen as in Parkinson's disease.

B. Vascular Parkinsonism

Vascular parkinsonism results from multiple small cerebral infarcts, located predominantly in the basal ganglia secondary

to hypertensive cerebrovascular disease. Some patients with vascular parkinsonism present with a progressive gait disorder without a medical history of strokes (Sudarsky, 1997). Chronic hypertension leads to fibrinoid necrosis and occlusion of arterioles supplying the basal ganglia. An akinetic rigid syndrome with urinary incontinence, dysarthria, abulia, and dementia may occur. The extrapyramidal signs may coexist without pyramidal dysfunction, including weakness, hyperreflexia, spasticity, pseudobulbar palsy, emotional lability, and Babinski's signs. These pyramidal signs may be important in differentiating this disorder from Parkinson's disease. The patient is slow and walks wide-based (unlike in Parkinson's disease) with short, shuffling, somewhat irregular footsteps. Postural stability may be impaired. As in Parkinson's disease, freezing and start hesitation may occur.

However, the upper body may show little or no parkinsonian features; thus facial hypomimia may occur. (Another term used for this disorder is lower body parkinsonism.) Another striking difference with Parkinson's disease is usually the absence of tremor and no fatigue or decrement of rapid alternating movements. In vascular parkinsonism symptoms are symmetric and contrast to Parkinson's disease. Parkinsonian patients usually are younger than those with vascular parkinsonism. However, if signs and symptoms are not clear-cut, the differential diagnosis may be difficult.

Computerized tomography shows multiple infarcts but sometimes misses small ones. Magnetic resonance imaging demonstrates infarctions in the deep gray matter structures and ischemic changes in periventricular white matter. According to Sudarsky, vascular parkinsonism accounts for 15–16% of the gait disorders among elderly patients (Sudarsky and Ronthal, 1983; Sudarsky, 1997).

C. Multiple System Atrophy

Multiple system atrophy refers to a sporadic, gradually progressive, idiopathic neurodegenerative process of adult onset characterized by varying proportions of cerebellar dysfunction, autonomic failure, pyramidal signs and parkinsonism, that is poorly responsive to L-dopa therapy. Cell loss and gliosis (without Lewy bodies) are not only present in substantia nigra, but also in multiple other structures, including striatum, olives, pons, cerebellum, intermediolateral cell columns and Onuf's nucleus in the spinal cord. Most commonly, multiple system atrophy begins early in the sixth decade of life, progresses more rapidly than Parkinson's disease, and has a lower life expectancy (median survival = 9.3 years). No case of multiple system atrophy has been reported before the age of 30.

Parkinsonism occurs in 90% of patients with multiple system atrophy and is the dominant motor disorder in 80% of these patients. In contrast to Parkinson's disease, the parkinsonism in multiple system atrophy is usually bilateral. Unlike Parkinson's disease, tremor is often not the classical rest tremor, but a postural or action tremor. Cerebellar dysfunction and pyramidal signs both occur in about half of patients (Quinn, 1989; Wenning *et al*., 1994). Cerebellar dysfunction as the dominant symptom occurs in about 20% of patients (Quinn, 1995). Autonomic failure appears in almost all patients with multiple system atrophy. In Parkinson's disease patients it may occur as well, mostly in a late stage of disease, whereas in multiple system atrophy it usually occurs earlier and more severely (Magalhaes *et al*., 1995). Indeed, in multiple system atrophy autonomic failure may precede the motor symptoms by months or even years. Frequently, the first symptom is impotence in men and incontinence in both men and women (Parkinson's disease usually causes just frequency increase and urgency due to hyperreflexia of the detrusor muscle). Postural hypotension is another common feature in multiple system atrophy, which may appear in Parkinson's disease as well, though less severely. Inspiratory stridor is present in about 30% of patients with multiple system atrophy. When combined with parkinsonism it is highly suggestive of the diagnosis of multiple system atrophy (Quinn, 1995). Other signs of autonomic failure are thermoregulation disturbances, gastro-intestinal problems and phenomena of Raynaud.

The response to levodopa of patients with multiple system atrophy is usually absent or poor. However, in about 30% of patients an initial response has been reported, usually temporary. Levodopa induced dyskinesias are usually absent in multiple system atrophy, so high doses of levodopa can be administered. Differentiating multiple system atrophy from Parkinson's disease may be very difficult, especially in early stages of disease. Some key features suggest nonidiopathic parkinsonism including: poor or no respons to levodopa therapy; cerebellar, pyramidal, or autonomic signs; symmetric start of symptoms; absence of classic resting tremor; early instability or falls; and rapid clinical progression.

Additional diagnostic tests may include external urethral (or anal) sphincter EMG, standard tests of cardiovascular autonomic function, and imaging of the brain. Computed tomography or magnetic resonance imaging sometimes shows cerebellar or brain-stem atrophy. Fluorodeoxyglucose positron emission tomography (PET) scanning may be useful as well.

D. Progressive Supranuclear Palsy

Progressive supranuclear palsy, or Steele-Richardson-Olszewski syndrome, is an idiopathic degenerative disease, not uncommon in the elderly, which mimics Parkinson's disease. It occurs at a rate of 0.3 per 100,000 per year (Golbe, 1993) and its prevalence is 1.46 per 100,000. Pathologic investigation shows cell loss and neurofibrillary tangles, mainly in the brain stem, globus pallidus, subthalamic nucleus, and dentates nucleus. The clinical presentation includes the tetrad of supranuclear gaze paralysis, axial rigidity, dementia, and pseudobulbar palsy. It is associated with bradykinesia, severe postural disorder and frequent falls. Supranuclear gaze paralysis affects vertical more than horizontal gaze. Voluntary downward gaze is slow and usually incomplete, but when the oculocephalic reflex is performed, full downward gaze is obtained. Pseudobulbar palsy is characterized by dysphagia and dysarthria. Dementia is progressive and consists of slowing of cognition, memory deficits, and personality changes suggestive of frontal lobe dysfunction (Litvan *et al*., 1996). Progressive nuclear palsy may be distinguished from Parkinson's disease by the absence of rest tremor, the extended neck posture, rigidity more truncal than in limbs, and abnormal eye movements. Progressive nuclear palsy patients have a stiff, broad-based gait with ataxia. In contrast to Parkinson's disease patients, they do

not turn en bloc, but pivot. During pivoting they also tend to fall backward.

E. Corticobasal Degeneration

Corticobasal degeneration presents with a unique pattern of progressive impairment. It appears in mid to late adult life, usually beginning after age 60. The duration of the illness until death is about 6 to 8 years. Pathologic and histologic evaluation reveal frontoparietal atrophy and neuronal loss, gliosis, and swelling of the cell body with resistance to staining methods (achromasia) (Kompoliti *et al*., 1998). Prototypic findings are combined parkinsonian signs, other movement disorder, and higher cortical dysfunction, with marked asymmetry of involvement. The most common extrapyramidal sign is rigidity, followed by bradykinesia. Sometimes tremor is also present but does not resemble the parkinsonian tremor. Tremor in corticobasal degeneration is more rapid (6–8 Hz), is mainly present during action, and varies in amplitude. Other movement disorders include myoclonus and dystonia. Higher cortical dysfunction includes dyspraxia, involving the limbs and ocular and orofacial muscles, cortical sensory loss, dementia (which usually occurs late in the disease), and aphasia. A striking feature of corticobasal degeneration is the ''alien hand/limb'' phenomenon (Stacy and Jankovic, 1992).

F. Normal-Pressure Hydrocephalus

Normal-pressure hydrocephalus is often idiopathic, but has also been associated with many neurological diseases. The classic triad of symptoms includes frontal dementia, urinary incontinence, and gait disorder with unsteadiness. It is associated with enlargement of the cerebral ventricles on CT or MRI and a cerebrospinal fluid pressure of 180 mm H_2O or less. A dynamic test is necessary to confirm the diagnosis of true (opposed to *ex vacuo*) hydrocephalus (Borgesen and Gjerris, 1982). The removal and 50 ml of cerebrospinal fluid may improve the symptoms of gait disorder (Sudarsky and Simon, 1987). Mental dysfunction improves less than gait after a shunt. The patient walks wide-based with small steps, feet ''glued to the floor,'' marked imbalance, and difficulty initiating walking. Postural instability with frequent falling may occur. Clinical signs may include hyperreflexia, extensor plantar responses and extrapyramidal signs, including hypokinesia and freezing during walking. Diagnosing normal-pressure hydrocephalus may be difficult since the three cardinal symptoms are common in the elderly. Moreover, gait disorder may precede other symptoms for several years and can be the only symptom for a long period. Normal-pressure hydrocephalus is a common cause of gait disorders in the elderly, while in dementia it accounts for only 0–5% of persons with dementia (Fisher, 1982). It should account for 4–6.7% of the gait disorders in the elderly (Sudarsky and Ronthal, 1983; and Sudarsky, 1997).

G. Metabolic and Endocrine Disorders

Some of these disorders may produce akinetic–rigid syndromes. Hypothyroidism may cause parkinsonism with motor slowing. Hypoparathyroidism, resulting in calcifications of the basal ganglia, may produce a clinical syndrome consisting of parkinsonism, chorea, cerebellar dysfunction or a mixed extrapyramidal–pyramidal syndrome, resembling the lacunar state (Kovacs *et al*., 1993). Metabolic and toxic disorders causes gait disorders in 2.5% of the elderly (Sudarsky and Ronthal, 1983; Sudarsky, 1997).

H. Drug-Induced Parkinsonism

Many drugs commonly prescribed in the geriatric practice can affect gait. It can be caused by drugs that deplete presynaptic dopamine stores (such as reserpine or tetrabenazine); neuroleptic drugs, such as phenothiazines (chlorpromazine), butyrophenones (haloperidol), thioxanthines (flupenthixol), and substituted benzamides (sulpiride); tricyclic antidepressants; prochlorperazine, used for motion sickness, vertigo, or unsteadiness; metoclopramide for gastrointestinal symptoms or migraine; the atypical calcium-blocking drug cinnarizine and flunarizine for vestibular disorders or hypertension; and benzodiazepines, chronic intoxication characterized by disorientation, sedation, or agitation and a progressive deterioration of gait.

Drug-induced parkinsonism results in bradykinesia and rigidity with facial amimia, dysarthria, and diminished or disappearing arm swing. Tremor is less common, but can be identical to the classic resting tremor of Parkinson's disease. Moreover, symptoms of drug-induced parkinsonism usually are asymmetrical, as in Parkinson's disease. Drug-induced parkinsonism often resolves quickly within weeks after stopping medication, although it may take months, especially if depot neuroleptic medications were used.

I. Senile Gait

Senile gait is defined as a gait abnormality of unknown etiology occurring in individuals older than 60 years (Koller *et al*., 1983). The clinical presentation is variable and not precisely defined, but can best be described as the gradual appearance of a broad-based gait with small steps associated with diminished arm swing, stooped posture, flexion of the hips and knees, uncertainty and stiffness in turning, occasional difficulty initiating steps, or a tendency toward falling (Critchley, 1948). They have difficulty in initiating walk, often shuffle, and their feet seem to be stuck to the floor. According to Sudarski and Ronthal (1983), this accounts for 16% of undiagnosed gait disorders in the elderly. Bloem *et al*. (1997) found a comparable percentage of 10% in a population of people over age 85. The underlying cause of this disorder remains unclear. Clinical and laboratory examinations fail to reveal any cause of this gait disturbance and some investigators state that it is a consequence of normal aging. Some believe that it is unlikely that these symptoms represent a true clinical entity (Elble *et al*., 1992). It is unclear whether there are multiple types of senile gait or whether it is a single progressive disease. It could also be a manifestation of extrapyramidal dysfunction (Critchley, 1948), frontal lobe disease (Meyer and Merrow, 1960), cerebellar dysfunction, hydrocephalus, or secondary to sensory abnormalities. It may be difficult to distinguish this type of gait disturbance from gait in Parkinson's disease. Symmetrical

signs, absence of tremor, and poor response to levodopa and the main differences between these entities.

V. Changes in Gait with Normal Aging

It is difficult to define age-associated changes in gait, because most of these changes can be attributed to several diseases commonly seen in elders. Some of the gait disturbances may reflect orthopedic, vascular, circulatory, respiratory, or other problems. However, some age-associated changes in posture and locomotion are nonspecific and mild. A short review of these changes is given below (Elble, 1997). These changes associated with normal aging may be difficult to distinguish from symptoms related to Parkinson's disease.

A. Gait Initiation

Gait initiation is a purposeful, stereotyped sequence of postural shifts that propels the body culminating in a forward step (Elble *et al*., 1994). Normal postural control and the integration of posture and movement are clearly involved. Normal old people initiate gait in nearly the same manner as normal younger people (Elble *et al*., 1994), but the older people generate smaller ankle moments of force during initiation of gait, resulting in a diminished moment of force propelling the body forward, probably due to weaker muscles or a desire to limit forward acceleration, thereby increasing the postural stability. In Parkinson's disease patients have great difficulty with taking the first step (start-hesitation). It occurs in 86% of Parkinson's disease patients. External cueing may be helpful in this condition.

B. Sitting and Standing

When preparing for standing while sitting, knees are flexed to bring the feet closer to the chair, resulting in a shorter distance that the center of mass must move forward. During the transition from sitting to standing and vice versa, there is a moment of postural instability, which may lead to falls (Schultz *et al*., 1992). In older people, reduced of motion in hips, knees, and spine is common. This may impede the shift of the total body center of mass over the feet when standing and over the chair when sitting. Weakness in the hips and knees may reduce moments of force as well, resulting in the necessity to use upper extremities or additional assistance (Elble, 1997). Parkinsonian patients have problems with rising from a chair, because they omit the above-mentioned preparation. They push their body up from the armrests of the seat and sometimes tend to fall back, thus requiring more than one attempt. In later stages they need help to get up from a chair.

C. Walking

Normal gait depends on normal functions of many systems, including neuromuscular, skeletal, circulatory, and respiratory system (Downton, 1993) and the differential diagnosis of gait disorders is extensive (see above). Older people walk more slowly and exhibit a shorter stride. As a result older people have a faster cadence (steps per minute) for a given speed of walking. Average velocity of normal walking is 20% lower than in younger people and average velocity of fast walking is 17% lower in older people (Elble *et al*., 1991). Walking speed declines with increasing age with a small decline of less than 1% per year (Bendall *et al*., 1989). Many older people show an increased toe-floor clearance during the ''swing-phase'' of walking. This may be regarded as a compensation to a greater risk of falling. They spend longer time in stance phases and shorter time in swing phases than young subjects. All these changes result in longer walking cycle duration. No differences in cadence have been noticed between younger and older people. In addition the hip rotation and knee flexion during swing phase is less and the ankle extension at the end of stance phase is less in older people. Postural sway when standing still is increased in the elderly. Also the posture differs from younger people: there is a tendency to stoop, probably because of dorsal kyphosis. Hips, knees, and ankles are in some degree of flexion. Some authors believe that this posture is due to balance difficulties, but there is little agreement about this (Cunha *et al*., 1987). Unlike Parkinson's disease, symptoms are usually bilateral and there is no ''freezing.''

D. Balance

In the control of posture and movement somatosensory, visual and vestibular feedback is necessary. Mild disturbances in any two of these modalities may result in significant functional impairment.

In older people, multiple sensory deficits are common. Pain and thermal sensitivity decrease with age (Prakash and Stern, 1973). Decrements in tactile sensitivity, joint position, stereognosis have been demonstrated with age (Skinner *et al*., 1984). There is a major loss of vibration sensation in the elderly, especially in the feet. About two-thirds of old persons show diminished vibratory function (Prakash and Stern, 1973). This might be due to age-related changes in receptor function, but could also be the result of underlying diseases which mainly affect elderly people, such as arthritic joint disease or diabetes mellitus.

Visual input is important for automatic balance responses, necessary for responses to uneven floors or other hazards. Age-related visual impairment is common and may be caused by several factors, such as presbyopia (due to decreasing accomodation) and cataracts. Other visual changes include macular degeneration and diabetic retinopathy.

Vestibular function is essential for the postural responses. A reduction in the number of vestibular hair cell loss and nerve cells is evident in aging and particularly prominent after age 60 (Richter, 1980). The number of hair cells in aged mice, for example, is about 80% of that in young adult mice (Konrad *et al*., 1999). Age-related changes in hearing function start in young adult life but become significant after age 65. Especially speech and loudness discrimination are affected, usually involving high frequencies.

The central integration of visual with somatosensory and vestibular information is, according to Teasdale *et al*. (1991), slower in older people, who tend to have reduced visual perception of motion, as demonstrated by Gilmore *et al*. (1992). With aging, a certain degree of cell loss occurs in the cerebellum which might contribute to locomotor impair-

ment in the elderly (Coleman and Flood, 1987). Finally, older people are more prone to adverse effects of medications (long-acting benzodiazepines), resulting in impaired balance. It remains unclear whether this is due to actual changes in receptor physiology or to a slower rate of excretion or metabolism. So postural support responses are slowed in older subjects and there is a change in the capacity to integrate sensory information. Patients with Parkinson's disease show postural instability. Usually, this occurs late in the disease, and is a prominent feature of stage III of Hoehn and Yahr. When pulling, retropulsion may occur as well as backward falls. In later stages patients may fall spontaneously. Analysis of compensatory body movements during standing on a moving treadmill indicated that the timing and amplitudes of adjustments were inappropriate in Parkinson's disease patients in comparison to healthy subjects (Dietz *et al*., 1993).

VI. Subclassification of Parkinson's Disease

The variability in expression of the clinical syndrome of Parkinson's disease is considerable and suggests the existence of subtypes with distinct clinical patterns, especially concerning the age of symptom onset, rate of disease progression, and clinical manifestation. This clinical heterogeneity probably reflects a broad spectrum of manifestations of one pathological event: the loss of pigmented neurons in the substantia nigra pars compacta and the presence of Lewy bodies. Several studies have tried to define clinical subgroups on the basis of distinguishing features, including family history of Parkinson's disease, variable progression, and age of onset of symptoms of disease.

A. Young-Onset versus Old-Onset Parkinson's Disease

Friedman has compared clinical expression of patients with onset age of symptoms above 70 years with patients with onset age below 45 years (Friedman, 1994). In this study there were some striking differences between these groups. The DATATOP (depreny1 and tocopherol antioxidative therapy of parkinsonism) study has investigated the variability in clinical expression by comparing several factors, like early versus late onset of disease, benign versus malign status, Hoehn-Yahr stage I versus Hoehn-Yahr stage II and tremor versus postural instability and gait disorder type (Jankovic *et al*., 1990). This study suggests that there are probably two different subtypes of Parkinson's disease: early onset and late onset of disease. Patients with early-onset Parkinson's disease progress at a slower rate, which has been confirmed by others (Goetz *et al*., 1988). These patients are more sensitive to levodopa and to levodopa-induced dyskinesias, and dyskinesias seem to appear earlier in those patients. Not only will they develop focal dystonia early in the course of illness, but also end-of-dose phenomenon is more often observed in patients with early onset of the disease (Quinn *et al*., 1987; Gibb and Lees, 1988b). Similarly, motor fluctuations, such as the wearing-off effect, tend to occur earlier in young-onset patients (Kostic *et al*., 1991). Initial symptom in this group is usually tremor. This is in contrast to Friedman's (1994) results which found that early-onset patients usually start with paresthesia and have bradykinesia as the dominant symptom. They tend to perform better on neuropsychological tests, but this may be explained by their younger age.

Patients with late onset of disease have a more aggressive form of Parkinson's disease with faster progression and more severe motor disability. They have as initial symptoms bradykinesia, postural instability, rigidity, and less often tremor, according to the DATATOP study. This study also suggests that motor deterioration in Parkinson's disease does not necessarily parallel cognitive decline and it is postulated that cognitive impairment in Parkinson's disease results mainly from a deficit correlated to dopaminergic dysfunction. According to Friedman (1994), late-onset patients with Parkinson's disease more often have tremor as both presenting and dominant symptom. Late-onset parkinsonian patients more frequently develop psychotic complications and less frequent dyskinesia as complication of levodopa treatment than young-onset ones. Friedman found a striking difference in symptomatology of psychotic complications. Whereas late-onset patients used to have simple, mostly visual hallucinations with preserved insight, early-onset ones tend to develop paranoid behavior without preserved insight. The number of early-onset patients with psychotic complications, however, was very low in this study. There was no striking difference in overall functioning based on activities of daily living between those two groups. According to Friedman (1994), the lesion in early-onset Parkinson's disease concerns predominantly the dopaminergic system. This monosystemic lesion may explain the greater susceptibility to dyskinesia (and the fact that bradykinesia is the dominant symptom of this disease). Lower susceptibility to dyskinesia in late-onset parkinsonian patients could be the result of age-related decline in the number of dopaminergic receptors in striatum. In contrast late-onset patients are more susceptible to developing psychotic complications, probably due to more widespread lesions of the central nervous system resulting from aging. Older people are in general more likely to develop psychotic reactions to various external stimuli (such as infections, intoxications) (Koponen, *et al*., 1989). Age-related brain atrophy involving also other neurotransmitter systems is probably the reason for the different symptoms in Parkinson's disease between old-onset and early-onset patients (Friedman, 1994). Some studies have observed a higher frequency of a first-degree relative with Parkinson's disease in early-onset patients (Barbeau and Pourcher, 1982; Stern *et al*., 1991), although other studies found no difference in the number of affected relatives among early- and late-onset cases (Quinn *et al*., 1987; Gibb and Lees, 1988b). Others have noted an increased exposure to farming and rural living in patients with early-onset of disease. Despite the differences in clinical manifestation, the cellular morphology and frequency of Lewy bodies in the substantia nigra are identical in early- and late-onset cases (Gibb and Lees, 1988b).

B. Other Subtypes of Parkinson's Disease

The existence of possible subgroups of Parkinson's disease, have also been investigated, including early-onset, tremor dominant, postural instability/gait disorder predominant, benign, and malignant forms. Comparing tremor-dominant to

postural instability/gait disorder-dominant Parkinson's disease revealed more severe motor disability in the postural instability/gait disorder group. Usually, patients with tremor as dominant symptom did not only have more severe tremor at rest, but also more severe action and postural tremor. Postural instability/gait disorder patients had, in addition to their greater postural and gait difficulties, more severe bradykinesia and rigidity (Jankovic *et al*., 1990).

Some authors have divided patients into benign and malignant groups based on duration of symptoms and stage of disease. Patients were arbitrarily considered to have a benign form of Parkinson's disease if they were Hoehn and Yahr stage 2 or less, combined with parkinsonian symptoms for 4 years or less. In contrast, patients with malignant Parkinson's disease were those with early postural imbalance, and disease duration less than 1 year. Patients with a benign form of Parkinson's disease usually were younger at onset of disease and had tremor as dominant symptom. Indeed, benign tremulous parkinsonism is a well-recognized subgroup of patients with a relatively nonprogressive, long-term course of disease. The benign group had an earlier onset than the malignant one and the latter one performed slightly worse on the Mini Mental State Examination, although this difference was not statistically significant after adjusting for age. To distinguish the benign form from the malignant one, other factors may be important as well, like response to medication, genetic factors, and cognitive impairment (Stern and Koller, 1993). A recent study shows that patients with a benign form of Parkinson's disease have mild dyskinesia, if present, and that none of these patients had dementia or hallucinations. All of them are responsive to drugs (Hely *et al*., 1999).

Recently Graham and Sagar (1999) have investigated the heterogeneity in Parkinson's disease using a data-driven approach. They suggested the existence of three distinct subtypes: a motor only subtype, without intellectual impairment; a motor and cognitive subtype; and a rapid progressive subtype.

The latter group is characterized by an older age of disease onset than the other subtypes, rapidly progressive motor and cognitive disability, and more orthostasis. Due to the rapid progression, patients belonging to this subtype have a shorter life expectancy than the other groups. This was confirmed by Louis *et al*. (1997), who found that mortality increases with age the development of dementia, and the severity of motor disability. Gender may be associated with a differential progression of Parkinson's disease. According to the Sydney multicenter study of Parkinson's disease, dyskinesia develops earlier in women during the first 10 years of disease. After 10 years there is no significant difference in the prevalence of dyskinesia, but women tend to have a higher score in Hoehn and Yahr stage (Hely *et al*., 1999).

VII. Brain Metabolism in Aging and Parkinson's Disease

During development and aging, the brain will change anatomically and physiologically to support the behavior of normal adults. Chugani *et al*. (1987) have investigated the maturation of the brain during the first years of life by using positron emission tomography (PET) and 2-deoxy-[^{18}F]-fluoro-D-glucose (FDG). They discovered that in the first 4 weeks of life (the neonatal period), the most important region of metabolic activity is the primary sensorimotor are, and that high activity is also found in the thalamus, brain stem, and cerebellar vermis (see Fig. 47.1). During the second postnatal month a small

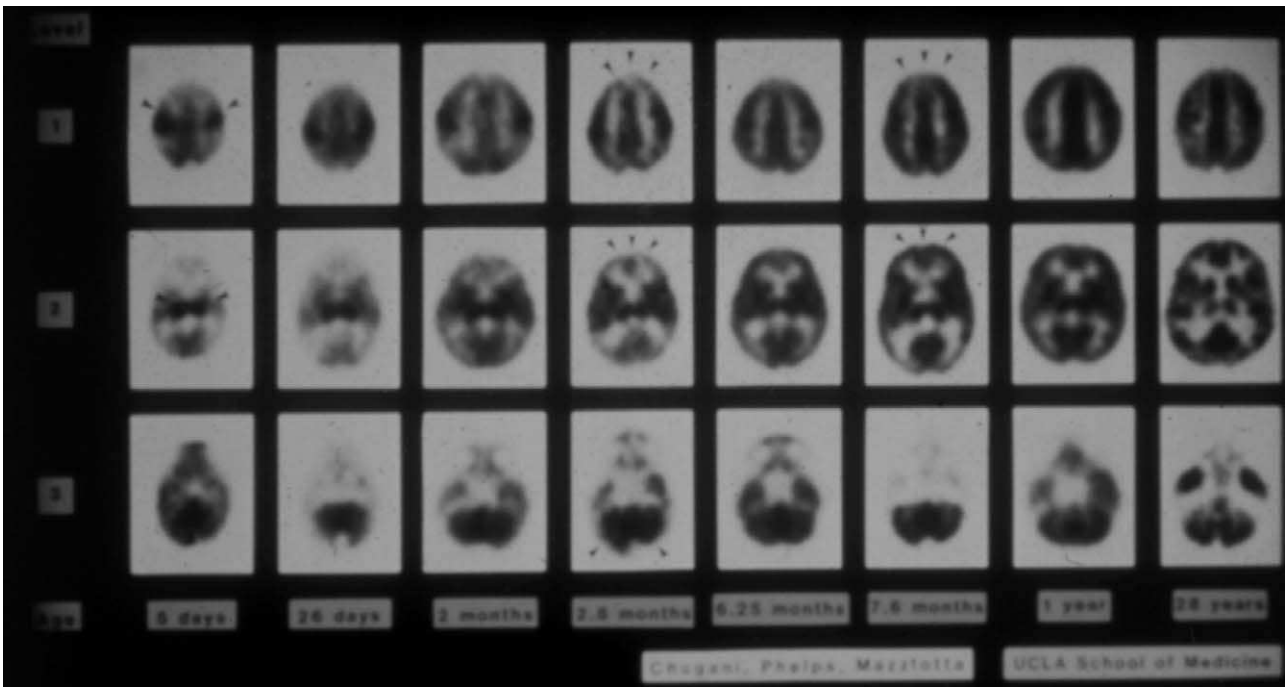

FIG. 47.1. PET study of human brain functional development (Chugani *et al*., 1987).

increase in metabolism in calcarine and temporal cortices can be seen. Approximately 3 months after birth, considerable rises in metabolic activity in the anterior parietal, temporal, and calcarine cortices as well as in basal ganglia and cerebellar cortex are found. By 1 year, the metabolic pattern resembles that in adults, but absolute values are lower than adult ones. Adult rates are reached by 2 years of age. Metabolic rates continue to rise until 3–4 years, so values, exceed those of adults by a factor of approximately 2. These high values are maintained until age 8–9. At this age, they begin to decline and by the end of the second decade adult values are reached. The highest increases in metabolic activity were observed in the cerebral cortices (Chugani *et al*., 1987).

Aging is associated with the degeneration of specific neural systems. Normal aging is predominantly characterized by metabolic changes in the prefrontal cortex. By using FDG-PET scans metabolism of these systems can be investigated. In middle age there is a trend in favor of frontal hypermetabolism. Moeller and co-workers (1996) have tried to explore the metabolic topography of aging and found various topographic profiles. One was characterized by relative frontal hypometabolism associated with convariate metabolic increases in the parietooccipital association areas, basal ganglia, midbrain and cerebellum. Another one revealed relative basal ganglia hypermetabolism associated with covariate decreases in frontal premotor cortex (Moeller *et al*., 1996) (Fig. 47.2, see color insert). In a recent study, Mielke *et al*. (1998) also found a decline of regional cerebral glucose metabolism in frontal areas (Mielke *et al*., 1998).

Although the most important lesion in Parkinson's disease is located in the substantia nigra and its dopaminergic projections, lesions of the presynaptic nigrostriatal dopamine system result in widespread abnormalities in regional brain metabolism. To define the metabolic topography of parkinsonism the same topographic strategy has been used. According to the results of Eidelberg and co-workers (1994) the metabolic profile of Parkinson's disease is characterized by increased activity in the lentiform nucleus, thalamus, pons, and cerebellum, whereas activity is decreased in the lateral frontal, paracentral, and parietal association areas (Fig. 47.3, see color insert). Increase in activity in the lentiform nucleus and thalamus in Parkinson's disease is consistent with experimental animal studies (Palombo *et al*., 1990; Mitchell *et al*., 1992). Increased metabolism in the ventral thalamus has been confirmed by others (Crossman *et al*., 1985; Palombo *et al*., 1990). The subject scores for the metabolic profile in Parkinson's disease correlated with the individual Hoehn and Yahr score and with rigidity and bradykinesia ratings, but not with tremor (Eidelberg *et al*., 1994). The reproducibility of this unique pattern of regional metabolic covariation in patients with Parkinson's disease has recently been assessed by Moeller *et al*. (1999). This topography appears to be highly reproducible across patient populations.

The Basal Ganglia Dopaminergic Systems in Normal Aging and Parkinson's Disease

It has been suggested repeatedly that age-related declines in substantia nigra cell number and striatal dopamine, which have been reported in humans with normal aging, may contribute to Parkinson's disease, although the mechanisms by which this occurs have yet to be identified. Many of the neurodegenerative changes in Parkinson's disease are, however, unlikely to be components of aging per se. In fact, some of the changes may be neuroprotective. For example, the age-related loss of dopamine transporter expression in the substantia nigra may reduce the risk of cell death resulting from toxins that enter dopamine neurons via the transporter. In addition, many compensatory changes in the dopamine system appear unique to Parkinson's disease. The elevation of D_2 receptors and decline of D_3 receptors play unique roles in the clinical manifestations of Parkinson's disease and are not observed in aging. In the larger picture, however, some of the age-related declines in behavior resemble those in Parkinson's disease, occur in other parkinsonian disorders, and may reflect exaggerated forms of aging. For example, the parkinsonian features observed in a consequential proportion of Alzheimer's disease cases may be caused by significant changes in the biochemistry of the presynaptic dopaminergic system and loss of postsynaptic D_2 receptors that are also observed with aging in animals and humans. As the beneficial response to L-dopa is typically absent in Alzheimer's disease cases exhibiting parkinsonism, it would suggest the possibility that changes with aging may contribute to a deteriorated response to L-dopa in these and other parkinsonian disorders.

I. Overview

Parkinson's disease is a neurodegenerative disorder with an insidious onset and a prolonged course over many years. The primary cause of the symptoms of this illness is the neuronal death of dopamine-producing neurons of the substantia nigra (SN) and the resultant depletion of dopamine in the striatum (Hornykiewicz, 1998). The therapeutic intervention for Parkinson's disease is based on the assumption that activation of postsynaptically located dopamine receptors will provide some return of balance to the system. The preferred mode of treatment of the symptoms of this illness is with levo-dopa (L-dopa) which is taken up by surviving dopamine neurons and converted to dopamine, which, in turn, can be stored and released. However, there remain long-term complications of L-dopa therapy, particularly motor fluctuations and dyskinesias, but also significant loss of antiparkinsonian effectiveness in many patients and inability to reverse dementia and depression (Fabbrini *et al*., 1988; Mouradian *et al*., 1988). Most symptoms of Parkinson's disease and experimentally induced parkinsonism are thought to occur as a result of loss of the nigrostriatal dopaminergic innervation. However, it is now evident that more than one dopamine system is affected in Parkinson's disease and that different clinical symptoms are linked to the differential degeneration of these systems. Lesions to the nigrostriatal pathway and its cells of origin in the ventral SN are most closely associated with rigidity and hypokinesia (Rinne, 1991; Vingerhoets *et al*., 1997; Jellinger, 1999). Dementia, which is prevalent in Parkinson's disease (Mayeux *et al*., 1992), is correlated with exaggerated cell loss in the medial nuclei of the SN (Jellinger, 1991; Jellinger and Paulus, 1992; Narabayashi, 1995) or origin of the mesolimbic dopaminergic system (Fig 48.1). Dementia is highly correlated with greater depressive symptomatology, greater motor deficits, and poorer response to antiparkinsonian medication, suggesting common mechanisms or alterations in the dopaminergic system (Mayeux *et al*., 1988; Ebmeier *et al*., 1990; Jellinger and Paulus, 1992; Aarsland *et al*., 1996; Tandberg *et al*., 1996, 1997; Hobson and Meara, 1999).

While the causes of this deterioration in Parkinson's disease are unknown, it has been suggested repeatedly (Carlsson and Winblad, 1976; Calne and Langston, 1983; Cohen, 1983;

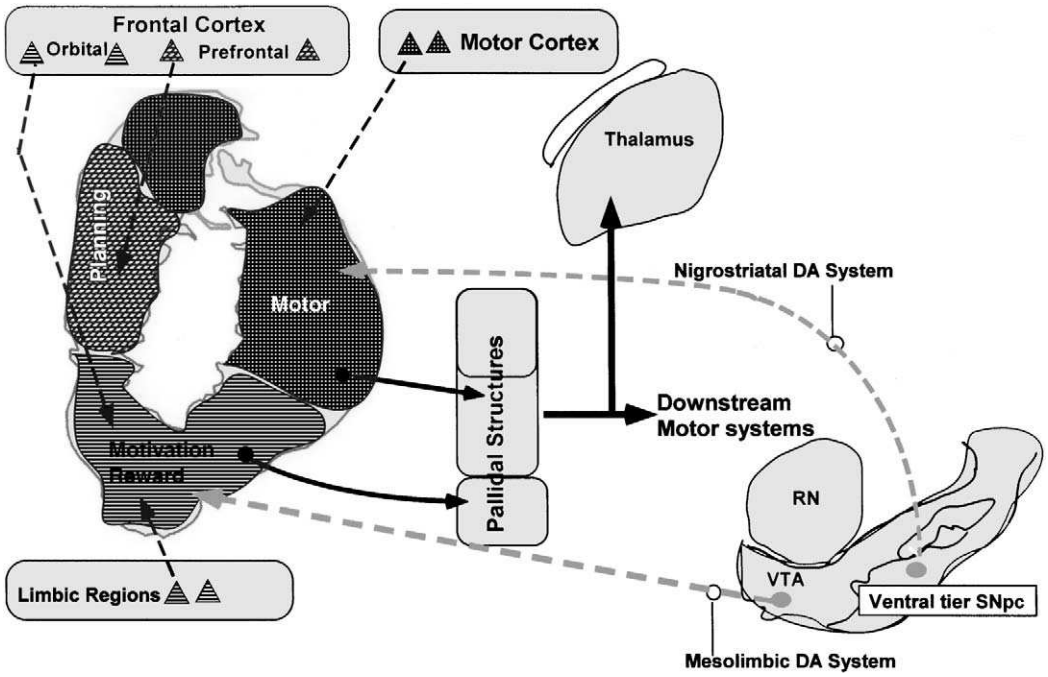

FIG. 48.1. Striatal territories, their cortical projections and innervation by divisions of the dopamine system. The dorsal striatum receives input from motor cortex, associated premotor cortices, and somatosensory cortex, is involved in motor and sensorimotor function and integration, and is innervated by the nigrostriatal dopaminergic system. The ventral striatum receives afferents from the orbital and medial prefrontal cortex and limbic and paralimbic cortices and integrates these signals under the modulatory influence of the mesolimbic dopaminergic system. The ventral striatum and mesolimbic dopaminergic system are involved in goal-directed behavior and changes in affective state.

Mann and Yates, 1983; Calne *et al*., 1986; Calne and Calne, 1988) that age-related declines in SN cell number and striatal dopamine, which have been reported in humans with normal aging (Carlsson and Winblad, 1976; McGeer *et al*., 1977; Fearnley and Lees, 1991), may contribute to Parkinson's disease, although the mechanisms by which this occurs has yet to be determined. Many of the neurodegenerative changes in Parkinson's disease (reduced dopamine terminals; SN cell loss) are, however, unlikely to be components of aging per se (McGeer *et al*., 1977; Gibb and Lees, 1987; German *et al*., 1989; Scherman *et al*., 1989; Fearnley and Lees, 1991). Compensatory changes that occur in Parkinson's disease, such as regulation of dopamine receptor number, also appear quite different from that occurring in aging. However, many aspects of aging, which are common across mammalian species, may contribute to the deterioration in Parkinson's disease. Additionally, parkinsonism may arise from more than one process that is associated with aging. For example, parkinsonism in Alzheimer's disease (AD) can be due to related Parkinson's disease pathology (Leverenz and Sumi, 1986; Ditter and Mirra, 1987; Mölsä *et al*., 1987; Liu *et al*., 1997) or to combination of factors conributing to dysfunction of the dopamine system (Murray *et al*., 1995; Joyce *et al*., 1997, 1998). Hence, an understanding of the relationship between changes in dopaminergic systems with aging and that in various parkinsonian disorders will aid in our understanding of the processes involved in the development of parkinsonian disorders.

II. Organization of the Presynaptic Dopaminergic System and Striatal Territories

It is well accepted that the functions of the striatum are related to its connections with other parts of the brain, particularly with the cortical regions that project to it. Different regions of the cortex provide nonoverlapping projections to the striatum segregated into a number of territories (Alexander *et al*., 1990; Parent and Hazrati, 1995). These territories, in turn, have principal dopamine projections. Two major divisions of the dopaminergic systems exist within the basal ganglia, the nigrostriatal and mesolimbic systems (Fig. 48.1). In the primate the source of the nigrostriatal and mesolimbic dopamine projections reflect a dorsal/ventral differentiation in the SN (Waters *et al*., 1988; Haber and Groenewegen, 1989; Gibb, 1992). Thus, based on the tracer studies, the mesolimbic dopaminergic system of the primate would include the A10 region (ventral tegmental area, parabrachial pigmented, paranigral nuclei) (Jimenez-Castellanos and Graybiel, 1987; Lynd-Balta and Haber, 1994a,b), whereas the origination of the ''nigrostriatal'' dopaminergic system would be more restricted to the ventral tier of the substantia nigra pars compacta SNpc (Szabo, 1980; Tanaka *et al*., 1982; Lynd-Balta and Haber, 1994b). The motor striatum (the dorsal part of the rostral putamen and most of the caudal putamen) receives dopaminergic innervation through the nigrostriatal pathway and topographic projections from the motor cortex, associated premotor cor-

tices (e.g., supplementary motor area, arcuate premotor area) and somatosensory cortex. Motor, premotor, and supplementary motor cortices, and the associated dorsolateral striatum are involved in motor and sensorimotor function and integration. The mesolimbic dopaminergic system innervates the ventral striatum (nucleus accumbens and ventral putamen), or limbic striatum, which is known to receive afferents from the orbital and medial prefrontal cortex, limbic and paralimbic cortices, thalamus, and amygdala (Haber and McFarland, 1999), and integrate these signals under the modulatory influence of the mesolimbic dopaminergic system (Mogenson *et al*., 1988; Lynd-Balta and Haber, 1994b). Association cortical inputs from the dorsolateral prefrontal, temporal, parietal, and cingulate cortices innervate large areas of the caudate nucleus and rostral putamen which receive dopaminergic innervation from both nigrostriatal and mesolimbic dopaminergic pathways. The dorsolateral prefrontal cortex and associated striatal territory is involved in procedural learning and strategic planning (Goldman-Rakic and Selemon, 1986). The limbic striatum has clearly been demonstrated to be involved in goal-directed behavior, locomotor activity, behavioral sensitization, and changes in affective state. The primate striatum (Haber and McFarland, 1999) and human striatum (Reiner *et al*., 1999) exhibit similar neurochemical organization of the striatum and efferent structures, suggesting that there is a similar organization into different territories. This would suggest that in the human striatum dopamine can act to modulate a wide variety of behavioral functions related to motor, cognition, motivation, and affect.

III. Aging and the Presynaptic Dopaminergic System

A. Parkinson's Disease: The Presynaptic Dopaminergic System

The most common methods for determining the extent of damage to the nigrostriatal and mesolimbic dopaminergic systems in Parkinson's disease is through measurement of cell loss in the midbrain dopaminergic neurons (German *et al*., 1989; Fearnley and Lees, 1991; Gibb, 1992), measurement of dopamine transporter levels in the striatum (Murray *et al*., 1995; Miller *et al*., 1997), or measurement of tyrosine hydroxylase (TH) labeling of dopamine terminals in the striatum (Ryoo *et al*., 1998). Parkinson's disease is correlated with specific patterns of cell loss in the substantia nigra, dopamine loss in the striatum, and loss of dopamine transporter binding sites. Cells in the ventrolateral SN, which give rise to the innervation to the dorsal and caudal putamen (Szabo, 1980; Tanaka *et al*., 1982; Lynd-Balta and Haber, 1994a), show the greatest cell loss in Parkinson's disease (German *et al*., 1989; Fearnley and Lees, 1991; Gibb, 1992) and that is correlated with loss of dopamine (Kish *et al*., 1992) and loss of dopamine transporter protein levels in the dorsal and caudal putamen (Chinaglia *et al*., 1992; Murray *et al*., 1995; Miller *et al*., 1997). This has been confirmed with *in vivo* imaging of the dopamine transporter in living Parkinson's disease cases. *In vivo* imaging of dopamine transporter by positron emission tomography (PET) ([^{11}C]WIN 35,428) and single-photon emission computed tomography (SPECT) ([^{123}I]β-CIT) has shown that there is generally a good correlation between symptom severity on the Hoehn and Yahr Staging Scale and Unified Parkinson's Disease Rating Scale (UPDRS) and degree of loss of binding to dopamine transporter (Frost *et al*., 1993; Seibyl *et al*., 1995; Asenbaum *et al*., 1997; Brucke *et al*., 1997; Müller *et al*., 1998; Tissingh *et al*., 1998; Rinne *et al*., 1999). [^{123}I]β-CIT binding shows a significant decrease in comparison to age-expected values ranging from 28 to 36% in Hoehn and Yahr stage 1 to 71 to 76% in Hoehn and Yahr stage V (Seibyl *et al*., 1995; Müller *et al*., 1998; Tissingh *et al*., 1998). Furthermore, the loss of dopamine transporter binding in the caudal putamen is greater than that in the caudate at all stages and those with unilateral symptoms show the greatest losses on the side contralateral to the affected limbs. Thus, the postmortem and *in vivo* findings are in agreement, indicating that, at least initially, the nigrostriatal dopaminergic system is more adversely affected in Parkinson's disease than the mesolimbic dopaminergic system.

Whether aging, per se, can contribute to the cell loss and reduction of dopamine transporter in the Parkinson's disease striatum is unclear. In studies of age-related changes in of the dopaminergic system in human, analyses of Western populations (largely Caucasian) have identified a 20 to 48% decline in melanized neurons between the ages of 20 and 70 years, with a greater emphasis on the smaller decline (McGeer *et al*., 1977; Thiessen *et al*., 1990; Fearnley and Lees, 1991; Tooyama *et al*., 1994). However, postmortem studies of human brain have demonstrated only a small age-related loss of striatal TH after early adolescence (McGeer *et al*., 1977; Wolf *et al*., 1991) and of [^{3}H]α-dihydrotetrabenazine binding to vesicular transporters located on dopamine terminals (Scherman *et al*., 1989). *In vivo* imaging of [^{11}C]dihydrotetrabenazine binding to the vesicular transporter are in agreement with the postmortem findings indicating an age-related loss only in the sixth decade of about 35% as compared to that seen in young adults (Frey *et al*., 1996). This would suggest that dopamine cell and dopamine terminal loss is not that consequential with advancing age in human brain.

Interestingly an analysis of SN in brain material derived from cases obtained in India (Muthane *et al*., 1998) did not observe a decline of melanized nigral neurons with age and, in that study, a much lower density of melanized neurons was observed in the SN as compared to that reported by Fearnley and Lees (1991) for Caucasians living in the United Kingdom. This suggests that a low number of nigral neurons, per se, does not lead to the symptoms of Parkinson's disease as the incidence of Parkinson's disease is lower in that population (Razdan *et al*., 1994) than in the United States or Europe (Pedro-Cuesta and Stawiarz, 1991; de Rijk *et al*., 1997). Fearnley and Lees (1991) also reported that the regions of the SN most susceptible to cell death in Parkinson's disease are the least affected with age. Similarly, age-related decline of dopamine in the striatum does not show regional features similar to that of Parkinson's disease (Kish *et al*., 1992). Thus, age-related SN cell loss per se is unlikely to be contributing to Parkinson's disease. However, as there is an age-related loss of striatal dopamine of a much greater magnitude than the cell loss accounts for (Adolfsson *et al*., 1979; Kish *et al*., 1992), it would suggest that there is decreased synthetic activity of nigral dopaminergic neurons with advanced age in humans that is functionally important.

TABLE 48.1 Presynaptic Dopamine System in Aging and Parkinsonian Disorders

	Striatal DAT	Striatal TH	Striatal DA	SN DAT	SN cell No.
Aging	45% Loss in putamen	↓ 20% In caudate and putamen	↓ 60% In caudate and putamen	↓ 70% In ventrolateral tier	↓ 20 To 30% in all regions
Parkinson's disease[a]	85% Loss in putamen	60% Loss in putamen	90% Loss in putamen	↓ 60% In ventrolateral tier	↓ 60% In ventrolateral tier
Alzheimer's with parkinsonism[a]	80% Loss in putamen	Normal to reduced	↓ 50% In caudate and putamen?	↓ 85% In ventrolateral tier	↓ 26% In ventrolateral tier

[a]All values are in relation to age-matched controls.
DA, dopamine; DAT, dopamine transporter; SN, substantia nigra; TH, tyrosine hydroxylase.

B. Aging and Dopamine Transporter Function

Studies in animals first suggested that decreased function of the presynaptic dopaminergic system could contribute to changes with age (Table 48.1). The overwhelming data indicate that loss of dopaminergic neurons of the SN and striatal dopamine with age is small or nonsignificant in most animal species (Sabel and Stein, 1981; Strong *et al*., 1982; Flood and Coleman, 1988; Marshall and Rosenstein, 1990; Fernandez-Ruiz *et al*., 1992; Friedemann and Gerhardt, 1992; Emerich *et al*., 1993; Irwin *et al*., 1994; Burwell *et al*., 1995). However, synthetic capability may be more affected. For example, Marshall and Rosenstein (1990) demonstrated that DOPA accumulation after NSD-1015 administration was reduced by 40% in aged male F344 rats. In addition, many investigators have found age-related loss in the capacity of dopamine uptake and/or dopamine transporter number in striatum of aged animals (Marshall and Rosenstein, 1990; Shimizu and Prasad, 1991; Friedemann and Gerhardt, 1992; Irwin *et al*., 1994; Gordon *et al*., 1995; Hebert and Gerhardt., 1998, 1999; Hebert *et al*., 1999) and loss of dopamine transporter mRNA in SN (Himi *et al*., 1995). These results suggest that dopamine release and uptake is likely compromised in aged rats (Friedemann and Gerhardt, 1992; Emerich *et al*., 1993; Gordon *et al*., 1995; Hebert and Gerhardt, 1998).

Functionally, this appears important as the age-related reduction in time-related performance and movement velocity are not related to loss of striatal dopamine levels/ nigral cell number (Emerich *et al*., 1993; Zoli *et al*., 1993; Burwell *et al*., 1995) in animal models of aging. These behavioral deficits appear to be more clearly related to reduced capacity of dopaminergic neurons to exhibit evoked release of dopamine (Friedemann and Gerhardt, 1992; Gordon *et al*., 1995; Hebert and Gerhardt, 1998), dopamine transporter levels (Shimizu and Prasad, 1991; Gordon *et al*., 1995; Hebert *et al*., 1999) or dopamine transporter function (Shimizu and Prasad, 1991; Hebert and Gerhardt, 1999), and reduced postsynaptic dopamine D_2 receptor number (De Blasi and Mennini, 1982; Joyce *et al*., 1986a; Lai *et al*., 1987; Han *et al*., 1989; Morelli *et al*., 1990). Thus, aging is not a pre-Parkinson's-disease state but rather may contribute to altered dopamine homeostasis. This has clear implications for other Parkinsonian conditions which may occur as a result of altered dopamine homeostasis and not from loss of dopamine innervation (see section III.C.).

Similar to that in animals age-related losses of striatal dopamine transporter sites and dopamine transporter mRNA in the SN have been identified in human brain (Zelnik *et al*., 1986; de Keyser *et al*., 1990; Bannon *et al*., 1992; van Dyck *et al*., 1995; Bannon and Whitty, 1997; Volkow *et al*., 1998; Ma *et al*., 1999). This suggests some age-related changes in the presynaptic components of the dopamine system are common across species. While PET imaging studies in human brain have suggested that there is a linear loss of striatal dopamine transporter with age (van Dyck *et al*., 1995; Volkow *et al*., 1998), the postmortem studies of dopamine transporter expression in the midbrain dopaminergic neurons indicate that the effect is much more marked after the fourth decade, perhaps after the age of 55 (Bannon *et al*., 1992; Bannon and Whitty, 1997; Ma *et al*., 1999). It is also evident from the postmortem studies that reduction in dopamine transporter expression is not due to some overall biochemical failure of these neurons as mRNA expression for TH is intact. The data, in fact, suggest that these neurons are selectively downregulating expression of dopamine transporter. In addition, there are significant differences in levels of expression of dopamine transporter mRNA among populations of the dopaminergic neurons that give rise to the nigrostriatal, as opposed to that seen in the mesolimbic dopaminergic system, with much higher expression in the ventral tier dopaminergic neurons innervating the dorsal striatum (Hurd *et al*., 1994; Haber *et al*., 1995). Importantly, the age-related loss of dopamine transporter is greatest in the population of cells of the ventral SN that has the highest expression of dopamine transporter in younger adults (Bannon and Whitty, 1997; Ma *et al*., 1999). It would be predicted, therefore, that the nigrostriatal dopaminergic system innervating the territories of the striatum underlying motor function would be functionally more affected than that of the mesolimbic dopamine system. This is meaningful for two reasons. First, the decline in dopamine transporter expression may actually protect those neurons from cell death in Parkinson's disease (Uhl, 1998). Second, there may be similar but far more exaggerated modification in dopamine transporter expression in the nigrostriatal dopamine system in other parkinsonian disorders, reflecting changes in dopamine utilization (Murray *et al*., 1995; Joyce *et al*., 1997).

Based on converging evidence, the formation and/or accumulation of toxic dopamine transporter substrates may be the primary cause of SN degeneration in Parkinson's disease (Hornykiewicz, 1998; Uhl, 1998). A model compound for substantiating this hypothesis is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which is known to produce parkinsonism in humans and in subhuman species via irreversible

damage to the dopaminergic neurons of the SN (Burns *et al*., 1983; Langston *et al*., 1983). The mechanism of the neurotoxic action of MPTP has been postulated to involve three essential steps: (1) crossing by MPTP of the blood–brain barrier, (2) its oxidation to MPP+ (1-methyl-4-phenylpyridinium) occurring largely in glial cells through catalyzation by MAO-B (Ransom *et al*., 1987), and (3) accumulation of MPP+, the toxic agent, in dopaminergic neurons by the high-affinity uptake system for dopamine (dopamine transporter) located on the plasmalemma of these neurons (Pifl *et al*., 1996; Gainetdinov *et al*., 1997). It has been well established that accumulation of MPP+ within dopaminergic neurons via the dopamine transporter is an absolute requirement for its neurotoxicity *in vivo* (Gainetdinov *et al*., 1997; Bézard *et al*., 1999). Inside the neuron, MPP+ is thought to act as a mitochondrial toxin, slowly sapping the neuron of its energy-producing potential and by production of reactive oxygen species (Cassarino and Bennett, 1999). The fact that the reduction of dopamine transporter expression in nigral neurons occurs to the greatest degree in the region most susceptible to cell death in Parkinson's disease suggest that these neurons may become less vulnerable to neurotoxins utilizing dopamine transporter (Bannon and Whitty, 1997; Ma *et al*., 1999). However, several papers have reported increased sensitivity in older C57 mice to neurotoxic effects of MPTP, as measured by initial losses of striatal dopamine levels or striatal dopamine transporter binding (Sershen *et al*., 1985; Ricaurte *et al*., 1987a; Date *et al*., 1990), recovery of striatal dopamine levels or TH-IR fibers with time post-MPTP (Ricaurte *et al*., 1987b; Nishi *et al*., 1989), or extent of cell loss in the SN and ventral tegmental area (VTA) (Gupta *et al*., 1986; Date *et al*.,1990). Importantly, as demonstrated by Irwin and associates (Irwin *et al*., 1992) truly aged mice do show less susceptibility to MPTP. The problem results from inappropriate age comparisons, mature (e.g., 8–12 months) and aged (over 20 months) mice are both likely to show enhanced sensitivity as compared to young (less than 3 months) mice because of development-related changes in the dopaminergic system and/or activity of MAO-B. Irwin and associates demonstrated that 10-, 16-, and 24-month-old mice are more sensitive to MPTP-induced loss of striatal dopamine than 2-month-old mice but 24-month-old mice were actually less sensitive than 10- or 16-month-old mice. Furthermore, the increased sensitivity in 10-, 16-, and 24-month-old mice was mirrored by enhanced activity of striatal MAO-B, but this was slightly reduced in advanced age (see also Rao *et al*., 1995). In contrast, there were no age-related differences in the capability of intraventricular MPP+, the active metabolite of MPTP, to produce striatal dopamine depletion. Hence, the age-related reduction of dopamine transporter in nigral neurons might be protective against the neurotoxicity of compounds that utilize DAT to accumulate inside dopaminergic neurons. Vice versa, it may be that cell death in Parkinson's disease is caused by a failure to downregulate the dopamine transporter (Uhl, 1998).

C. Parkinsonism with Alzheimer's Disease

Parkinsonian features can result from one or more alterations in the nigrostriatal dopaminergic system. Up to 40% of AD patients develop features of Parkinson's disease but because the symptoms of rigidity and bradykinesia predominate, tremor is infrequent and response to L-dopa is minimal it can be clinically differentiated from Parkinson's disease (Chui *et al*., 1985; Mayeux *et al*., 1985; Morris *et al*., 1989). Some studies have identified pathologic alterations similar to those observed in Parkinson's disease, but they occur in only a small percentage of the AD cases with parkinsonian features (Leverenz and Sumi, 1986; Ditter and Mirra, 1987; Mölsä *et al*., 1987; Murray *et al*., 1995; Liu *et al*., 1997). Other evidence suggests a more complex disturbance in the biochemistry of the nigrostriatal dopaminergic system in these patients. PET studies with [^{18}F]fluorodopa uptake show no evidence for marked loss of dopamine terminals in AD cases with parkinsonian signs (Tyrrell *et al*., 1990). Our studies of the neurons of origin of the nigrostriatal dopaminergic system in AD cases with parkinsonian features (AD/Park) indicate that they are not extensively depleted and are capable of synthesizing TH, but are markedly affected in the synthesis of dopamine transporter normally expressed at terminal sites in the striatum (Murray *et al*., 1995; Joyce, *et al*., 1997). Numbers of dopamine transporter binding sites in the striatum are almost as low as that in Parkinson's disease and is correlated with strongly suppressed dopamine transporter mRNA expression in the SN (Fig 48.2). Nonetheless, TH expression in the dopamine terminals and SN appears normal. How this occurs remains unclear but processes associated with AD pathology may lead to accumulation of dopamine transporter protein in the cell body and to downregulation of the dopamine transporter mRNA. Liu and associates (1997) have shown that the numbers of neurofibrillary tangles and neuropil threads are higher in the SNpc of AD/Park than in AD, suggesting that it may be a contributor to cell dysfunction. The presence of neurofibrillary tangles in the dopaminergic neurons might ''trap'' cytoskeletal and noncytoskeletal proteins (e.g., dopamine transporter) that are normally orthogradely transported to neuronal processes (Nakashima and Ikuta, 1985; Tabaton *et al*., 1985; German *et al*., 1987; Mann *et al*., 1987). As in Parkinson's disease with Lewy bodies, these NFTs could induce parallel disturbances in cellular function and processing of proteins so as lead to a feedback regulation of the levels of dopamine transporter mRNA. Thus, presynaptic components of the nigrostriatal dopaminergic system in patients with AD/Park are severely affected but the underlying pathology is distinct from that of Parkinson's disease.

We have hypothesized that these alterations in the presynaptic dopaminergic system in AD/Park directly contribute to the parkinsonian features of AD/Park. We believe that the significantly reduced levels of dopamine transporter would result in very low levels of releasable dopamine and a high dependence on exaggerated synthesis of dopamine to maintain extracellular levels of dopamine. A review of results from the genetic deletion of the dopamine transporter gene in mice demonstrates that lack of dopamine transporter leads to a marked increase in extracellular dopamine but profound changes in pre- and postsynaptic parameters of dopamine homeostasis (Jones *et al*., 1998; Gainetdinov *et al*., 1999). The lack of dopamine transporter leads to 300-fold increase in amount of time needed for dopamine to be cleared *and* a marked ($\sim$75%) reduction in dopamine released in response to electrical stimulation and high K^+ stimulation ($\sim$90%). In fact, the total striatal tissue dopamine levels, reflecting intraneuronal vesicular storage

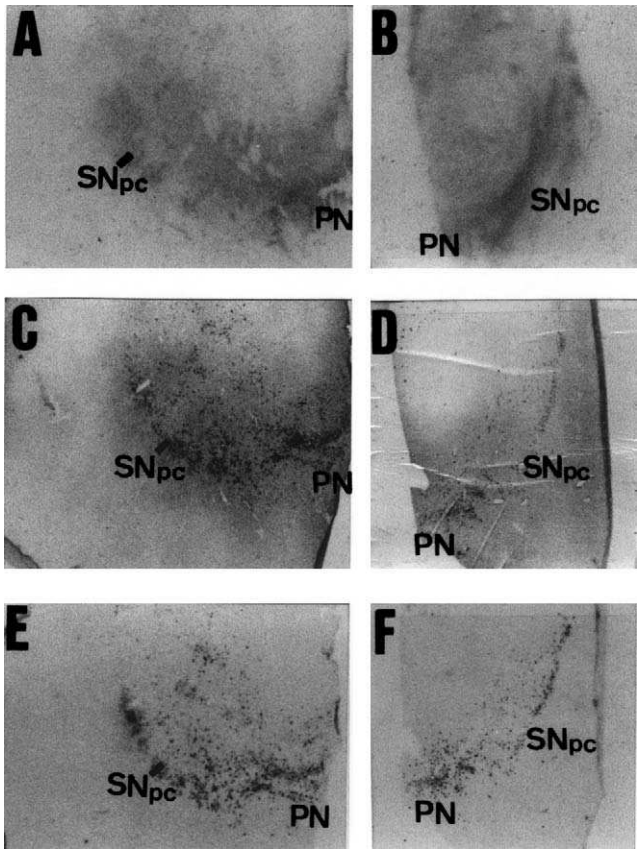

FIG. 48.2. Reduced expression of dopamine transporter mRNA but not TH or TH mRNA in the SN of AD/Park case as compared to age-matched control. Photomicrographs of the original autoradiographs demonstrating the distribution of (A, B) TH protein by immunoautoradiography, (C, D) dopamine transporter mRNA, and (E, F) TH mRNA in the midbrain of a control case (A, C, E) and an AD/Park case (B, D, F) in nearly adjacent sections. Note that the levels of TH-IR and TH mRNA are nearly similar in these cases but DAT mRNA levels are markedly decreased in the AD/Park case (modified from Joyce *et al*., 1997).

pool of dopamine, are drastically reduced (to ~5% of wild type) but dopamine synthesis is elevated by over 200%. In addition, functional studies of D_2 autoreceptor function indicate a marked desensitization to regulation of neuronal firing rate, nerve terminal dopamine release, and synthesis. Thus the maintenance of extracellular dopamine is highly dependent on the ongoing synthesis of dopamine. If dopamine synthesis could not be maintained with increasing age (Marshall and Rosenstein, 1990; Himi *et al*., 1995; Hebert and Gerhardt, 1998), then extracellular dopamine would be significantly decreased along with the loss of releasable dopamine. Thus, a hypoactive dopamine state would exist. At a critical level of hypoactivity a deterioration in function resulting in impairments of time-related performance, movement velocity, and other behavioral changes related to parkinsonism would occur (Marshall and Berrios, 1979; Gallagher and Burwell, 1989; Friedemann and Gerhardt, 1992; Emerich *et al*., 1993; Irwin *et al*., 1994; Burwell *et al*., 1995). We believe that similar conditions prevail in AD/Park and with advancing age a reduction in the capacity to synthesize dopamine by nigral neurons does lead to diminished extracellular dopamine levels. Decreases in postsynaptic D_2 receptor number (Joyce *et al*., 1998), which may result from the sustained extracellular dopamine over a prolonged period of time, would also contribute to diminished response to dopamine (see section V.D). Interestingly, as the mesolimbic dopamine system exhibits much lower native expression of dopamine transporter and dopamine transporter expression is modified to a much lesser degree (e.g., Bannon and Whitty, 1997; Ma *et al*., 1999) but exhibit similarly high levels of TH, age-related changes in dopamine transporter function would be less evident in this dopaminergic system. Thus, an exaggerated hypodopaminergic function would occur in the terminal sites of the nigrostriatal dopaminergic system in AD/Park resulting in parkinsonism that is relatively resistant to relief by L-dopa.

IV. Striatal Circuits and Dopamine Receptors

Five distinct subtypes of G-protein coupled dopamine receptors mediate the actions of dopamine, three of which, D_2, D_3, and D_4, belong to the D_2 subfamily (Civelli *et al*., 1993). These receptor subtypes are differentially expressed in regions of the human brain and, therefore, might mediate different actions of dopamine (Joyce and Meador-Woodruff, 1997). It has been widely studied how dopamine regulates output pathways of the striatum via interaction with different dopamine receptors that are, in turn, differentially expressed in these output pathways (see below). However, to date, all effective dopamine agonists stimulate the D_2 receptor, and changes in expression of this receptor have been hypothesized to underlie the deteriorated response to antiparkinsonian agents in Parkinson's disease. Furthermore, research has almost solely focused on how loss of dopamine regulates expression of D_1 and D_2 receptor mRNAs in the output pathways of the striatum, with little information on other receptor subtypes.

A. D_1 and D_2 Receptors

The functional territories of the striatum have different classes of neurons that give rise to segregated efferents. For the motor striatum (dorsal putamen in human) the striatal-pallidal-thalamo circuitry has been well established. In rat, the caudate-putamen gives rise to two distinct efferent pathways. "Direct" pathway neurons express Substance P (preprotachykinin, mRNA) and project to the entopeduncular nucleus (analogous to the internal segment of the globus pallidus in primates) and substantia nigra pars reticulata (SNr). "Indirect" pathway neurons express enkephalin (preproenkephalin, mRNA) and project to the globus pallidus (external segment in primates) and subthalamic nucleus. The influence of the direct and indirect pathways are considered to be opposing and are thought to function in focusing movements, to increase or decrease the probability of movement, and to scale movement (Levy *et al*., 1997). The neurotransmitter dopamine tonically modulates these two pathways via inhibition of the indirect pathway and excitation of the direct pathway (Fig. 48.3A, see color insert). In the rat neostriatum, "direct," or striatonigral, and "indirect," or striatopallidal, output neu-

rons preferentially express D_1 and D_2 receptors, respectively, with little overlap (Gerfen *et al*., 1990; Curran and Watson, 1995; Le Moine and Bloch, 1995). Loss of dopamine leads to changes in expression levels for D_1 and D_2 receptors, and changes in dopamine-mediated activity of the direct and indirect pathways (Fig. 48.3B, see color insert). It is often assumed that in the primate neostriatum the D_1 and D_2 receptors are similarly segregated. Ontogenetic studies have shown that in the neonatal human neostriatum the D_1 receptor is expressed in neurons expressing substance P but not enkephalin (Brana *et al*., 1996) and the D_2 receptor expression tends to overlap with that of enkephalin. Their findings also demonstrated that, in contrast to what was expected from similar studies in rodents, D_2 receptor mRNA and enkephalin mRNA do not display identical, overlapping expression patterns in striatal neurons during human ontogeny (Brana *et al*., 1997). However, to the best of our knowledge, no comprehensive double-labeling study has been done in the adult primate brain to establish the cellular expression of dopamine receptor mRNAs.

As initially postulated by Heimer and Wilson (1975) it has now been convincingly demonstrated that there are parallel efferent circuits originating from the dorsal and ventral striatum with analogous ''direct'' and ''indirect'' pathways. In the rat, the nucleus accumbens projects primarily to the ventral pallidum and the core of the nucleus accumbens projects to the lateral ventral pallidum which send projections to the subthalamic nucleus and SNr. The shell of the nucleus accumbens project to the medial ventral pallidum, which provides efferent to the mediodorsal thalamus. As cells in the shell coexpress D_1 mRNA and Substance P and the cells in the core preferentially express D_2 mRNA and enkephalin (Curran and Watson, 1995; Lu *et al*., 1998), they are presumed to modulate direct and indirect ventral striato-pallidol-thalamic pathways.

B. D_3 Receptor

The dopamine D_3 receptor has high homology with the D_2 receptor and shares many pharmacological features of the latter including high affinity for D_2 receptor antagonists clinically used in treatment of schizophrenia and D_2 agonists for treatment of Parkinson's disease. In the rodent, the D_3 receptor is generally much less abundant in the brain than the D_2 receptor but the difference is particularly striking in the caudate-putamen. D_3 binding sites and mRNA are densest in the nucleus accumbens the limbic region of the striatum, whereas in the caudate-putamen D_3 binding sites are low and mRNA is barely detectable (Bouthenet *et al*., 1991). The accumbens shell, which is the prime source of the ''direct'' efferents to the medial ventral pallidum contains considerably higher concentrations of D_3 binding sites and D_3 mRNA than the core, which is the opposite for D_2 mRNA and binding sites. Studies have shown that in the rat nucleus accumbens the D_3 receptor mRNA is expressed at higher concentrations in neurons expressing the D_1 dopamine receptor, Substance P, prodynorphin, and/or neurotensin, with little overlap with D_2 mRNA (Curran and Watson, 1995; Ridray *et al*., 1998). However, one comprehensive double-*in situ* hybridization histochemistry study has shown that in the rat nucleus accumbens the D_3 receptor is coexpressed with both D_1 and D_2 receptor in Substance P and enkephalin-expressing neurons, respectively (Le Moine and Bloch, 1996). Nonetheless, the data are strongest that in the rat D_3 receptor is preferentially localized in the direct output neurons to the medial ventral pallidum expressing the D_1 receptor (Curran and Watson, 1995).

This limited distribution of the D_3 receptor suggested that its functions are related to the mesolimbic rather than the nigrostriatal dopamine system (Sokoloff *et al*., 1990). In the human, the highest expression of D_3 receptor is in the ventral striatum (Fig. 48.4, top), but is also enriched in the association areas of the caudate nucleus and putamen (Murray *et al*., 1994; Meador-Woodruff *et al*., 1996; Morissette *et al*., 1998; Gurevich and Joyce, 1999). This indicates a more important role of the D_3 receptor in mediating multiple actions of dopamine. The expected segregation of the D_3 receptor to ventral striatal output neurons that coexpress the D_1 receptor mRNA and preproenkephalin mRNA is less clear for the nonhuman primate and human than the rat. In the monkey very few neurons of the ventral pallidum send projections directly to the thalamus, which indicates that the primate ventral pallidum has characteristics similar to the elements of globus pallidus

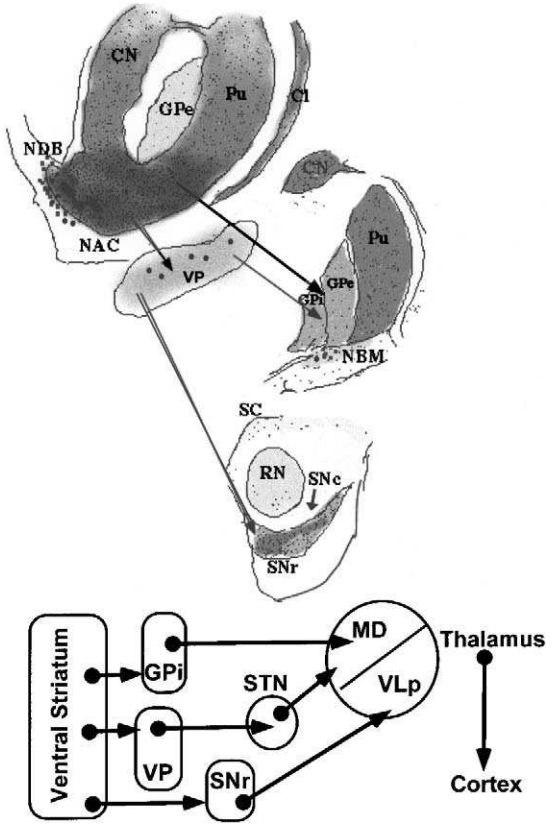

FIG. 48.4. The ventral striatum, D_3 receptors, and the associated circuitry. There are parallel efferent circuits originating from the dorsal and ventral striatum with analogous ''direct'' and ''indirect'' pathways. In the primate, projections from the ventral striatum project to the ventral pallidus which, similar to the GPe, provides projections to the subthalamic nucleus and then the thalamus. Projections from the ventral striatum to the globus pallidus and SNr are, in contrast, directly projecting to the thalamus. The D_3 receptor (gray shading) and D_3 mRNA positive neurons (dots and circles) exhibit higher expression in the ventral striatum than the dorsal striatum and in the regions that receive the projections of the ventral striatum (adapted from Gurevich and Joyce, 1999).

external (GPe) (Haber *et al*., 1993). In addition to the ventral pallidum, the nucleus accumbens also projects to the medial portion of the globus pallidus internal (GPi) and medial portion of the SNr, which do project to thalamus (Fig. 48.4, bottom). This suggests that some neurons of the primate (including the human) nucleus accumbens projecting to the ventral pallidus express enkephalin and that these might coexpress the D_3 receptor and the D_2 receptor. Our studies of the D_3 receptor distribution in the human suggested an overlap in the D_3 and D_2 receptor expression, as D_3 mRNA is expressed in at least 30% of the neurons of the ventral striatum and D_2 mRNA in over 75% of the neurons (Gurevich and Joyce, 1999). Thus, there may be a coexpression of D_3 and D_2 mRNA in a subset of neurons that project to the ventral pallidus as well as in D_1/Substance P neurons. The D_3 receptor-expressing neurons in the human ventral striatum (Fig. 48.4) may give rise not only to the ''direct'' pathway from the ventral striatum to the medial globus pallidus (which innervates anteroventral and mediodorsal nuclei of the thalamus), but also to ''indirect'' projections to the ventral pallidus (which innervates the subthalamic nucleus, substantia nigra pars reticulata and hypothalamus). It seems likely that the D_1/D_3 receptor coexpression and D_2/D_3 receptor coexpression occurs in different projection (neuropeptide expressing) neurons of the ventral striatum. We have hypothesized that in human ventral striatum neurons coexpressing the D_2 and D_3 receptors project to the ventral pallidus (expressing enkephalin) and those coexpressing the D_3 and D_1 receptors ventral pallidus (expressing Substance P) project to the globus pallidus. No studies examining expression of D_1/D_3 or D_2/D_3 receptors with neuropeptide mRNAs have been completed in the human. Expression levels of dopamine receptor mRNAs in these neurons relative to loss of dopamine in Parkinson's disease is also unknown.

V. Dopamine Receptor Contributions to Parkinsonism

A. Dopamine Receptor Changes with Aging

Studies of changes in dopamine receptors in animals have found reductions with age, most consistently for that of the D_2 receptor. In animals the reduction in D_2 receptor number (Severson and Finch, 1980; De Blasi and Mennini, 1982; Joyce *et al*., 1986a; Norman *et al*., 1987; Han *et al*., 1989; Morelli *et al*., 1990) is due to both reduced mRNA levels and synthesis (Norman *et al*., 1987; Han *et al*., 1989; Morelli *et al*., 1990; Della Vedova *et al*., 1992; Weiss *et al*., 1992; Dobie *et al*., 1993; Merchant *et al*., 1993; Mesco *et al*., 1993; Zhang *et al*., 1995). Interestingly, the evident regionally selective effects of the reduction in D_2 receptor number (Joyce *et al*., 1986a; Morelli *et al*., 1990) is not correlated with regionally similar changes in D_2 mRNA levels or enkephalin neurons (colocalized D_2 mRNA) (see Dobie *et al*., 1993; Zoli *et al*., 1993; Zhang *et al*., 1995). This suggests that posttranslational modifications and/or loss of D_2 mRNA-positive neurons may also occur with advanced age (Han *et al*., 1989; Sakata *et al*., 1992; Zhang *et al*., 1995). Reduced D_1 receptor number has also been found in aged rats (Battaglia *et al*., 1988; Han *et al*., 1989; Morelli *et al*., 1990), but other reports are negative (Burwell *et al*., 1995). One study reported reduced D_1 mRNA containing neurons but not mRNA in aging rats (Zhang and Roth, 1997). However, another study has determined that DARP-32 containing neurons (colocalized D_1 mRNA) are not reduced in aged rats but DARP-32 immunoreactive processes were reduced (Zoli *et al*., 1993). Thus, mechanisms underlying the possible reduction in D_1 receptor number are still not conclusive (Table 48.2).

Most studies of the reduction in dopamine receptors with age assumed a linear process and/or utilize a minimal number of time points to establish the age-related decline. Closer examination of scatter plots of data from several studies of striatal tissue, however, suggests a triphasic course of decline (Severson and Finch, 1980; Levin *et al*., 1981; Randall *et al*., 1985; Lai *et al*., 1987). Similarly, in humans it has been assumed that there is a linear process of the age-related decline (Morelli *et al*., 1990; Volkow *et al*., 1998; Wang *et al*., 1998) and this is often utilized to correct for comparisons between neurodegenerative processes and age-matched controls for PET and SPECT imaging. In fact, studies utilizing many age points have identified a nonlinear loss in human striatum (Seeman *et al*., 1987a; Rinne *et al*., 1990a; Antonini *et al*., 1993). This is important, because the loss of D_2 receptors is paralleled by the loss of presynaptically located dopamine transporter number in human (Volkow *et al*., 1998) and animal studies (Marshall and Rosenstein, 1990; Shimizu and Prasad, 1991; Friedemann and Gerhardt, 1992; Irwin *et al*., 1994; Gordon *et al*., 1995; Hebert and Gerhardt, 1998, 1999; Hebert *et al*., 1999). It is now evident that the age-related loss of dopamine transporter in humans is probably not linear with the major

TABLE 48.2 Dopamine Receptors in Aging and Parkinsonian Disorders

	D_2 receptor	D_2 mRNA	D_1 receptor	D_1 mRNA	D_3 receptor
Rat aging	↓ 50–70% In caudate-putamen	↓ 25% In caudate-putamen	↓ 40%? In caudate-putamen	No change	↑ 26% In nuc acb
Human aging	↓ 40–50% In caudate and putamen	Not analyzed	↓ 40% In caudate and putamen	Not analyzed	No change or increase
Parkinson's disease[a]	↑ 26% In putamen	Not analyzed	↑ 26% With dyskinesias	Not analyzed	↓ 20–40% in nuc acb
Alzheimer's with parkinsonism[a]	↓ 40 And 25% in caudate and putamen	Not analyzed	No change	Not analyzed	No change

[a]All values are in relation to age-matched controls. nuc acb, nucleus accumbens.

reduction after age 55 (Bannon *et al*., 1992; Bannon and Whitty, 1997; Ma *et al*., 1999). Although the mechanisms responsible for the decrease in the expression of these proteins with age are not known, the correlation between transporters and receptors, even after accounting for age effects, suggest that their expression may reflect, in part, functional demands on dopaminergic pathways. In fact, they may be linked as is has been shown in dopamine transporter knock-out mice that there is a reduction in D_2 receptor mRNA (Gainetdinov *et al*., 1999). If loss of dopamine transporter leads, initially, to increased dopamine then, as suggested by Shinkai *et al*. (1997), this increased dopamine could lead to death of D_2 receptor synthesizing neurons. While the mechanisms for this are not known, it could possibly contribute to the decline in D_2 receptor number with age (Han *et al*., 1989; Sakata *et al*., 1992; Zhang *et al*., 1995).

This age-related loss of D_2 receptors is functionally relevant as there is a specific correlation between loss of D_2 receptors and reaction time performance and sensorimotor responsiveness in aged rats (MacRae *et al*., 1988) and these impairments are reversed by dopamine uptake inhibitors or the mixed dopamine agonist apomorphine (Marshall and Berrios, 1979; Marshall and Altar, 1986; Hebert and Gerhardt, 1998). The reduced locomotor response to dopaminergic drugs, as well as the loss of spontaneous locomotor and sensorimotor responsiveness (Friedemann and Gerhardt, 1992; Burwell and Gallagher, 1993; Emerich *et al*., 1993; Dorce and Palermo-Neto, 1994; Irwin *et al*., 1994; Hebert and Gerhardt, 1998) in aged animals appears to be most closely related to the loss of D_2 receptors from motor division of the striatum (Joyce *et al*., 1986a; Morelli *et al*., 1990; Dobie *et al*., 1993), but other functional effects have not been explored in detail. One study has not found a reduction in D_2-like receptors, in which age-related behavioral decline was found (Burwell *et al*., 1995). However, that study utilized [^{125}I]epidepride which binds to both D_2 and D_3 receptors (Murray *et al*., 1994). In contrast, selective labeling of the D_3 receptor showed that D_3 receptor is elevated in striatum and nucleus accumbens of aged rats (Wallace and Booze, 1996) and mRNA levels, unlike for D_2, are unchanged in striatum or slightly elevated in nucleus accumbens of aged rats (Valerio *et al*., 1994).

This, coupled with research on the behavioral response to dopamine agonists, suggests that there are functionally important regional and/or receptor specific changes with aging. Whereas there is decreased locomotor response to mixed dopamine agonists (apomorphine) or dopamine-releasing agent amphetamine, there is increased stereotypic response to these drugs with advanced age (Ushijima *et al*., 1987; Stoessl *et al*., 1989; Dorce and Palermo-Neto, 1994; Crawford and Levine, 1997). One study utilizing a more selective D_2/D_3 agonist (quinpirole) also showed that there was a shift in the behavioral response in aged rats to less locomotor activity and rearing to more intense stereotypies (Crawford and Levine, 1997). While this appears contradictory to the reports of the decreased in D_2 receptor number with age, one explanation for this is that the intense stereotypies induced by mixed dopamine agonists may be more dependent on costimulation of D_2 and D_1 receptors in young rats but less so in aged rats. This may occur through changes in the ratio of D_2 to D_1 receptors if the loss of D_2 receptors is greater than D_1 receptors. However, some data suggest that a loss of D_1 receptors occur with age (Battaglia *et al*., 1988; Han *et al*., 1989; Morelli *et al*., 1990), but others are negative (Burwell *et al*., 1995). An alternative explanation is that loss of D_2 receptor and elevation of D_3 receptor with age alters their relative balance. As these two receptors appear to be restricted to different populations of neurons, it may well be that age-related changes in some behavioral responses to dopamine agonists may reflect changes in the responses of D_2 receptor and of D_3 receptor-linked striatal efferents.

B. D_2 and D_3 Receptors and Parkinson's Disease

1. D_2 Receptors Are Functionally Relevant in Parkinson's Disease

Dopaminergic receptor stimulation that results in relief of parkinsonian motor signs is most consistently observed with drugs that interact with D_2-like receptors (Nomoto *et al*., 1985; Loschmann *et al*., 1992; Vermeulen *et al*., 1999). Evidence for efficacy of D_1 agonist stimulation in experimental nonhuman primate models of parkinsonism have been more difficult to interpret as they produce dyskinesias and their antiparkinsonian relief develops rapid tolerance (Vermeulen *et al*., 1999). Recent introduction of new D_1 agonists may challenge this but these agonists are only partially selective for the D_1 receptor having only 14-fold selectivity versus D_2 receptors (Shiosaki *et al*., 1996). Therefore, it is likely that their antiparkinsonian activity occurs through stimulation of D_2-like or D_2 and D_1 receptors. Hence, there is good reason to focus our efforts on understanding where D_2 agonists act to ameliorate Parkinson's disease symptoms. The D_2 receptor family includes three subtypes, D_2, D_3, and D_4 (Joyce and Meador-Woodruff, 1997), which exhibit distinct pharmacological properties and are concentrated in the brain in different regions. Within the basal ganglia D_2 and D_3 and only extremely low levels of the D_4 receptor are expressed (Joyce and Meador-Woodruff, 1997; but see Khan *et al*., 1998), indicating that stimulation of D_2 and D_3 receptors prominently contribute to the antiparkinsonian effects of most compounds used. It has been presumed that it is activity at D_2 receptors that is most relevant to the antiparkinsonian effects of dopaminergic agents (but see section V.B.2). This was because the other subtype, the D_3 receptor, was originally shown to be more selectively localized to the limbic regions of brain in rats and at low levels of expression, whereas D_2 receptors are at high levels throughout the striatum (see section IV.B). In addition, upregulation of the D_2 receptor by dopamine deafferentation and downregulation by dopaminergic stimulation is consistent with a prominent role of the D_2 receptor in this regard (Reches *et al*., 1982, 1984; Alexander *et al*., 1991; Goulet *et al*., 1997; Elsworth *et al*., 1998).

The elevation of striatal D_2 receptor number found in experimental animal models of parkinsonism have also been observed in Parkinson's disease but the relationship to duration of the illness and therapeutic intervention is less clear. We (Joyce, 1993; Ryoo *et al*., 1998) and others (Bokobza *et al*., 1984; Seeman *et al*., 1987b; Piggott *et al*., 1999a) have observed 25–35% increases of D_2 receptors in postmortem studies of Parkinson's disease. *In vivo* studies in Parkinson's

disease with PET ([^{11}C]*N*-methyl-spiperone, [^{11}C]raclopride) and SPECT ([^{123}I]-IBZM) have been utilized to explore the relationship between disease duration and/or chronic drug therapy and D_2 receptor number. Consistent with the postmortem studies, elevation of D_2-like receptor binding of tracer injections of these radioligands have been identified in the striatum of early Parkinson's disease and those without L-dopa treatment (Guttman *et al*., 1986; Rinne *et al*., 1990b,c; Knable *et al*., 1995; Turjanski *et al*., 1997; Ichise *et al*., 1999). Typically the hemisphere contralateral to the parkinsonian symptoms shows the most significant elevation (Rinne *et al*., 1990b,c; Knable *et al*., 1995; Ichise *et al*., 1999) and, with appropriate imaging, the putamen is seen to be most affected (Antonini *et al*., 1997a; Turjanski *et al*., 1997). A reduction in D_2-like receptor binding of these radioligands has been observed with increased disease duration (Hagglund *et al*., 1987; Antonini *et al*., 1995, 1997a) and/or complicated response to L-dopa (Guttman *et al*., 1986; Brooks *et al*., 1992; Pizzolato *et al*., 1995) and has led to the speculation that the loss of D_2 receptors contributes to a deteriorated response to L-dopa in Parkinson's disease (Pizzolato *et al*., 1995). Postmortem studies by ourselves and other groups indicate that with appropriate discrimination between D_2 receptor subtypes that D_2 receptors are *not* reduced at any stage in Parkinson's disease, but the D_3 receptor is reduced (Rinne *et al*., 1991; Ryoo *et al*., 1998; Piggott *et al*., 1999a). This cannot be adequately explored with *in vivo* imaging because: (1) there are not suitable imaging agents that discriminate between D_2 receptor subtypes; and (2) the accurate diagnosis of Parkinson's disease is made with no more than 80% confidence with experienced clinicians (Daniel and Lees, 1993).

Several PET and SPECT imaging studies have suggested that chronic treatment with L-dopa in Parkinson's disease cases leads to downregulation of D_2 receptors, and, thus, to a deteriorated response to treatment (Brucke *et al*., 1991; Brooks *et al*., 1992; Guttman *et al*., 1997; Turjanski *et al*., 1997). However, the results of those studies are questionable since the studies did not compare groups that were similar with respect to duration of illness *and* the presence or absence of drug treatment. Furthermore, the specific examination of short-term treatment of 3 to 4 months with L-dopa or a D_2 agonist could not be observed to downregulate [^{11}C]raclopride binding to D_2 receptors in Parkinson's disease (Antonini *et al*., 1994). Additionally, the results of PET and SPECT studies may be misleading as this requires the accurate diagnosis of Parkinson's disease, which can be wrong in at least 20% of clinically diagnosed parkinsonian disorders (Daniel and Lees, 1993). In fact, some groups have suggested that those parkinsonian cases with lower D_2 receptor number determined by PET/SPECT imaging are typically never responsive to L-dopa or dopamine agonists and are not true Parkinson's disease (Schelosky *et al*., 1993; Antonini *et al*., 1997b; J. C. Schwarz *et al*., 1998). While we (Joyce, 1993) and others (Bokobza *et al*., 1984; Seeman *et al*., 1987b) have observed increases in [^{3}H]spiroperidol binding to D_2 receptors in Parkinson's disease, we did not find an elevation in their number in a recent study using the radioligand [^{125}I]epidepride to label D_2-like receptors (Joyce *et al*., 1998). [^{125}I]epidepride nonselectively labels D_3 and D_2 receptors with equally high affinity and has very low affinity for the D_4 receptor (Murray *et al*., 1994), whereas [^{3}H]spiroperidol has low affinity for the D_3 receptor (Sokoloff *et al*., 1990). In contrast, our results with selective labeling of D_2 and D_3 receptors suggest that D_2 receptors remain elevated in Parkinson's disease even with long disease duration (Ryoo *et al*., 1998; also see Piggott *et al*., 1999a) but a loss of D_3 receptors in the late stages may be correlated with a loss of a therapeutic response to L-dopa or specific clinical symptoms (see below). This issue is important since SPECT imaging agents ([^{123}I]IBZM) and at least one of the PET imaging agents ([^{11}C]raclopride) have equal affinity for D_2 and D_3 receptors. Hence, results of the PET/SPECT imaging studies of depamine receptors and Parkinson's disease may be confounded by the use of nonselective radioligands.

2. Changes in Expression of D_3 Receptors in Parkinson's Disease

Studies in the rat indicate D_3 receptors may be regulated by loss of dopamine afferents differently from the D_2 receptor and produce a reduction in receptor number and mRNA expression (Lévesque *et al*., 1995). Initial reports in MPTP-treated monkey model of parkinsonism and in Parkinson's disease did not identify changes in D_3 receptor number with loss of dopamine innervation (Hurley *et al*., 1996a,b). We examined D_2 and D_3 receptor changes associated with the onset and recovery of parkinsonian signs in MPTP-treated cats (Schneider *et al*., 1986; Schneider and Rothblat, 1991). We established that increases in D_2 receptor number or mRNA expression did not correspond with the onset of parkinsonian signs but peaked after the parkinsonism was established. Loss of D_3 receptors, on the other hand, corresponded to injury to the mesostriatal dopaminergic system and was related to the initial expression of parkinsonian signs (Fig. 48.5). MPTP-treated cats, unlike other animals, exhibit spontaneous recovery from the parkinsonism. Relief from parkinsonism was associated with elevation of D_3 receptor number but permanent reduction of parkinsonian signs was related to normalization of both D_2 and D_3 receptor number. Temporally, the normalization of D_3 receptor number also corresponded to increased extracellular dopamine in the ventral striatum, possible via sprouting dopamine fibers in the area. We hypothesize that in parkinsonism, partial recovery and full recovery may involve regulation of different dopamine receptor subtypes and possible alterations in coexpression of dopamine receptors at least in a subset of striatal neurons. Subsequent studies have partially confirmed those findings, identifying a reduction of D_3 receptor number in MPTP-treated monkeys and in Parkinson's disease when parkinsonian signs are apparent (Morissette *et al*., 1998; Ryoo *et al*., 1998; Piggott *et al*., 1999a).

How does this relate to our findings in Parkinson's disease? We had explored changes in D_2 and D_3 receptor while simultaneously measuring the extent of dopamine fiber loss in striatum of autopsied cases with relatively short or long histories of Parkinson's disease (Ryoo *et al*., 1998). Dopaminergic innervation to the caudal putamen was heavily reduced and to a lesser extent in the rostral putamen in Parkinson's disease but the mesolimbic dopaminergic system was less affected. D_3 receptors were profoundly reduced in Parkinson's disease by 40 to 45%, particularly in the ventral striatum and was due to a change in B_{max} values. In contrast, D_2 receptors were elevated

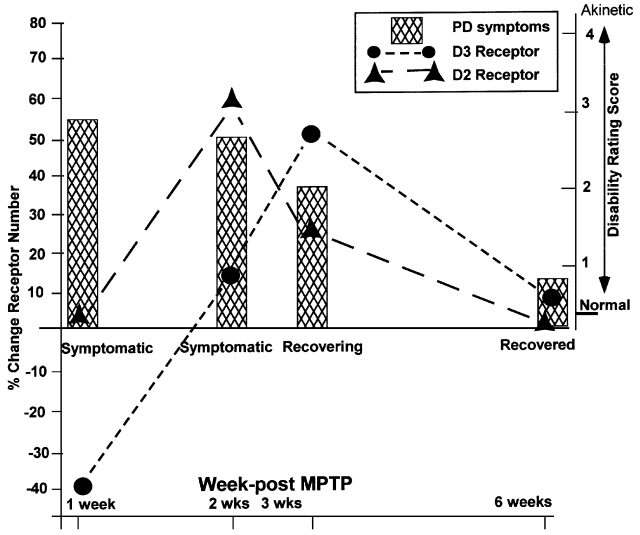

FIG. 48.5 Alterations in striatal D_2 and D_3 receptor number in MPTP-treated cats in relation to symptom severity. MPTP-treated cats initially show severe akinesia related to the loss of dopamine innervation but over 6 weeks exhibit behavioral recovery. The initial akinesia and recovery better correlated with changes in D_3 receptor number than D_2 receptor number. Akinesia rating scale (right axis) is shown in the hatched bars and the percentage change in striatal D_2 and D_3 receptor number (left axis) by the dotted lines.

in Parkinson's disease in the dorsal putamen by 15%, consistent with our previous results (Joyce, 1993). Interestingly, the reduction in D_3 receptor number occurred in Parkinson's disease cases with a duration of greater than 9 years, typically when the clinical benefits of L-dopa were reduced and behavioral symptoms such as depression were present. D_2 receptors were elevated in Parkinson's disease in all cases, regardless of disease duration. As the reduction of D_3 receptor number was small (-17%) in the overall Parkinson's disease sample of Piggott and associates (1999a) and was not found in that of Hurley *et al*., (1996b), it may suggest that clinically defined subgroups are more affected. To provide preliminary information on relationship between clinical subgroups of Parkinson's disease and changes in D_3 receptor number we processed tissue from an additional 13 Parkinson's disease cases that met clinical and neuropathological criteria for Parkinson's disease and 6 controls. Clinical information regarding presence or absence of dementia and whether the Parkinson's disease cases had become relatively resistant to the beneficial response of L-dopa was acquired (poor vs good responder). Tissue from the striatum was processed for D_3 receptor autoradiography, TH immunoautoradiography (TH-IR), and dopamine transporter autoradiography (Fig. 48.6, see color insert).

Dopamine transporter binding in all Parkinson's disease cases was lower than measures of TH-IR, which reflects, in part, the lowered dopamine transporter mRNA but elevated TH mRNA in remaining nigral neurons (Joyce *et al*., 1997). Nonetheless, the dorsal putamen was reduced by 95% for dopamine transporter and 50% for TH, indicating substantial loss of dopaminergic innervation (Fig. 48.6). Overall for the Parkinson's disease group the nucleus accumbens was less affected exhibiting a reduction of 65% for dopamine transporter and 30% for TH-IR. When differentiated by Parkinson's disease only versus Parkinson's disease with dementia (with or without AD) there was a greater loss of dopaminergic innervation in the nucleus accumbens for the Parkinson's disease with dementia as determined with TH-IR, but less of a difference measured with dopamine transporter binding. Measurement of D_3 receptor number showed only a small decline for the Parkinson's disease group as a whole but significant differences emerged (even with the small *n*) for the subgroups. Having Parkinson's disease with an additional diagnosis of dementia (with or without AD) or had become a poor responder to antiparkinsonian medication was correlated with lower D_3 receptor number (-28%). Piggot and associates (1999a) and our own results have shown that D_3 receptor number is elevated in the ventral striatum of AD, so the reduction in the Parkinson's disease with dementia group is unlikely to be due to AD pathology per se. It may be related to the greater loss of dopaminergic innervation in the nucleus accumbens. The Parkinson's disease cases reported as poor responders to Parkinson's disease medication all had originally responded well to Sinemet, were not identified at neuropathology as having progressive supranuclear palsy or other Parkinson-like diagnosis with known poor response to antiparkinsonian medication and typically also did not respond to direct dopamine agonists. Thus, we believe that reduced D_3 receptor number is correlated with certain subgroups of Parkinson's disease and may also be related to a further diminishment in the mesolimbic dopamine system.

While the mesolimbic dopamine system is relatively spared in Parkinson's disease (Murray *et al*., 1995; Dymecki *et al*., 1996; Miller *et al*., 1997, 1999), cell loss within the VTA and loss of dopamine afferents in the nucleus accumbens may increase with duration of illness and/or be associated with specific symptoms (Zweig *et al*., 1989; Jellinger, 1991; Chinaglia *et al*., 1992; Narabayashi, 1995; McRitchie *et al*., 1997). It has been proposed that rigidity, tremor, and secondary akinesia (that related to rigidity) start first with degeneration of the ventral tier of the SNc followed by spread of the pathology to the dorsal tier and medial nuclei (source of the mesolimbic dopamine system), which may produce primary akinesia (bradykinesia and psychomotor retardation), dementia, and depression. This spreading of pathology from one functional system to another might be one of the key factors responsible for the progressive worsening of the disease and increase in nonresponders with disease duration (Jellinger, 1991; Narabayashi, 1995). Studies in experimental models of Parkinson's have found that mesolimbic dopamine loss are related to deficits in initiation of movement and specific aspects of goal-directed behavior (Carey, 1983; Wolterink *et al*., 1990; Salamone *et al*., 1997; Meeker *et al*., 1998), as well as some aspects of cognitive function (Salamone, 1992; McCullough *et al*., 1993; Ploeger *et al*., 1994). While the focus has been on D_2 receptor effects of antiparkinsonian agents, D_3-preferring agonists can be effective in ameliorating motor symptoms in Parkinson's disease patients (Hubble *et al*., 1995; Molho *et al*., 1995; Shannon *et al*., 1997) and MPTP-treated monkeys (Blanchet *et al*.. 1997). In monkeys treated with MPTP to produce severe akinesia, the D_3-preferring agonist PD 128,907 was found to be equally potent as apomorphine in reversing the hypoactivity, and this effect was blocked by the D_3 antagonist U-99194A

(Blanchet *et al*., 1997). Similarly, L-dopa reversal of MPTP-induced hypoactivity in monkeys is dose-dependently inhibited by the D_3 antagonist nafadotride (Hadjtahar *et al*., 1999). Hence, regulation of the D_3 receptor may be important in understanding the response of Parkinson's disease cases to antiparkinsonian medication. We hypothesize that permanent loss of postsynaptically located D_3 receptors in some Parkinson's disease cases, perhaps associated with additional damage to the mesolimbic dopaminergic system, contributes significantly to specific impairments in Parkinson's disease. It is not evident that these changes are caused by age-related alterations in the dopaminergic system. There is no evidence that D_3 receptors decrease with age after 55 years of age (Piggott *et al*., 1999b) but there is some evidence for a greater impact on cell loss in the A10 region and dorsal tier of the SN with advanced age (Fearnley and Lees, 1991; Piggott *et al*., 1999b). A systematic analysis of the relationship between D_3 receptor, clinical state of Parkinson's disease, loss of mesolimbic dopaminergic system, and response to drug treatment would greatly add to our understanding of this illness and new therapeutic interventions.

C. D_1 Receptors and Parkinson's Disease

1. Therapeutic Intervention in Parkinson's Disease and the D_1 Receptor

It is generally thought that dopamine receptor agonists mainly exert their action in Parkinson's disease through stimulation of D_2-like receptors (Langtry and Clissold, 1990; Kopin, 1993), whereas L-dopa through conversion to dopamine acts to stimulate multiple receptors. For several reasons it was considered essential that stimulation of D_1 receptors should provide beneficial actions in Parkinson's disease. As outlined in section IV, the output neurons to the globus pallidus forming the "direct route" (Fig. 48.3), contain D_1 receptors, whereas the cells of origin of the indirect route express D_2 receptors. Dopamine is able to modulate the balance of activity of the direct and indirect pathways by simultaneously facilitating the activity of the direct pathway (stimulation of D_1 receptors) and inhibiting the activity of the indirect pathway (stimulation of D_2 receptors). In addition, D_2 receptor agonist induction of motor activity in rats is abolished by depletion of dopamine or administration of a D_1 receptor antagonist (Molloy *et al*., 1986; Arnt *et al*., 1987; Clark and White, 1987). Behavioral responses to the D_2 agonist could be restored by administration of a D_1 agonist. Moreover, a D_1 agonist given alone to normosensitive rats does not produce stereotypies but does so when coadministered with a D_2 agonist. Rats and mice depleted of dopamine respond to a D_1 agonist with a locomotor response and show additive responses with a D_2 agonist (Arnt *et al*., 1987; Clark and White, 1987). Therefore, it can be suggested that the restoration of a complete repertoire of motor activity requires the stimulation of both D_1 and D_2 receptors in the parkinsonian brain (Clark and White, 1987).

Evidence for efficacy of D_1 agonist stimulation in experimental nonhuman primate models of parkinsonism has been more difficult to interpret (Vermeulen *et al*., 1999). In the MPTP-lesioned monkey model of Parkinson's disease, the partial but selective D_1 agonist SKF-38393 failed to stimulate motor behavior (Nomoto *et al*., 1985; Boyce *et al*., 1990). Newly developed agents (e.g., A-86929) that are full agonists at the D_1 receptor do stimulate motor behavior of MPTP-lesioned monkeys, act synergistically with D_2 receptor agonists, and have efficacy in Parkinson's disease (Grondin *et al*., 1997; Asin *et al*., 1997; Rascol *et al*., 1999). Nonetheless, several of these compounds lose their efficacy in stimulating motor behavior upon sustained administration and induce dyskinetic behavior. Additionally, these agonists are only partially selective for D_1 receptors having only 14-fold selectivity versus D_2 receptors (Shiosaki *et al*., 1996). Therefore, it is likely that their antiparkinsonian activity occurs through stimulation of D_2 or D_2 and D_1 receptors. Their efficacy in Parkinson's disease may be further complicated by the fact that the majority of Parkinson's disease cases are coadministered L-dopa and chronic L-dopa treatment appears to reduce D_1 receptor mRNA (Morissette *et al*., 1996) and produce internalization of the receptor (Muriel *et al*., 1999). While it is not clear what the functional impact of this is, receptor availability for interactions with G-proteins may be compromised. Hence, therapeutic response to D_1 agonists may be unlikely in Parkinson's disease.

2. D_1 Receptors and L-Dopa Induced Dyskinesias

In our recent study of dopamine receptor changes in Parkinson's disease we determined that there was an increase in D_1 receptor number in the putamen (Joyce *et al*., 1998). However, the scatter graph of the data indicated that there were two groups of Parkinson's disease cases, those with high numbers and those with low numbers of D_1 receptors. Previous studies of striatal D_1 receptor expression in Parkinson's disease cases have often shown increases in D_1 receptor number but significant variability is observed suggesting a bimodal population (Joyce, 1993; Rinne *et al*., 1985; Seeman *et al*., 1987b). The increase in D_1 receptors may reflect changes in one subpopulation of the cases as a result of L-dopa treatment (Rinne *et al*., 1985; Seeman *et al*., 1987b). This is supported by results in nonhuman primate models of parkinsonism. The pattern of dopamine fiber loss in Parkinson's disease is closely mimicked by administration of MPTP in monkeys to make them parkinsonian (Burns *et al*., 1983; Joyce *et al*., 1986b). These animals also develop abnormal involuntary movements similar to what happens in patients with advanced Parkinson's disease in response to L-dopa. Stimulation of D_1 receptors plays an important role in the induction of the dyskinesias (Blanchet *et al*., 1996; Grondin *et al*., 1999). Moreover MPTP-treated monkeys show an increase in D_1 receptor number that is enhanced by chronic administration of L-dopa that leads to abnormal involuntary movements (Graham *et al*., 1993; Blanchet *et al*., 1995; Rioux *et al*., 1997). Hence, the increase in D_1 receptors may contribute to the unwanted extrapyramidal side-effects of L-dopa treatment that occurs in some advanced Parkinson's disease cases. This is difficult to reconcile with the fact that L-dopa appears to lead to downregulation of D_1 mRNA and internalization of the D_1 receptor (Morissette *et al*., 1996; Muriel *et al*., 1999). However, it may be that distinct populations of neurons expressing D_1 receptors are differentially affected by dopamine loss and L-dopa administration.

Both D_1 (Gerfen *et al*., 1990; Joyce, 1991) and D_3 receptors (Levesque *et al*., 1995) are reduced following 6-OHDA lesion in rats, which may be due to their extensive colocalization in a subset of striatal neurons expressing Substance P (Curran and Watson, 1995; Le Moine and Bloch, 1996; Ridray *et al*., 1998). The D_3 receptor reduced by dopamine depletion can be induced to increase in the nucleus accumbens and dorsal caudate-putamen (typically exhibiting low expression) by chronic treatment with L-dopa or D_1 agonists (Bordet *et al*., 1997). Since the effect of L-dopa can also be prevented by blockade of the D_1 receptor, this upregulation of the D_3 receptor may occur through stimulation of the D_1 receptor in neurons coexpressing D_1 and D_3 receptors. The elevation of D_3 mRNA levels in 6-OHDA lesioned rats was concomitant with behavioral sensitization to L-dopa that could be blocked by the preferential D_3 receptor antagonist nafadotride. These results have led to the hypothesis that the D_3 receptor plays a direct role in the L-dopa-induced behavioral sensitization (J. Schwartz *et al*., 1998). Morisette and associates (1998) have reached similar conclusions studying MPTP-treated monkeys. The monkeys exhibit substantial declines in D_3 receptor number, which can be reversed with D_1 but not D_2 agonist treatment. As the D_1 agonist treatment resulted in effective alleviation of parkinsonian signs but also induced dyskinesias, D_3:D_1 receptor interactions may be involved in D_1 agonist-induced dyskinesias. As the D_3 receptor is increased with advancing age, it may provide a fundamental underlying change in D_3:D_1 receptor ratio that is exacerbated with dopamine deafferentation and L-dopa treatment. The D_3 receptor elevation in a subpopulation of D_1 neurons seems to play an important role in behavioral sensitization under conditions of excessive dopaminergic stimulation. However, in a specific test of the hypothesis the D_3 receptor antagonist nafadotride failed to reduce L-dopa-induced dyskinesias in MPTP-treated monkeys (Hadjtahar *et al*., 1999). Thus, the role of the D_1 receptor in the therapeutic response or unwanted behavioral effects of L-dopa in Parkinson's disease remain unresolved.

D. Parkinsonism in Alzheimer's Disease and Loss of D_2 Receptors

While the parkinsonian features observed in a consequential proportion of AD cases may be caused by significant changes in the presynaptic dopaminergic system (Tyrrell *et al*., 1990; Murray *et al*., 1995; Joyce *et al*., 1997), other modifications in the dopaminergic system may also contribute to it. This is suggested by studies in other parkinsonian disorders such as progressive supranuclear palsy and multiple system atrophy, where there is both substantial impact on the presynaptic dopaminergic system (Jellinger *et al*., 1980; Kish *et al*., 1985; Goto *et al*., 1989; Brucke *et al*., 1997) and reduced numbers of postsynaptic D_2 receptors (Brooks *et al*., 1992; Antonini *et al*., 1995). Typically these patients do not respond well to L-dopa or direct dopamine agonists (Quinn, 1994). Similar conditions may exist for AD/Park and one study using SPECT identified a reduced number of D_2 receptors in the striatum of AD (Pizzolato *et al*., 1996). The authors hypothesized that a loss of D_2 receptors could contribute to the parkinsonian features that were apparent in a number of the cases. Moreover, the decline in the number of postsynaptic striatal D_2 receptors could be one of the characteristic pathologic changes of AD, which would distinguish it from Parkinson's disease in which the number of D_2 receptors is elevated (Joyce, 1993; Ryoo *et al*., 1998). Several studies of post-mortem brains have also found losses of D_2 and/or D_1 receptors in the striatum of AD cases (Reisine *et al*., 1978; Cross *et al*., 1984; Rinne *et al*., 1986; Cortés *et al*., 1988). However, those studies made no attempt to distinguish between AD with and without Parkinsonian features and the relationship to dopamine receptor changes in the striatum. To that end we characterized the patterns of dopamine receptor changes in cases of AD, Parkinson's disease, and AD/Park compared to neurologically intact controls (Joyce *et al*., 1998). We have observed differences in the two AD groups, with a decreased density of D_2 receptors in AD cases with parkinsonism but not in those without the parkinsonian features. No change in D_1 receptor number was found. We believe that the decline in the number of postsynaptic striatal D_2 receptors could be one of the characteristic pathologic changes of AD/Park that distinguish it from AD without parkinsonian features. Our results also suggest that, along with changes in the ability to process dopamine appropriately (Murray *et al*., 1995; Joyce *et al*., 1997), the loss of D_2 receptors in those AD cases exhibiting parkinsonian symptoms might explain the incomplete response of these patients to L-dopa treatment (Duret *et al*., 1989; Merello *et al*., 1994). Interestingly, the extensive depletion of striatal dopamine transporter sites, reduced dopamine transporter mRNA expression in SN, and lowered D_2 receptor resemble exaggerated phenomenon observed with aging. It would suggest the possibility that changes with aging may contribute to at least some parkinsonian disorders.

VI. Conclusions

It has been often proposed that age-related declines in SN cell number and striatal dopamine which have been reported in humans with normal aging, may contribute to Parkinson's disease. A review of the published papers indicates that the neurodegenerative changes in Parkinson's disease are, however, unlikely to be components of aging per se. The age-related reduction of dopaminergic neurons of the SN and striatal dopamine fibers is relatively restricted and not topographically related to Parkinson's disease. Other changes, in fact, may be neuroprotective. For example, the age-related loss of dopamine transporter expression in the SN may reduce the risk of cell death resulting from toxins that enter dopaminergic neurons via the transporter, and this reduction may fail to take place in Parkinson's disease. The pattern and extent of cell and fiber loss in Parkinson's disease suggests factors unrelated to aging per se contribute to the neuropathology. In addition, many compensatory changes in the dopamine system appear unique to Parkinson's disease. The elevation of D_2 receptors and decline of D_3 receptors play unique roles in the clinical manifestations of Parkinson's disease and are not observed in aging. However, age-related changes in the dopaminergic system may contribute to the deterioration in clinical response to antiparkinsonian drugs in Parkinson's disease and the development of other clinical signs and symptoms. Additional research on the impact of aging on the mesolimbic

dopaminergic system may help in understanding what occurs in late-stage Parkinson's disease. In the larger picture, moreover, some of the age-related declines in behavior resemble that in Parkinson's disease, occur in other parkinsonian disorders, and may reflect exaggerated forms of aging. For example, loss of dopamine transporter expression in the SN, an age-related reduction in dopamine synthesis and loss of postsynaptic D_2 receptors may cause the parkinsonian features observed in a consequential proportion of AD cases. These changes are observed with aging in animals and humans but not to the same degree. Unlike in Parkinson's disease, the beneficial response to L-dopa is typically absent in AD/Park. Hence, a better understanding of age-related modifications in the dopamine system may help us develop novel pharmacological treatments of this and related disorders.

Huntington's Disease

Huntington's disease is one of several devastating neurodegenerative diseases, including amyotrophic lateral sclerosis and Alzheimer's disease (AD), which are characterized by late onset in adult life. Their debilitating symptoms include cognitive dysfunction, behavioral changes and mood disturbances, and movement disorders, and in the cases of amyotrophic lateral sclerosis and Huntington's disease paralysis and death can occur. As the mean age of the population increases, so does the frequency of occurrence of these disorders. Symptoms are associated with region-specific loss of neurons within the central nervous system (CNS), but to date the mechanism of this selective neuronal death remains unknown. Several different etiological processes may play roles, and strong evidence from studies in humans and in animal models suggests the involvement of energy metabolism dysfunction, excitotoxic processes, and oxidative stress. The recent development of transgenic mouse models expressing the human Huntington's disease mutation has provided novel opportunities to determine the chronological order of events underlying the selective neuronal death seen in the disease, which have hitherto been impossible to determine in humans.

I. Introduction
